Chapter 131
Waist Circumference and Cardiovascular Risk

Heribert Schunkert, Marcello Ricardo Paulista Markus, and Jan Stritzke

Abstract The epidemic of obesity poses a global concern because of its related health problems. The related risk appears to be directly linked to the increased deposition of fat in the body. While most adipose tissue is located under the skin, intra-abdominal fat is more closely associated with the risk of several chronic diseases. A simple measurement of such visceral fat is waist circumference, which is strongly correlated with the risk for diabetes mellitus and cardiovascular disease. The relative contribution of intra-abdominal fat to total body fat is influenced by sex, age, race/ethnicity, physical activity and total adiposity. Excess visceral adiposity/ectopic fat affects the incidence of the metabolic syndrome. Given the long-term health implications of this syndrome it was suggested to add the combination of elevated waist circumference and triglycerides to the list of variables considered in global risk algorithm, which thereby transforms it into a global cardiometabolic risk assessment algorithm. There is an urgent need to increase the awareness among both health professionals and the general public about the health hazards of central or abdominal obesity. Although maintaining a healthy weight should continue to be a cornerstone in the prevention of chronic diseases and premature death, maintaining a healthy waist size should also be an important goal.

131.1 Introduction

Obesity is a complex metabolic disorder characterized by a positive balance between energy intake and expenditure that increases the risk for diabetes mellitus (DM), hypertension, coronary heart disease, dyslipidemia, certain cancers, and obstructive sleep apnea, among other comorbidities (Baskin et al. 2005; Ness-Abramof and Apovian 2008). The precise mechanisms underlying these associations are still poorly understood.

Although overweight and obesity by themselves are associated with an increased risk, the pattern of fat distribution is also important in risk stratification. Most adipose tissue (about 85% of total adipose tissue mass) is located under the skin (subcutaneous fat), and a smaller amount (about 15%) is located within the abdomen (intra-abdominal fat) in lean and obese persons. (Klein et al. 2007) Excess abdominal fat (also known as central or upper-body fat) is associated with an increased risk of cardiometabolic disease. However, precise measurement of abdominal fat content requires the use of expensive radiological imaging techniques. Therefore, waist circumference (WC) is often used as a surrogate marker of abdominal fat mass because it correlates with abdominal fat mass (subcutaneous and intra-abdominal) (Pouliot et al. 1994) and is associated with cardiometabolic disease risk (Kissebah et al. 1982). However, measurement of WC has not been widely adopted in clinical practice, and the anatomical, metabolic, and clinical implications of WC data can be confusing.

Intra-abdominal (visceral) fat is more closely associated with the risk of several chronic diseases than a more peripheral (subcutaneous) fat distribution and large studies have suggested that waist circumference or the waist–hip ratio, as indicators of abdominal obesity, may be better predictors of the risk of disease than the BMI, an indicator of general adiposity (Yusuf et al. 2005; Hu 2007). Besides that, even when body weight is kept constant or decreases during the aging process, total and regional adiposity may increase due to predominant decreases in lean body mass. For instance, data from our research group (Markus et al. 2010) revealed that hypertensive individuals who normalized their blood pressure values after 10 years of follow-up due to changes in their dietary habits had, on average, a decrease in total body weight, fat-free mass and fat mass. Nevertheless, the aging process resulted, at the same time, in an increase in waist circumference and waist–hip ratio due to a redistribution of their fat deposits from subcutaneous to intra-abdominal. One may even question if the benefit in the blood pressure control due to weight loss can supplant the detrimental increase in waist circumference, as fat distribution has substantive effects on morbidity and mortality risk (Huang et al. 2005). Moreover, some studies have shown that abdominal adiposity is an important predictor of the risk of death (Simpson et al. 2007; Zhang et al. 2007). In a large European cohort study,

the associations of BMI with the risk of death were J-shaped, with higher risks of death observed in the very low and upper BMI categories than in the middle categories (Pischon et al. 2008). By contrast, abdominal fat distribution was positively associated with the risk of death when this risk was adjusted for BMI. These associations tended to be stronger among participants with a lower BMI than among those with a higher BMI. Thus, measurement of both general and abdominal adiposity provides a better assessment of the risk of death, particularly among people with a lower BMI. These results underscore the importance of assessing the distribution of body fat even among persons of normal weight and challenge the use of cutoff points to define abdominal obesity, at least when they are used to predict the risk of death (Pischon et al. 2008; Executive summary of the clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults 1998b; Obesity: preventing and managing the global epidemic. Report of a WHO consultation 2000).

131.2 Waist Circumference and Related Risk

131.2.1 Waist Circumference and CV Risk

Identification of patients with high cardiovascular risk, an immanent task of primary care physicians, is laborious, cost intensive, and, thus, difficult to perform. Conversely, waist circumference (WC), given its association with multiple risk factors, is an easy-to-use tool for initial assessment of cardiovascular risk. Data from the German Metabolic and Cardiovascular Risk Project (GEMCAS) were used to predict the validity of measuring waist circumference in primary care and its correlation with the prevalence of risk factors and the risk score assessment (SCORE) of the European Society of Cardiology (ESC) (Schunkert et al. 2008). The SCORE risk assessment is derived from a large data set of prospective European studies and predicts fatal atherosclerotic CVD events over a ten-year period. This risk estimation is based on the following risk factors: gender, age, smoking, systolic blood pressure, and total cholesterol. The threshold for high risk based on fatal cardiovascular events is defined as "higher than 5%," using a composite coronary endpoint. The global cardiovascular risk, using the SCORE, was assessed in 10,323 men (aged 35–65) and 18,852 women (aged 45–65). Logistic regressions and Spearman correlations were used to evaluate the interdependence of WC and cardiovascular risk factors, as well as the estimated cardiovascular risk. Of these unselected individuals, 21.9% had an increased WC (women >80–88, men >94–102 cm) and a further 36.5% had a high WC (women >88, men >102 cm). The proportion of patients with a low HDL-cholesterol was higher in high WC compared to normal WC (prevalence rate ratio (Schunkert et al.) 1.88 [95%CI: 1.74–2.02] in men and 2.97 [2.75–3.21] in women). The same applied to elevated triglycerides (PRR 1.72 [1.62–1.84] and 2.57 [2.36–2.80], respectively), impaired fasting glucose (PRR 2.30 [2.13–2.49] and 3.66 [3.29–4.06]), and elevated blood pressure (PRR 1.27 [1.23–1.30] and 1.57 [1.52–1.62]), respectively (Table 131.1). A SCORE score result necessitating action (>5% risk) was observed in 24.12% of men (age-adjusted PRR of 1.27, 95%CI: 1.12–1.44) and 3.19% of women (age-adjusted PRR of 1.77, 95%CI: 1.26–2.49) with a high WC as compared to 10.88% of men and 0.95% of women with a normal WC (Fig. 131.1).

Furthermore, there are various studies showing associations between waist circumference and risk of diseases. The INTERHEART study reported the effect of various measures of adiposity on rates of acute myocardial infarction (AMI) by comparing acute myocardial infarct cases and standardized controls of varying ethnicity from 52 countries (Yusuf et al. 2004). BMI showed a modest association with AMI, but this association was lost after adjustment for other risk factors.

Otherwise, the waist–hip ratio and the waist and hip circumferences were highly associated with the risk of AMI, even after adjustment for other risk factors. Moreover, the EPIC-Norfolk study reported that waist circumference, but not BMI, was a significant estimate for all CHD events during 9.1 years and that hip circumference appeared to protect against CHD (Canoy et al. 2007). Taken together, a redefinition of obesity based on waist circumference, instead of BMI, is a better estimate of CHD in most ethnic groups and the notion can be supported that abdominal adiposity, not subcutaneous adiposity, is closely linked to the onset of CHD (Shimabukuro 2009).

The Atherosclerosis Risk in Communities (ARIC) study determined the contribution of risk factors on ischemic stroke subtypes.(Ohira et al. 2006) In addition to the traditional risk factors, such as hypertension, current smoking, and T2DM, the waist–hip ratio was associated with increased risk for non-lacunar and cardioembolic stroke, but not with lacunar stroke.

A meta-regression analysis (de Koning et al. 2007) consisting of 15 studies (12 with primary outcome of coronary heart disease, three with primary outcome of stroke), comprising 258,114 participants (35.7% men) with a mean age of 57 years, and over 1,520,864 person-years with a mean follow-up of 5.9 years, where 4,355 cardiovascular disease events were recorded, was performed by Koning et al. (Table 131.2). The analyses demonstrated that the risk of incident CVD increases in men and women with elevations in waist circumference or waist–hip ratio. Specifically, a 1-cm increase in waist circumference is associated with a 2% increase and a 0.01 increase in the waist–hip ratio is associated with a 5% increase in risk of future cardiovascular disease after adjusting for age and cohort characteristics (Table 131.3).

Finally, more recently, the analyses of two German cohort studies (DETECT and SHIP) by Schneider et al. (2010), concluded that waist–height ratio (WHtR) represents the best predictor of cardiovascular risk and mortality, followed by waist circumference (WC) and waist–hip ratio (WHR) and their results discouraged the use of the body mass index (BMI). The analyses showed a positive association of the composite endpoint (incident stroke, myocardial infarction, or cardiovascular death) with WHtR, WC, and WHR, but not with BMI. There was no heterogeneity among studies. The relative risks in the highest versus the lowest sex- and age-specific quartiles of WHtR, WC, WHR, and BMI, after adjustment for multiple confounders, were 2.16 (1.39–3.35), 1.59 (1.04–2.44), 1.49 (1.07–2.07), and 0.57 (0.37–0.89), respectively. Separate analyses of sex and age groups yielded comparable results.

131.2.2 Waist Circumference and Metabolic Risk

In the Paris Prospective Study I, which investigated the mortality of 6,678 middle-aged men who were free of T2DM and CHD at baseline, sagittal abdominal diameter, a substitute for waist circumference, and the presence of MetS were associated with an increase in sudden death, as with non-sudden death from AMI (Empana et al. 2007). Sudden death could be related to arrhythmic events, including lethal ventricular fibrillation, because patients with MetS had significantly higher values of corrected QT interval and QT dispersion on ECG, which reflects myocardial refractoriness and electrical instability (Pietrasik et al. 2007).

131.2.3 Waist Circumference and Vascular Risk

A recent prospective cohort study revealed a positive relationship between waist–hip ratio, not BMI, and PAD prevalence (Planas et al. 2001). Mechanisms (if any) by which obesity may cause PAD could be different from those for CHD, as they do have different risk profiles (e.g., cigarette smoking is more strongly associated with the development of PAD than CHD) (Leng et al. 1995).

Numerous studies have shown a clear relationship between obesity and the risk of idiopathic venous thrombo-embolism (deep vein thrombosis and pulmonary embolism), independent of other traditional risk factors (Darvall et al. 2007; Samama 2000). For instance, in a study from Sweden, men with a waist circumference ≥100 cm had a fourfold higher risk of venous thrombo-embolism than with those with a waist <100 cm.(Darvall et al. 2007) More recently, a Danish prospective study (Diet, Cancer, and Health) with 27,178 men and 29,876 women, from 50 to 64 years of age with 10 years of follow-up, showed that hip circumference was positively associated with venous thrombo-embolism in women, but not in men, whereas waist circumference was positively associated with

venous thrombo-embolism in men, but not in women (Severinsen et al. 2009). Obese patients have chronically raised intra-abdominal pressure and decreased blood velocity in the common femoral vein. Inactivity and poor gait, as well as other comorbidities, may collectively impair venous return from the lower limbs. Alternatively, obesity, in particular visceral obesity, may have a prothrombotic propensity via mechanisms including actions of adipocytokines, increased activity of the coagulation cascade and decreased activity of the fibrinolytic cascade, inflammation, oxidative stress, endothelial dysfunction, and disturbances in lipids and glucose homeostasis (Shimabukuro 2009).

131.3 Waist Circumference and Risk Assessment

Traditional risk factors, such as hypertension, elevated low-density lipoprotein-cholesterol, smoking, and diabetes mellitus, have long been linked to CVD. One key criticism is that associations between CVD and the metabolic syndrome, which are also linked to these risk factors, cannot account for all potentially confounding variables, which make such comparisons rather difficult (Gami et al. 2007). On the other hand, although remarkable progress has been made in the management of the classical risk factors, abdominal obesity/MetS and T2DM have reached such epidemic proportions that CVD remains a major cause of morbidity and mortality worldwide (Shimabukuro 2009). Moreover, as already discussed, abdominal obesity is the most prevalent form of the clustering of proatherogenic and pro-inflammatory abnormalities associated with insulin resistance.

The extent by which the specific clustering of visceral obesity abnormalities increases the overall CVD risk remains to be elucidated. The American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD), as well as the International Chair on Cardiometabolic Risk, have emphasized the critical importance of first using global risk calculators, such as the Framingham risk score, the PROCAM algorithm, or the European SCORE (Kahn et al. 2005).

However, there is evidence to suggest that the risk assessment algorithms may not accurately estimate the global CVD risk in patients with visceral obesity/MetS. Besides that, it is also claimed that the Framingham risk score does not properly assess lifetime risk, particularly among young adults or adolescents with abdominal obesity (Grundy 2007), who are not considered at risk of CVD by current algorithms because of their youth. On the other hand, a clinical diagnosis of visceral obesity, insulin resistance, or of the metabolic syndrome is not sufficient to assess global risk of cardiovascular disease. To achieve this goal, physicians should first pay attention to the classical risk factors while also taking into account the additional risk resulting from the presence of abdominal obesity and the metabolic syndrome, which should be considered to be another modifiable CVD risk factor.

Thus, it is essential to develop a risk assessment model of global CVD in the presence of traditional risk factors and the emerging markers found in individuals with visceral obesity. Després et al. defined this model as global cardiometabolic risk (Despres et al. 2008). Under this model, cardiometabolic risk is the global risk of CVD resulting from the presence of traditional risk factors combined with the possible additional contribution of the MetS. It is important to highlight that the global CVD risk algorithms already consider three (HDL-cholesterol, blood pressure, and glucose) of the five metabolic syndrome features. Moreover, as the most prevalent form of the MetS is observed among patients with excess visceral adiposity/ectopic fat, Després proposed that the combination of elevated waist circumference and triglycerides was enough to screen for patients with an excess of visceral/ectopic fat and insulin resistance (Lemieux et al. 2000). Therefore, further attention should be given to add "hypertriglyceridemic waist" to the list of variables considered in global risk algorithms (Lemieux et al. 2000; Lemieux et al. 2007), which will ultimately lead to the global cardiometabolic risk assessment algorithms (Fig. 131.2).

131.4 Practical Methods and Techniques

Waist circumference is actually a perimeter, which provides an estimate of body girth at the level of the abdomen. Different studies used different anatomic landmarks to determine the exact location for measuring WC, including 1) midpoint between the lowest rib and the iliac crest; 2) the umbilicus; 3) narrowest (minimum) or widest (maximum) WC; 4) just below the lowest rib; and 5) just above the iliac crest. The specific site used to measure WC influences the absolute WC value that is obtained (Wang et al. 2003). The most commonly used sites reported in studies that evaluated the relation between morbidity or mortality rate and WC were the midpoint between the lowest rib and the iliac crest (29%), the umbilicus (28%), and the narrowest WC (22%). Although sites that use an easily identifiable and reproducible landmark (e.g., just above the bony landmark of the lilac crest) might be more precise and easier to use than other sites, we are not aware of data from any studies that demonstrate an advantage of one measurement site over others. WC measurements should be made around a patient's bare midriff, after the patient exhales while standing without shoes and with both feet touching the floor and arms hanging freely. The measuring tape should be made of a material that is not easily stretched, such as fiberglass. The tape should be placed perpendicular to the long axis of the body and horizontal to the floor and applied with sufficient tension to conform to the measurement surface. In a research setting, WC measurements are typically taken thrice and recorded to the nearest 0.1 cm. Although specific techniques have been recommended for measuring WC in the clinical setting (Douketis et al. 2005; Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults–The Evidence Report. National Institutes of Health 1998a), there is no approach uniformly accepted. Training technicians and even patients to use an appropriate technique for measuring WC is essential to obtain reliable data; special tape measures,

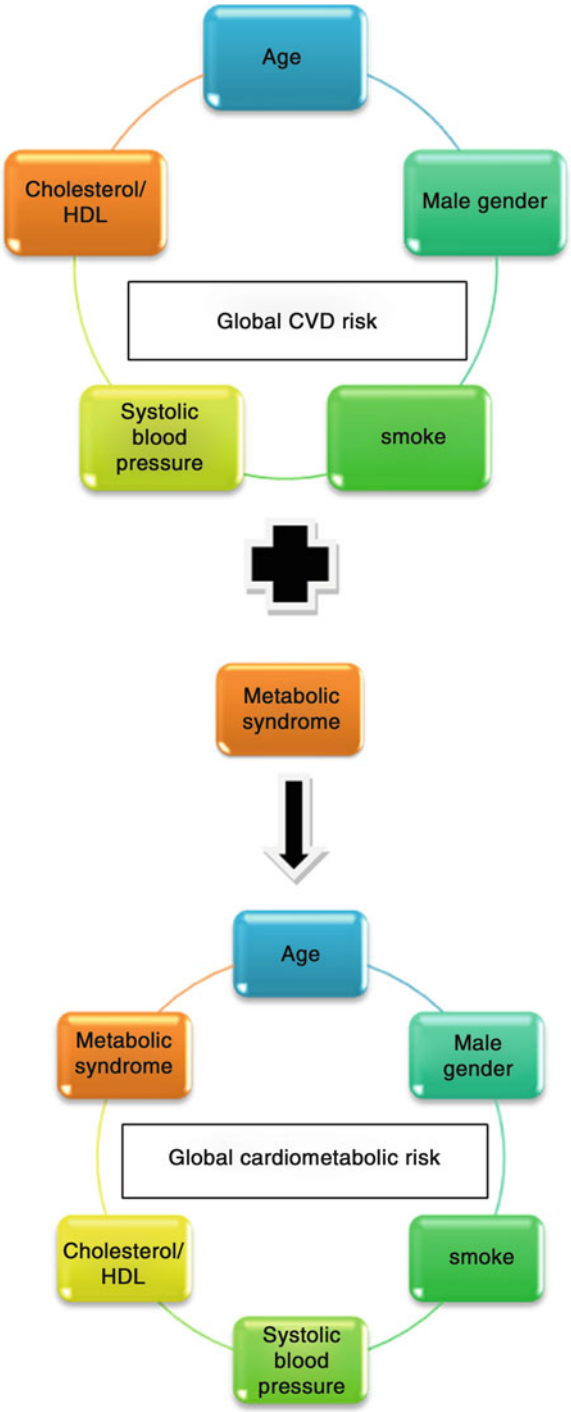

Fig. 131.2 Global cardiometabolic risk. The global cardiometabolic risk is the result of the traditional global CVD risk, which includes age, male gender, smoke, systolic blood pressure and total cholesterol and HDL cholesterol plus metabolic syndrome

instructional manuals, and videotapes are available for this purpose (2008). The reproducibility of WC measurements at all sites is high for both men and women (e.g., at the iliac crest site, intraclass correlation coefficient, r = 0.998 and r = 0.999, respectively) (Wang et al. 2003). The correlation between technician- and self-measured WC after proper training can also be high for men (r = 0.95)

Table 131.4 Ethnic specific values for waist circumference (Data presented are reprinted by permission of the publisher of reference (The IDF consensus worldwide definition of the Metabolic Syndrome 2006))

	Waist circumference	
Country/ethnic group	Men	Women
Europids[a]	≥94 cm	≥80 cm
In the USA, the ATP III values (102 cm male; 88 cm female) are likely to continue to be used for clinical purposes		
South Asians	≥90 cm	≥80 cm
Based on a Chinese, Malay, and Asian-Indian population		
Chinese	≥90 cm	≥80 cm
Japanese[b]	≥90 cm	≥80 cm
Ethnic South and Central Americans	Use South Asian recommendations until more specific data are available	
Sub-Saharan Africans	Use European data until more specific data are available	
Eastern Mediterranean and Middle East (Arab) populations	Use European data until more specific data are available	

[a]In future epidemiological studies of populations of Europid origin, prevalence should be given using both European and North American cut points to allow better comparisons

[b]Originally, different values were proposed for Japanese people but new data support the use of the values shown above

and women (r = 0.89), respectively (Rimm et al. 1990). However, self-reported measurements are prone to a systematic bias, and there is a nontrivial underestimate of self-measured WC at all anatomic sites (Klein et al. 2007).

The American recommendation for waist circumference thresholds for increased cardiometabolic risk in men (>102 cm) and women (>88 cm) were derived from WC values that correlated with a BMI ≥ 30 (1998a). The National Health and Nutrition Examination Survey III (NHANES III) found that about 14% of women and about 1% of men had a "high" WC but a normal BMI (18.5–24.9) (Meisinger et al. 2006). In addition, about 70% of women who were overweight (BMI 25.0– 29.9) had a WC > 88 cm and about 25% of men who were overweight had a WC > 102 cm. An estimate based on data available from the World Health Organization's MONICA Project, conducted in > 32,000 men and women from Europe, Australia, and New Zealand, suggests that about 10% of participants, who had a BMI < 30, had a WC above the recommended cut points for increased risk (Meisinger et al. 2006). It is not known what portion of subjects who had a large WC would have been identified as having increased cardiometabolic risk, based on findings from a standard medical evaluation. Therefore, the optimal WC criteria needed to identify patients at increased risk of metabolic disease, who would otherwise not be identified by evaluating BMI and/or other standard cardiometabolic risk factors, is not known and will likely require adjustments based on BMI, sex, age, and race/ethnicity (Klein et al. 2007).

Central obesity is most easily measured by waist circumference in persons with a BMI between 25.0 and 34.9, resulting in gender- and race/ethnic-group-specific cut points as defined by the guidelines (Table 131.4). Although a higher cut point is currently used for all ethnic groups in the USA for clinical diagnosis, it is strongly recommended that, for epidemiological studies and, wherever possible, for case detection, ethnic-group-specific cut points should be used for people of the same ethnic group, wherever they are found. Thus, the criteria recommended for Japan would also be used in expatriate Japanese communities, as would be those for South Asian males and females, regardless of place and country of residence (Tan et al. 2004; The IDF consensus worldwide definition of the Metabolic Syndrome 2006).

It is a consensus that these pragmatic cut points are taken from various data sources and that better data will be needed to link these to risk (2006).

131.5 Visceral Fat Management

Obesity management goals should encompass a reduction in total cardiovascular morbidity and mortality. Losing 5–10% of body weight reduces the traditional CV risk factors in obese subjects (Klein et al. 2007). Increasing physical activity, in combination with a diet that emphasizes fresh fruits and vegetables, whole grains, and low-fat dairy products, can help patients to reduce their weight and obesity comorbidity. Less is known about the long-term effect of weight loss on the development of T2DM and CVD outcomes in the form of death, myocardial infarction, and stroke. Currently, ongoing clinical trials use health-promoting lifestyle interventions, new drugs, and even surgery, all of which are aimed at weight loss, reduction in disease manifestations, and improved outcomes (Pi-Sunyer et al. 2007). A trial to answer the most important question whether the improvements in cardiovascular risk factors by managed weight loss will be associated with reduction in long-term cardiovascular events is under investigation (The Look AHEAD (Action for Health in Diabetes) trial) (Pi-Sunyer et al. 2007) and the expected data are essential for the future development of effective CVD prevention strategies.

131.6 Applications to Other Areas of Health and Disease

131.6.1 To Measure or Not to Measure? That Is the Question

The crucial answer to this question, even in individuals not related to the Prince of Denmark (Shakespeare 1601), should not only be based on statistical predictivity of fat distribution measures, but also on practical considerations, such as added burden to already busy clinical practices and the acceptability of the measures to patients and clinicians. Although determination of waist circumference looks simple and requires only a tape measure, there is no standardized protocol in research or clinical practice setting, and studies have used various locations of waist circumferences. In addition, there is no standard cut point for defining central obesity. The International Diabetes Federation proposed sex- and ethnicity-specific cut points for central obesity as measured by waist circumference (2006). However, these cut points are controversial and are complicated to use in clinical practice. Finally, it is unclear whether waist circumference should be recommended to all patients or only to subgroups of patients. Fat distribution may have greater added value beyond BMI in predicting morbidity and mortality among patients who are of normal weight or moderate overweight than among those who are overtly obese, as assessed by BMI. Obviously, a waist circumference measurement is unnecessary for morbidly obese patients (BMI $\geq$ 35).

Taken together, it seems that, among various measurements of fat distribution, waist circumference is the most practical and the simplest to interpret. Despite several unresolved questions regarding the use of fat distribution measures in clinical practice, mounting evidence indicates the importance of monitoring changes in waist size. There is an urgent need to increase the awareness among both health professionals and the general public about the health hazards of central or abdominal obesity. Although maintaining a healthy weight should continue to be a cornerstone in the prevention of chronic diseases and premature death, maintaining a healthy waist size should also be an important goal (Hu 2007).

Summary Points

- The obesity epidemic poses a global concern because of its related health problems.
- The most appropriate adiposity markers for assessing the risk of disease and death are debated.
- Most adipose tissue is located under the skin (about 85%) and a smaller amount (about 15%) is located within the abdomen (intra-abdominal or visceral fat).
- The relative contribution of intra-abdominal fat to total body fat is influenced by sex, age, race/ethnicity, physical activity, and total adiposity.
- Intra-abdominal fat is more closely associated with the risk of several chronic diseases than a more peripheral (subcutaneous) fat distribution.
- Waist circumference or the waist–hip ratio, as indicators of abdominal obesity, may be better predictors of the risk of disease than the body mass index, an indicator of general adiposity.
- A simple measurement of waist circumference is strongly correlated with risk for diabetes mellitus and cardiovascular disease.
- Insulin resistance is a key factor associated with a typical atherogenic dyslipidemic state, a prothrombotic profile, a state of inflammation, an elevated blood pressure, and dysglycemia.
- The waist–hip ratio and the waist and hip circumferences were highly associated with the risk of acute myocardial infarction. The waist–hip ratio was associated with increased risk for non-lacunar and cardioembolic stroke and peripheral arterial disease. The waist circumference was associated with a higher risk of venous thrombo-embolism.
- Després defined a global cardiometabolic risk model, which results from the presence of traditional risk factors combined with the possible additional contribution of elevated waist circumference and triglycerides to the list of variables considered in global risk algorithms, which will ultimately lead to the global cardiometabolic risk assessment algorithms.
- Increasing physical activity, in combination with a diet that emphasizes fresh fruits and vegetables, whole grains, and low-fat dairy products, can help patients to reduce their weight and obesity comorbidity.
- Taken together, it seems that among various measurements of fat distribution, waist circumference is the most practical and the simplest to interpret.
- Despite several unresolved questions regarding the use of fat distribution measures in clinical practice, mounting evidence indicates the importance of monitoring changes in waist size.
- There is an urgent need to increase the awareness among both health professionals and the general public about the health hazards of central or abdominal obesity.
- Although maintaining a healthy weight should continue to be a cornerstone in the prevention of chronic diseases and premature death, maintaining a healthy waist size should also be an important goal.

Key Features

Table 131.5 Key points

1.	The obesity epidemic poses a global concern because of its related health problems.
2.	Intra-abdominal fat is more closely associated with the risk of several chronic diseases than a more peripheral (subcutaneous) fat distribution.
3.	A simple measurement of waist circumference is strongly correlated with risk for diabetes mellitus and cardiovascular disease.

Acknowledgment The authors wish to acknowledge Renate Domeier for her assistance with preparation of the chapter.

Chapter 132
Anthropometry, Body Surface Area and Cardiopulmonary Bypass: Determining the Pump Flow Rate of the Heart–Lung Machine Using Body Size

R. Peter Alston

Abstract Cardiopulmonary bypass (CPB) is the keystone that enables heart surgery to be safely performed on hundreds of thousands of patients around the world each year. During CPB, two crucial factors, the oxygen content of arterial blood and the pump flow rate, determine whether sufficient oxygen is supplied to the body to match its metabolic demands. With modern oxygenators, full oxygenation of the arterial blood is easily achieved. However, the pump flow rate remains important as both too low and too high flow rates may be harmful.

Traditionally, pump flow rate has been based on body surface area (BSA), estimated from height and weight, commonly using the formula of du Bois and du Bois. This formula was developed nearly a century ago from an original sample of only nine subjects. Although it may have been of acceptable accuracy for the population at that time, it might no longer be appropriate for the increasing number of obese patients now presenting for heart surgery. Recent research findings, using the saturation of haemoglobin with oxygen in the mixed-venous blood [$\bar{S}vO_2$] as a measure of the adequacy of the perfusion of the body, would suggest that lean body mass (LBM) might be a better basis for determining pump flow rate during CPB than BSA.

Alternatively, guiding pump flow rate during CPB via inline, real-time $\bar{S}vO_2$ could overcome the important limitations of any determination based on an anthropometric estimate of body size. However, the introduction of either LBM or $\bar{S}vO_2$ to determine pump flow rate would require further research, including a randomised control trial in a very large number of patients undergoing heart surgery with CPB. Therefore, regardless of the limitations associated with the use of BSA to determine pump flow rate, it would appear that this will remain the standard method for the foreseeable future.

Abbreviations

BSA	Body surface area
BMI	Body mass index
CPB	Cardiopulmonary bypass
LBM	Lean body mass

VO_2 Systemic oxygen uptake.

132.1 Introduction

Cardiopulmonary bypass (CPB) is the technique of mechanically replacing the functions of the heart and lungs to supply oxygen for all the metabolic requirements of the body. John Gibbon pioneered CPB in clinical practice more than 55 years ago and, subsequently, this technique became the keystone that has enabled millions of patients around the world to safely undergo heart surgery.

CPB has two essential functions, the mechanical pumping of blood throughout the body and gas exchange to remove carbon dioxide from and add oxygen to the blood. As the pump flow rate controls the volume of blood that is pumped around the body per unit time, usually expressed in units of litres per minute (l min^{-1}), it is the equivalent of cardiac output in the intact cardiovascular circulation. Determining the correct pump flow rate is critical; rates that are too low will result in systemic hypoperfusion and, as a consequence, potential organ damage, and rates that are too high may also be deleterious by causing hypertension and excessive bleeding.

Whilst techniques may vary from institution to institution, pump flow rate has historically been based upon body surface area (BSA). The aim of this chapter is to explore why pump flow rate became based on this particular anthropometric measure and why it may no longer be appropriate today. Alternative methods of determining pump flow rate will be considered and their relative merits and potential for replacing BSA will be assessed. Before doing so, a brief overview of the technique of CPB will be given and the methods by which the efficiency of CPB is assessed will be considered.

132.2 Cardiopulmonary Bypass

132.2.1 Technique of Cardiopulmonary Bypass

A full description of CPB is beyond the scope of this chapter and readers wishing further detail are referred to a textbook dedicated to the theory and clinical practice of CPB (Gravlee et al. 2008). However, the basic principles are as follows. Venous blood is drained from the body, usually directly from a cannula inserted into the inferior vena cava and indirectly from the superior vena cava via a cannula placed in the right atrium, into a reservoir (Fig. 132.1). Blood from the inferior and superior vena cavae have different oxygen contents and their combination in the common venous line is termed mixed-venous blood. The mixed-venous blood is partially deoxygenated and, normally, the haemoglobin in this blood is nearly 75% saturated with oxygen. The blood is then pumped through an oxygenator that removes carbon dioxide and adds oxygen to the blood. From the oxygenator, the decarboxylated and oxygenated blood flows back into the arterial vascular system, usually via a cannula inserted into the ascending aorta, to supply oxygen for the metabolic needs of the body (Table 132.1).

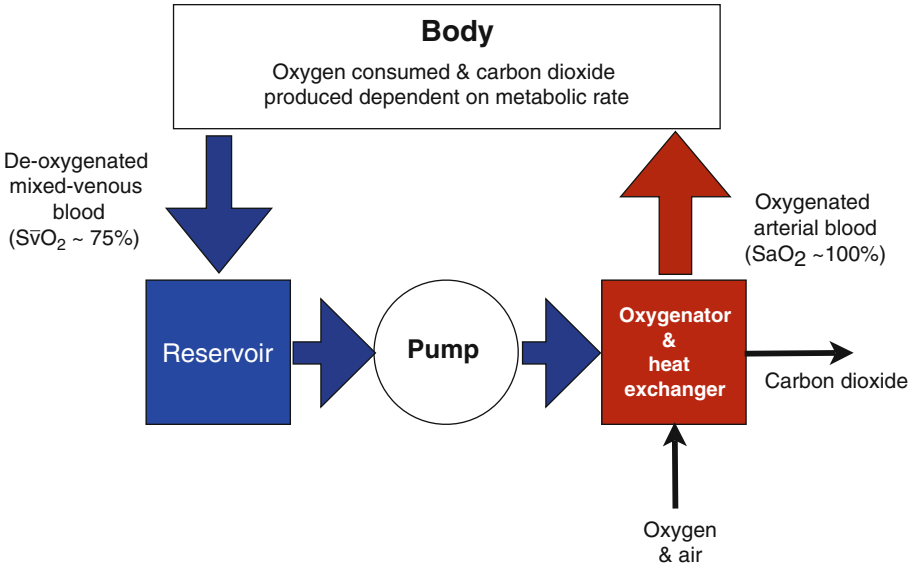

Fig. 132.1 Schematic diagram of a cardiopulmonary bypass circuit. Schematic diagram of a cardiopulmonary bypass (CPB) circuit. The body consumes oxygen (systemic oxygen uptake) in a quantity required to match its metabolic rate and produces carbon dioxide (systemic carbon dioxide output). Venous blood is drained from the body, usually directly from a cannula inserted into the inferior vena cava and indirectly from the superior vena cava via a cannula placed in the right atrium, into a reservoir. Blood from the inferior and superior vena cavae have different oxygen contents and their combination in the common venous line is termed mixed-venous blood. The mixed-venous blood is partially deoxygenated and, normally, the haemoglobin in this blood is nearly 75% saturated with oxygen. The blood is then pumped from the reservoir into an oxygenator through which passes a mixture of oxygen and air that removes carbon dioxide from and adds oxygen to, the blood. The flow rate of the pump is the volume of blood pumped through the body per unit time (l min^{-1}) and is equivalent to the cardiac output in the intact cardiovascular system. Blood can also be cooled to induce hypothermia or heated to rewarm the patient back to normothermia (37°C) at the end of CPB. Oxygenated blood, with haemoglobin that is nearly 100% saturated with oxygen, then flows back into the body's arterial system, usually via a cannula placed in the ascending aorta

Table 132.1 Key facts about cardiopulmonary bypass

- The primary functions of the heart and lungs are to supply oxygen to and remove carbon dioxide from the body.
- Cardiopulmonary bypass (CPB) mechanically replaces the functions of the heart and lungs.
- The mechanical device used for CPB is commonly called a heart–lung machine.
- The first successful use of CPB to perform heart surgery was in 1953.
- CPB now enables heart surgery to be safely performed on hundreds of thousands of patients every year around the world.
- Hypothermia is often used with CPB because it increases the margin of safety as it reduces the metabolic rate and therefore the body's oxygen requirement.
- The flow rate of the pump during CPB is the volume of blood circulating through the body per unit time and is equivalent to the cardiac output in the intact cardiovascular system.
- Along with the oxygen content of arterial blood, the pump flow rate determines how much oxygen is delivered to the body.
- Pump flow rates that are too high or too low may be harmful.
- For about 50 years, the pump flow rate for individual patients has been based on a multiple, commonly 2.4, of body surface area.

Key facts about cardiopulmonary bypass including its function of replacing the heart and lungs, supplying oxygen and removing carbon dioxide from the body, its history and the importance of the pump flow rate.

132.2.2 Hypothermia

A heat exchanger is incorporated with the oxygenator and this allows the body to be cooled to induce hypothermia. Hypothermia has traditionally been used to increase the margin of safety during CPB. The degree of hypothermia depends on the surgical requirement, for example, heart valve surgery is generally performed at lower temperatures than coronary artery bypass grafting surgery. The body's temperature may be reduced from normothermia of 37°C by a few degrees, to induce mild hypothermia, all the way down to 15°C, for profound hypothermia, or somewhere in between. By reducing metabolic rate, hypothermia makes it easier to ensure that the oxygen supply during CPB is an adequate match to the oxygen demands of the body, especially when using low rates of pump flow. This was particularly important during the early years of CPB, as the oxygenators of this time often had only a limited capacity to oxygenate the blood and this may have been insufficient for patients with a large body size. The heat exchanger is also used towards the end of CPB to add heat energy to the blood and thus re-warm the body back to normothermia.

132.3 Assessing the Adequacy of Cardiopulmonary Bypass

132.3.1 Blood Oxygenation and Carbon-Dioxide Removal

The first essential function of CPB is gas exchange, removing carbon dioxide and adding oxygen to the blood. Early oxygenators were not efficient at this process and, originally, the only way that their effectiveness could be assessed was by intermittent arterial blood sampling and remote analysis on a bench blood-gas analyser. Inevitably, there was a time delay before the results were available for interpretation by the perfusionist operating the CPB machine, during which period there may have been important changes in the clinical condition of the patient. Therefore, the standard practice was to make the blood hyperoxic to maintain a margin of safety. Today, modern oxygenators achieve gas exchange with a high degree of efficiency. Moreover, in-line blood gas monitors, available for over two decades, allow real-time display of oxygen and carbon dioxide tensions, thus providing continuous assessment of the efficiency of gas exchange. Therefore, in current practice, this function of CPB is reliable and safe.

132.3.2 Pump Flow Rate

Ensuring systemic oxygen delivery and carbon-dioxide removal is the other essential function of CPB and this is achieved by mechanically pumping the blood around the body. In the intact circulation, this is the function of the heart and, unless there is heart failure, systemic oxygen delivery is matched to the metabolic requirements of body. This function is measured by the cardiac output and, during CPB, the pump flow rate is its equivalent. During the early years of CPB, low pump flow rates were favoured, as less efficient heart–lung machines could be used, there was less blood loss and a lower volume of blood was required to prime the circuit (Andersen 1958). However, others argued for the use of a pump flow rate during CPB that equated with a normal cardiac output (Kirklin et al. 1956).

Although carbon-dioxide output can also be used (Alston et al. 2003), the adequacy of pump flow rate has traditionally been assessed by systemic oxygen uptake (VO_2) (Paneth et al. 1957; Andersen and Senning. 1958; Clark 1958; Clowes et al. 1958; Vetto et al. 1958; Cheng et al. 1959; Starr 1959; Galletti and Brecher 1962) Table 132.2. With these methodologies, the terms carbon dioxide output and VO_2 are used because the fluxes in body temperature that occur during CPB cause important changes in the solubility of these gases, making it impossible to determine the actual rates of carbon-dioxide production or oxygen consumption by the body. As, under normal conditions the metabolism of the body is aerobic, these measures are indirect calorimetric estimates of the body's metabolism. The ratio between carbon dioxide output and VO_2 depends on the relative proportions of carbohydrate, fat and protein that are being metabolised. As a result, the carbon dioxide output will be slightly less than VO_2 and the relative difference in volume per unit time represents the respiratory quotient.

132.3.3 Fick's Principle

Traditionally, VO_2 has been calculated using Fick's principle. Samples of mixed-venous and arterial blood are simultaneously aspirated from the CPB circuit and the pump flow rate noted. The saturations of haemoglobin with oxygen, partial pressures of oxygen and haemoglobin concentrations in the arterial and mixed-venous blood samples are measured using a blood-gas analyser. The oxygen content in the arterial and mixed-venous blood samples are then calculated using the formula in Table 132.3. Finally, using the formula in Table 132.4 the difference in oxygen content between arterial and mixed-venous blood is then multiplied with the pump flow rate, moderated by surface area, to obtain VO_2.

Table 132.2 Key facts of systemic oxygen uptake

- The systemic oxygen uptake (VO_2) is the total amount of oxygen consumed to metabolise substrates so as to produce the energy that runs the normal functions of the body.
- The rate of VO_2 depends on the metabolic rate of the body: the VO_2 is low at rest and is high during exercise.
- Temperature has a marked effect on metabolic rate and hence, VO_2. For example, fever increases VO_2 and hypothermia decreases VO_2.
- VO_2 is commonly calculated using Fick's principle, which requires measurement of the oxygen content of arterial and mixed-venous blood and the cardiac output, or pump flow rate during cardiopulmonary bypass (see Table 132.3).
- The rate of carbon dioxide output is always less than the rate of VO_2.
- The ratio of carbon dioxide output to VO_2 is called the respiratory quotient and depends on the substrates that the body is metabolising.

Key facts about systemic oxygen uptake (VO_2) and its relationship to the metabolism and temperature of the body; also, how VO_2 is calculated and its relationship to systemic carbon dioxide output

Table 132.3 Formula for calculating the oxygen content of blood

$$CO_2 = Hb * 1.34\ SO_2 + 0.003 * PO_2$$

The formula for calculating the oxygen content of blood from measurements of haemoglobin concentration, the saturation of haemoglobin with oxygen and the oxygen partial pressure, where: CO_2 = oxygen content of blood (ml^{-1} l), Hb = concentration of haemoglobin in blood (g^{-1} l), SO_2 = saturation of haemoglobin with oxygen (%), 1.34 = Hufner's factor, 0.003 = solubility factor of oxygen in blood at 37°C and PO_2 = partial pressure of oxygen in blood (kPa)

Table 132.4 Formula for calculating systemic oxygen uptake using Fick's principle

$$VO_2 = (CaO_2 - C\bar{v}O_2) * Q/BSA$$

Systemic oxygen uptake during cardiopulmonary bypass may be calculated using Fick's principle with the above formula, if the oxygen contents of arterial and mixed-venous blood and the pump flow rate are known, where: VO_2 = systemic oxygen uptake (ml min^{-1} m^{-2}), CaO_2 = oxygen content of arterial blood (ml l^{-1}), $C\bar{v}O_2$ = oxygen content of mixed-venous blood (ml l^{-1}), Q = pump flow rate (l m^{-2}) and BSA (body surface area)

132.3.4 Limitations of Fick's Principle

Unfortunately, this technique is error prone, as it requires measuring seven different variables, each having its own measurement error and these errors are then compounded by the arithmetical combination (Alston et al. 2003). In addition, VO_2 calculated in this way is directly related to several important predictor variables, limiting its use in statistical analyses.

132.3.5 Measuring Systemic Oxygen Uptake in the Gas Phase

Rather than using Fick's principle, a more statistically independent and less error-prone approach to determine VO_2, is to measure the concentrations of oxygen in the oxygenator's gas supply and exhaust (High et al. 2000). VO_2 can then be calculated by compounding the difference between oxygen concentrations of gas entering and exhausting the oxygenator with the gas flow rate. However, as the volume of carbon dioxide produced by the body is less than the oxygen consumed, the exhaust gas flow rate is less than the measured inflow rate. Whilst it is possible to correct for this difference using a dilutional gas (High et al. 2000), this would be complex in clinical practice. In addition, because the solubility of oxygen and, particularly, carbon dioxide, is influenced by temperature, this technique would be prone to error during induction of hypothermia and re-warming (Alston et al. 2006). Therefore, like the previous technique based on Fick's principle, calculating VO_2 based on measurements of the oxygenator's gas inflow rate and the difference between input and exhaust oxygen concentrations also has important limitations.

132.3.6 $S\bar{v}O_2$ as an Estimate of the Adequacy of Pump Flow Rate

Mixed-venous haemoglobin saturation with oxygen $S\bar{v}O_2$ requires measurement of a single variable and offers a statically independent estimate of the adequacy of pump flow rate (Alston et al. 2006). As this is the average of all the tissues supplied, it can estimate the efficacy of the pump flow rate in supplying the body with oxygen. Moreover, it is now possible to do this with in-line, real-time measurement of $S\bar{v}O_2$ (Table 132.5)

132.4 Why Base Pump Flow Rate on Body Surface Area?

One of the challenges facing the pioneers of CPB was the variance in the size of patients requiring heart surgery, ranging from tiny infants to large adults. For this reason, one focus of early research was the determination of adequate pump flow rates for patients of different sizes. Initially, pump flow

Table 132.5 Key facts of oxygen carriage in the blood and the importance of $S\bar{v}O_2$

- Oxygen is carried in the blood: a very small amount is in solution in the plasma and the vast majority is carried by haemoglobin.
- The amount of oxygen attached to haemoglobin is described as the percentage of the maximum that can possibly be carried and is referred to as saturation.
- The haemoglobin in arterial blood during CPB is nearly always close to 100% saturated with oxygen.
- Oxygen is extracted from the haemoglobin by the body as it passes through the tissues.
- The amount of oxygen extracted from haemoglobin varies, depending on the metabolic activity of the tissues through which it is passing, producing blood that has different saturations with oxygen.
- On returning to the heart, blood from the inferior and superior venae, that are of differing saturations with oxygen, are mixed and this is termed the mixed-venous haemoglobin oxygen saturation ($S\bar{v}O_2$).
- $S\bar{v}O_2$ is an estimate of the adequacy of pump flow rate to supply oxygen in amounts that match the metabolic demands of the body during CPB.
- The normal level of $S\bar{v}O_2$ is nearly 75%. Commonly, low levels of $S\bar{v}O_2$ indicate hypoperfusion and high levels of hyperperfusion.

Key facts about oxygen transport in the blood and extraction of oxygen by the tissues; also, the importance of mixed-venous haemoglobin saturation with oxygen $S\bar{v}O_2$ as an estimate of the adequacy of pump flow rate during CPB

rates were based on body weight, but body surface area (BSA) soon became the international standard. To this day, with some minor variation between institutions, pump flow rates are still predetermined using BSA. However, as will be discussed, these predetermined pump flow rates may no longer be appropriate for today's patients.

From the late nineteenth century onwards, there was a widespread belief that the metabolic rate of a homogeneous animal, regardless of species, was related to its BSA. This idea was crystallised by the work of Max Rubner who created the 'law of surface area', stating that the heat value of the metabolism of a resting individual is proportional to their body surface area (Rubner 1883; Chambers 1952). Given the difficulties inherent in the measurement of BSA, this law was difficult to disprove.

As measurement by direct calorimetry was too complex for the clinical setting, BSA seemed an acceptable alternative estimate of metabolic rate. For this reason, efforts at the beginning of the twentieth century concentrated on the calculation of BSA from simple mathematical formulae of body dimensions and during the rest of the century there were many attempts to simplify the equations (Gibson and Numa 2003). Despite an uncertain relationship with metabolic rate and the questionable accuracy of many of the derived formulae, indexing a variety of physiological functions to BSA became standard in medicine at this time. Glomerular function and, notably for this chapter, cardiac output are examples of this practice.

Much of the original work to determine what was an adequate pump flow rate during CPB was undertaken in animals, commonly canine, and pump flow rates were usually based on body weight. Indeed, body weight was also used in the first series of heart surgery in humans to determine the pump flow rate during CPB (Clark 1958; Kirklin et al. 1958). Adequate flow rates were believed to be those which equated with the cardiac output that supplied the metabolic needs of a human under light general anaesthesia (Clark 1958; Kirklin et al. 1958; Galletti and Brecher. 1962). This was because of the mistaken belief that 'somnolent metabolic rate' was lower than basal metabolic rate (Galletti and Brecher 1962). On this basis, Kirklin's group at the Mayo Clinic originally used a flow rate of 75 ml min^{-1} kg^{-1} (Kirklin et al. 1958).

The use of BSA to determine pump flow rate is attributed to Emerson Moffitt whose study of these early patients and his expression of pump flow rate as litres per minute per square metre (l min^{-1} m^{-2}) led to the realisation that 75 ml min^{-1} kg^{-1} did not approximate to the cardiac output of the lightly anaesthetised patient (Kirklin et al. 1958). As a result, the Mayo Clinic changed to pump

flow rates, based upon BSA, of 2.3 l min^{-1} m^{-2} (Kirklin et al. 1958). This revised flow rate was also determined by their observation that the VO_2 of humans on CPB was 110–120 ml min^{-1} m^{-2} and that, if $\bar{S}vO_2$ was to be maintained at 75%, the normal level in the intact circulation, the oxygenator would have to add 110–120 ml min^{-1} m^{-2} and, therefore, the pump flow rate would have to be in the range of 2.2–2.5 l min^{-1} m^{-2} (Kirklin et al. 1957).

132.5 Body Surface Area May Be an Inappropriate Predictor of Oxygen Uptake

The formula of du Bois and du Bois that is commonly used to determine BSA for CPB was based upon measurements undertaken in only nine patients nearly 100 years ago (du Bois and du Bois 1916). Although this may have provided an acceptable accuracy for the population at that time, obesity is now far more prevalent than in 1953 when CPB was first introduced into clinical practice. In patients who are obese, a far greater proportion of fat, relative to lean tissue, contributes to BSA. Lean tissue, such as muscle, is the major determinant of basal metabolic rate and, therefore, should be an important predictor of how much oxygen the body requires during CPB (Bogardus et al. 1986). Consequently, when based upon BSA, pump flow rates may be higher than required to provide an adequate VO_2 in obese patients, with the potential of causing hypertension and excessive bleeding.

132.6 Other Body Size Estimates That May Predict Systemic Oxygen Uptake During Cardiopulmonary Bypass

132.6.1 Body Mass Index

For heart surgery with CPB in the obese patient, an estimate of body fat might be a better predictor of oxygen uptake. Although abdominal girth has recently been introduced as a measure of obesity, body mass index (BMI) has traditionally been the anthropomorphic measure most widely used to determine the relative amount of body fat. Therefore, BMI might be a useful estimate for VO_2 in today's increasingly obese patients undergoing CPB. However, as with any surrogate measure, because BMI is only an estimate of the proportion of body fat, there are limitations related to its accuracy and ability to discriminate (Prentice and Jebb. 2001).

132.6.2 Lean Body Mass

If an estimate of body fat is not necessarily the answer, then an estimate of the amount of lean tissue might be a better approach. Lean tissue is far more metabolically active than fat and therefore consumes the majority of oxygen in the body. Lean body mass (LBM) provides an estimate of how much of the body's mass is composed of lean tissue and, consequently, could provide a better estimate of systemic oxygen consumption during CPB than BSA.

A number of ways of actually measuring or estimating LBM are discussed earlier in this book in the chapters of Sect. 1: Tools and techniques in anthropometry: techniques and general methods.

Table 132.6 Estimation of lean body mass using skinfold thicknesses

Density = (*c* – *m*) * log (biceps + triceps + suprailiac + subscapularis skinfold thicknesses),
where *c* and *m* are regression coefficients, obtained from a table, which relate to gender and various age groups.
Total fat (%) = (4:95/density – 4:5) * 100
Lean body mass (%) = 100 – % fat
Lean body mass (kg) = (100 – % fat) * weight (kg)

Lean body mass may be estimated by measuring the skinfold thicknesses at four sites and using the above formulae (Durnin and Womersley 1974)

However, measurements of skinfold thicknesses provide a simple estimate of LBM that can be easily made in the clinical environment with minimal training and simple equipment (Table 132.6).

132.7 Predictors of $\bar{S}v0_2$ During Cardiopulmonary Bypass

With the aim of determining which estimate of body size best predicted systemic metabolism, and hence VO_2, during CPB, the author and colleagues undertook a study of $\bar{S}vO_2$ during CPB (Alston et al. 2006). A total of 48 patients undergoing elective cardiac surgery with CPB were enrolled and, prior to surgery, height, weight and skinfold thicknesses were measured. Following induction of general anaesthesia, CPB was established using a standardised technique. The body was cooled to induce systemic hypothermia and, except for brief reductions for surgical interventions, the pump flow rate was maintained at a constant value of 2.4 l min^{-1} m^{-2} throughout CPB.

During CPB, arterial and mixed-venous blood samples were taken at three time points, cooling (10 min after commencing CPB), stable hypothermia and rewarming (a nasopharyngeal temperature of approximately 36°C). The sampling periods were chosen to cover the range of thermal conditions that patients experience during CPB and nasopharyngeal temperatures, as an estimate of metabolic rate, were recorded at each time point. Blood samples were then subjected to blood-gas analysis and measurement of $\bar{S}vO_2$ using standardised techniques.

132.7.1 Correlates of $\bar{S}v0_2$

For the initial exploration of the data, the mean $\bar{S}vO_2$ from the three sampling times was correlated with BSA, BMI, LBM and nasopharyngeal temperature. Significant univariate correlations with $\bar{S}vO_2$ were only found for BMI, LBM and nasopharyngeal temperature. These predictor variables were then entered into a stepwise multiple regression model with $\bar{S}vO_2$ as the dependant variable. The final regression model included only the inverse of nasopharyngeal temperature ($\beta = 0.615$, $p < 0.001$) and LBM ($\beta = 0.256$, $p < 0.028$) (Figs. 132.2 and 132.3).

132.7.2 Body Temperature and $\bar{S}v0_2$

The strong inverse association found between $\bar{S}vO_2$ and nasopharyngeal temperature is clearly explained by the fundamental effect of temperature on the body's metabolism. Hypothermia reduces metabolic rate and hence oxygen consumption by the body. As the pump flow rate was constant,

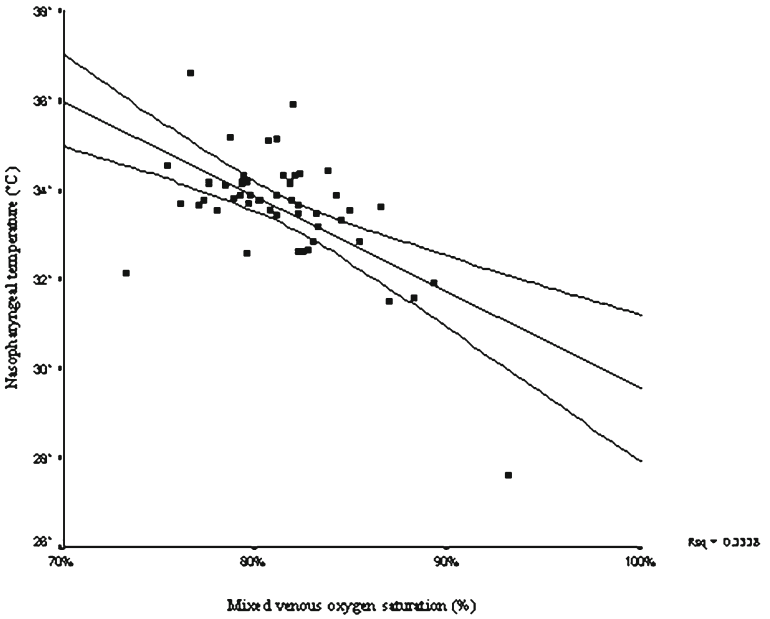

Fig. 132.2 Scatter plot of the saturation of mixed-venous haemoglobin with oxygen against nasopharyngeal temperature. Scatter plot of the saturation of mixed-venous haemoglobin with oxygen $S\bar{v}O_2$ against the nasopharyngeal temperature during cardiopulmonary bypass, showing a negative correlation. As the temperature of the body decreases, the metabolic rate decreases and, therefore, less oxygen is extracted. Assuming that the arterial blood is fully oxygenated and pump flow rate is maintained constant, then, according to Fick's principle, the oxygen content of venous blood must increase, resulting in a higher $S\bar{v}O_2$ (Reprinted from Alston et al. 2006. With permission)

systemic oxygen delivery was also constant and, according to Fick's principle, $S\bar{v}O_2$ must rise, resulting in an inverse relationship with body temperature. Conversely, $S\bar{v}O_2$ must be lower at higher body temperatures, if the pump flow rate is not altered.

132.7.3 $S\bar{v}0_2$ and Body Surface Area

Although BSA did not predict $S\bar{v}O_2$, there were a number of limitations that may explain the lack of a significant association in this study. Most importantly, pump flow rates were not randomly assigned and were determined by BSA, which may have reduced any variance in $S\bar{v}O_2$ between patients. Nevertheless, as indicated by their BMI, these patients were obese and BSA may not have been an accurate estimate of the mass of metabolically active tissue.

132.7.4 $S\bar{v}0_2$ and Body Mass Index

Although BMI was found to be a significant univariate correlate of $S\bar{v}O_2$, the subsequent regression analysis did not find BMI to be a significant predictor of $S\bar{v}O_2$. Based on age, sex and race, BMI is

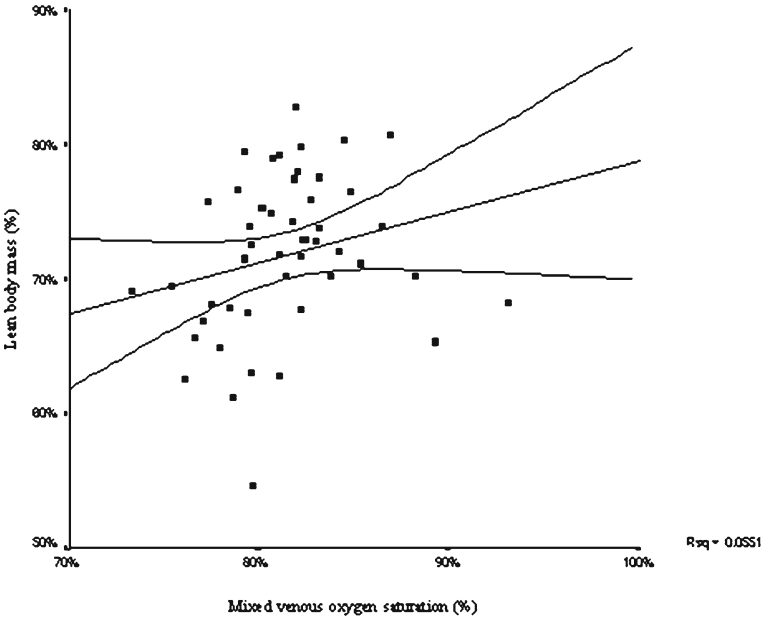

Fig. 132.3 Scatter plot of the saturation of mixed-venous haemoglobin with oxygen against lean body mass. Scatter plot of the saturation of mixed-venous haemoglobin with oxygen $S\bar{v}O_2$ versus lean body mass (LBM) during cardiopulmonary bypass showing a positive correlation. Fick's principle would indicate that patients with a higher LBM would have a higher systemic oxygen uptake, hence a lower $S\bar{v}O_2$. However, this study's findings suggest that using BSA underestimates the mass of metabolically active tissue patients with a low percentage of fat and overestimates it in patients who are obese. This inaccuracy will result in variance in $S\bar{v}O_2$ that produces a positive correlation with LBM as a more accurate estimate of the mass of metabolically active tissue in the body (Reprinted from Alston et al. 2006. With permission)

a good estimate of the percentage of body fat and, therefore, it should be an acceptable inverse estimate of lean tissue. In this study, as the population size was insufficient to detect associations of a small or moderate effect size, a true association between BMI and $S\bar{v}O_2$ may not have been identified.

132.7.5 $S\bar{v}0_2$ and Lean Body Mass

Alston and colleagues also found a significant association between LBM and $S\bar{v}O_2$, suggesting that the conventional calculation of 2.4 times BSA to determine pump flow rate does not completely estimate the VO_2 during CPB. According to Fick's principle, patients with a higher LBM would have a higher VO_2 and thus a lower $S\bar{v}O_2$. Nevertheless, the authors found a positive correlation between LBM and $S\bar{v}O_2$. Although interpretation is difficult, because BSA was used to calculate the pump flow rate, the explanation for this counter-intuitive finding could simply be that using BSA underestimates the mass of metabolically active tissue in patients with a high LBM and overestimates it in patients with a low LBM. Therefore, at pump flow rates of 2.4 l min^{-1} m^{-2}, patients with a high LBM are relatively overperfused and those with a higher mass of fat are relatively underperfused.

132.8 Using Lean Body Mass to Determine Pump Flow Rates During Cardiopulmonary Bypass

If, as the study by Alston and colleagues would suggest, LBM is a more accurate predictor of VO_2 than BSA, could LBM be used clinically to determine pump flow rates during CPB? Although, with appropriate training, it is relatively simple to calculate LBM by measurement of weight and skinfold thickness, the difficulty lies in determining and validating an appropriate formula to allow the calculation of pump flow rates from LBM.

Such an undertaking would require at least two further studies. First, it is needed to using a range of pump flow rates in order to devise a formula using LBM to calculate flow rates and then to compare the pump flow rates, based on that formula, with those calculated conventionally using BSA. Second, to determine the efficacy and safety of the new technique, a randomised controlled trial with a very large population would be required to compare the effects on important clinical outcomes, such as mortality, stroke, myocardial infarction and renal failure. For example, the current ATACAS trial, examining the effects of the antifibrinolytic, tranexamic acid, and aspirin on major ischaemic events after coronary artery bypass surgery requires a population size of 4,600 (Myles et al. 2008). Given the long history and perceived safety of CPB using pump flow rates based on BSA and the study size and complexity required to introduce LBM into clinical practice, it seems unlikely that this will occur.

132.9 Using Real-Time Measurement of Mixed-Venous Oxygen Saturation as an Alternative to Anthropomorphic Estimation of an Adequate Pump Flow Rate

The findings of the study undertaken by the author and colleagues would suggest that using a fixed, standardised pump flow rate is an insensitive approach, as it does not take into account individual variations in LBM and temperature (Alston et al. 2006). Reducing pump flow during induced hypothermia to a fixed level, such a 1.6 l min^{-1} m^{-2}, is one common approach. However, this is a relatively crude tactic and may only be appropriate for stable periods of hypothermia, but not for the thermally unstable periods that are required to induce hypothermia and rewarm the patient to normothermia.

Controlling the pump flow rate to maintain $S\bar{v}O_2$ at a safe fixed level would be sensitive to the important factors, including LBM and temperature, which determine metabolism and, therefore, VO_2. When Golan proposed this approach, some 50 years ago, it was impractical, as measurement of $S\bar{v}O_2$ was by intermittent blood sampling and remote bench oximetry (Gollan 1959). This involved an inevitable delay before the results could be interpreted, during which time there may have been many changes to the patient's systemic oxygen delivery and uptake. In-line monitors that measure $S\bar{v}O_2$ in real-time are now in routine clinical use. Determining pump flow rates by such in-line $S\bar{v}O_2$ monitors should allow the safe use of lower flow rates, especially during hypothermia, whilst ensuring the adequacy of systemic perfusion.

Whilst using $S\bar{v}O_2$ appears to be a physiologically satisfying approach to controlling pump flow rates during CPB, one has to be cautious before introducing such a technique. During low pump flow, tissue hypoperfusion may occur as a result of shunting in the capillary beds. Such shunting might result in apparently normal levels of $S\bar{v}O_2$, whilst organ damage was occurring. As discussed previously, when considering LBM, demonstration that any new technique is effective and safe would require a randomised controlled study, in a very large number of patients undergoing heart

surgery with CPB. Although evaluation of $\bar{S}vO_2$ to control pump flow rate during CPD, would, potentially, be less complex than the LBM study, it would still require a very large population to compare important clinical outcomes, such as mortality, myocardial infarction and renal failure between patients having pump flow rates controlled with $\bar{S}vO_2$ with those having rates controlled according to BSA. Therefore, until such a study is undertaken, it is most likely that pump flow rates during CPB will continue to be determined by the anthropometric measure of BSA, regardless of the associated limitations.

132.10 Applications to Other Areas of Health and Disease

132.10.1 Using BSA to Index Cardiac Output

Cardiac output is the volume of blood ejected from the left ventricle of the heart per unit time, usually expressed as litres per minute. Commonly, cardiac output is assessed in patients of different sizes by indexing it to 1 m^2 of BSA. If BSA is not an accurate means of matching pump flow to metabolic rate in humans undergoing cardiopulmonary bypass, then the logic of indexing cardiac output by BSA may also be flawed.

This potential flaw could therefore be relevant when using a cardiac index of 1.6–1.8 l min^{-1} m^{-2} as a definition of low cardiac output. Patients with a cardiac index below these thresholds are defined as having cardiac failure and are treated with positive inotropic agents, such as adrenaline. If indexing to BSA is flawed, then some patients may be being overtreated and others undertreated with positive inotropic agents in order to obtain a potentially flawed threshold of cardiac index.

132.10.2 Using Systemic Oxygen Uptake to Guide Treatment of Critically Ill Patients

Some goal-directed treatments of critically ill patients are based on achieving a threshold of VO_2, usually by increasing cardiac output with positive inotropic agents, such as adrenaline. As with cardiac output, if indexing to BSA is not appropriate, some patients may not receive treatment when they should and, vice versa, other patients may be treated when they should not be treated.

132.11 Practical Methods and Techniques

The anthropometric measures used in this chapter require accurate measurement of weight and some, also weight.

132.11.1 Body Surface Area

As discussed in detail earlier in this book in the chapter entitled ‘Analysis and comparison of the methods to measure body surface area and of the estimated values’, there are several different ways of measuring and estimating BSA. For clinical practice, it is calculated from the height and weight

of the patient. Whilst there are a number of formulae for estimating BSA from height and weight, that of du Bois and du Bois has traditionally been used to calculate pump flow rate during CPB (du Bois and du Bois 1916):

$$\mathrm{BSA}(\mathrm{m}^2) = \mathrm{weight}\left(\mathrm{kg}\right)^{0:425} * \mathrm{height}\left(\mathrm{m}\right)^{0:725} * 0:007184$$

132.11.2 Body Mass Index

$$\mathrm{BMI}\ (\mathrm{kg\ m}^{-2}) = \mathrm{weight}\left(\mathrm{kg}\right) * \mathrm{height}\ (\mathrm{m})^{-2}$$

132.11.3 Lean Body Mass

There are a number of different ways of measuring LBM, including electrical bioimpedence, air displacement, dual energy X-ray absorptiometry, magnetic resonance imaging and computed tomography and these methods are described in detail in the chapters of Section 1: Tools and techniques in anthropometry. However, they are expensive and less readily available in the clinical setting. An appropriately trained person can perform an alternative technique simply and inexpensively using skinfold thicknesses. In addition to accurately weighing the patient, estimation of LBM by this technique requires measurement of skinfold thicknesses at four sites on the body (biceps, triceps, subscapular and suprailiac) using the guidelines of the International Society for the Advancement of Kinanthropometry (Marfell-Jones et al. 2006). Linear regression equations, which take into account age and sex, are then applied to estimate body density and, from this, the percentage of fat is determined and, thus, LBM can be calculated (Table 132.6) (Durnin and Womersley 1974).

Summary Points

- Cardiopulmonary bypass (CPB) is the keystone allowing cardiac surgery to be safely performed on hundreds of thousands of patients each year around the world.
- CPB is used to replace the functions of the heart and lungs to enable surgery to be performed on the heart.
- CPB has two essential functions, the mechanical pumping of blood around the body and gas exchange to remove carbon dioxide and oxygenate the blood.
- Pump flow rate during CPB is one of two crucial factors that determine whether there is an adequate supply of oxygen to and removal of carbon dioxide from the body.
- Too low or too high a pump flow rate may cause adverse effects.
- Accurate determination of the correct pump flow rate is essential for the safe use of CPB.
- Heart surgery is performed on humans with a wide variety of body sizes, from small infants to obese adults.
- Pump flow rate has to supply sufficient oxygen to match the body's metabolic rate.
- Hypothermia is commonly used during CPB as this reduces metabolic rate and so increases the margin of safety.
- Body surface area (BSA) has been used to calculate pump flow rate during cardiopulmonary bypass for nearly 50 years.
- BSA is not measured directly, but is calculated from height and weight using a formula devised nearly 100 years ago from only nine human subjects.

- Obesity is far more common now than when the formula for BSA was devised and, therefore, this formula may no longer be appropriate for patients presenting for heart surgery today.
- Research indicates that BSA may not be the most accurate means of determining pump flow rate during CPB.
- Lean body mass LBM) may be a more sensitive measure of metabolic rate and could be used to determine pump flow rates during CPB.
- Using in-line, real-time measurement of the saturation of mixed-venous blood with oxygen $\bar{S}vO_2$ to control pump flow rate during CPB would overcome variations in metabolic rate resulting from different body sizes and changes in body temperature.
- The introduction of LBM or $\bar{S}vO_2$ in the determination of pump flow rates would require a randomised controlled trial in a very large number of patients undergoing heart surgery with CPB.
- For the foreseeable future, it is therefore most likely that pump flow rate during CPB will continue to be determined by the anthropometric measure of BSA, regardless of its limitations.

Chapter 133
Anthropometric Measurements, Adipokines and Abdominal Aortic Calcification

Adam Franklin Parr and Jonathan Golledge

Abstract Obesity and arterial calcification are associated with increased cardiovascular morbidity and mortality. The relationship between obesity and abdominal aortic calcification has been under investigated. The majority of research has focused on the relationship between clinical anthropometric measures and aortic calcification, with mixed results. Numerous calcification measurement protocols have hindered appropriate analysis of the literature. However, recently a reproducible computed tomography method for aortic calcification quantification has been published. Similarly, many methods are available for anthropometric assessment. Clinical measures include body mass index, waist circumference, waist to hip ratio, skin fold and percent body fat. Alternatively, computed tomography can be reproducibly utilized to measure abdominal adipose diameters, area and volume.

Recently, the relationship between calcification and anthropometric measurements has been investigated by computed tomography. It was found that a measure of visceral adiposity was associated with abdominal aortic calcification. In addition, visceral adiposity was positively and negatively correlated to circulating concentrations of osteoprotegerin and leptin, respectively. This has provided a possible pathogenic mechanism for the accumulation of abdominal aortic calcification.

The aims of this chapter are two fold:

1. To outline the various anthropometric and calcification protocols currently employed for vascular research.
2. To review the current literature regarding the relationship between anthropometric measures and abdominal aortic calcification.

133.1 Introduction

Obesity and arterial calcification have independently been linked to increased cardiovascular events, such as stroke and myocardial infarction (Wilson et al. 2001). The mechanisms underlying the negative effects of obesity appear to be complex, with a variety of cytokines and metabolic effects implicated (Van Gaal et al. 2006). Many anthropometric measurements have been employed to study fat distribution patterns and their role in cardiovascular disease (Janssen et al. 2004): for example, waist-to-hip ratio (WHR), body mass index (BMI) and more recent imaging-based assessments (Golledge et al. 2008) (Table 133.1). Using these techniques, central adipose deposition has been independently correlated to the presence of occlusive coronary and peripheral arterial disease (Golledge et al. 2007b).

Arterial calcification has been measured by a variety of techniques, such as plain X-ray and computed tomography (CT) throughout the arterial system (Jayalath et al. 2005). The association of coronary artery calcification with cardiovascular morbidity and mortality has been extensively investigated (O'Malley et al. 2000), with much less attention given to aortic mineralisation. Whereas combined aortic and coronary atherosclerosis is not uncommon, many of the characteristics of coronary and aortic pathology are different. For example, the aorta is more prone to aneurysm formation than the coronary arteries and there appear to be some differences in risk factor profiles of patients with pathology centred at different artery sites (Michel 2001).

The association of obesity and coronary artery calcification appears well established (Allison and Wright 2004; Kim et al. 2008). The link between abdominal aortic calcification and obesity is less well established. Recently, visceral adiposity has been implicated as a causative factor in abdominal aortic calcification (Golledge et al. 2008). The mechanisms driving this process are largely unknown. Insulin resistance is believed to be a major mechanism by which central obesity accelerates atherosclerosis (Van Gaal et al. 2006). However, other factors, such as adipokines, and other cytokines, such as osteoprotegerin, may play a role (Golledge et al. 2008). This article will review the literature surrounding the association between fat distribution and abdominal aortic calcification.

133.2 Literature Review

The literature was searched through MEDLINE and Cochrane databases, limited to publications in English. The titles and abstracts of studies identified were reviewed for their appropriateness and a manual search of reference lists was also performed. The search terms were 'abdominal aorta' AND

Table 133.1 Commonly employed anthropometric measurements in vascular research

Measurement	Units	Interpretation	Advantages	Disadvantages
Clinical				
Body mass index	kg/m^2	Normal level: 18.5–24.9 Overweight: 25.0–29.9 Obese: 30.0–39.9 Morbidly obese: ≥40.0	Easy to perform	Does not distinguish between muscular physique and fat
Waist circumference	cm	Normal IDF levels – European: $F < 80$ cm; $M < 94$ cm South Asians and Chinese: $F < 80$ cm; $M < 90$ cm	Surrogate marker of visceral adipose	Many different definitions are in use
Waist-to-hip ratio	0–1	Normal IDF level: F < 0.85; M < 0.90	Easy to perform	Does not directly measure visceral compared to subcutaneous adiposity
Computed tomography				
Fat diameters	SC or ratio	Closer to 1 = increased visceral compartment	Good reproducibility Easy to perform	No current definition of obesity
Fat area	cm^2 or ratio	Area of visceral or subcutaneous fat on one CT slice	Easy to perform	May not be representative of whole abdomen
Fat volume	cm^3 or ratio	Total abdominal fat Total visceral fat Visceral/subcutaneous ratio	Takes into account all abdominal fat	Time consuming Varying CT protocols and reproducibility data

'calcification'. A total of 298 publications were initially identified prior to further selection. These papers were examined for relevance related to anthropometric measurements. The search terms 'abdominal aorta' AND 'calcification' AND 'obesity' yielded three articles.

133.3 Practical Methods

133.3.1 Anthropometric Measurements

Anthropometry is the measurement of variation in body dimensions in humans. Whereas this encompasses measurements of most body regions, its use in vascular surgery is often synonymous with defining body fat composition.

133.3.2 Clinical Measurements

Clinical data are the primary method for defining anthropometric measurements. For physical examination, patients should wear thin, loose-fitting clothing and remove their footwear. Examination should begin with height (to the nearest 1.0 cm) and weight (to the nearest 0.1 kg) measurements. From these measurements, BMI can be computed [(weight in kg)/(height in meters)^2]. The BMI can be categorised into World Health Organization (WHO) classifications: underweight (<18.5); normal (20–24.9); overweight (25–29.9); obese (30–39.9); and morbidly obese (≥40). Waist circumference, measured at the midpoint between the 12th rib and the iliac crest at the end of gentle expiration, and hip circumference, measured at the level of the greater trochanter, should also be assessed. WHR [waist circumference (cm)/hip circumference (cm)] can then be determined. The WHO guidelines recommend ratios <0.85 for females and <0.90 for males. Additional measurements could include body fat percentage, midhumeral circumference (to nearest 1 mm) and triceps skinfolds (to nearest 0.2–0.5 mm, depending on the calliper).

133.3.3 Computed Tomography

Recently, CT fat distribution and quantification has been utilised in patients undergoing assessment for abdominal aortic pathology (Golledge et al. 2008). There are two major methods currently being employed for CT assessment of abdominal adiposity: adipose diameter and volume measurements.

133.3.3.1 Diameter Measurements

Axial CT slices can be used to determine anthropometric diameter measurements for assessment of visceral adiposity (Fig. 133.1). Measurements are made with electronic callipers (to the nearest millimetre) on the most cephalad CT slice in which the iliac crest appears. Two anterior-posterior diameters are measured by creating a vertical line from the anterior abdominal skin through the middle of the vertebral body to the skin of the posterior surface. AP1 represents the entire length of

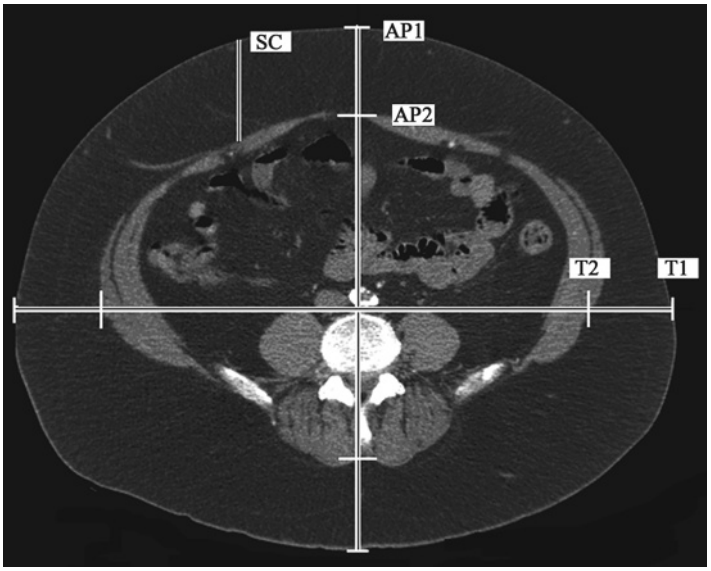

Fig. 133.1 Illustration of anthropometric measurements made from computed tomography images. The anterior-posterior line is drawn and measured as total line (*AP1*) and linea alba to posterior aspect of the spinous process (*AP2*). The anterior-posterior ratio (*APR*) is calculated by dividing AP2/AP1. The transverse line is drawn and measured as total line (*T1*) and anterior aspect of external obliques (*T2*). The transverse ratio (*TR*) was calculated by dividing the T2/T1. The subcutaneous fat depth (*SC*) was measured as shown (Reprinted from Golledge et al. 2008, with permission)

Table 133.2 Relationship of computed tomography anthropometric diameters to clinical anthropometric measurements (Reprinted from Golledge et al. 2008. With permission)

Measurement	AP1	AP2	T1	T2
Waist circumference	$r = 0.73$, $p < 0.0001$	$R = 0.66$, $p < 0.0001$	$r = 0.62$, $p < 0.0001$	$r = 0.66$, $p < 0.0001$
Waist-to-hip ratio	$r = 0.43$, $p = 0.01$	$R = 0.51$, $p = 0.002$	$r = 0.32$, $p = 0.04$	$r = 0.37$, $p = 0.03$
Body mass index	$r = 0.43$, $p = 0.01$	$R = 0.19$, $p = 0.25$	$r = 0.60$, $p < 0.0001$	$r = 0.48$, $p = 0.003$

This table depicts correlations and significance of waist circumference, waist-to-hip ratio and body mass index in relation to diameter measurements

Fat diameters are most closely correlated to waist circumference.

AP1 Anterior-posterior diameter – skin to skin, *AP2* Anterior-posterior diameter – muscle to muscle, *T1* Transverse diameter – skin to skin, *T2* = Transverse diameter – muscle to muscle

this line, whereas AP2 is the distance from the linea alba to the posterior aspect of the spinous process. The anterior–posterior ratio (APR) was calculated as AP2/AP1. Two similar transverse diameters were made by creating a horizontal line passing through the most anterior aspect of the vertebral body. T1 represented the entire length of this line, whereas T2 was the distance from the anterior surface of the right external oblique to that of the left. The transverse ratio (TR) was calculated as T2/T1. Interpretation of the anthropometric diameters is often subject to confusion. A larger visceral compared to subcutaneous compartment would lead to an increase in both ratios. In a study of 148 patients, AP and T diameters were associated with waist circumference, waist-to-hip ratio and BMI (see Table 133.2) (Golledge et al. 2008). A further estimate of the subcutaneous fat is made by creating a vertical line from the anterior aspect of the skin to that of the external oblique at a point 50 mm

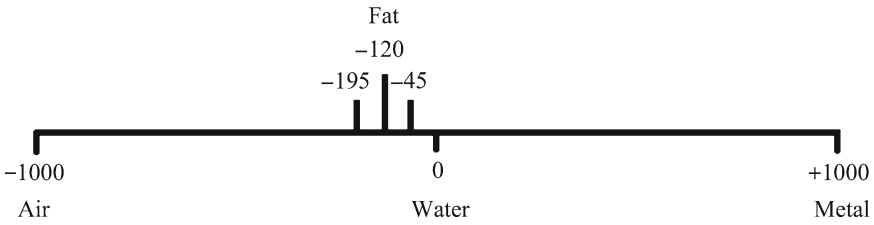

Fig. 133.2 A representation of the computed tomography radiographic grey scale with illustration of adipose densities. Numbers are presented in Hounsfield Units (*HU*). Radiographic density spectrum is from air (−1,000 HU) to metal (+1,000 HU). Adipose density has a Center HU (*CH*) of −120 HU and a Window-width HU (*WH*) of 75 HU. As a result, the upper and lower limit of WH is −195 to −45 HU

right of the umbilicus (SC). A reproducibility study of 15 patients measured repeat diameters with multiple observers (Golledge et al. 2008). The intra-observer coefficient of variation was 0.9%, 0.7% and 4.0% for APR, TR and SC, respectively. The inter-observer coefficient of variation was 2.6%, 3.2% and 10% for APR, TR and SC, respectively.

133.3.3.2 Adipose Thresholds

Recently, techniques have been developed to estimate adiposity using threshold density levels on CT (Maurovich-Horvat et al. 2006). CT workstations can be used to identify tissues based on density profiles, known as thresholding. Parameters are defined by Hounsfield units (HU), setting the Center Hounsfield Unit (CH) level and a Window-width Hounsfield Unit (WH) for the tissue of interest. Past studies have used various thresholds to define adipose tissue (Jensen et al. 1995; Yoshizumi et al. 1999; Maurovich-Horvat et al. 2006). Commonly, a CH of -120 HU and a WH of 75 HU (−195 to −45 HU) are used (Maurovich-Horvat et al. 2006) (see Fig. 133.2). The abdominal fat area or volume can then be estimated over a selected region of interest. The slice(s) chosen for area and volume measurements vary between protocols (Yoshizumi et al. 1999; Maurovich-Horvat et al. 2006). One volumetric protocol assesses from the most superior level of the first sacral vertebral body to 125-mm cephalad (Maurovich-Horvat et al. 2006). Manual separation of the visceral and subcutaneous compartment then occurs by semi-automated tracing of the abdominal muscular wall separating the two compartments (see Fig. 133.3). This allows absolute evaluation of visceral and subcutaneous compartments in addition to ratio generation. Reproducibility of these methods is often unreported (Nicklas et al. 2004). However, a subcohort of 100 patients from the Framingham Heart Study was assessed for intra- and inter-observer reproducibility of abdominal fat measurements (Maurovich-Horvat et al. 2006). Reproducibility was high, with both assessments displaying intraclass correlation coefficient of 0.99.

133.4 Arterial Calcification

Initially, theories regarding vascular calcification suggested that minerals deposited passively in vessel walls (Jayalath et al. 2005). Increasing evidence suggests that vascular calcification is an active and regulated process. In this active model, a process analogous to bone formation occurs.

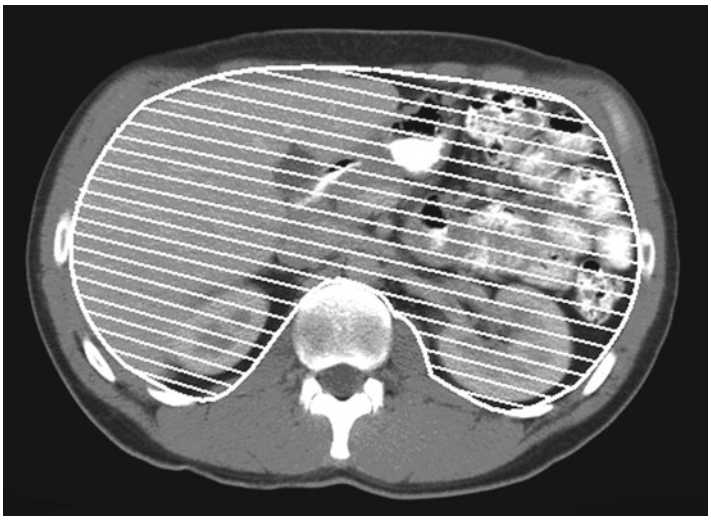

Fig. 133.3 Intra-abdominal fat quantification on computed tomography. The *white line* represents the region of interest, with the threshold area (*white hash*) set for adipose density (as displayed in Fig. 133.2)

133.4.1 Classification

Anatomically, vascular calcification is classified into intimal and medial deposition (Jayalath et al. 2005). This variation is increasingly being recognised as a dichotomous process. Intimal calcification is generally associated with the development of atherosclerosis. Conversely, medial calcification occurs independently of atherosclerosis and shares an association with metabolic disturbances, such as diabetes mellitus and renal failure. Unfortunately, differentiation between types rarely occurs in the literature and can be difficult to do in many imaging assessments, such as plain X-ray.

133.4.2 Abdominal Aortic Calcification

Currently, there is no agreed measurement method or grading scale for abdominal aortic calcification. Table 133.3 displays various methods which have been used to assess abdominal aortic calcification. Table 133.4 displays the key facts of this phenomenon. The relationship between abdominal aortic calcification and both local pathological and overall patient outcomes is of significant interest.

133.4.2.1 Relationship to Abdominal Aortic Aneurysm

The association of abdominal aortic calcification and abdominal aortic aneurysm (AAA) is controversial. AAA is a weakening of the aorta usually affecting the infrarenal segment and is commonly defined by an aortic diameter ≥30 mm (Golledge et al. 2006). It represents an important cause of mortality in the older population. Intimal calcification has been associated with increased aortic diameters in patients who do not have AAAs (Allison et al. 2008). Most studies have shown no association between CT-detected aortic calcification and AAA growth (Vega de Ceniga et al. 2006; Parr et al. 2009).

Table 133.3 Description of various methods for abdominal aortic calcification assessment

Modality	Calcification score	Description
Plain lateral lumbar x-rays	Aortic calcification score	Calcification scores 0–3 across four segments making an overall score of 0–24
	Length involved	Calcification lengths ≤1 cm, 2–5 cm, 6–10 cm, and >10 cm
Ultrasound	High or low	Calcification greater or less than 50% of the intimal maximal AAA circumference
	Present or absent	High echogenic plaques considered calcification
Computed tomography	Calcification appearance	Thin, discontinuous; thin, continuous; thick, discontinuous; thick, continuous; and abrupt break in thin or thick continuous pattern
	Aortic calcification index 1	A total of 15 CT slices (1cm intervals) above iliac bifurcation, with each slice subdivided into 16 sectors. Each sector scores positive, if calcification is present. The score is from 0 to 240
	Aortic calcification index 2	Proportion of aortic circumference covered by calcification. Patients were then grouped into I 0–10%, II 11–30%, III 31–50%, and IV 51–100%
	Aortic calcification index 3	Two slices (at bifurcation and 1 cm superior) were analysed and calcification expressed as an average percentage
	Aortic calcification index 4	Calcification score from 0 to 4 at the area of maximal dilation
	Aortic calcification index 5	Minimal (<10% of aortic circumference), moderate (10–15%) and severe (>50%) at the aortic neck, area of maximal diameter and aortic bifurcation
	Aortic calcification volume	Infra-renal aortic calcification volume (cm^3) as determined by density on post-analysis software; CH = 1,400; WH= 2,000
EBCT	Agatston scores	Intimal calcification mostly detected

This table describes the currently used methods to measure calcification. No consensus "gold standard" is recognised. However, aortic calcification volume is highly reproducible

CT Computed tomography, *CH* Center Hounsfield unit, *WH* Window width Hounsfield unit, *AAA* Abdominal aortic aneurysm, *CH* Center Hounsfield unit, *WH* Window width Hounsfield unit, *EBCT* External beam computed tomography

Table 133.4 Key facts of aortic calcification

1. Aortic calcification occurs by a complex process of biomineralisation
2. This is thought to occur by an active process
3. Two types of aortic calcification are anatomically recognised; medial or intimal depending on the vascular layer of deposition
4. Medial calcification is associated with metabolic derangements, such as diabetes mellitus and renal failure, and is often seen in the aorta
5. Intimal calcification is primarily associated with atherosclerosis
6. Coronary calcification is associated with vessel occlusion, and, hence, coronary events
7. The role of aortic calcification is less clear, as aortic occlusive disease is relatively rare
8. Aortic calcifications' positive relationship to cardiovascular events is becoming increasingly evident; however, this may reflect an overall vascular state
9. Aortic calcification may be associated with reduced abdominal aortic aneurysm growth rates

This table outlines key features pertaining to abdominal aortic calcification. The significance of abdominal aortic calcification is still unclear.

By contrast, a recent ultrasound study reported that patients with ≥50% aortic wall calcification had significantly slower AAA progression than their less-calcified counterparts (Lindholt 2008). Rupture rates have not been reported to be associated with aortic calcification quantity. However, a focal gap of otherwise circumferential wall calcification has been associated with AAA rupture (Siegel et al. 1994). Thus, currently, the importance of calcification in AAA pathology is unclear.

133.4.2.2 Relationship to Cardiovascular Events

Coronary artery calcification has repeatedly been associated with cardiovascular events, such as myocardial infarction (O'Malley et al. 2000). Whereas aortic calcification is associated with coronary calcification (Kuller et al. 1999), its independent significance has been relatively under investigated. Aortic atherosclerosis has a number of differences from atherosclerosis at other sites. For example, aortic atherosclerosis appears to have less potential to lead to arterial occlusion since aortic occlusion is less common than coronary artery occlusion (Jayalath et al. 2005). In some studies, the presence of aortic calcification has been associated with coronary artery disease, peripheral vascular disease, cardiovascular disease mortality and future coronary heart disease (Wilson et al. 2001). Large studies employing reproducible imaging techniques are required to confirm the association of aortic calcification with cardiovascular events (Jayalath et al. 2005).

133.4.3 Relationship Between Clinical Anthropometric Measurements and Abdominal Aortic Calcification

Waist circumference has been associated with increased cardiovascular events (Bigaard et al. 2005). However, the relationship between clinical anthropometric measurements and abdominal aortic calcification is unclear (see Table 133.5). Studies have related increased BMI to both low (Shinagawa et al. 1992; Reaven et al. 2005) *and* high (Allison et al. 2007) calcification. However, most studies concluded BMI was not associated with aortic calcification presence (Jie et al. 1995; Kuller et al. 1999; Blancher et al. 2001; O'Donnell et al. 2002; Arai et al. 2002; Allison et al. 2004) or progression (Hak et al. 2000). Conversely, BMI and WHR appear to be positively correlated to coronary calcification (Kuller et al. 1999; Allison et al. 2004, 2007). WHR has been correlated to aortic calcification when using CT (Kuller et al. 1999), but not lateral X-rays (Jie et al. 1995), in postmenopausal women. Total body fat percentage and body weight appear to be correlated with increased aortic calcification (Alexanderson et al. 2006; Allison et al. 2007). No significant association was found between suprailiac or triceps skinfold measurements and aortic calcification (Kuller et al. 1999).

The inconsistency of clinical anthropometric results could be accounted for by the variation in calcification measurement techniques and protocols that have been used, many without clear reproducibility (Lindholt 2008). In addition, confounding factors, such as diabetes, hypertension and smoking, are known to be strongly associated with arterial calcification and obesity, and therefore may affect associations in different cohorts (Jayalath et al. 2005). Alternatively, the inherent deficiencies of clinical measurements may be responsible for the lack of consistency between results. For example, WHR may not be a reliable index of visceral/subcutaneous fat distribution in obese individuals.

Table 133.5 Methods and results of major studies relating clinical fat measurements to abdominal aortic calcification

Study	Patients	Method	Region assessed	Results
O'Donnell et al. (2002)	2,151	Lateral lumbar X-ray calcification score	Abdominal aorta	Calcification was not correlated with BMI ($r = -0.03$)
Allison et al. (2007)	1,078	EBCT	Abdominal aorta	Patients with calcification ($n = 593$) had similar BMI (26.9 vs 26.6) and percent body fat (29.5 vs 29.5)
Shinagawa et al. (1992)	845	CT – ACI 3	Abdominal aorta	Calcification was highest in men with low BMI
Hak et al. (2000)	720	US – High or low	Abdominal aorta	BMI was not associated with calcification progression at 9 years reassessment
Allison et al. (2004)	650	EBCT	Diaphragm to iliac bifurcation	No association between aortic calcification and BMI Total body fat (5%) (OR 0.6–0.9, 95% CI 0.4–1.7) was not correlated with aortic calcification
Reaven et al. (2005)	309	EBCT	Upper pole of right kidney to iliac bifurcation	BMI was increased in subjects with low calcification scores (mean 32.9) compared to those with high scores (mean 31.2), $p < 0.05$
Kuller et al. (1999)	169	EBCT	Aortic arch to the iliac bifurcation	BMI was related to increased coronary calcification ($p = 0.03$) but not aortic calcification ($p = 0.43$) WHR was correlated to coronary ($p = 0.004$) and aortic calcification ($p = 0.07$)
Alexanderson et al. (2006)	168	Lateral lumbar X-ray calcification score	Abdominal aorta	Aortic calcification was inversely associated with peripheral lean mass even after adjusting for age and BMI ($p < 0.05$)
Jie et al. (1995)	113	Lateral lumbar X-ray length	Abdominal aorta	BMI (mean 26.5 vs 25.4, $p = 0.07$) and WHR (mean 0.84 vs 0.84, $p = 0.81$) were not associated with aortic calcification
Blancher et al. (2001)	110	US – present or absent	Arterial calcification	No association of BMI with arterial calcification, as determined by presence or absence of calcification of the carotids, aorta, iliofemoral axis and legs
Arai et al. (2002)	29	CT – ACI 3	1 cm above and including iliac bifurcation	BMI was similar between the groups with high and low calcification (22.7 vs. 23.2 kg/m^2)

This table describes the 11 major studies examining fat measurements and abdominal aortic calcification. Studies utilised various regions of the abdominal aorta, calcification protocols and patients

EBCT external beam computed tomography, *BMI* Body mass index, *WHR* Waist-to-hip ratio, *CT* Computed tomography, *US* Ultrasound, *CVD* Cardiovascular disease, *ACI 3* Aortic calcification score 3, *OR* Odds ratio

133.4.4 Relationship Between CT Anthropometric Measurements and Abdominal Aortic Calcification

In a small number of studies, CT-measured visceral adipose volume was found to be a stronger predictor of cardiovascular events than other measures of obesity (Nicklas et al. 2004). The relationship between fat distribution and abdominal aortic calcification has been relatively little studied. One study (Shinagawa et al. 1992) examined 845 patients for abdominal adiposity and calcification using CT. They found that males with low subcutaneous fat had increased aortic calcification.

Table 133.6 Table outlining key facts in anthropometric measurements and abdominal aortic calcification

1. Computed tomography methods can reliably be employed to measure anthropometric parameters
2. Increased calcification of the abdominal aorta predicts increased cardiovascular morbidity and mortality
3. Leptin is negatively associated with visceral adiposity
4. Osteoprotegerin is associated with increased visceral adiposity and vascular calcification
5. Aortic calcification is associated with increased visceral adiposity, as estimated by computed tomography

This table displays the key facts relating to anthropometric measurements and abdominal aortic calcification

Table 133.7 Association of anterior-posterior ratio (APR) tertiles with calcification, lipids and cytokine concentrations (Reprinted from Golledge et al. 2008. With permission)

	APR tertile 1	APR tertile 2	APR tertile 3	*P* value
Number	50	49	49	
APR	0.73 ± 0.05	0.84 ± 0.02	0.91 ± 0.02	<0.0001
TPR	0.86 ± 0.07	0.91 ± 0.04	0.94 ± 0.03	<0.0001
SC (mm)	34.9 ± 10.9	23.9 ± 6.1	16.0 ± 6.6	<0.0001
Aortic calcification volume (mm^3)	1,256 ± 1,184	1,871 ± 1,762	2,266 ± 1,820	0.01
Adiponectin (μg/ml)	8.33 ± 4.36	9.49 ± 4.48	10.26 ± 5.09	0.25
Leptin (ng/ml)	36.22 ± 28.79	21.00 ± 25.56	12.04 ± 13.62	<0.0001
Resistin (ng/ml)	25.69 ± 19.97	24.69 ± 13.20	25.45 ± 10.74	0.45
OPG (pM)	6.37 ± 2.37	6.53 ± 2.37	7.82 ± 3.26	0.01
OPN (ng/ml)	26.0 ± 19.1	24.5 ± 18.5	24.6 ± 18.2	0.89
MGP (nM)	24.9 ± 18.6	25.7 ± 14.6	29.8 ± 18.7	0.20

This table examines the association of anterior-posterior ratio (APR) tertiles with calcification, lipids and cytokines. Increasing intra-abdominal compartment compared to subcutaneous compartment (APR) is correlated positively with calcification volume and osteoprotegerin and negatively with leptin concentration. Numbers are mean ± standard deviation
APR Anterior-posterior ratio, *TPR* Transverse ratio, *SC* Subcutaneous adipose depth, *OPG* Osteoprotegerin, *OPN* Osteopontin, *MGP* Matrix Gla protein

This was only the case in middle-aged men and not women. In 85 patients, they further analysed the visceral/subcutaneous ratio in relation to calcification. An increasing ratio, hence, increased visceral adiposity, was associated with decreased calcification. However, this paper was not published in English and only the abstract was available.

Recently, a prospective study involving 148 vascular patients assessed the relationship between abdominal aortic calcification and CT anthropometric diameters (Golledge et al. 2008). Table 133.6 outlines key facts related to this study. Inclusion criteria into the study were (1) diagnosis of symptomatic peripheral vascular disease (55%) or AAA (45%); and (2) CT angiogram required to further assess diagnosis. The exclusion criteria were (1) previous surgical repair of AAA; and (2) patient deemed not suitable for a CT angiogram. Abdominal aortic calcification was quantified by validated techniques (CH 1,400 HU; WH 2,000 HU) with excellent reproducibility (intra- and inter-observer coefficient of variation approximately 1%). Anthropometric measurements were measured as outlined above.

Traditional risk factors among the patients included male gender (72%), diabetes (26%), hypertension (66%), current smoking (39%) and ex-smoker (35%). Mean age, cholesterol, triglyceride, high-density lipoprotein, low-density lipoprotein and creatinine concentrations were 67.7 ± 9.4 years, 4.89 ± 1.71 mM, 1.96 ± 1.21 mM, 1.27 ± 0.34 mM, 2.80 ± 1.64 mM and 97.8 ± 39.5 μM, respectively.

The study identified an association between a surrogate measure of visceral adipose and aortic calcification. Specifically, abdominal aortic calcification was positively correlated with APR ($r = 0.27$, $p = 0.001$) and TR ($r = 0.26$, $p = 0.001$), but negatively correlated with SC ($r = -0.28$, $p = 0.001$). Tertiles of APR and TR were associated with aortic calcification volume (Table 133.7). Taking into account traditional risk factors (age, gender, smoking history, diabetes, hypertension and lipids), APR ($\beta = 0.26$, $p = 0.006$) and TR ($\beta = 0.23$, $p = 0.01$) were independently associated with aortic calcification volume.

Table 133.8 Key facts of adipokines

1. Adipose tissue is highly metabolically active
2. It manufactures and secretes many important proteins
3. These products are known as adipokines
4. Adipokines include leptin, adiponectin, resistin and various cytokines
5. Adipokines have various cardiovascular roles under investigation, such as regulation of insulin resistance

This table outlines the basic facts pertaining to adipokines

133.4.5 Mechanism of Calcification

The mechanisms underlying the more detrimental effects of visceral compared to peripheral and subcutaneous adipose are presently not defined. It has been postulated that visceral adipose tissue releases different quantities of adipokines (Diamant et al. 2005). More precisely termed adipose-derived hormones, these include leptin, adiponectin and resistin, which are released from adipocytes and act on peripheral tissues. Table 133.8 displays the key facts regarding adipokines.

133.4.5.1 Leptin

In animal models, leptin plays an important role in inhibiting appetite and has also been shown to inhibit visceral deposition of fat (Friedman and Halaas 1998). In humans, leptin gene expression in subcutaneous adipocytes has also been previously negatively correlated to visceral fat volume (Diamant et al. 2005). The concentration of leptin has been demonstrated to be higher in subcutaneous compared to visceral adipose biopsies (Lihn et al. 2004). Serum leptin strongly negatively correlated with increasing size of the visceral compartment, as determined by CT fat diameters (see Table 133.7). (Golledge et al. 2008). In patients with high visceral to subcutaneous compartment ratio, the relatively smaller volume of superficial adipocytes may account for the lower concentration of circulating leptin. Whether the visceral compartment directly produces factors inhibiting leptin production remains to be defined (Golledge et al. 2007a). The negative association of leptin with visceral adipose deposition does not explain the link between visceral obesity and aortic calcification.

133.4.5.2 Osteoprotegerin

Osteoprotegerin, also known as osteoclastogenesis inhibitory factor, is a bone cytokine. Osteoprotegerin-deficient mice develop severe osteoporosis and medial calcification (Min et al. 2000). Human osteoprotegerin has been independently associated with cardiovascular events and general arterial and abdominal aortic calcification (Clancy et al. 2006). Furthermore, one study (Golledge et al. 2008) found an association between serum osteoprotegerin and visceral compartment size as determined by CT fat diameters (see Table 133.7). It has been demonstrated that adipose tissue contains stem cells capable of differentiating into osteoblasts in vitro and that similar control pathways modulate bone and adipocyte differentiation (Iribarren et al. 2007). Thus, it is possible that the components of visceral adipose are able to produce osteoprotegerin or other cytokines, which can control the development of vascular calcification and atherosclerosis. This hypothesis requires further investigation.

133.4.6 Applications to Other Areas of Health and Disease

Intimal vascular calcification is a general marker of atherosclerosis load. Whether abdominal aortic calcification, as a pathological process, is detrimental remains unclear. It may simply be a marker of atherosclerosis load.

Summary Points

- Abdominal obesity, as determined by waist circumference, has been associated with increased cardiovascular events.
- Visceral adipose volume on CT has been found to be the stronger predictor of cardiovascular event.
- On CT, there appears to be an association between the size of the visceral compartment and the severity of abdominal aortic calcification.
- There appears to be a correlation between the visceral compartment size and circulating osteoprotegerin concentrations, which is a proposed mechanism that may contribute to the poor prognosis associated with visceral adipose deposition.

Financial Disclosure and Conflict of Interest JG is supported by grants from the NHMRC, Australia (project grants 540403, 540404, 540405) and NIH, USA (RO1 HL080010), and a Practitioner Fellowship from the NHMRC, Australia (431503).

Anthropometry in Organ Disease

Chapter 134
Body Composition in Liver Cirrhosis

Lindsay D. Plank and John L. McCall

Abstract Patients with liver injury resulting in cirrhosis exhibit marked derangements in body composition. This is not surprising given the central role played by the liver in substrate metabolism. Progressive loss of muscle mass accompanies worsening liver disease and in end-stage disease patients typically appear wasted in the extremities with a distended abdomen due to ascites and peripheral edema. The ascites and edema in cirrhotic patients masks the profound weight loss that would otherwise occur. For this reason, malnutrition in these patients is often underdiagnosed and the widely used 2-compartment model which partitions the body into a fat compartment and a fat-free compartment is inadequate for characterizing the important features of their body composition.

Measurements of body protein stores using neutron activation analysis in a large group of cirrhotics of diverse etiology highlighted the extent of malnutrition in these patients. Significant malnutrition was evident even in patients with well compensated cirrhosis and malnutrition worsened with the severity of liver disease. Protein depletion was more severe in males compared to females irrespective of disease severity. Measurement of cellular mass of the body based on assessment of total body potassium confirmed the marked depletion of muscle mass in cirrhotic patients. Fat mass depletion was shown to increase with severity of disease and to be more marked in females than males. Total body water, expressed as a fraction of the fat-free mass, was significantly elevated, with 45% of Child's A and 80% of Child's C patients falling outside the normal reference range. Overhydration of the fat-free mass was often present in patients with no clinical evidence of fluid retention. Cirrhosis was associated with loss of bone mineral and reduced bone mineral density. There is some evidence suggesting that malnutrition may underlie the pathophysiology of bone loss in these patients.

Body composition assessment which provides detailed information on body compartments that is not confounded by fluid retention is essential to understanding the extent of compositional derangement that occurs in the cirrhotic patient.

134.1 Introduction

The liver is the central organ of intermediary metabolism and has a major role in the metabolism of protein, carbohydrate, and fat. Nutrients absorbed from the digestive tract are transported directly to the liver via the portal circulation. Nutrient blood levels are maintained within narrow limits by the liver despite wide variation in substrate availability. Not surprisingly, injury to the liver may lead to profound derangements in macro- and micronutrient metabolism with subsequent effects on body composition.

Liver cirrhosis is characterized by a progressive reduction in liver cell mass and function, as well as distortion of normal architecture that interferes with normal portal blood flow. Loss of synthetic and metabolic function leads to derangements in blood clotting, depletion of essential proteins, such as albumin, and a wide range of metabolic abnormalities. Portal hypertension contributes to ascites and the portal-systemic shunting results in variceal formation and predisposes to hepatic encephalopathy. The hemodynamic changes that accompany cirrhosis include increased splanchnic blood flow, reduced peripheral vascular resistance, and reduced renal blood flow. These changes, together with reduced plasma oncotic pressure due to hypoalbuminemia, result in impaired water excretion and sodium retention, and contribute to ascites and peripheral edema. Cirrhosis of all causes predisposes to the development of hepatocellular carcinoma, which is the fifth leading cause of cancer death worldwide and responsible for nearly half of all deaths related to cirrhosis. Key features of cirrhosis are summarized in Table 134.1.

The most common causes of liver cirrhosis in USA and Europe are related to alcohol and infection with hepatitis C. Hepatitis B is the predominant cause of cirrhosis in the Asia-Pacific and sub-Saharan Africa. Non-alcoholic steatohepatitis is becoming increasingly important in affluent societies. There are a wide variety of other causes of cirrhosis, including inherited diseases (e.g., alpha-1 antitrypsin deficiency, hemochromatosis, and Wilson's disease), autoimmune hepatitis, and cholestatic liver diseases, such as primary biliary cirrhosis and primary sclerosing cholangitis.

The Child-Pugh scoring system, based on serum bilirubin, serum albumin, prothrombin activity, and presence and severity of ascites and encephalopathy, is the most commonly used classification for severity of liver disease. Based on an aggregate score, patients are categorized as grades A, B, or C (Pugh et al. 1973). The probability of 5-year survival without transplantation for a Child A patient is approximately 80–90% compared with 20–30% for Child C cirrhosis.

The patient with advanced cirrhosis typically has a large distended abdomen due to ascites, muscle wasting of the extremities, and dependent edema. Tissue wasting is obvious and multiple factors may

Table 134.1 Key features of cirrhosis

1.	Liver cirrhosis is scarring of the liver with distortion of the normal architecture and progressive loss of function as the disease advances.
2.	There are many causes of cirrhosis, but the most common are chronic viral infections, alcohol, and conditions that prevent normal excretion of bile (cholestatic liver disease).
3.	Depending on the underlying cause, further deterioration can sometimes be prevented by appropriate treatment.
4.	Cirrhosis can be diagnosed by a combination of blood tests and radiological findings, or a liver biopsy.
5.	Cirrhosis is often asymptomatic in the early stages.
6.	Cirrhosis results in portal hypertension and formation of abnormal vessels (varices), which can rupture and bleed into the gut.
7.	Loss of protein synthetic function results in impaired blood clotting and low levels of albumin in the blood.
8.	Loss of metabolic function causes jaundice and other metabolic derangements.
9.	In the later stages, fluid accumulates in the abdomen (ascites) and legs (edema).
10.	Secondary effects on the kidney (hepatorenal syndrome) and brain (hepatic encephalopathy) commonly occur in end-stage cirrhosis.
11.	Cirrhosis is associated with a very high incidence of primary liver cancer.
12.	Liver transplantation is the only effective treatment for end-stage cirrhosis.

This table lists key facts relating to cirrhosis, including the effects on other organ systems and the symptoms that may be evident

contribute to the malnutrition, including anorexia with reduced calorie and nutrient intake, maldigestion, and malabsorption. Weight loss, often used to identify the malnourished patient, may be masked by water retention. Similarly, a simple two-compartment body composition model comprising fat and fat-free mass (FFM) does not provide information on muscle or lean tissue wasting in these patients and more detailed body compartmentalization is required (Morgan et al. 2006).

134.2 Body Protein

Protein is a vital structural and functional component of the body, and loss of body protein is associated with loss of function (Windsor and Hill 1988a, b). The 'gold standard' for measurement of this component is in vivo neutron activation analysis. In this technique, the subject is irradiated in a neutron field and characteristic gamma rays are emitted as a result of neutron interactions with nitrogen nuclei. By counting these gamma emissions and with appropriate calibration of the machine, total body nitrogen is determined, which is then converted to protein given that nitrogen is almost exclusively confined to protein in the body at a mean level of 16%. Total body protein (TBP) has been measured using this technique in patients with alcohol-related cirrhosis (Prijatmoko et al. 1993) and in patients with cirrhosis due to a wide range of causes (Peng et al. 2007). In the latter study, 268 patients with cirrhosis due to hepatitis B (n = 77), hepatitis C (n = 71), hepatitis B and C (n = 2), alcohol (n = 43), cholestatic liver disease (n = 28) and a variety of other causes (n = 47) were measured and the distribution of TBP is shown in Fig. 134.1 for the men and women, separately. These distributions are shifted downward in comparison to those for healthy volunteers.

TBP may be expressed as a protein index (PI) equal to the ratio of measured TBP to that predicted from regression equations developed from the healthy volunteers based on sex, age, height and weight (Peng et al. 2007). In these equations, a patient-recalled pre-illness weight was used. As shown in Fig. 134.2, PI for the patients was distributed around a mean of 0.82 (SD 0.11), suggesting an average depletion of protein stores of 18%. This mean is close to the 5th percentile of the distribution of PI for the volunteers (centered at 1.00 with SD 0.09) and patients with a PI < 0.82 can be regarded as being significantly malnourished. Of the 268 patients, significant protein depletion was

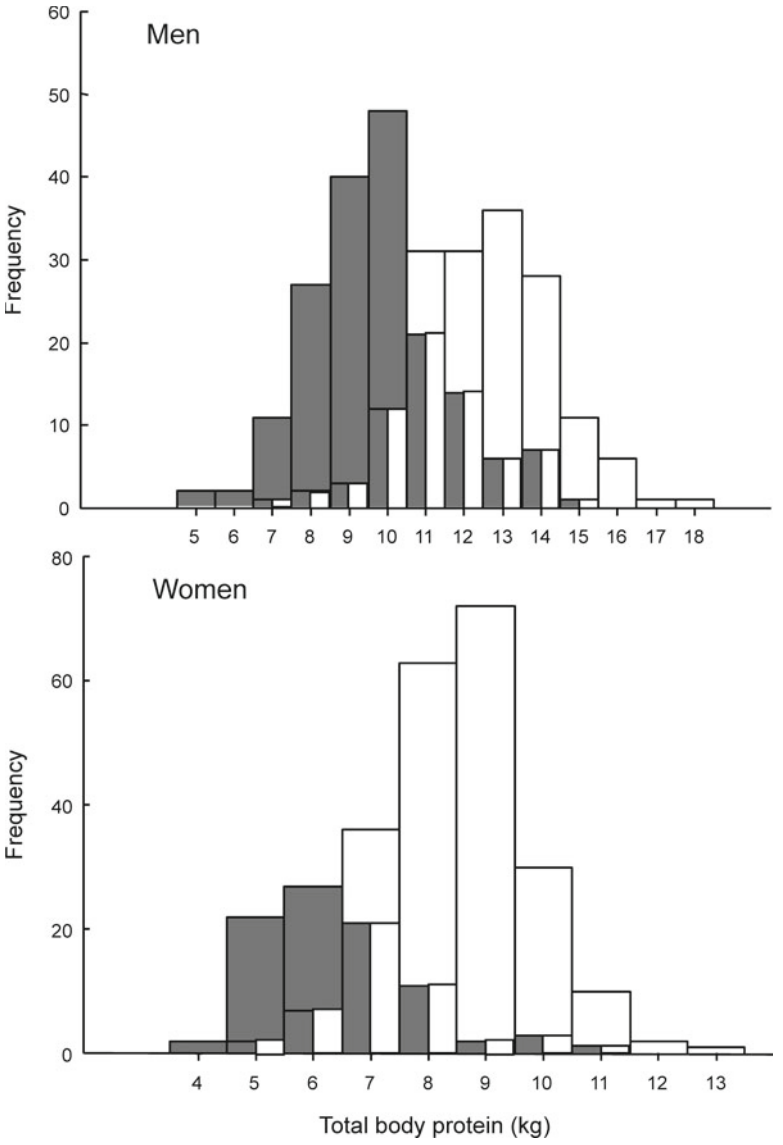

Fig. 134.1 Distributions of total body protein for men and women with liver cirrhosis compared to those for healthy volunteers. Distributions of total body protein for 179 men and 89 women with liver cirrhosis (*shaded bars*) are shifted downward in comparison with those for 163 male and 223 female healthy volunteers (*open bars*) (From Peng et al. (2007). The American Society for Nutrition)

seen in 138 (51%) patients and these were predominantly men, with 113 (63%) men being protein depleted compared to 25 (28%) women ($P < 0.0001$).

Patients with alcoholic liver disease were significantly more protein depleted than patients with viral cirrhosis, cholestatic disease, and others ($P < 0.0001$, Fig. 134.3). The prevalence of protein depletion increased with disease severity, as defined by Child-Pugh grade (Fig. 134.4). Protein depletion was observed in just over 40% of patients with Child A cirrhosis compared with 72% of patients with Child C cirrhosis. Irrespective of disease severity or etiology, protein stores in women were better conserved than in men.

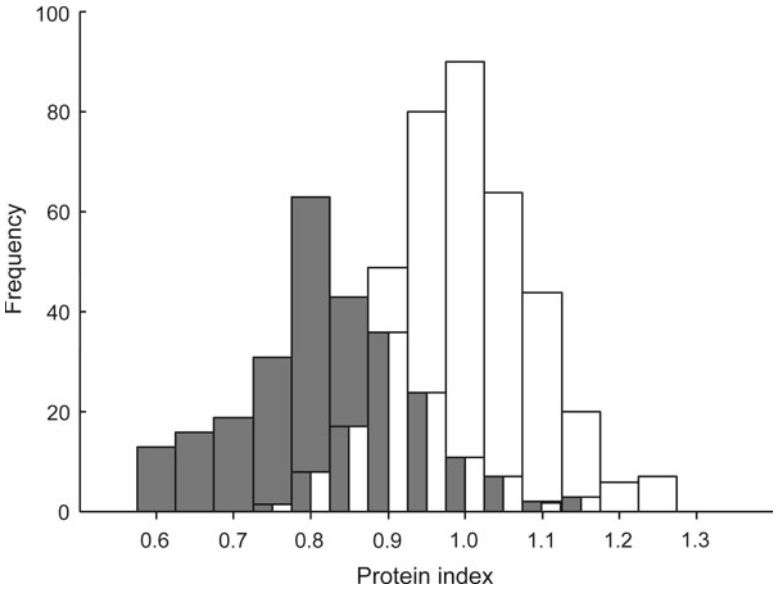

Fig. 134.2 Distributions of the ratio of measured to estimated pre-illness total body protein (protein index) in cirrhosis patients and healthy volunteers. Comparison of the distribution of protein index for 268 patients with liver cirrhosis (*shaded bars*) to that for 386 healthy volunteers (*open bars*) shows the marked depletion of body protein in the cirrhotic patients, which is close to 20% on average (From Peng et al. (2007). The American Society for Nutrition)

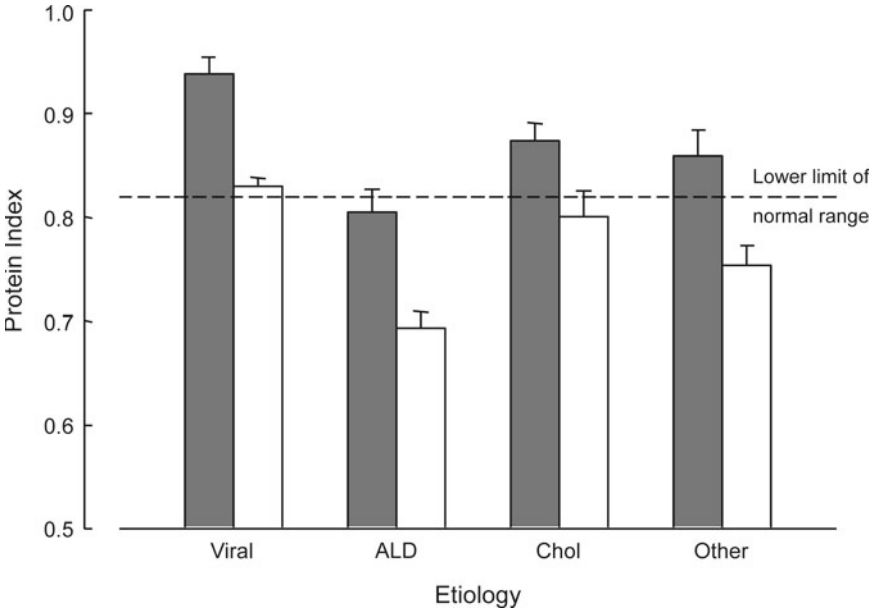

Fig. 134.3 Protein index in men and women with liver cirrhosis grouped according to etiology. Protein depletion, as assessed by protein index (ratio of measured to estimated pre-illness total body protein), for 179 men (*open bars*) and 89 women (*shaded bars*) with liver cirrhosis varies with etiology (*ALD* alcoholic liver disease, *Chol* cholestatic liver disease). By two-factor ANOVA: $P = 0.87$ for etiology × sex interaction, $P < 0.0001$ for etiology effect, and $P < 0.0001$ for sex effect. The dashed line shows the lower 2SD limit of protein index for healthy controls. Results are expressed as mean (± SEM) (From Peng et al. (2007). The American Society for Nutrition)

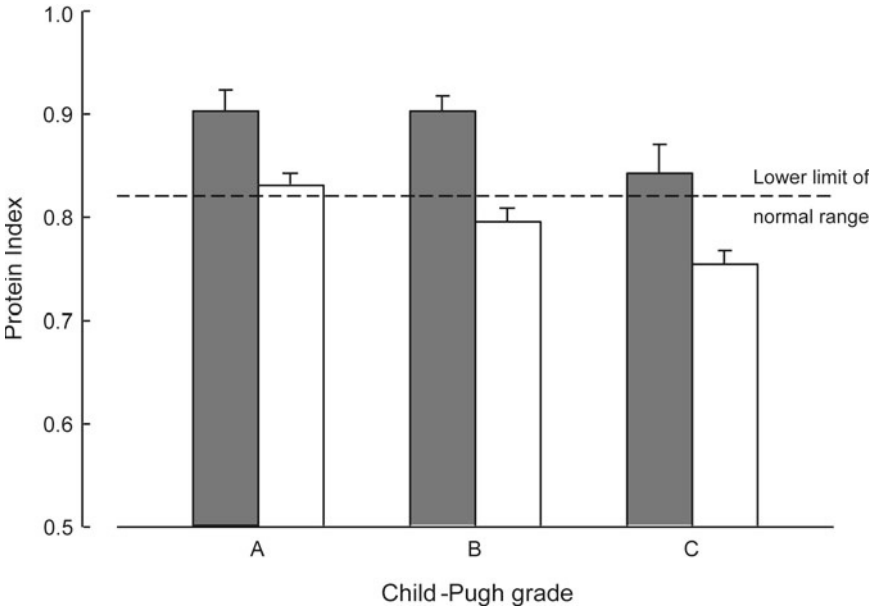

Fig. 134.4 Protein index in men and women with liver cirrhosis grouped according to severity of liver disease. Protein depletion, as assessed by protein index (ratio of measured to estimated pre-illness total body protein), for 179 men (*open bars*) and 89 women (*shaded bars*) with liver cirrhosis increases with worsening severity of liver disease, as assessed by Child-Pugh grade. By two-factor ANOVA: $P = 0.49$ for grade × sex interaction, $P = 0.003$ for grade effect, $P < 0.0001$ for sex effect. The dashed line shows the lower 2SD limit of protein index for healthy controls. Results are expressed as mean (± SEM) (From Peng et al. (2007). The American Society for Nutrition)

A widely used approach for assessing protein depletion and malnutrition in cirrhosis uses measurements of mid-arm circumference (MAC) and triceps skinfold thickness (TSF) to derive estimates of mid-arm muscle circumference (MAMC) using the relation TSF – πMAC. Severe muscle mass depletion is defined as MAMC below the 5th percentile of reference normal data based on age and sex (e.g., Frisancho 1981) and moderate depletion as MAMC below the 10th percentile. This anthropometric technique requires experienced operators and relies on the assumption that the upper arm is relatively unaffected by the water retention that often accompanies cirrhosis (Italian Multicentre Cooperative Project 1994). Alberino et al. (2001) showed in consecutive hospitalized cirrhotic patients (143 male, 69 female) that severe muscle depletion worsened with disease severity and that the prevalence of muscle mass depletion was higher in males than females (Fig. 134.5). Patients with upper-extremity edema were excluded from this study. Others have also found that muscle-mass depletion, identified by reduction in mid-arm muscle area, was more evident in males than females (Italian Multicentre Cooperative Project 1994).

Progressive loss of muscle stores with worsening disease may be due, at least in part, to abnormal fuel metabolism in the cirrhotic patient. After overnight fasting, cirrhotic patients exhibit increased rates of fat oxidation and gluconeogenesis and reduced rates of glucose utilization and glycogenolysis compared to normal controls (Owen et al. 1981). This metabolic profile, similar to that seen in healthy volunteers after 2–3 days' starvation, is consistent with reduced glycogen storage capacity of the cirrhotic liver. A longitudinal 12-month study showed that TBP status of cirrhotic patients could be significantly improved by nighttime nutritional supplementation (Plank et al. 2008). Protein stores were maintained in those patients randomized to daytime supplementation (Fig. 134.6).

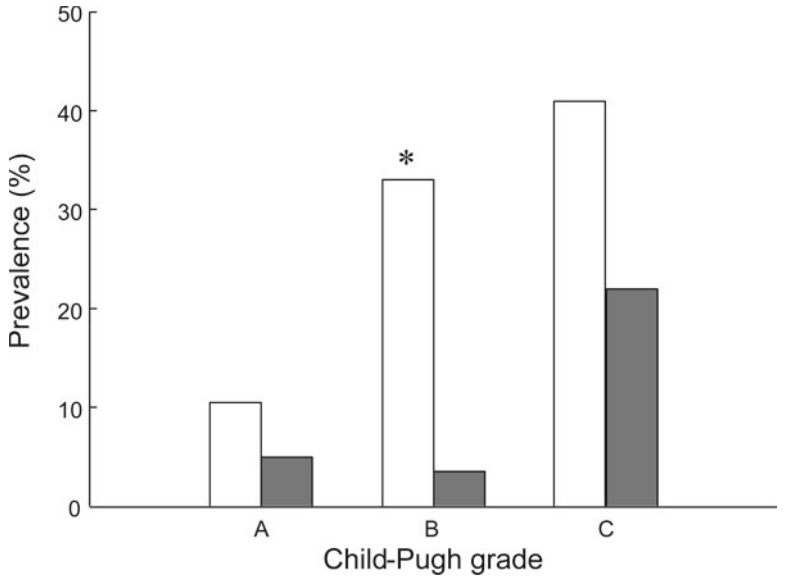

Fig. 134.5 Prevalence of severe muscle depletion assessed by mid-arm muscle circumference in male and female cirrhotics grouped according to severity of liver disease as assessed by Child-Pugh grade. Severe muscle depletion (mid-arm muscle circumference < 5th percentile) tended to be more prevalent in male (*open bars*, $n = 143$) patients with cirrhosis than female (*shaded bars*, $n = 69$) patients, irrespective of disease severity. *$P < 0.001$ versus females (Adapted from Alberino et al. (2001). By permission of Elsevier Science)

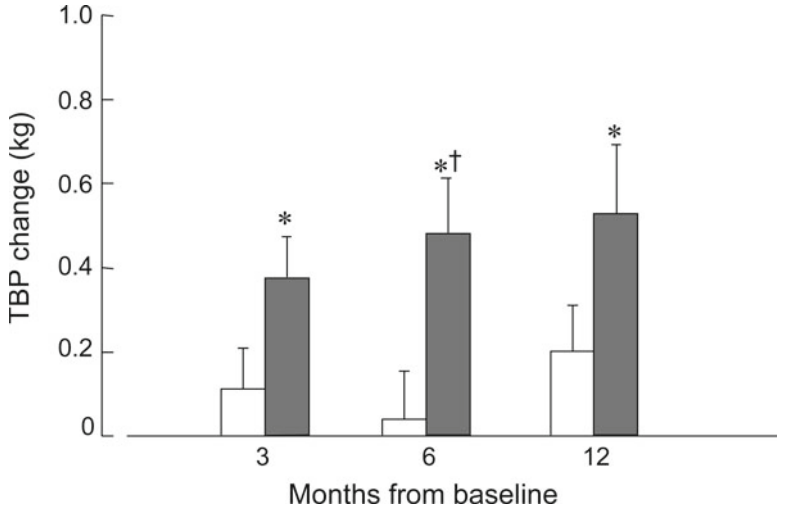

Fig. 134.6 Total body protein changes in patients having daytime or night-time nutritional supplementation over a 1-year period. Significant gains in total body protein (TBP) were seen after three ($n = 42$), six ($n = 40$) and 12 ($n = 39$) months of nighttime nutritional supplementation in cirrhotic patients (*shaded bars*). Patients randomized to daytime nutritional supplementation (*open bars*) showed no change in TBP stores at three ($n = 40$), six ($n = 35$) and 12 ($n = 30$) months. *$P < 0.003$ versus zero change. †$P = 0.02$ for comparison of groups. Results are expressed as mean (± SEM) (From Plank et al. (2008). By permission of John Wiley & Sons)

134.3 Body Fat

Depletion of body fat stores accompanies the malnutrition characteristic of cirrhotic patients and may be caused by the increased reliance on lipids as a fuel source, coupled with poor nutritional intake and intestinal fat malabsorption (Matos et al. 2002). The traditional approach to body-fat estimation is underwater weighing. This technique is impractical in patient populations and an alternative approach, air-displacement plethysmography using the Bod Pod® (Life Measurement Instruments, Inc., Concord, CA), may find application in cirrhosis in the future. Many body-composition centers now have access to whole-body dual-energy X-ray absorptiometry (DXA) to partition body tissue into fat, non-fat soft tissue and bone mineral compartments. For accurate partitioning, a fundamental assumption of this approach is that the soft tissue is normally hydrated. However, in practice, any differences in measured composition that can be ascribed to fluid changes are likely to be relatively minor (Pietrobelli et al. 1998). Total fat mass measurements by DXA before and after paracentesis of ascites in cirrhotic patients were not different (Haderslev et al. 1999). Good agreement between body fat measured by DXA and a multicompartment model was shown by Strauss et al. (2000) in 198 adult cirrhotic patients. In this four-compartment model, body fat was derived as the difference between body weight and the sum of total body protein measured by IVNAA, total body water (TBW) measured by deuterium dilution and bone mineral content (BMC) measured by DXA. Such multicompartment models can be considered the gold standard for fat-mass estimation.

Fat-mass depletion has most commonly been assessed in cirrhosis using triceps skinfold thickness or upper-arm fat area and comparing these measurements with established normal data (e.g., Frisancho 1981). Alberino et al. (2001) found that the prevalence of severe fat depletion, defined as TSF below the 5th percentile of the reference norms, tended to increase with severity of the liver disease and was markedly lower in males than in females (Fig. 134.7). A similar sex difference was seen by Riggio et al. (1997), where DXA measurements of percent body fat in age-, sex-, and BMI-matched controls were compared to those from cirrhotic patients with no ascites or detectable edema.

Bioelectrical impedance analysis (BIA) is an easily applied, non-invasive and inexpensive technique that is widely used in studies of healthy individuals. In the study by Strauss et al. (2000), both single-frequency impedance analysis and multifrequency impedance spectroscopy estimates of fat mass, based on equations developed in healthy populations, were compared to measurements using DXA. Both impedance techniques substantially overestimated fat mass and the 2SD limits of agreement were wide. Such discrepancy is not surprising, given that BIA measurements most closely reflect body water and, in patients with abnormal and widely varying fluid status, estimation of fat-free mass or fat mass is problematic. No equations relating BIA resistance and reactance values to fat mass have been developed in a cirrhotic population.

134.4 Body Water

Measurements of TBW in healthy adults are widely used to estimate FFM, based on the constancy of the ratio of TBW to FFM observed not only in human adults but also across a wide range of mammalian species (Schoeller 2005). The generally accepted value for this ratio is 0.73 (Pace and Rathbun 1945). An increase in this ratio accompanies most illnesses. In these conditions, TBW does not provide an accurate estimate of FFM and the ratio itself provides an important indicator of the extent of overhydration. The dilution principle that the amount of a tracer injected into an unknown volume is

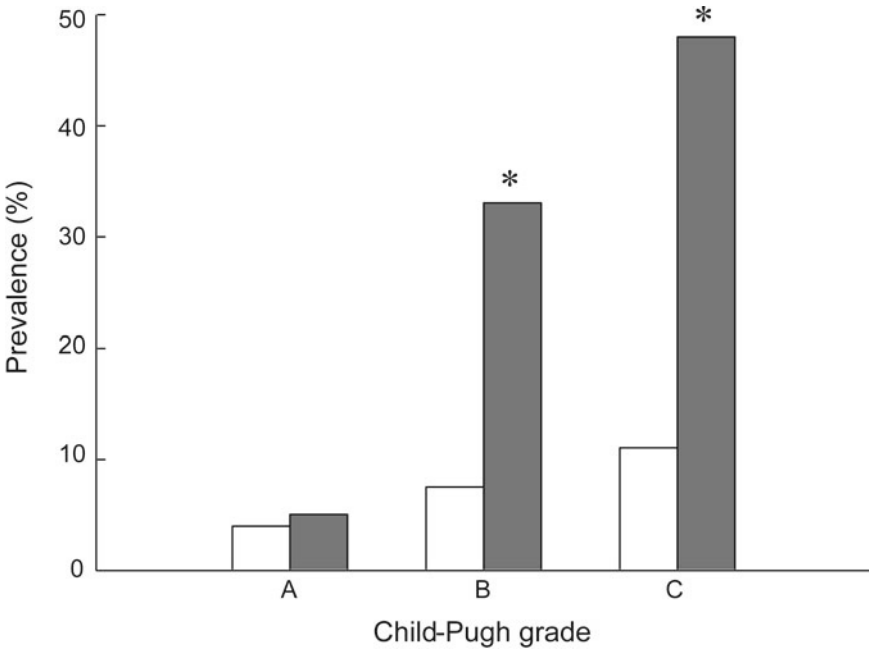

Fig. 134.7 Prevalence of severe fat depletion assessed by triceps skinfold thickness in male and female cirrhotics grouped according to severity of liver disease as assessed by Child-Pugh grade. Severe fat depletion (triceps skinfold thickness < 5th percentile) was more prevalent in female (*shaded bars*, $n = 69$) patients with Child's B and C cirrhosis than in their male counterparts (*open bars*, $n = 143$). *$P < 0.001$ versus males (Adapted from Alberino et al. (2001). By permission of Elsevier Science)

the same both before and after thorough mixing in that volume underlies the classical approach to estimating TBW. Deuterium or tritium, as deuterated or tritiated water, is commonly used as a tracer. Tracer equilibration is generally complete within 2.5–3 h in healthy individuals. In cirrhotic patients where water retention often manifests as ascites, there is some lack of agreement in the literature regarding the required equilibration time with at least 4–5 h suggested by the oxygen-18 data of McCullough et al. (1991), whereas Zillikens et al. (1992a) found 2.5 h was adequate using deuterated water.

Peng et al. (2007) derived TBW based on a six-compartment model for the body. In this approach, TBW equals the difference between body weight and the sum of TBP, measured by IVNAA, total body fat and BMC, measured by DXA, non-bone minerals, and glycogen. The small non-bone mineral and glycogen compartments (typically summing to less than 1 kg) are estimated from TBP and total minerals, respectively, based on the sizes of these compartments in the Reference Man (Snyder et al. 1975). Significant over-hydration was defined as a TBW to FFM ratio >0.76, which represented two standard deviations above the mean (0.73) for the distribution of this variable in a large group of healthy volunteers. Peng et al. (2007) showed that the prevalence of overhydration increased with severity of disease. In compensated cirrhosis, 45% and 73% of Child's A and B patients, respectively, were overhydrated, compared with 80% of Child's C patients. The percent hydration of the FFM is shown in Fig. 134.8, as a function of disease severity. A similar pattern was seen in men with alcohol-related cirrhosis, where TBW was estimated by deuterium dilution and FFM by a multicompartment model (Prijatmoko et al. 1993). In that study, hydration of the FFM was 77.7% in the 17 Child's A patients and 82.6% in the six Child's C patients. It is noteworthy that overhydration, as determined by the TBW:FFM ratio, was seen in patients who show no clinical evidence of fluid retention (Morgan et al. 2006).

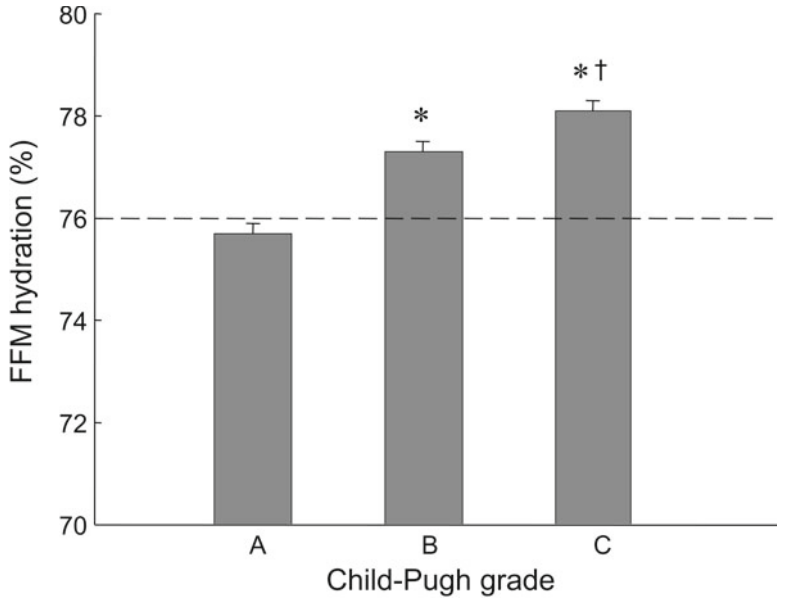

Fig. 134.8 Fat-free mass hydration in patients grouped according to severity of liver disease. Percent hydration of the fat-free mass (FFM) measured in 268 patients with liver cirrhosis increased with severity of liver disease, as assessed by Child-Pugh grade. The *dashed line* shows the upper 2SD limit of hydration for healthy controls. *$P < 0.0001$ versus Child's A; †$P < 0.017$ versus Child's B. Results are expressed as mean (± SEM) (Data from Peng et al. 2007)

The BIA technique, by virtue of its portability and ability to provide immediate results, offers potential for routine clinical use. McCullough et al. (1991) compared single-frequency BIA estimates of TBW with those from dilution of oxygen-18 labeled water in cirrhotic patients with and without ascites. Although a small study, it was clear that, in the latter group, the BIA results were unsatisfactory, with a poor correlation between the two methods (r = 0.17). In patients without ascites, an excellent correlation was seen (r = 0.98). In addition, the BIA technique measured a mean change of only 2.1 L in TBW before and after paracentesis, averaging 6.9 L in the patients with ascites. This inability to detect fluid changes in the trunk area, found also by others (Guglielmi et al. 1991; Zillikens et al. 1992b), is a reflection of the very small contribution to the overall body resistance contributed by truncal tissue. In healthy individuals, application of multifrequency BIA allows the partitioning of TBW into extra- and intracellular compartments. In cirrhotic patients without ascites, impedance measurements at three frequencies were shown to provide reliable estimates of TBW and extracellular water, as determined by deuterium and bromide dilution, respectively (Borghi et al. 1996). Bioimpedance spectroscopy applied to a group of cirrhotics, some with ascites, yielded wide limits of agreement for TBW and extracellular water when compared with the deuterium and bromide estimates, especially when ascitic patients were included, such that routine use for individual patients is questionable (Lehnert et al. 2001).

134.5 Body Cell Mass

The body cell mass (BCM), the cellular compartment of the fat-free mass, was originally conceptualized by Moore et al. (1963) as "the working, energy-metabolizing portion of the human body in relationship to its supporting structures" and is generally assessed most directly by measurement of

total body potassium (TBK). Given that TBK is almost wholly (>98%) intracellular (Forbes et al. 1962), changes in this quantity will reflect changes in cellular mass unless intracellular potassium concentration is reduced. A number of studies in cirrhotic patients indicate that TBK loss is due to depletion of BCM and not to changes in intracellular concentration (Mas et al. 1981; Vitale et al. 1985). Although not widely available, whole-body counters designed to measure the natural radioactivity of the body from ^{40}K are most commonly used to estimate TBK. Selberg et al. (1999) showed, in 225 cirrhotics covering a wide range of etiologies and severity of disease, a profound loss of TBK when compared with healthy controls and with normal predicted values, based on age and height. This observation is consistent with loss of muscle tissue and, therefore, body protein, in these patients. Although not statistically significant, TBK trended downward with Child-Pugh grade. Diuretic therapy had no noticeable effect on TBK loss.

134.6 Bone Mineral

DXA provides a non-invasive measurement of BMC, the inorganic calcified content of bone, and bone mineral density (BMD), an areal density calculated by dividing BMC by the projected area of the skeleton. Riggio et al. (1997) showed in both male and female cirrhotics of mixed etiology, a significant reduction in these measures in comparison with age-, sex-, and BMI-matched controls. In the much larger study from Peng et al. (2007), BMD divided by height, which provides a measure of volumetric density that is independent of frame size, was similarly significantly lower than that in healthy controls, for both males and females. In that study, BMD or BMD/height did not differ significantly between Child-Pugh or between etiological groups. BMD/height tended to be lower, however, in patients with significant protein depletion than in those without ($P = 0.05$). In patients with alcoholic cirrhosis, reduction in BMC and BMD was shown also to be more closely related to malnutrition than the liver disease per se (Santolaria et al. 2000).

Sex-adjusted values of BMD measured at sites, such as the lumbar spine or femoral neck that have been referenced to peak bone mass in the normal population (so-called T-scores), indicate high prevalences of osteopenia (*T*-scores between -1 and -2.5) and osteoporosis (*T*-scores < -2.5) in cirrhotic patients. In a group of cirrhotics of diverse etiology, osteopenia was present in almost 40%, and osteoporosis in 20% of women and 30% of men (Crawford et al. 2003). Not dissimilar results were seen in patients with cirrhosis due to hepatitis C or alcohol measured before liver transplantation (Carey et al. 2003).

134.7 Applications to Other Areas of Health and Disease

Detailed body composition analysis that involves assessment of the principal compartments of the body is essential to understanding the type and magnitude of the derangements that occur in a number of disease states. Most particularly, these include conditions where large shifts in fluid and fluid distribution may occur. Patients who are critically ill due to serious sepsis or major traumatic injury fall into this category. Other patient groups where abnormal fluid status is present include those with end-stage renal disease, heart failure, and those in the early postoperative phase after a major surgical operation. In all these patient groups, depletion of muscle, and hence protein, stores occurs to a greater or lesser extent.

Compartmental analysis that provides measures, such as total body protein or total body potassium, has application in investigations of energy metabolism. For example, such analysis provides

an appropriate means of assessing hypermetabolism in patients where fluid excess may be present. Accurate compartmental analysis may also provide measures with application for prediction of survival, particularly in chronic catabolic conditions, where, for instance, disease progression is associated with increasing muscle loss.

Summary Points

- Body composition of patients with cirrhosis is markedly deranged.
- Full understanding of these derangements requires compartmental assessment of the body that is not confounded by fluid retention.
- Malnutrition, recognized by significant reduction in protein stores, is highly prevalent in cirrhotic patients.
- Regardless of etiology, body protein depletion, and, hence, malnutrition, increases in prevalence with the severity of underlying liver disease.
- Males are more protein depleted than females, whereas the reverse is true for fat depletion.
- An expanded total body water space is a characteristic of the cirrhotic patient.
- Higher than normal total body water as a fraction of the fat-free mass occurs even in patients with no clinical evidence of fluid retention.
- Depletion of the cellular mass of the body, as assessed by total body potassium measurement, seen in these patients provides further evidence of muscle loss.
- Loss of bone mineral and bone mineral density is seen in a significant proportion of cirrhotic patients and these losses appear to be associated with malnutrition.

Chapter 135
Liver Damage Severity Evaluated by Liver Function Tests and the Nutritional Status Estimated by Anthropometric Indicators

Alfredo Larrosa-Haro, Erika F. Hurtado-López, Rocío Macías-Rosales, and Edgar M. Vásquez-Garibay

Abstract Pediatric patients with chronic liver disease (CLD) may present impaired growth and acute malnutrition. In most pediatric series the prevalence of these nutritional-related conditions is high. Secondary malnutrition mechanisms include low caloric intake, malabsorption of lipids and fat soluble vitamins and increased energy expenditure. In children younger than 5 years, the degree of liver damage is closely related to growth impairment and their current nutritional status; both may be predicted by liver function tests such as direct bilirubin, albumin and gamma-glutamyl transpeptidase.

Anthropometry has been widely used to evaluate the nutritional status of children with CLD. In infants and toddlers, growth can be properly assessed by measuring head circumference and length; in older children growth may be evaluated by height. When ascitis and/or hepatosplenomegaly are present, weight for height might underestimate the current nutritional status. Arm anthropometrics could become an alternative tool in identifying malnutrition since it estimates muscle mass or fat stores; recent observations of DXA in infants with CLD have shown a good correlation between body compartments and arm anthropometric indicators.

In addition to its prognostic value, the crucial reason for anthropometrically evaluating a patient with CLD is to recommend nutritional intervention which will improve growth and current nutritional status or at least avoid its deterioration.

135.1 Introduction

Infants and children with chronic liver disease (CLD) may present impaired growth, protein–energy malnutrition, fat-soluble vitamin deficiencies, and diminished bone mineralization (Ramaccioni et al. 2000; Stephenson et al. 2001; Heubi et al. 2002). These nutritional-associated disorders are thought to be secondary to the interaction of factors, such as reduced caloric intake, lipid- and fat-soluble vitamin malabsorption, increased energy expenditure, altered intermediate metabolism, hormonal dysregulation, and chronic anemia related to hypersplenism and portal hypertension (Shepherd et al. 1991; Madden and Morgan 1999; Roggero et al. 1997).

Anthropometrics has been used as a tool to assess the nutritional status of children with CLD (Sokol and Stall 1990; Wasserman et al. 1999; McDiarmid et al. 2002). Although the anthropometrical indicators based on weight (weight for height, weight for age, and body mass index) have been extensively used in pediatric patients with liver disease, they may not accurately assess the current nutritional status due to liver and spleen enlargement and particularly to ascitis and peripheral fluid retention (Hurtado-López et al. 2007). Arm anthropometrical indicators could well become an alternative tool in the nutritional evaluation of children with CLD. Arm composition is not altered as much as weight when fluid retention occurs (Hurtado-López et al. 2007; de Onis and Habicht 1996; Macías-Rosales et al. 2004), and is probably not modified at all by ascitis and liver and/or spleen enlargement.

The association between the degree of liver damage and the nutritional status in pediatric patients with end-stage liver disease has been reported in multivariate analysis studies (McDiarmid et al. 2002; Hurtado-López et al. 2007). Hurtado et al. demonstrated that liver damage severity evaluated by liver function tests could predict the nutritional status measured by anthropometrical indicators (Hurtado-López et al. 2007).

The aims of this chapter are: (a) to discuss the value of nutritional status assessment by anthropometric indicators in pediatric patients with CLD; (b) to present some novel data describing liver function tests that indicate liver damage severity and its correlation with anthropometrical nutritional status indicators; and (c) to underline the clinical implications of an accurate nutritional diagnosis in infants and children with CLD.

135.2 Prevalence of Growth Impairment and Malnutrition in Children with CLD

The association between growth impairment and malnutrition in children with CLD has been described over the last two decades. Cywes et al. reported diminished speed growth velocity and vitamin and other micronutrient deficiencies in infants and children with biliary atresia (Cywes and

Table 135.1 Frequencies and percentages of height for age, weight for height, and medium upper-arm circumference (MUAC) for age < −2SD in 79 pediatric patients with chronic liver disease. The patients were distributed by pediatric age groups. Percentages were calculated from total sample

Millar 1990). Shepherd et al. demonstrated progressive nutritional deterioration in a group of 37 pediatric patients waiting for liver transplants; the nutritional indicators were low-speed growth velocity and loss of cell mass measured by total body potassium (Shepherd et al. 1991).

The nutritional status of pediatric patients with CLD has been anthropometrically evaluated by several authors. The anthropometrical indicators used in most studies have been height for age and weight for height; however, some authors have also reported their experience with arm indicators (Sokol and Stall 1990; Wasserman et al. 1999; Chin et al. 1992; Charlton et al. 1992; Vegnente et al. 1992). The general consensus of these studies is that the proportion of growth impairment and malnutrition in infants and children with CLD is undoubtedly high.

In a study by Hurtado et al. at a pediatric referral hospital's Liver Clinic, growth impairment (height for age < −2SD) was identified in 44.3% out of 79 pediatric patients with CLD (Hurtado-López et al. 2007). In the same sample, acute malnutrition (weight for height < −2SD) was identified in 11.4% of the cases. In identifying cases with *z*-score < −2SD, medium upper arm circumference (MUAC) for age increased 32 percentage points compared to weight for height; however, when MUAC was adjusted for height, this difference persisted by almost 8 percentage points (Hurtado-López et al. 2007). This disparity between the proportion of malnutrition identified by MUAC and weight for height – the most used acute malnutrition indicator – was associated with the ascitis incidence present in 20% of the cases studied. In the ascitis subgroup ($n = 19$), cases identified with < −2SD when MUAC was 75%, whereas weight for height demonstrated acute malnutrition in 25% ($p < 0.003$). In this study, in children 5-year-old or younger, growth impairment distribution and malnutrition by age groups showed a higher proportion of cases (Table 135.1). Risk analyses by age groups (infants plus preschoolers vs school age children plus adolescents) showed significant odds ratios with height for age (OR 3.8, CI.3–11.2), MUAC for age (OR 15, CI 3.9–61.8), and MUAC for height (OR 8.3, CI 1.4–64.3). These results clearly showed that children younger than 6 years of age with CLD had an increased risk of acute and chronic malnutrition.

In a cross-sectional study by Larrosa et al. 256 pediatric patients demonstrated that children with CLD had the highest rate of chronic malnutrition (height for age < −2SD, 38.9%) and the second highest rate of protein–energy malnutrition when evaluated with MUAC for age (Larrosa-Haro et al. 2006). Frequencies and percentages of growth impairment and malnutrition distributed by diagnoses are presented in Table 135.2.

135.3 Correlation of Growth and Body Composition Anthropometric Indicators

If height is considered to be the anthropometric axis of growth, then, in normal subjects, it might predict the effect of other growth anthropometric indicators, such as head circumference. However, in CLD pathology, these variables and their interactions are less well known. In a study of 79 pediatric

Table 135.2 Frequencies and percentages of grouped *z*-scores < −2SD of height for age, weight for height and medium upper-arm circumference (MUAC) for age in 256 outpatients or hospitalized pediatric patients seen in the Department of Gastroenterology and Nutrition in a pediatric referral hospital. The data are related to the five more frequent diagnoses. Percentages were calculated from total sample (Hurtado 2005)

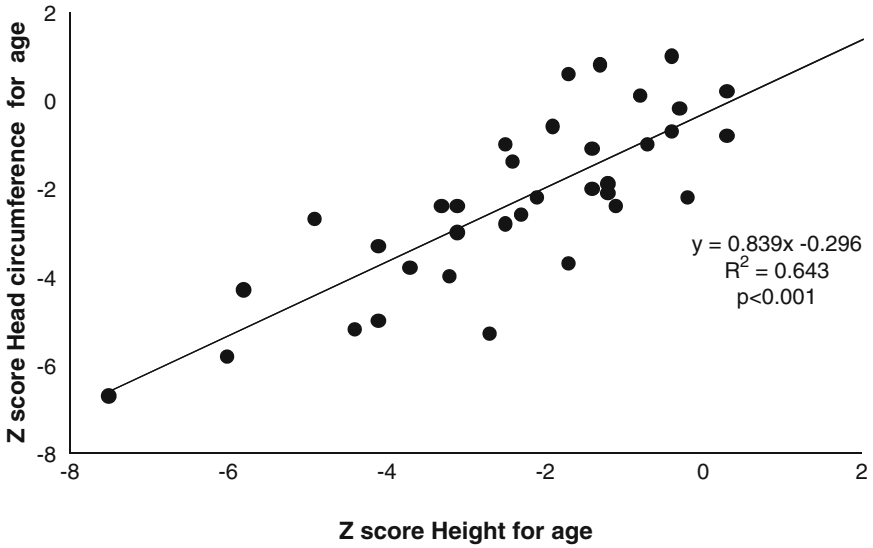

Fig. 135.1 *z*-Scores linear regression of height for age (independent variable) and head circumference for age (dependent variable) in 79 children with chronic liver disease

patients with CLD (Hurtado 2005), height for age *z*-scores showed a strong and highly significant correlation with head circumference *z*-scores (Fig. 135.1); children with lower height for age *z*-scores had lower head circumference *z*-scores. The statistical association involving these two variables in our children with CLD suggests that height and head circumference impairment are closely related. Similar to the implications of early growth retardation in final adult height, the impairment of head circumference size could be related to neurodevelopment delays or other unknown conditions.

The bivariate correlations of height for age *z*-scores with weight for height and arm anthropometrical *z*-scores in a group of children with CLD are presented in Table 135.3. Correlations with weight for height were not statistically significant. However, all arm indicators showed significant correlations with height. It is interesting to point out that the highest R^2 values were for indirect arm indicators, particularly, arm muscle area and total arm area. These anthropometric findings seem to underline the close interaction between growth and body composition, when framed by the complex biological events that take place in children with diseased livers.

Table 135.3 *z*-Scores correlation of height for age and the anthropometric body composition indicators in 79 pediatric patients with chronic liver disease. Triceps skinfold and arm areas were calculated for age (United Network for Organ Sharing)

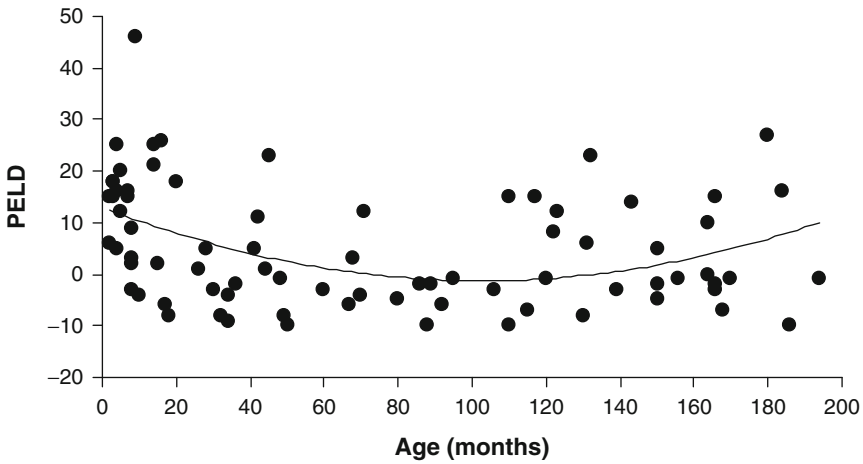

Fig. 135.2 PELD scores correlation age in months in 79 pediatric patients with chronic liver disease (Larrosa-Haro et al. 2006)

135.4 Liver Damage Severity and Nutritional Status

The pediatric end-stage liver disease (PELD) score is a quantitative classification of liver damage (United Network for Organ Sharing); it is currently used in North America to select pediatric patients for liver transplant. This evaluation tool includes three liver function tests (conjugated bilirubin, albumin, and INR), two anthropometric indicators (weight for height and height for age), age, and gender. With higher PELD scores, the probability of gastrointestinal bleeding, liver encephalopathy, admission to a pediatric intensive care unit, and death, is increased. Infants and adolescents are the pediatric CLD age groups with the severest liver damage. Biliary atresia and most metabolic disorders are present early in life and are associated with severe liver damage. In all pediatric age groups with CLD (Fig. 135.2), these disorders account for the highest proportion and severity of acute and chronic malnutrition. Table 135.4 shows the mean values of PELD scores distributed by pediatric age groups in a series of infants and children with CLD. Bivariate correlations of PELD scores with anthropometrical *z*-score indicators are presented in Table 135.5; the highest "*r*" values were observed with direct and indirect arm indicators (Hurtado 2005).

In a recent study by Hurtado et al. several multivariate regression models performed with liver function tests as independent variables and anthropometrical indicators as dependent variables showed that

Table 135.4 PELD scores of 79 pediatric patients with chronic liver disease. Results are reported in means and SD. The patients are distributed by pediatric age groups (Larrosa-Haro et al. 2006)

Age groups	*n*	PEDL score	
		Mean	SD

b Anthropometrical indicators increased value for each added unit of every liver function test. *β Z* score of *b*. *r* correlation coefficient. r^2 determination coefficient

nutritional status may be predicted by biochemical liver damage severity indicators (Hurtado-López et al. 2007). The liver function tests with higher correlations were conjugated bilirubin and albumin; the anthropometrical indicators with the highest R^2 were height and arm indicators (Table 135.6). These interesting findings underline the correlation between liver damage severity and nutritional status and reflect the close relationship of liver function to growth and current nutritional status.

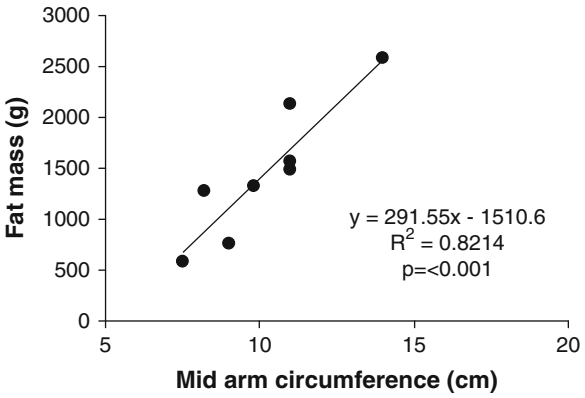

Fig. 135.3 Mid arm circumference (cm) bivariate correlation with fat mass (g) by dual X-ray absorptiometry in eight infants with chronic liver disease ($r = 0$, $R^2 = 0.67$, $p = 0.044$)

135.5 Validation of Arm Anthropometrics

Double X-ray absorptiometry, one of the current gold standard techniques to measure body composition with plausible correlations, has been used to measure fat stores and muscle mass in children in order to validate the anthropometric accuracy (Brambila et al. 2006). However, to our knowledge, there are no corroborating arm anthropometrics studies in infants with CLD. Preliminary results in an ongoing study by the authors of this chapter have shown statistical bivariate correlations of most arm anthropometrical indicators with body composition compartments evaluated by double X-ray absorptiometry (unpublished data, Fig. 135.3).

135.6 Clinical Implications of Secondary Malnutrition

Pediatric patients younger than six year with CLD, particularly those with end-stage liver disease, should be evaluated periodically and frequently. The clinical rationale for this protocol is the overall identification of complications, such as liver encephalopathy, acute or chronic anemia secondary to gastrointestinal bleeding and systemic infections, as well as specific conditions related to the primary disease. Although anthropometric measurements are routinely performed at these evaluations, many times, they are not converted into anthropometrical indicators and, as a result, an adequate nutritional diagnosis is not attained. As already shown in this chapter, anthropometrical indicators might become an accurate way of identifying liver-function deterioration and could become valuable in the global assessment of particular cases.

Clinical trials published in the last two decades have shown the value of nutritional intervention in pediatric patients with CLD (Table 135.7). These studies have demonstrated two facts: (a) in children with CLD, the energy requirements, proteins, and other nutrients are higher than the daily recommended intake; and (b) nutritional intervention with specific nutrients, such as medium-chain triglycerides or branched-chain amino acids, increasing energy and nutrient intake by formula fortification, and/or enteral nutrition with continuous infusion, may improve or at least avoid nutritional status deterioration for weeks or months (Shepherd et al. 1991; Macías-Rosales et al. 2004; Charlton et al. 1992; Moreno 1991; Chin et al. 1990). The final nutritional outcome depends on the evolution of the primary liver disease. On the other hand, nutritional intervention may offer energy stores and specific nutrients that deal with medical complications and special situations, such as a liver transplant. This could modify the final height and the growth of the central nervous system growth along the first 36 months of life.

Table 135.7 Clinical trials related to nutritional intervention in pediatric patients with chronic liver disease

	Reference	Setting	*n*	Design	Intervention	Results
[AU2]	Charlton et al. (1992)	Institute of Child Health, University of Birmingham.	10 Advanced cirrhosis	Open clinical trial	Enteral nutrition	Improvement in weight, height, and arm indicators. No

135.7 Applications to Other Areas of Health and Disease

Anthropometrics is a valuable tool to measure growth and estimate body composition. This technique is sensitive to gender phenotype and changes in body compositions that occur throughout pediatric age groups. In this chapter, we underlined its pros and cons in evaluating growth and nutritional status in pediatric patients with liver disease. Given the specific growth and body composition characteristics of the different kinds of pediatric pathology, anthropometrics should be tested and analyzed in each one of these fields. The new 2006 WHO reference patterns constitute an important advance that permit comparisons of anthropometric data from children measured in different geographic areas. Specific parameters are still needed as reference patterns for arm areas in children younger than 6 years of age.

135.8 Practical Methods and Techniques

135.8.1 Anthropometrical Standardization

Before data are collected, an anthropometrical standardization should be done. Consistency (intra-group individual measurements) and validity (inter-group comparison with a gold standard) may be evaluated with Pearson bivariate correlations; when the value of "*r*" is equal to or below 0.8, the anthropometrical technique should be reviewed and corrected until the desired intra- and inter-group correlations, ideally around 0.9, are obtained (Villasis-Keever et al. 2001).

135.8.2 Weight

Babies are weighed without diapers on a leveled pan scale with a beam and a movable weight, making sure the weight is distributed equally on each side of the pan's center. Weight is recorded to the nearest 5 grams. Children older than 2 years will be weighed with a movable weight platform-beam scale; subjects are measured without shoes and minimum clothing. Weight is recorded to the nearest 100 g (Frisancho 1990).

135.8.3 Length or Height

In children less than 2 years of age, the length is measured and recorded to the nearest 0.1 cm in a recumbent position using an infantometer. An assistant holds the infant's head while the examiner straightens its legs holding the feet with toes pointed up moving the footboard against the feet. In children older than 2 years, height is measured and recorded to the nearest 0.1 cm using a standiometer with a movable block. The subjects are measured while standing, without shoes, heels together, back as straight as possible, and arms hanging freely; the head is positioned in the Frankfort horizontal plane and the movable block is brought down until it touches the head (Frisancho 1990).

135.8.4 Mid-Upper-Arm Circumference (MUAC)

With the right or left arm bent at the elbow at a 90° angle while the upper arm is held parallel to the side of the body, the distance between the acromion and the olecranon is measured with a fiberglass tape and the midpoint between these two spots is marked; the side of the body to be measured may be selected in accordance with the side measured in the selected reference pattern. The baby's arm must hang loosely down the side of its body while relaxed. A fiberglass metric tape is positioned at the marked midpoint and the circumference is recorded to the nearest 0.1 cm (Frisancho 1990). Babies should sit on their mother's laps. Children are measured standing up.

135.8.5 Triceps Skinfold (TSF)

TSF should be measured with a skinfold caliper at the previously marked midpoint of the posterior right upper arm, with the arm extended in the same relaxed position used for MUAC. The examiner grasps a vertical pinch of skin and subcutaneous fat between thumb and forefinger about 1 cm above the previously marked midpoint pulling away gently from the underlying muscle. The skinfold caliper is placed at the marked midpoint while maintaining the skinfold grasp. Readings are taken in millimeter as soon as the caliper comes in contact with the skin and the dial reading has stabilized. Babies should sit on their mother's laps and children are measured standing up (Frisancho 1990).

135.8.6 Total, Muscular, and Arm Fat Areas

Arm areas may be calculated with MUAC and TSF measurements, according to the formulas described by Frishancho (Frisancho 1990); results are expressed in square millimeters.

135.8.7 Reference Patterns, Indices, and Nutritional Status Indicators

For infants, children and adolescents, anthropometrical indicators obtained from height, weight, MUAC, and triceps skinfold may be calculated with the 2006 WHO parameter. However, arm areas reference patterns are lacking the 2006 WHO documents; hence, these may be calculated with other parameters (Frisancho 1990; Sann et al. 1988; WHO Child Growth Standards 2006).

Summary Points

- In infants and children with chronic liver disease, the prevalence of growth impairment and malnutrition is high.
- Head circumference *z*-score for age may be used as an anthropometrical indicator of growth in children with CLD.
- The significant bivariate correlations of height with arm anthropometrical indicators underline the close interactions between growth and body composition.

- Biochemical liver damage indicators predict the severity of growth impairment and malnutrition in children with CLD.
- Children with CLD need more than the recommended daily intake of energy, proteins, and other nutrients.
- Nutritional intervention with particular nutrients, such as medium-chain triglycerides or branched-chain amino acids, increasing the energy and nutrient intake by formula fortification, and enteral nutrition with continuous infusion may improve or at least avoid nutritional deterioration for weeks or months.

Key Features

Table 135.8 Key points of liver damage severity evaluated by liver function tests and the nutritional status estimated by anthropometric indicators in children with chronic liver disease

1. CLD associates with growth impairment and malnutrition.
2. Head circumference predicts height in the first 3 months of life.
3. Growth indicators have strong correlations with body composition anthropometrical indicators.
4. Biochemical indicators of liver damage predict growth impairment and acute malnutrition.
5. Nutriment requirements of children with CLD are higher than the DRIs.
6. Nutritional intervention in children with CLD may improve or at least avoid deterioration of their nutritional status.

Chapter 136
Waist Circumference Correlates and Hepatic Fat Accumulation

Yuichiro Eguchi, Toshihiko Mizuta, Iwata Ozaki, Dita Salova, Masato Yoneda, Koji Fujita, Hideyuki Hyogo, Hideki Fujii, Masafumi Ono, Yasuaki Suzuki, Takaaki Ohtake, Yoshio Sumida, and Kazuma Fujimoto

Abstract Nonalcoholic fatty liver disease (NAFLD) is a common cause of chronic liver disease and is a major public health problem worldwide. It has been suggested that simple fatty liver, the most common type of NAFLD, is a reversible condition in which large vacuoles containing triglycerides accumulate in hepatocytes. Simple fatty liver is often a precursor to non-alcoholic steatohepatitis, which can progress to liver cirrhosis and hepatocellular carcinoma. NAFLD is considered one of the phenotypes of metabolic syndrome, which is characterized by obesity, type 2 diabetes mellitus, hyperlipidemia and hypertension. Obesity, particularly abdominal obesity, is a major risk factor for NAFLD. Several recent studies have revealed a relationship between excessive visceral fat accumulation and the severity of hepatic fat accumulation. On the other hand, in the current definitions of metabolic syndrome, waist circumference measurement has been proposed as a simple and useful estimate of abdominal obesity, taking into account sex differences in waist circumference. Recent studies have also reported that waist circumference could be a marker for hepatic fat accumulation. In this chapter, we first discuss the relationship between waist circumference, hepatic fat accumulation and liver function. Finally, we discuss the sex and age-group differences in these relationships, based on recent findings.

136.1 Introduction

Non-alcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease and a major public health problem. It has been recognized that simple fatty liver (non-alcoholic fatty liver), the most common type of NAFLD, is a reversible condition in which large vacuoles containing triglycerides accumulate in hepatocytes. Simple fatty liver is often a precursor to non-alcoholic steatohepatitis (NASH), which can progress to liver cirrhosis and hepatocellular carcinoma. Recent surveys indicate that NAFLD may account for approximately 80% of cases with liver dysfunction in many countries. NAFLD is considered to be one of the phenotypes of metabolic syndrome, which is characterized by abdominal obesity, type 2 diabetes mellitus, hyperlipidemia, and hypertension. It is also well recognized that visceral fat accumulation is a more important risk factor than subcutaneous fat for NAFLD and metabolic syndrome (Marchesini et al. 2003; Stranges et al. 2005; Kogiso et al. 2007; Jakobsen et al. 2007; Sung et al. 2007; Leite et al. 2009). Furthermore, recent studies have reported that hepatic fat accumulation, but not visceral fat accumulation, is associated with the metabolic complications of obesity (Kotronen et al. 2007; Wasada et al. 2008, Fabbrini et al. 2009).

Waist circumference is widely used as an indirect measurement of abdominal obesity in many epidemiologic studies and is included as a criterion in the NCEP-ATP III and IDF consensus definition of the metabolic syndrome. We previously reported that the degree of hepatic fat accumulation, as estimated by ultrasonography and CT, is correlated with visceral fat area estimated by abdominal CT in patients with NAFLD (Eguchi et al. 2006). However, in clinical practice, it is not always possible to evaluate visceral fat accumulation by abdominal CT. Several studies revealed that visceral fat accumulation estimated by waist circumference was closely related to NAFLD (Sabir et al. 2001; Eguchi et al. 2006; Jakobsen et al. 2007). Measuring waist circumference is an essential part of clinical practice for the management of NAFLD, in addition to measuring body weight and body mass index (BMI); indeed, waist circumference should be measured in most research studies. Hu et al. reported that the validity of BMI as a marker of body fatness in older adults decreased as a result of changes in body composition associated with aging. However, waist circumference has been shown to be a good predictor of adiposity, particularly abdominal obesity (Hu 2008).

In this chapter, we review the clinical and epidemiologic studies that report waist circumference, an essential anthropometric measurement for the evaluation of visceral obesity and hepatic fat accumulation. We also report results from the joint multicenter NAFLD research database in Japan.

136.2 NAFLD and Its Progression to Non-alcoholic Steatohepatitis and Liver Cirrhosis

NAFLD is the most common cause of chronic liver disease in adults in USA, European countries, and Asia in parallel with the increase of obesity in developed countries. NAFLD is recognized as the hepatic manifestation of insulin resistance and metabolic syndrome (Table 136.1). The incidence and prevalence of NAFLD are thought to be rising, as the prevalence of obesity and type 2 diabetes has dramatically increased in two decades. The estimated prevalence of NAFLD is 20–30%, whereas that of NASH is estimated to be 3–5%. NAFLD occurs in patients of both sexes, all ethnicities and

Table 136.1 Key facts of nonalcoholic fatty liver disease

1. Non-alcoholic fatty liver disease (NAFLD) refers to the presence of hepatic steatosis characterized by lipid droplets' accumulation within hepatocytes without intake of ethanol
2. Insulin resistance and metabolic syndrome are associated with the pathogenesis and progression of NAFLD
3. NAFLD is a clinical pathological term for a spectrum of structural findings ranging from simple steatosis to non-alcoholic steatohepatitis (NASH) with progressive hepatic fibrosis, liver cirrhosis, and hepatocellular carcinoma
4. The "two-hits" model of NASH pathogenesis has been proposed Day et al., whereby a "first hit" (hepatic steatosis) increases the sensitivity of the liver to the secondary hepatic injury and oxidative stress, lipid peroxidation, mitochondrial dysfunction, and inflammatory adipocytokines provide the "second hit" that triggers NASH
5. NAFLD is clinically suspected in subjects with asymptomatic elevation of serum aminotransferase levels, radiological findings of fatty liver, and hepatomegaly
6. Only histological examination of the liver can confirm the diagnosis of NAFLD and its clinical severity (i.e. steatosis alone or advanced stages of NASH)
7. Therapies for NAFLD are limited. Moderate and gradual weight reduction can result biochemical and histological improvement
8. Pharmacological treatments have been demonstrated with antioxidants, insulin sensitizers, hepatoprotectants, and lipid-lowering agents. However, without larger randomized studies, no pharmacological treatments can be recommended at this time

This table lists the key facts of nonalcoholic fatty liver disease including the pathogenesis, diagnosis and therapies

in all age groups. NAFLD has few symptoms and is clinically characterized by a slight elevation of the serum aminotransferase levels, hyperglycemia, and insulin resistance in combination with obesity. It has been suggested that NAFLD subtypes differ in their potential for progression. Most patients with simple fatty liver do not progress to overt liver disease. By contrast, non-alcoholic steatohepatitis (NASH) can progress to liver cirrhosis and hepatocellular carcinoma. NASH, which was first described by Ludwig (Ludwig et al. 1980), is characterized by histopathologically macrovesicular steatosis, hepatocellular ballooning and lobular inflammation with scatterd leukocytes and monocytes. Hepatocyte ballooning degeneration, Mallory's hyaline (hyaline cytoplasmic inclusions of cyto keratin within hepatocyte), and pericellular and perisinusoidal fibrosis are discriminating findings suggestive of progressive NASH. The transition of simple fatty liver to NASH is not clearly demarcated and each clinical symptom is similar. According to Day and James (1998), the pathogenesis of NASH comprises two steps. The first step is characterized by the accumulation of triglyceride droplets in the hepatocyte cytoplasm as simple fatty liver. This is mainly a consequence of peripheral resistance to insulin, whereby the transport of fatty acids from excessive visceral fat to the liver is increased. The second step is induced by oxidative stress and inflammatory cytokines from an excessive visceral fat tissue, such as tissue necrosis factor-alpha (TNF-alpha), tumor growth factor-beta (TGF-beta), and IL-6. This leads to exacerbation of insulin resistance, further oxidative stress, and organelle dysfunction within liver cells, resulting in an inflammatory process, hepatocellular degeneration, and fibrosis. Hepatic fibrosis can progress to liver cirrhosis, which initially occurs in a micronodular pattern, but macronodular regeneration may develop.

The diagnosis can be made by liver biopsy and/or by imaging, such as abdominal computed tomography (CT), magnetic resonance imaging, magnetic resonance spectroscopy, and ultrasonography. Liver biopsy is the gold standard, particularly for NASH, for evaluation of steatosis, inflammation, and fibrosis. However, liver biopsy is invasive and is sometimes associated with incidental peritoneal bleeding. Noninvasive evaluation of liver fat accumulation is mainly performed based on ultrasonographic findings and abdominal CT, using the liver/spleen attenuation ratio (L/S ratio) (Fig. 136.1 and Table 136.2). The CT numbers (in Hounsfield units) of region of interest (ROI) of 60 mm^2 in the periphery of the liver and the spleen, away from major vessels, are measured at five points in each organ, and the mean numbers are used to determine L/S ratio as an index of fat accumulation in the liver.

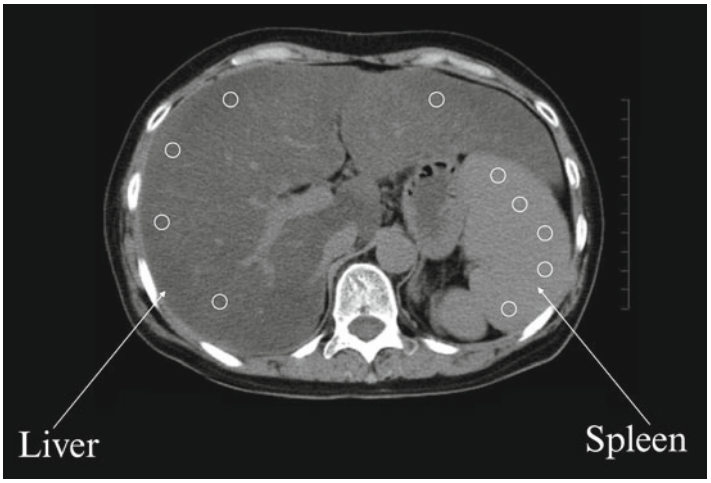

Fig. 136.1 Hepatic fat accumulation and the measurement of the liver/spleen attenuation ratio (L/S ratio). This CT image of a case with severe fatty liver shows very low CT attenuation. The CT values (in Hounsfield units) were determined for five 60-mm^2 regions of interest (*ROI*) placed in the periphery of the liver and the spleen, away from major vessels. The mean values were used to determine the L/S ratio as an index of fat accumulation in the liver

Table 136.2 Key facts of liver/spleen attenuation ratio

1. Hepatic steatosis can be non-invasively diagnosed with ultrasonography (US), computed tomography (CT), and magnetic resonance (MRI). These radiologic modalities have several advantages and disadvantages when compared with gold standard liver biopsy
2. Non-contrast-CT has been widely used for detecting fatty infiltration in the liver
3. Hepatic steatosis produces a low-density hepatic parenchyma on CT scanning, with an inverse correlation with the degree of fatty infiltration
4. CT has a low attenuation of hepatic parenchyma in steatosis, with the liver appearing darker than the spleen rather than brighter. The severity of the steatosis correlates not only with the liver density, but also for the liver to spleen attenuation ratio.
5. All measurements were manually obtained by four or five circular region-of-interest (ROI) cursors in the liver parenchyma and four in the spleen, with care being taken to avoid vessels, artifacts, and other areas that might have spuriously increased or decreased measurements. The measurements in each segment of the liver and spleen were averaged as follows:

   Liver/spleen attenuation ratio = Average attenuation value of liver/Average attenuation value of spleen

6. Although CT scanning is widely available, it is particularly limited in serial assessments of hepatic steatosis due to significant radiation exposure

This table lists the key of liver/spleen attenuation ratio including the principle and methods

136.3 Waist Circumference and Hepatic Fat Accumulation

It has been hypothesized that visceral fat releases free fatty acids and various adipokines and thereby stimulates fat accumulation in the liver. Free fatty acids released from visceral fat are transported via the portal vein to the liver, as demonstrated in a study by Nielsen et al. (2004). Using tracer methods, they found a direct association between the amount of visceral fat and the delivery of free fatty acids to the liver.

Visceral fat accumulation is significantly correlated with waist circumference, indicating that waist circumference is a good marker for visceral obesity (Hu 2008). Between 2001 and 2009, 19 studies involving at least 100 subjects reported an association between waist circumference and fatty liver. As shown in Table 136.3, some studies reported associations between waist circumference and hepatic fat accumulation. Among the studies that used waist circumference as a marker for visceral fat accumulation, two studies (Sabir et al. 2001; Eguchi et al. 2006) found a significant correlation

Table 136.3 Summary of clinical studies that evaluated the association between waist circumference and non-alcoholic fatty liver disease among 100 subjects or more

First author and year of publication (ref.) ethnicity or country of residence	No. of subjects (% female)	Mean age (years)	Results description
Sabir, 2001 (14) Turkey	68 obese females 40 non-obese female controls	44 (SD, 9) 34 (SD, 9)	Significant correlation between WC and liver fat content (obese persons: $r = 0.45$, $p < 0.0001$; non-obese individuals: $r = 0.58$, $p < 0.0001$)
Marchesini, 2003 Italy	304 individuals with NAFLD (17% female)	42 (SD, 12)	Individuals with NASH had significantly higher WC than those with fatty liver ($p < 0.024$)
Shen et al., 2003 (16) China	4,009 individuals (36% female)	46 (SE/SD not given)	WC was significantly associated with NAFLD ($p = 0.0000$)
Hsiao, 2004 (17) Taiwan	210 obese individuals (78% female)	36 (SD, 10)	In multivariate logistic regression analysis (including sex, age, BMI, serum ferritin level, and HOMA-IR), WC was significantly associated with fatty liver (per 1-cm increase in WC: OR = 1.10, 95% CI = 1.04–1.16)
Bugianesi et al., 2005 (20) Italy	174 individuals with NAFLD (10% female) 42 controls matched for BMI (20% female)	41 (SD, 11) 43 (SD, 11)	Individuals with NAFLD had significantly higher WC than controls ($p < 0.0001$)
Stranges, 2005 United States	195 individuals with hypertension (59.0% female) 702 controls without hypertension (67.3% female)	58 (SD, 11)	Individuals with a gamma-glutamyl transpeptidase concentration had a graded increase associated with the increase of WC ($p < 0.001$)
Targher, 2005 (22) Italy	65 males without fatty liver 35 males with fatty liver	43 (SD, 4) 41 (SD, 4)	Men with fatty liver had significantly higher WC than men without fatty liver ($p < 0.01$)
Church, 2006 (24) Non-Hispanic Caucasian	194 males without NAFLD 24 males with NAFLD	52 (SD, 7) 51 (SD, 5)	In multivariate logistic regression analysis (including age and alcohol consumption), WC was significantly directly associated with NAFLD (per 1-cm increase in WC: OR = 1.11, 95% CI = 1.06–1.17). Additional adjustment for visceral fat area attenuated the association (OR = 1.05, 95% CI = 0.97–1.10), whereas additional adjustment for subcutaneous abdominal fat area did not affect the association (OR = 1.10, 95% CI = 1.02–1.17)
Eguchi, 2006 (25) Japan	129 individuals with NAFLD (49% female)	59 (SD, 12)	WC was associated with the severity of fatty liver (mild, moderate, or severe) ($p < 0.0001$)
Oh et al., 2006 (28) South Korea	3,091 individuals with NAFLD (33% female)	48 (SD, 11)	Individuals with an elevated ALT concentration had significantly higher WC than individuals with a normal ALT concentration ($p < 0.001$)
Zelber, 2006 (30) Israel	326 individuals (53% female)	51 (SD, 10)	In multivariate logistic regression analysis (including sex, age, BMI, HOMA, and triglycerides), WC was significantly associated with NAFLD (for WC >102 cm in males and WC >88 cm in females: OR = 2.9, 95% CI = 1.3–6.4)

(continued)

Table 136.3 (continued)

First author and year of publication (ref.) ethnicity or country of residence	No. of subjects (% female)	Mean age (years)	Results description
Park, 2007 South Korea	117 overweight men with NAFLD 117 controls	43 (SE, 1)	In multivariate logistic regression analysis (including age, BMI, percentage body fat, iron, triglycerides, Apo B, and HOMA), WC was significantly associated with NAFLD (per 4.6-cm increase in WC: OR = 1.67, 95% CI = 1.10–2.62)
Kogiso, 2007 Japan	348 individuals with NAFLD (17.2% females) 906 controls (55.1% female)	52–59 (SD, 14)	In multivariate logistic regression analysis (including body weight, BMI, fasting blood glucose, and triglycerides), WC was significantly associated with NAFLD (for WC <85 cm in males and <95 cm in females: OR = 5.02, 95% CI = 1.74–14.52)
Kotronen, 2007 United States	271 non-diabetic individuals (59.8% females)	38 (SD, 12)	Liver fat determined by MRS was significantly associated with WC (females: $r = 0.59$, $p < 0.0001$; males: $r = 0.56$; $p < 0.0001$)
Sung, 2007 South Korea	36654 non-diabetic individuals (37.2 5 female)	41 (SD, 9)	In multivariate logistic regression analysis (including age and BMI), WC was significantly associated with sonographically assessed fatty liver and elevated ALT (per 1-cm increase in WC; males with normal ALT: OR = 1.03, 95% CI = 1.01–1.04; females with normal ALT: OR = 1.06, 95% CI = 1.03–1.08; males with elevated ALT: OR = 1.11, 95% CI = 1.09–1.12; females with elevated ALT: OR = 1.06, 95% CI = 1.04–1.09)
Wasada, 2008 Japan	142 individuals with NAFLD (25% female)	53 (SD, 9)	High-molecular-weight adiponectin concentration, insulin-like growth factor binding protein 1, and HOMA were significantly associated with WC ($r = -0.414$, $r = -0.345$ and $r = 0.396$, respectively, all $p < 0.001$)
Ishibashi, 2008 Japan	221 individuals with NAFLD (46.6% female)	55.2 (SD, 11.9)	Hepatic fat accumulation determined by CT scan was associated with WC in males, but not in females (males, $r = -0.356$, $p < 0.01$; females, NS), and hepatic fat accumulation was associated with visceral fat accumulation in both sexes (males, $r = -0.269$, $p < 0.01$; females, $r = -0.319$, $p < 0.01$)
Kogiso et al., 2009 Japan	57 individuals with NAFLD (42.1% female) 173 controls (65.3% female)	55.8–62.8 (SD, 6.1–14.8)	WC increased with the severity of NAFLD (normal, NAFLD with normal ALT, and NAFLD with elevated ALT) ($p < 0.01$)
Leite, 2009 Brazil	125 individuals with NAFLD (70.4% female) 55 controls (69.2% female)	54.3 (SD, 8) 55.6 (SD, 7)	WC increased with the severity of hepatic steatosis (normal, mild, moderate, or severe) ($p < 0.01$)

All of 19 studies showed the association between waist circumference and the severity of fatty liver disease

SD standard deviation, *WC* waist circumference, *NASH* non-alcoholic steatohepatitis, *NAFLD* non-alcoholic fatty liver disease, *BMI* body mass index, *HOMA-IR* homeostasis model assessment-insulin resistance, *OR* odds ratio, *CI* confidence interval, *ALT* alanine aminotransferase, *MRS* magnetic resonance spectroscopy, *CT* computed tomography

between waist circumference and the severity of hepatic fat accumulation. Sabir et al. reported that the severity of hepatic fat accumulation estimated by ultrasonography was significantly correlated with BMI, waist–hip ratio, waist circumference, and visceral fat thickness estimated by ultrasonography in 68 obese and 40 non-obese subjects. Our study of 126 patients with NAFLD demonstrated that the liver–spleen ratio calculated by CT and the severity of hepatic steatosis estimated by ultrasonography are closely correlated with visceral fat accumulation estimated by abdominal CT. Previous studies have indicated that visceral fat accumulation evaluated by CT at the umbilical level is correlated with visceral fat volume, and that the accumulation of risk factors for metabolic syndrome is related to an increase in visceral fat area.

In six studies that reported multivariate logistic regression analyses, the analyses included adjustment for metabolic factors associated with hepatic fat accumulation (Hsiao et al. 2004; Church et al. 2006; Zelber-Sagi et al. 2006; Park et al. 2007; Kogiso et al. 2007; Sung et al. 2007). In the multivariate logistic regression analysis performed by Hsiao et al., waist circumference was significantly associated with the existence of fatty liver in Taiwanese subjects. Similarly, Church et al. reported that waist circumference was significantly associated with NAFLD in non-Hispanic Caucasian subjects. In that study, additional adjustment for visceral fat area attenuated the association, whereas additional adjustment for subcutaneous abdominal fat area did not affect the association. Zelber et al. reported that waist circumference was significantly associated with NAFLD in Israelis and Park et al. reported a similar association in South Korean individuals. Kogiso et al. reported that waist circumference significantly associated with NAFLD in Japanese subjects. Sung et al. reported that waist circumference was significantly associated with sonographic findings of fatty liver and elevated ALT in South Koreans.

Fifteen studies were carried out in men and women, three studies were carried out in men only, and one was carried out in women only. Our study investigated differences between sexes in terms of the association between waist circumference and hepatic fat accumulation in Japanese patients with NAFLD. The results indicated that the differences in associations between waist circumference and hepatic fat accumulation were at least partly related to differences in the distribution of visceral fat and subcutaneous fat at the umbilical level (Ishibashi et al. 2008).

136.4 Relationship Between Waist Circumference and the Severity of Hepatic Fat Accumulation in a Multicenter Study

This article introduces evidence for sex and age differences in the correlation between waist circumference/visceral fat accumulation and hepatic fat accumulation, based on analyses of the Japan Study Group for NAFLD (JSG-NAFLD) database. This database was established for multicenter clinical research in Japanese subjects with NAFLD in 2009. Clinical cases registered in the JSG-NAFLD database (499 cases: 276 males and 223 females; age 20–84 years, mean 51.7 years) were included in this analysis. All subjects were diagnosed as NAFLD based on clinical findings and ultrasonography, and underwent liver biopsy and abdominal CT scans. Waist circumference was measured at the umbilical level in an upright position during a light breath exhalation, as described in other chapters in this Handbook.

As shown in Figs. 136.1–136.4, which represent analyses of the JSG-NAFLD database, there is a significant relationship between waist circumference and visceral fat accumulation evaluated by CT. The analyses also show a relationship between visceral fat accumulation and hepatic fat accumulation estimated by the L/S ratio. In the total study population and in both sexes, there was a significant relationship between waist circumference and hepatic fat accumulation (Figs. 136.2 and 136.3), and between hepatic fat accumulation and aminotransferase levels. It should be noted that there was a

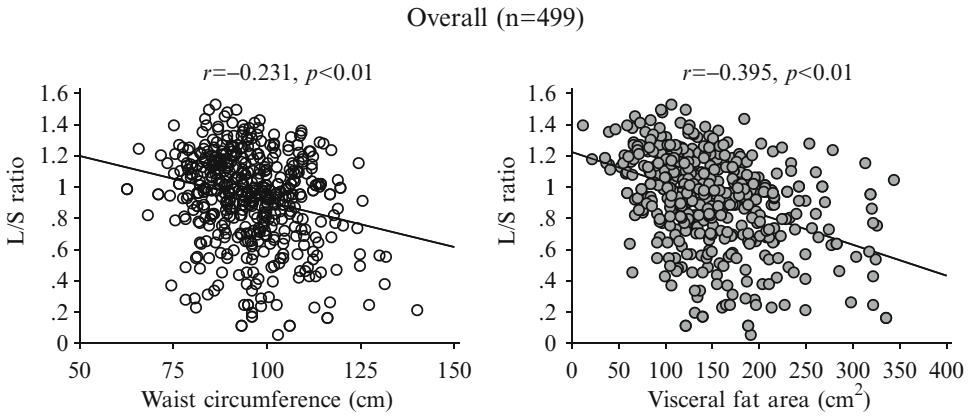

Fig. 136.2 Relationship between liver/spleen attenuation ratio (L/S ratio) and waist circumference/visceral fat area. Significant negative correlations were found between waist circumference (*left*) and visceral fat area determined by abdominal plain CT (*right*) in 499 subjects with NAFLD (liver/spleen ratio and waist circumference: $r = –0.231$, $p < 0.01$; L/S ratio and visceral fat area: $r = –0.395$, $p < 0.01$)

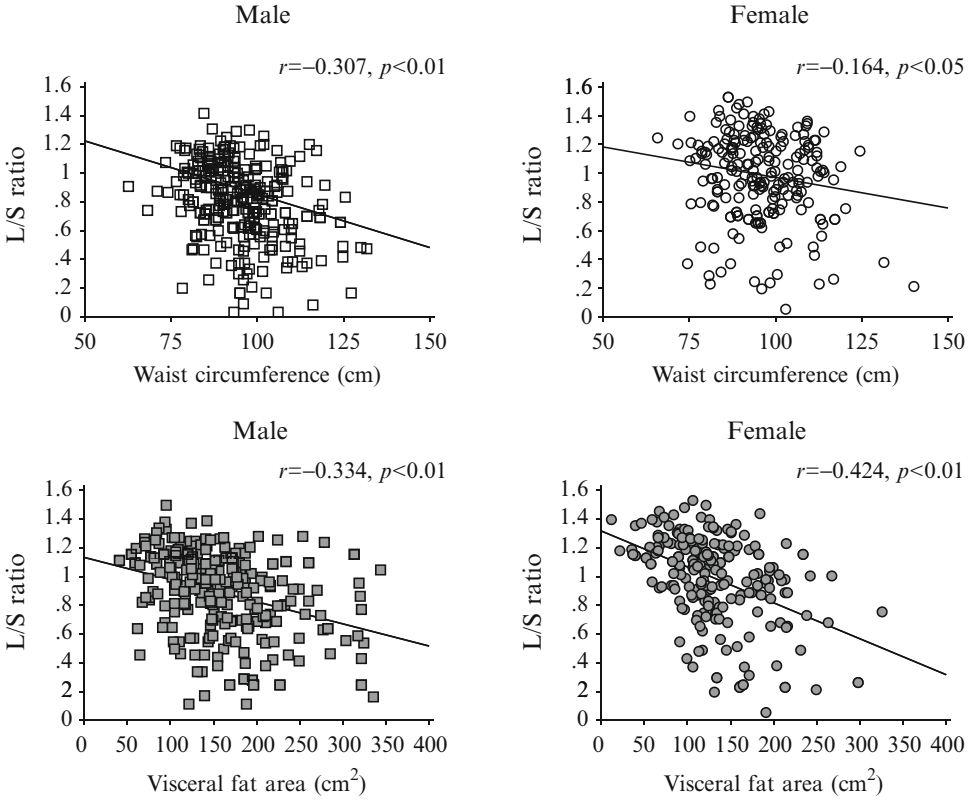

Fig. 136.3 Relationship between liver/spleen ratio (L/S ratio) and waist circumference/visceral fat area in males and females. In males ($n = 276$), there is a significant negative correlation between L/S ratio and waist circumference (*upper left*) and between L/S ratio and visceral fat area determined by abdominal plain CT (*lower left*) (L/S ratio and waist circumference: $r = –0.307$, $p < 0.01$; L/S ratio and visceral fat area: $r = –0.334$, $p < 0.01$). In females ($n = 223$), there is a weak negative correlation between L/S ratio and waist circumference ($r = –0.164$, $p < 0.05$) (*upper right*) and a stronger negative correlation between L/S ratio and visceral fat area ($r = –0.424$, $p < 0.01$) (*lower right*)

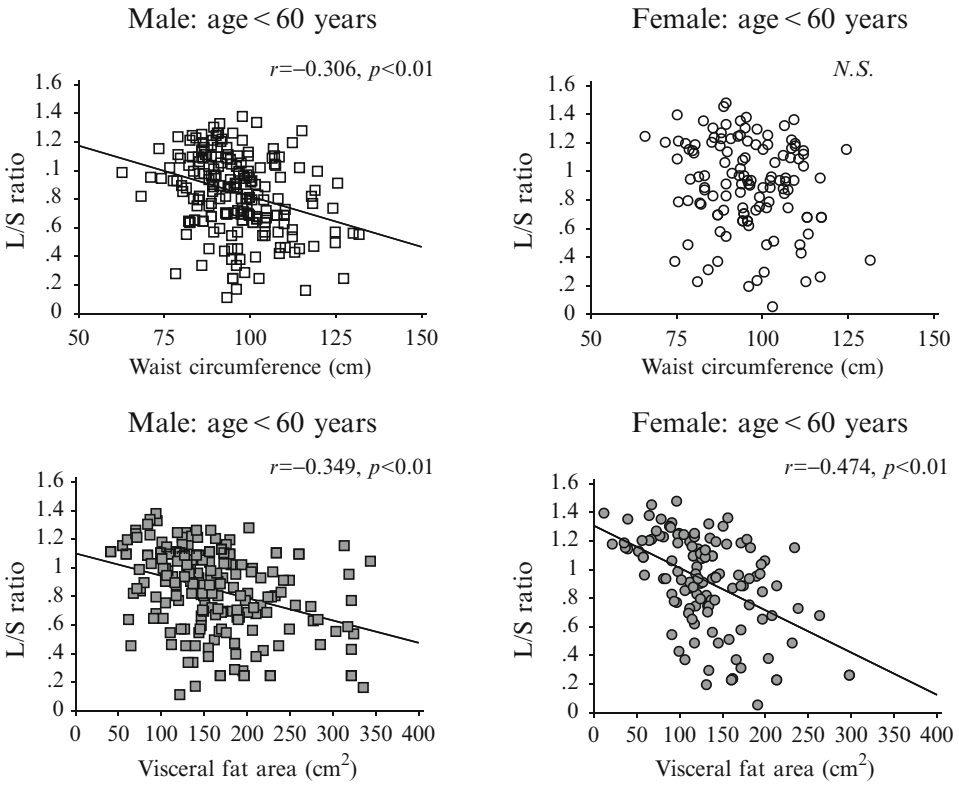

Fig. 136.4 Relationship between liver/spleen ratio (L/S ratio) and waist circumference/visceral fat area in males and females aged <60 years. In males (n = 198), there is a significant negative correlation between L/S ratio and waist circumference (*upper left*) and between L/S ratio and visceral fat area determined by abdominal plain CT (*lower left*) (L/S ratio and waist circumference: r = –0.306, p < 0.01; L/S ratio and visceral fat area: r = –0.349, p < 0.01). In females (n = 130), there is no correlation between L/S ratio and waist circumference (*upper right*), but there is a significant negative correlation between L/S ratio and visceral fat area (r = –0.474, p < 0.01) (*lower right*)

weaker correlation between waist circumference and hepatic fat accumulation in females than in males (Fig, 136.3, upper panel). By contrast, the significant correlations between visceral fat area and hepatic fat accumulation were comparable in both sexes (Fig. 136.3, lower panel).

136.5 Age and Sex Differences in the Relationship Between Waist Circumference and Hepatic Fat Accumulation

Analyses of the JSG-NAFLD database revealed that there is an age difference in the relationship between waist circumference and the degree of hepatic fat accumulation in NAFLD patients. In particular, the relationship between waist circumference/visceral fat accumulation and hepatic fat accumulation has been assessed for males and females aged <60 or ≥60 years. In individuals aged <60 years, the relationship between waist circumference and hepatic fat accumulation showed a significant negative correlation in males, but not in females aged <60 years (Fig. 136.4). Meanwhile, there was a significant positive correlation between visceral fat accumulation and hepatic fat

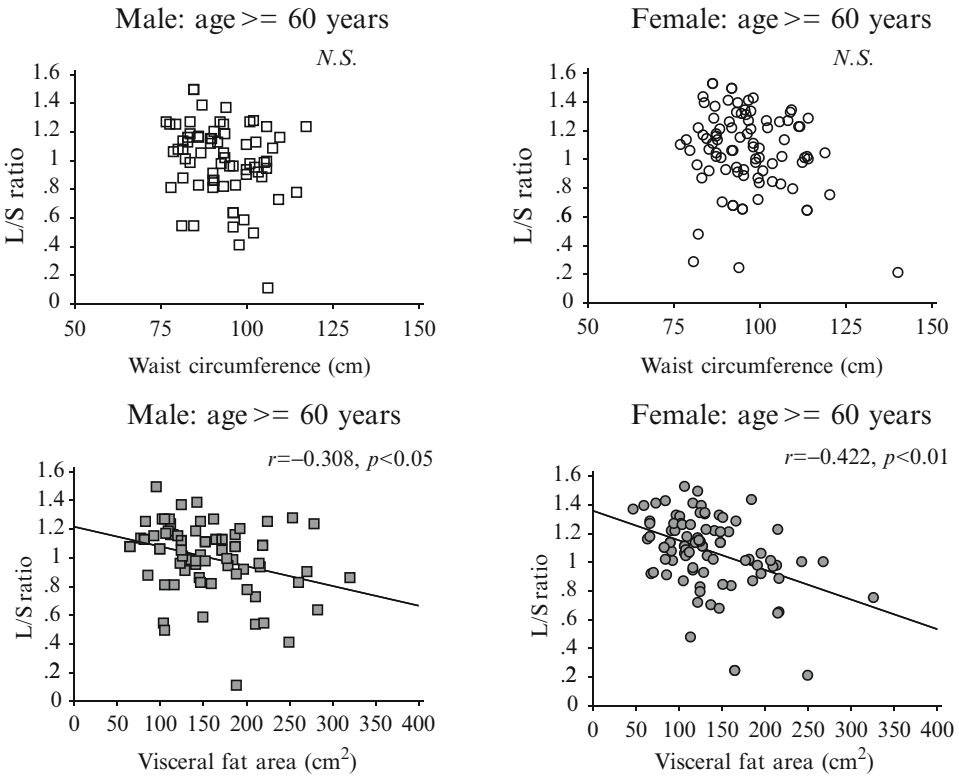

Fig. 136.5 Relationship between liver/spleen ratio (L/S ratio) and waist circumference/visceral fat area in males and females aged ≥60 years. In both groups (males, $n = 78$; females, $n = 93$), there is no correlation between L/S ratio and waist circumference (*upper left and right*, respectively). On the other hand, there is a significant correlation between L/S ratio and visceral fat area determined by abdominal plain CT (*lower left and right*, respectively) (L/S ratio and visceral fat area: males, $r = –0.308$, $p < 0.01$; females, $r = –0.422$, $p < 0.01$)

accumulation in males and females aged <60 years with NAFLD. On the other hand, the relationship between waist circumference and hepatic fat accumulation showed no significant correlation in males or females aged ≥60 years (Fig. 136.5, upper panel), but there was a significant correlation between visceral fat accumulation and hepatic fat accumulation in this age group (Fig. 136.5, lower panel).

Waist circumference is an excellent and easy method to evaluate visceral obesity in NAFLD patients, as for patients with metabolic syndrome. At the same time, it is important to be aware that waist circumference reflects not only visceral fat accumulation but also subcutaneous fat accumulation at the umbilical level. Waist circumference dose not allow us to discriminate between visceral organs (e.g., gastrointestinal tract), subcutaneous abdominal fat, and intra-abdominal fat. In males, the correlation between waist circumference and hepatic fat accumulation indicates that waist circumference reflects visceral fat accumulation, which agrees with the results of previous studies conducted in patients with a variety of metabolic abnormalities, including NAFLD (Targher et al. 2005; Church et al. 2006; Park et al. 2007). A recent study using abdominal ultrasonography showed results similar to those of the present study: waist circumference was correlated with hepatic fat accumulation in males, but not in females (Park et al. 2007). One reason for this may be that, in females, not only visceral adipose accumulation, but also subcutaneous adipose accumulation

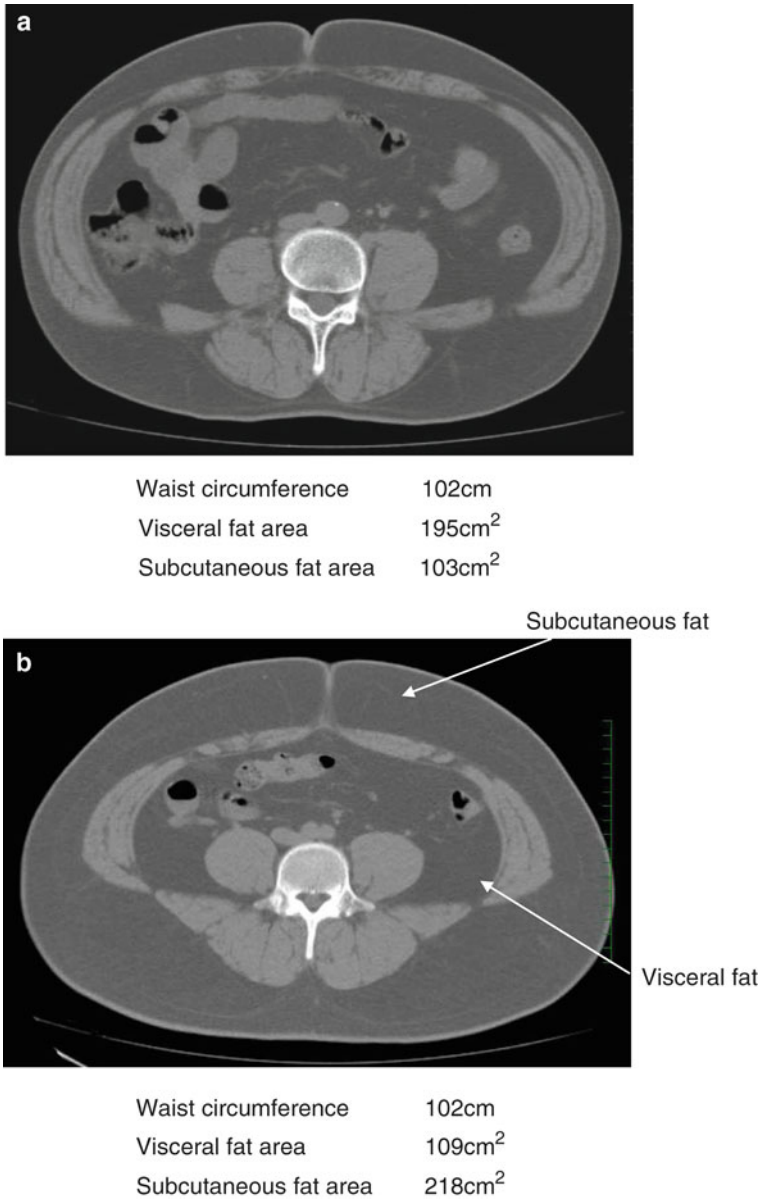

Fig. 136.6 Typical distributions of visceral and subcutaneous fat. Abdominal CT at the level of the umbilicus showing abdominal obesity. Each subject with abdominal obesity shows different distributions of visceral and subcutaneous fat, despite similar waist circumference (**a**), visceral fat-dominant abdominal obesity; (**b**), subcutaneous fat-dominant abdominal obesity)

contributes to waist circumference at the umbilical level. As shown in Fig. 136.6, abdominal CT at the level of the umbilicus shows abdominal obesity. Each subject with abdominal obesity shows different distributions of visceral/subcutaneous fat volume despite similar waist circumference (Fig. 136.6a, visceral fat-dominant abdominal obesity; Fig. 136.6b, subcutaneous fat-dominant abdominal obesity). Ishibashi et al. reported that the ratio between visceral fat area and subcutaneous fat area, and between visceral fat area and total fat area (visceral fat area plus subcutaneous fat area), as measured at the umbilicus, were markedly higher in males than in females ($p < 0.01$) (Ishibashi et al. 2008). Overall, the reasons for the differing results in each sex and age group remain to be elucidated.

136.6 Current Knowledge and Need for Further Studies of Waist Circumference and Hepatic Fat Accumulation

A recent study proposed a novel formula to predict liver fibrosis in patients with non-alcoholic steatohepatitis using the waist/hip ratio (Savvidou et al. 2009). A prospective study reported that 1 year of intense nutritional counseling led to histological improvements in non-alcoholic steatohepatitis in addition to a decrease in waist circumference (Huang et al. 2005). Further studies are needed to clarify the roles of sex, age, and ethnicity on waist circumference as a marker for visceral fat and subcutaneous fat accumulation at an umbilical level. In clinical practice, the investigators should remember that the relationship between waist circumference and hepatic fat accumulation is weaker in females than in males, although recent studies results indicate that waist circumference may be used as a very sensitive marker for hepatic fat accumulation in the general population.

136.7 Conclusions

Waist circumference is a convenient anthropometric measurement for the evaluation for hepatic fat accumulation. This measure might also predict liver enzyme levels, which are affected by the development of fatty liver disease. Investigators should take into account the sex- and age-group differences when evaluating the relationship between waist circumference and hepatic fat accumulation.

136.8 Application to Other Areas of Health and Disease

Since waist circumference is a marker for visceral fat accumulation, many studies suggest that metabolic disorders associated with lifestyle-related diseases and the metabolic syndrome might be evaluated by measuring waist circumference.

Summary Points of Waist Circumference and Hepatic Fat Accumulation

- Waist circumference is a convenient and essential anthropometric measurement that can be used to evaluate fatty liver disease associated with obesity, diabetes mellitus, or the metabolic syndrome.
- A significant association has been found between waist circumference, which is correlated with visceral fat accumulation and hepatic fat accumulation, and liver function.
- The relationship between waist circumference and hepatic fat accumulation is more prominent in males than in females.
- The correlation between waist circumference and hepatic fat accumulation is comparable to that between visceral fat accumulation and hepatic fat accumulation.
- Investigators should be aware of sex- and age-group differences in the relationship between waist circumference and hepatic fat accumulation.

Chapter 137
Ultrasonographic Anthropometry: An Application to the Measurement of Liver and Abdominal Fat

Marisa Chiloiro and Giovanni Misciagna

Abstract Non-alcoholic fatty liver disease is a spectrum of disorders characterized by an abnormal accumulation of triglycerides in the liver, and is recognized as the most common hepatic lesion, with an estimated prevalence of 15–39% in more industrialized countries. Many potential risk factors for non-alcoholic fatty liver disease have been identified, such as obesity, insulin resistance, hyperlipidemia and diabetes. Visceral adiposity seems to be the major contributor to a fatty liver in the insulin-resistant state. In fact, epidemiological evidence suggests that visceral adiposity is more associated with a fatty liver than the body mass. Direct assessment of hepatic fat obtained by biopsy is considered the gold standard, but it is a very invasive method. Fatty infiltration of the liver and abdominal fat can also be measured by Computerized Tomography, Magnetic Resonance Imaging, and ^{1}H Magnetic Resonance Spectroscopy. Unfortunately, these accurate methods for measuring fat mass are very sophisticated and expensive and have limited applicability in routine clinical settings. Ultrasound has been proposed as an alternative non-invasive technique for measuring fatty liver and subcutaneous and visceral fat thickness, because it may overcome some limitations of skinfold thickness and more sophisticated anthropometric methods.

Abbreviations

BMI	Body mass index
bc	Biceps skinfold
CRP	C-reactive protein
TC	Computerized Tomography
^{1}H MRS	^{1}H magnetic resonance spectroscopy
FM	Fat mass
FFAs	Free fatty acids
IAF	Intra-abdominal fat
ICC	Intra-class Correlation Coefficient
WC	Waist circumference
WHR	Waist-to-hip circumference ratio
MRI	Magnetic Resonance Imaging
NAFLD	Non-alcoholic fatty liver disease
NASH	Non-alcoholic steatohepatitis

137.1 Introduction

Non-alcoholic fatty liver disease (NAFLD) is recognized as the most common hepatic lesion worldwide, with an estimated prevalence of 15–39% in Western countries and 9–13% in the East (Park et al. 2006). It is associated with overweight and obesity, and its distinctive trait is an intrahepatic accumulation of lipids. (Nakao et al. 2002) Many potential risk factors for NAFLD have been identified besides overweight and obesity, with insulin resistance, hyperlipidemia, and diabetes being among the most common. It has been hypothesized that visceral adiposity is a more important predictive factor for a fatty liver than body mass index (BMI) (Fishbein et al. 2006). The diagnosis of NAFLD can be made using different methods: liver biopsy, the gold standard, as well as noninvasive radiological methods, such as computed tomography (CT), magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), and ultrasonography (US). Many studies have reported that US, the most simple and cost-effective method among the radiological options, is useful for making a qualitative and quantitative evaluation of fatty liver and visceral and subcutaneous adiposity (Hirooka et al. 2005). The body fat distribution has been assessed using anthropometric measurements, such as skinfolds and waist-to-hip circumference ratios (WHR). Although the WHR is simple to measure and provides a valid estimation of the proportion of abdominal or upper-body fat, it does not distinguish between the deep abdominal (visceral) fat and subcutaneous abdominal fat depots.

The prevalence of obesity and associated metabolic morbidities is dramatically increasing also in childhood (Toriano et al. 1995). The BMI is considered to offer the best combination of weight and height to assess adiposity, and is widely accepted as a measure of overweight and obesity, and of adiposity in adults. However, the BMI has limitations when applied to pediatric populations. The rapid changes in weight and height that occur during growth complicate its interpretation in children. Waist circumference in childhood is a better predictor of the amount of intra-abdominal fat than BMI. The growing incidence of fatty liver in children may be occurring in parallel with visceral obesity. In fact, abdominal obesity contributes to the reduction of hepatic and systemic insulin sensitivity, and likely plays a role also in the pathogenesis of fatty liver disease.

137.2 Non-alcoholic Fatty Liver Disease and Its Measurement By Ultrasound

137.2.1 Definition

The term non-alcoholic fatty liver disease covers a spectrum of liver diseases, ranging from benign, non-progressive, simple hepatic steatosis (non-alcoholic fatty liver, NAFL) to non-alcoholic steatohepatitis (NASH), in which fat in the liver is associated with inflammation and a variable degree of

fibrosis, and that can progress to liver cirrhosis (Angulo 2002). The histological changes in NAFLD are identical to those in alcoholic liver disease, and the former diagnosis can be made in a subject only after excluding the consumption of more than 20 g of alcohol per day. NAFLD includes simple forms of steatosis, either alone (type 1 NAFLD) or with inflammation, but no hepatocyte ballooning or fibrosis (type 2 NAFLD). The term NAFLD is used either when the pathology of the metabolic liver disease is not known or to refer to the full spectrum of fatty liver disease that can also include cases of cryptogenic cirrhosis, where steatohepatitis and steatosis are still present. Furthermore, NAFLD is considered to be one of the phenotypes of the metabolic syndrome, which is characterized by obesity with visceral fat accumulation, diabetes mellitus, hyperlipidemia, and hypertension (Carr et al. 2004).

137.2.2 Prevalence

NAFLD may affect any age and race. The true prevalence of NAFLD is unknown, but it is estimated to affect 15–39% of the general population in different countries. In Italy, the reported prevalence of NAFLD is 20–30% and that of NASH is 2–3% (Clark et al. 2003). The prevalence of NAFLD is higher in patients with obesity, ranging from 57.5% to 74% (Angulo 2002), and with type 2 diabetes mellitus (28–55%) and hyperlipidemia (20–92%). NAFLD affects 2.6% of children, and this figure increases from 22.5% to 52.8% in obese children (Carr et al. 2004). In most case series, the characteristic patient with NAFLD is a middle-aged woman, but in other series there is a higher prevalence of NAFLD in males than in females. Furthermore, many patients with NAFLD are non-obese and non-diabetic, with normal liver tests and lipid profile. Regardless of the body mass index, the presence of type 2 diabetes mellitus significantly increases the risk and severity of non-alcoholic fatty liver disease.

137.2.3 Histological Findings

Liver biopsy features of NAFLD include steatosis, mixed inflammatory cell infiltration, hepatocyte ballooning and necrosis, glycogen, hyaline Mallory bodies, and fibrosis. The presence of these features, alone or in combination, accounts for the wide spectrum of non-alcoholic fatty liver diseases. Hyaline Mallory bodies are notably sparse or absent in children with NAFLD. The distribution of lipids may be macrovesicular, with hepatocytes distended by a single vacuole displacing the nucleus, or microvesicular, with numerous droplets surrounding a central nucleus. Widespread microvesicular steatosis is characteristically an acute condition, in which the impairment of fatty acid β-oxidation reflects a more general perturbation of mitochondrial and ribosomal functions, both within and outside the liver. Regardless of the etiology, microvesicular steatosis is widely acknowledged to have a poor prognosis, death being caused by liver failure and extrahepatic causes. Macrovesicular steatosis, by contrast, is typically associated with a longer duration disturbance of the hepatic lipid metabolism, and has up to now been considered a benign condition. Further evidence supporting a role for steatosis in liver progression to cirrhosis comes from the observation that the steatosis of non-alcoholic etiologies is frequently associated with the development of necroinflammation (so-called non-alcoholic steatohepatitis or NASH). The causes of NASH are the same as those of simple steatosis, and include obesity, non-insulin-dependent diabetes mellitus, jejuno-ileal bypass/gastroplasty surgery, parenteral nutrition, bacterial contamination of the small bowel, and drugs. The severity of the steatosis, as in alcoholic steatohepatitis, is one of the main factors associated with steatohepatitis and fibrosis in non-alcoholics.

137.2.4 Pathogenesis

The correlation between the steatosis severity and the necroinflammation/fibrosis in alcoholics and non-alcoholics does not prove that fat is per se causal in the development of more advanced disease. An alternative explanation is that a common mechanism may be responsible for both steatosis and necroinflammation in all forms of fatty liver, with steatosis acting as a surrogate marker of the intensity of the stimulus. A wide variety of mechanisms has been implicated in the necroinflammation that develops after excessive alcohol intake. Recently, evidence has emerged that at least two of these mechanisms play a role in the pathogenesis of NASH: (1) oxidative stress/lipid peroxidation and (2) endotoxin-mediated cytokine release, which explains the striking histological similarity between NASH and alcoholic steatohepatitis, and implicates steatosis as a direct contributor to inflammation and/or fibrosis.

The pathogenesis of NAFLD is still unclear. Hepatic steatosis is due to lipid accumulation, mainly triglycerides, within hepatocytes. The mechanisms leading to lipid accumulation are not completely understood, but they could potentially be either the result of insulin resistance (Bruun et al. 2005) and a decreased disposal of fatty acids due to impaired mitochondrial β-oxidation or a deficient production of very low density lipoproteins. Albeit still inconclusive, some lines of evidence, mainly derived from studies in animal models of fatty liver, suggest that oxidative stress/lipid peroxidation, bacterial toxins, overproduction of tumor necrosis factor-α, alterations of hepatocyte adenosine triphosphate stores and cytochrome P450 Cyp2E1/Cyp4A enzyme activity may play a role in the genesis and progression of NAFLD. Lipid peroxidation seems to increase with the severity of the steatosis. Malondialdehyde, an end product of lipid peroxidation, activates hepatic stellate cells, stimulating collagen production and fibrogenesis. It may also contribute to the inflammation by activating nuclear factor-kB (NF-kB), which regulates the expression of pro-inflammatory cytokines, such as tumor necrosis factor-α and interleukin-8. Another end product of lipid peroxidation, 4-hydroxynonenal, is a strong chemo-attractant for neutrophils.

137.2.5 Ultrasonographic Diagnosis

Fatty infiltration of the liver can be determined by US, CT, MRI, H magnetic resonance spectroscopy (HMRS), and by liver biopsy, the gold standard. However, the sensitivity and specificity of these radiological methods for the detection of fatty infiltration of the liver is generally unsatisfactory.

There are four sonographic signs of diffuse fatty changes in the liver (Gore 1994):

1. A diffuse hyperechoic echotexture (bright liver),
2. An increased liver echotexture as compared with the kidneys,
3. Vascular blurring,
4. Deep attenuation.

In a small retrospective study, a combination of these parameters allowed the diagnosis of fatty liver (defined histologically as fat present in >30% of each lobule) to be made with a sensitivity of 83% and a specificity of 100%. Recently, using both 10- and 3.5-MHz transducers, the frequency-dependent attenuation of an ultrasound beam passing through the liver was well correlated with its fat content (Fusamoto et al. 1991).

To obtain a semiquantitative evaluation of fat in the liver, we adopted a scoring system (Semiz et al. 2007; Toriano et al. 1995). The degree of fatty infiltration of the liver was graded according to the ultrasonographic appearance of the liver echotexture, the hepatic echo penetration, and the clarity

Table 137.1 Cohen's K as a measure of intra- and inter-observer variability of the ultrasonographic partial scores for liver steatosis

Item	Time	Radiologist A	Radiologist B
Contrast between liver and kidney tissue	T_1	0.73	
	T_2	0.43	
		0.43	0.50
Deep penetration of ultrasound	T_1	0.15	
	T_2	0.35	
		0.43	0.47
Clear visibility of blood vessels, specifically veins	T_1	0.07	
	T_2	0.50	
		0.78	0.68

Table 137.2 Pearson's Correlation Coefficient and the intraclass correlation coefficient of the total liver steatosis score between two radiologists

	Pearson *r*		Intraclass *r*	
Time	Radiologist A	Radiologist B	Radiologist A	Radiologist B
T_1	0.87		0.84	
T_2	0.77		0.77	
	0.81	0.77	0.78	0.85

of the hepatic blood vessels, as well as the liver-diaphragm differentiation in echo amplitude. Each criterion was assigned a score indicating the level of fatty liver infiltration. A score of 2 indicated a definite positive (++) fatty liver infiltration for that criterion. A score of 1 was assigned for a probably positive (+) finding based on the criterion. When a negative (-) evaluation for fatty liver was obtained, a score of 0 was assigned to the criterion. The sum of the scores for the three criteria was considered to be an indicator of the severity of fatty infiltration. Thus, the fatty liver score ranged from 0 to 6, whereby a total score of 1–2 indicated mild fat infiltration, a score of 2–4 moderate, and a total score ≥5 severe fat infiltration (absence of steatosis = score 0).

The intra- and inter-observer variations (measured by Cohen's K, Pearson's and the intraclass correlation coefficient) of the partial and total scores that we obtained for the assessment of liver steatosis by ultrasonography are shown in Tables 137.1 and 137.2. The inter-observer variability between two radiologists was evaluated at both times T_1 and T_2, and the intra-observer variability for each radiologist was evaluated between times T_1 and T_2.

137.2.6 Other Imaging Techniques Utilized for the Diagnosis of NAFLD

The most accurate measurement techniques are magnetic resonance imaging and computed tomography, but they are expensive and not available for routine use.

The liver fat content can also be semiquantitatively estimated by MRI as well as CT scans. Normally, the CT attenuation values for the liver range from 50 to 75 Hounsfield units when a non-contrast-enhanced scan is obtained. With increasing hepatic steatosis, liver attenuation values decrease by 1.6 Hounsfield units for every milligram of triglycerides per gram of liver tissue. Thus, in subjects with a fatty liver, the hepatic attenuation is less than that of blood vessels, giving the appearance of a contrast-enhanced scan, when no contrast has been used. When intravenous contrast

is used, both liver and splenic attenuation values increase, but the hepatic values increase to a lesser degree than the splenic values. When a diagnosis of fatty liver is based simply on a qualitative assessment of the differential attenuation during a contrast-enhanced CT scan, the sensitivity and specificity are 54% and 95%, respectively (Jacobs et al. 1998).

Using a cutoff of 20.5 Hounsfield units at 80–100 s after intravenous contrast injection, a fatty liver can be diagnosed with 86% sensitivity and 87% specificity. At 100–120 s, a difference of hepatic and splenic attenuation of 18 Hounsfield units determines a 93% sensitivity and specificity. Thus, the diagnostic accuracy of differential changes in hepatic–splenic attenuation is time dependent and protocol specific. These data were supported by another study in which the sensitivity was even lower (54–71%) (Johnston et al. 1998).

137.3 Abdominal Fat and Its Measurement By Ultrasound

137.3.1 Abdominal Fat

Truncal obesity seems to be a significant risk factor for NAFLD, even in subjects with a normal body mass index (Omagari et al. 2002).

In the last few years, many epidemiological studies have indicated that a regional body fat distribution with abdominal accumulation, regardless of the total body fat as assessed by the BMI, may represent a major independent risk factor for several pathological conditions, specifically, diabetes and cardiovascular disease (Bouchard et al. 1990).

Furthermore, recent findings have shown that central adiposity can be an independent predictor of hepatic steatosis. The body fat distribution was assessed using anthropometric measurements, such as skinfolds and the waist-to-hip circumference ratio. Although the WHR is simple and convenient for epidemiological studies and provides a useful estimation of the proportion of abdominal or upper-body fat, it does not distinguish between the accumulation of deep abdominal (visceral) fat and subcutaneous abdominal fat. Several studies have shown that the detrimental influence of abdominal obesity on metabolic processes is mediated only by the intra-abdominal fat depot (Wajchenberg 2000), in particular, the visceral adipose tissue (VAT).

Abdominal adipose tissue includes distinct anatomical depots: a subcutaneous fat depot and an intra-abdominal fat depot, that can be further subdivided into intraperitoneal and retroperitoneal depots (Wajchenberg 2000). Visceral fat accounts for up to 10–20% of total fat in men and 5–8% in women, and increases with age in both genders.

Fat around abdominal organs in the mesentery and omentum, known as visceral fat, is different from the fat present in subcutaneous areas (subcutaneous fat). The type of fat cells (adipocytes), their endocrine function, lipolytic activity, and response to insulin and other hormones differ between subcutaneous adipose tissue and visceral adipose tissue. Inflammatory cells (macrophages) are more prevalent in visceral than subcutaneous fat (Bruun et al. 2005).

Because of its anatomical position, visceral fat venous blood is drained directly into the liver through the portal vein. This contrasts with subcutaneous fat where venous drainage is through systemic veins. The portal drainage of visceral fat provides direct access of free fatty acids (FFAs) and adipokines secreted by visceral adipocytes to the liver (Fusamoto et al. 1991). Adipokines activate a hepatic immune mechanism with the production of inflammatory mediators, such as C-reactive protein (CRP).

137.3.2 Anthropometric and Ultrasonographic Assessment of Abdominal Fat

The body mass index is a useful indicator of overall adiposity. However, different fat compartments may have a specific metabolic risk Waist circumference (WC) is an easily obtainable but imprecise measure of abdominal adiposity (Poirier and Despres 2003) because it is a function of both the subcutaneous adipose tissue (SAT) and the VAT compartments. Intra-abdominal fat (IAF) can be estimated using anthropometric data. The indices most frequently used are waist circumference, waist-to-hip or waist-to-thigh ratio, truncal skinfold, and predictive equations of IAF derived from anthropometric data. The waist-to-hip ratio is certainly the most popular index in clinical use. For research purposes, however, the accuracy of these indirect methods is inadequate. For example, the waist-to-hip or waist-to-thighs ratios are poor measurements of IAF per se. In addition to IAF, they include subcutaneous fat and gluteal or leg muscle mass, the latter playing a potential role in peripheral insulin sensitivity. Therefore, a precise assessment of VAT requires imaging with radiographic techniques, such as computed tomography or magnetic resonance imaging. Fat accumulated in the lower body (the pear shape) is subcutaneous, whereas fat in the abdominal area (the apple shape) is largely visceral. The localization of fat in women is influenced by several factors, such as heredity and steroid sex hormones. Some researchers suggest that the drop in the estrogen level at menopause is also associated with an increased level of corticoid stress hormones that promotes the accumulation of abdominal fat.

Anthropometry is a dimensional approach that describes the adipose tissue mass. However, adipose tissue mass is not synonymous with fat mass because fat is a chemical not an anatomical entity. It is important to distinguish between *body fat*, an amount of fat, and *body fatness*, a compositional description. The numerical and statistical properties of the amount of fat (kg) differ from those of the composition (proportion or percentage). Although the two are correlated (r = 0.7–0.8), each has a unique specificity. Here, body fat refers to the fat mass (FM) and body fatness to the percentage of fat in the body weight (%Fat).

The anthropometric assessment of body fat and fatness is based on the measurement of skinfold thickness, weight, stature, circumferences, and diameters.

A skinfold is a direct measure of subcutaneous adipose tissue (SCAT) and dermis thickness, and a series of representative skinfold measurements will characterize the average SCAT thickness and provide an estimate of the SCAT mass. Skinfold thicknesses are usually measured as a compressed double fold. Compression varies according to the site, sex, age, nutritional status, and even within groups that are homogeneous for these variables. Ultrasound has been proposed as an alternative to other noninvasive techniques to measure subcutaneous and visceral fat thickness because it may overcome some limitations (see below) of the caliper-based anthropometric measurements (Armellini et al. 1993).

137.3.3 Correlation Between Anthropometric and Ultrasonographic Evaluation of Subcutaneous Fat

Using ultrasound to measure uncompressed SCAT, Kuczmarski did not find this method better than calipers (Fanelli and Koch 1987). To study the correlation between subcutaneous adipose tissue thickness measured by ultrasound, and skinfold thickness measured by calipers, as well as its variation by gender, we studied 260 children between 3 and 6 years of age (Chiloiro et al. 2003). All children were normal weight. Measurements of the triceps (tc), biceps (bc), suprailiac (si), and subscapular (ss) skinfold thicknesses were obtained using Holtain Skinfold Calipers (Holtain Ltd, Crymych, UK). All

Table 137.3 Correlation between calipers and ultrasonographic skinfold thickness measurements

Caliper skinfold	Thickness (cm)	Pearson correlation coefficient
tc	23,313 ± 4,073	$r = 0.33$; $p = 0.003$
bc	14,311 ± 3,216	
ss	20,903 ± 6,420	
si	20,440 ± 5,878	$r = 0.34$; $p = 0.003$
Ultrasonographic skinfold		
tc	16,229 ± 4,782	
bc	13,153 ± 5,083	
ss	16,235 ± 6,408	
si	16,617 ± 4,748	

Table 137.4 Anthropometric data in children (Mean ± SD)

Variables	Values (M ± SD)
Height (m)	1.45 ± 0.12
Weight (kg)	56.04 ± 14.96
BMI (kg/m²)	26.07 ± 3.73
BMI *z*-score	2.01 ± 0.39
Waist circumference (cm)	81.10 ± 10.70
Hip circumference (cm)	93.31 ± 10.65
Waist-to-hip circumference	0.869 ± 0.061

measurements were taken three times at each site, and the mean values were used. Measurements of subcutaneous fat layer were performed using a 7.5-MHz linear-array probe. The skinfold measurements were performed at the same marked sites where the anthropometric measurements were carried out. Our results showed a high correlation between ultrasound and caliper measurements at all sites studied, the highest correlation being found at the triceps site ($R = 0.64$, $p < 0.0001$).

A recent study shows that, in obese children, the correlation between anthropometric and US measurements of skinfold thickness is present for the triceps and suprailiac sites (Semiz et al. 2007). These sites are the ones where adipose tissue accumulates in obese subjects. The lack of correlation in the other sites considered for skinfold thickness evaluations can be explained by the fact that the correlation between caliper and US skinfold thickness is more reliable in non-obese than in obese subjects (Cataldo et al. 1997). In fact, in another work on obese children, we showed a positive correlation between anthropometric and US measurements of skinfold thickness only for triceps and suprailiac skinfolds (Table 137.3). The most relevant anthropometric data on the children we studied are shown in Table 137.4.

137.4 Correlation Between Abdominal Fat and Non-alcoholic Fatty Liver Disease Measured By Ultrasound in Children and Adults

137.4.1 Abdominal Fat and Non-alcoholic Fatty Liver Disease in Children

The prevalence of fatty liver in obese children has been evaluated by ultrasonography. Tominaga et al. (1995) found a 22% overall prevalence of fatty liver in children with a BMI ≥20, and Franzese et al. (1997) also used ultrasound to identify a fatty liver in 38 out of 75 obese children (52.8%).

The high prevalence of a fatty liver in our study (64%) was similar to the figure reported by Sagi et al. (2007) (about 60%) and the prevalence of children with steatosis and altered liver function is similar to that reported by those authors (17% vs. 15.5%). A fatty liver was positively correlated with anthropometric measurements including the BMI, waist and hip circumference, subscapular and suprailiac skinfold thickness, and the duration of obesity, but not with the liver enzymes. It has been shown that the liver enzymes concentration is not able to identify patients with a fatty liver. In fact, altered liver enzymes are present in only 10% of obese children with steatosis (Franzese et al. 1997) and a high percentage of patients with a fatty liver show liver enzymes in the normal range (Fishbein et al. 2003). In another work, (Chiloiro et al. 2008) we examined the relationship between anthropometric and biochemical parameters and a fatty liver at ultrasound in obese children. A total of 94 subjects (59 boys, 35 girls; mean age ± standard deviation = 9.7 ± 2.2 years) were studied. An ultrasonic appearance of hepatic steatosis was diagnosed in 60 out of 94 children (64%); the scoring system assigned 48 out of the 60 children (80%) to the weak steatosis group, nine out of 60 (15%) to the moderate steatosis group, and three out of 60 (5%) to the severe steatosis group.

In the whole sample, a fatty liver (yes/no) was positively associated with anthropometric measurements using logistic regression. These were: duration of obesity (OR = 1.19; CI 95% 1.01–1.42; p = 0.04); z-score BMI (OR = 3.3; CI 95% 1.08–10.2; p = 0.036); subscapular skinfold thickness (OR = 1.11; CI 95% 1.02–1.20; $p = 0.01$); suprailiac skinfold thickness (OR = 1.16; CI 95% 1.05–1.27; $p = 0.002$); waist circumference (OR = 1.11; CI 95% 1.05–1.18; $p < 0.001$); and hip circumference (OR = 1.06; CI 95% 1.01–1.12; $p = 0.012$).

137.4.2 Abdominal Fat and Non-alcoholic Fatty Liver Disease in Adults

In a population survey of subjects 30–89 years of age (Dr Marisa Chiloiro's Thesis for the Board Certification in Radiology, University of Palermo, 2009), the correlation between the fatty liver score and anthropometric parameters (BMI, waist circumference, and visceral and subcutaneous adipose tissue), as well as metabolic alterations that characterize the metabolic syndrome, was evaluated. In addition, the thickness of the subcutaneous and visceral adipose tissue was measured in all the subjects by ultrasound using standard scanning. To measure the subcutaneous fat, epigastric transverse scanning was done down the center of the xypho–umbilical line (Fig. 137.1). The same point was used to measure the visceral fat (Fig. 137.2), between the posterior surface of the abdominal wall and the anterior wall of the abdominal aorta. The thickness was measured in millimeters. In total, 2,966 subjects were examined, to study myocardial infarction and diabetes type 2 and their association with many potential metabolic (arterial pressure, BMI, fasting blood cholesterol, triglycerides, and glucose) and behavioral risk factors (diet, alcohol, and tobacco smoking). All the subjects underwent a standardized ultrasound examination of the liver for hepatic steatosis. The ultrasonographic findings were explored graphically and correlated with the metabolic syndrome variables using Pearson's r and contingency tables (with the aid of STATA 10 statistical software). The thickness of the subcutaneous and visceral adipose tissue, in millimeters, was correlated with the liver steatosis score, as shown in Table 137.5 and in Figs. 137.3 and 137.4. In Table 137.6, it can be seen that the liver steatosis score is directly associated with body weight and BMI, visceral adipose tissue measured by ultrasound, blood triglycerides, glucose, and GPT, and inversely associated with cholesterol HDL. It is not associated with height, total blood cholesterol, alkaline phosphatase, total bilirubin, cholesterol LDL, GOT, and GGT. Finally, the relationship of liver steatosis with systolic and diastolic blood pressure and with subcutaneous adipose tissue is uncertain. The prevalence of fatty

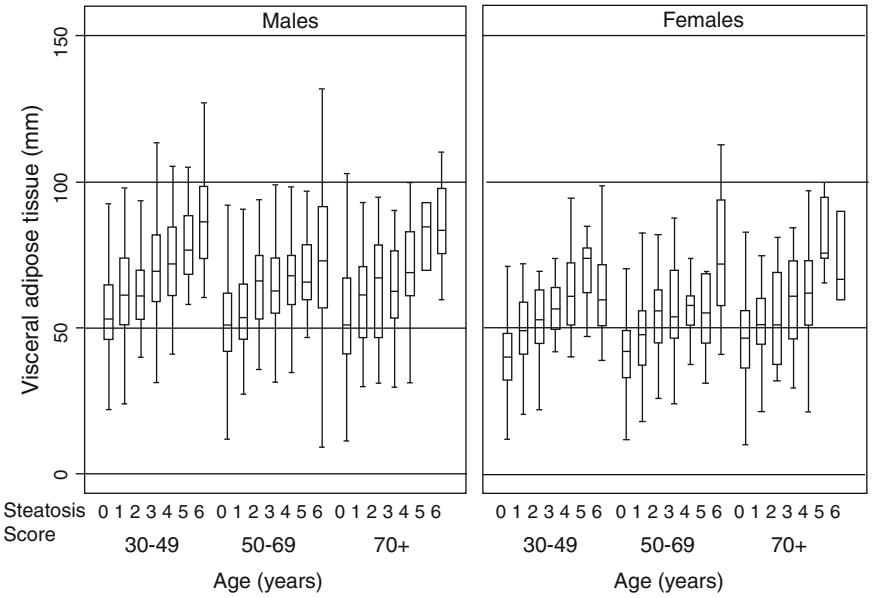

Fig. 137.4 Correlation between the liver steatosis score and visceral adipose tissue, stratified by age and gender

liver in the general population studied is 42.3%, of which 35% is accounted for by non-alcoholic and 7.3% by alcoholic fatty liver disease (anamnestic data). Furthermore, the percentage of subjects with scores ranging from 1 to 6 is similar in non-alcoholic and alcoholic steatosis.

As shown in these tables and in Figs. 137.3–137.5, there is a linear correlation between the fatty liver score, the BMI, and the thickness of the subcutaneous and visceral abdominal fat.

137.5 Conclusions

The findings presented in this paper show that ultrasonography can be useful to detect fatty liver and abdominal (subcutaneous and visceral) fat accumulation, and that fatty liver and visceral fat, evaluated by ultrasonography, are correlated. Fatty liver and visceral fat accumulation are associated with the metabolic syndrome. Therefore, fatty liver and visceral fat measured by ultrasonography can be useful parameters helping to better characterize the metabolic syndrome, and to evaluate the effects of behavioral and/or clinical interventions. The good agreement between two radiologists in the ultrasound evaluation of fatty liver suggests that sonography can be used for epidemiological studies and clinical research. In the hands of a skilled gastroenterologist or radiologist, ultrasonography could complement the evaluation of liver diseases, including fatty liver. Since ultrasonography cannot distinguish a simple fatty liver from steatohepatitis, that is detected only by liver biopsy, further studies are required to assess the relationship between fatty liver and steatohepatitis graded by histopathology and visceral fat accumulation. Ultrasonographic evaluation of fatty liver and of visceral and subcutaneous abdominal fat can also be used by nutritionists to evaluate body composition, as a noninvasive integration of bioimpedentiometry and DEXA.

Summary Points

- Obesity is highly prevalent in Western industrialized countries and is associated with increased visceral fat and with liver steatosis.
- Standardized measurements of liver steatosis and visceral fat can be made by ultrasonography, and these measurements can be used to monitor the effect of behavioral and drug interventions.
- The relationship between anthropometric parameters and fatty liver measured by ultrasound was evaluated in 94 obese children. A fatty liver was positively associated with the BMI, subscapular and suprailiac skinfold thickness, and waist and hip circumference.
- Liver steatosis and visceral and subcutaneous fat were measured by ultrasonography in a population sample of 2,966 subjects resident in an area of Southern Italy. The grading of liver steatosis is directly associated with the BMI and visceral fat in males and females in all age ranges.

Acknowledgments The authors wish to thank Vito Guerra for the statistical analysis and his assistance in the preparation of the manuscript.

Chapter 138
Dissecting the Architecture of Bone Strength-Related Phenotypes for Studying Osteoporosis

Xiaojing Wang and Candace M. Kammerer

Abstract This chapter provides a brief overview of methods being used to dissect the underlying architecture of bone strength-related phenotypes, especially with regard to identifying risk factors for osteoporosis, a complex, common disease. The first section comprises a brief background on the known genetic and environmental factors that influence development of osteoporosis. In the next section, we describe the concept of bone strength and how studies of its components may facilitate our understanding of the etiology of osteoporosis. The advantages and disadvantages of several state-of-art two and three dimensional imaging technologies used for assessment of components of bone strength in human populations are described in the third section. These methods include: dual x-ray absorptiometry (DXA), quantitative computed tomography (QCT), quantitative ultrasound (QUS), and magnetic resonance imagining (MRI). In the fourth section, results from the use of different methods of bone assessment on an Afro-Caribbean population are compared. Finally, we describe how these methods could potentially be extended to study other complex diseases.

Abbreviations

aBMD	Areal bone mineral density
BMI	Body mass index
CSA	Cross-sectional area
DXA	Dual x-ray absorptiometry
ENPP1	Ectonucleotide pyrophosphatase/phosphodiesterase 1
ESR1	Estrogen receptor-α
LRP5	Low density lipoprotein receptor-related protein 5
MRI	Magnetic resonance imagining
QCT	Quantitative computed tomography
QUS	Quantitative ultrasound
SSI	Strength strain index
SXA	Single X-ray absorptiometry

vBMD	Volumetric bone mineral density
WNT	Wingless-type

138.1 Introduction

138.1.1 Osteoporosis and Osteoporotic Fracture

Osteoporosis is a systemic skeletal disease characterized by low bone mass and the microarchitectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fractures.

Osteoporosis is prevalent among the elderly, both sexes, and all racial groups. Although most US women under the age of 50 years have normal bone mass (usually measured as bone mineral density, BMD), 27% have low bone density (osteopenia). The most clinically meaningful trait for the consequences of osteoporosis, and the one resulting in serious individual and societal concerns is fracture. In 2000, the estimated worldwide incidence of osteoporotic fractures was nine million, and 56.2 million persons had a fracture-related disability [Fast facts on Osteoporosis, National Osteoporosis Foundation]. Osteoporotic fractures are responsible for considerable pain, decreased quality of life, lost workdays, disability, and even death; greater than 25% of people with hip fractures die within 5 years of fracture. By the age of 80 years, 70% of women are osteoporotic at the hip, lumbar spine, or forearm. Epidemiologic studies from North America have estimated the lifetime risk of common fragility fractures among white women aged 50 years to be 17.5% for hip fracture, 15.6% for clinically diagnosed vertebral fracture, and 16% for distal forearm fracture. The corresponding risks among men are 6%, 5%, and 2.5%, respectively. A British study using the General Practice Research Database estimated the lifetime risk of any fracture to be 53.2% for 50-year-old women and 20.7% for 50-year-old men. Thus, a substantial number of older men and women are at increased risk for fractures.

The prevalence of hip fractures varies widely among and within countries. In general, people who live in latitudes farther from the equator seem to have a higher incidence of fracture. The highest rates of hip fracture are seen among individuals living in northern Europe, especially in Scandinavian countries, where the age-adjusted 1-year cumulative incidence was 903/100,000 for women and 384/100,000 for men in Norway in 1989. Fracture incidence rates are intermediate in the populations of Asia, China, and Kuwait and lowest in populations with African ancestry. Whereas studies in central Norway suggest stabilization in fracture rates in recent years, a study from California reported a doubling of hip-fracture rates among Hispanic patients, whereas no significant change occurred among men or women of African or Asian ancestry. An Australian study concluded that, although the increase in hip-fracture rates during most of the past century may have ended, the number of admissions for hip fracture is still rising because of an aging population. Although fracture incidence in developing countries is lower, this difference is partially explained by demographics; for example, in Latin America, only 5.7% of the population is over 65 years. As the population ages, the incidence of fractures is likely to increase in these countries. Further compounding this expected increase in fracture risk is the poor appreciation of the role of osteoporosis in fragility fracture in some countries. For example, in one Lebanese study, fewer than 10% of hip-fracture patients received any therapy for osteoporosis.

Although fractures are the most clinically meaningful consequence of osteoporosis, they are stochastic events resulting from both bone-related factors (mass, size, architecture, microarchitecture, and intrinsic properties of bone material) and bone-independent factors (falls, protective responses, soft-tissue padding, etc.). Because the pathogenesis of fragility fracture usually involves trauma, it is not necessarily associated with reduced bone strength, and should be used neither synonymously nor interchangeably as a phenotype for osteoporosis. The most commonly used surrogate for bone strength is BMD, especially areal BMD (aBMD) that is measured by dual X-ray absorptiometry (DXA, described in more detail later). In fact, the operational definition of osteoporosis is aBMD of the hip or lumbar spine that is ≤2.5 standard deviations below the mean aBMD of a reference population of adults.

138.1.2 Identifying Genetic and Environmental Factors That Influence Fractures or aBMD

The etiology of osteoporosis involves a complex interplay of environmental and genetic factors. Knowledge of the environmental and genetic risk factors for osteoporosis is important for several reasons: first, it will facilitate our understanding of the pathophysiology of the disorder, as well as identify individuals at increased risk. In addition, such knowledge will contribute to the clinical treatment of individual patients and may even help in the design of individual-specific preventative strategies – one of the goals of personalized medicine. In the short term, identification of specific environmental factors will benefit discovery of additional genes that influence susceptibility for developing osteoporosis; filtering out the effects of environmental 'noise' should increase detection of genetic 'signals'.

138.1.2.1 Environmental Risk Factors

Environmental risk factors of osteoporosis can be grouped into different categories: those that influence the risk of falling and responses to trauma; those that influence the accretion and loss of BMD throughout the life course; and those that influence the skeletal strength independent of BMD. The most important factor influencing BMD is age. Beginning in early adulthood, continuous irreversible bone loss happens throughout the aging process. In fact, bone mass decreases, whereas bone size and area may be enlarged, resulting in weaker bone. Another major risk factor is gender; in general, men have stronger bones than women and, hence, the prevalence of osteoporosis in men is less than in women. However, the relationship between gender and bone is not constant over time, partly due to hormonal changes. For example, in women, BMD decreases sharply after menopause, most likely due to estrogen depletion. By contrast, the strong correlation between higher BMD and elevated prostate cancer rate in older men appears to be related to endogenous levels of hormones, growth factors, and cytokines. Gender differences in bone loss may also be due to other factors, such as calcium scarcity, especially during breast-feeding. The third important risk factor of BMD is body weight (or related factors, such as BMI, body fat mass, and body lean mass). Considerable evidence supports its role as a strong positive determinant of bone strength by exerting continuous stress (loading force) to stimulate bone growth. Geographic ancestry also influences risk; individuals with European or Asian ancestry have lower BMD, whereas individuals of African descent have higher BMD and lower fracture incidences. Other environmental risk factors associated with fracture risk or low BMD include: smoking status, dietary intake, medical history, *etc*.

138.1.2.2 Genetic Risk Factors

Although environmental factors play an important role in osteoporosis, heredity is also important, as indicated in part by the relationship between geographic ancestry and fracture risk or BMD. A trait is heritable if relatives are more similar (e.g., they are more likely to have osteoporosis) than are non-relatives. One method by which to quantify the degree of similarity is to estimate the heritability. This is the proportion of the total phenotypic variation in a trait that is attributable to genes and is usually assessed using data on twins or families. There is substantial evidence that genes influence the risk of osteoporosis and BMD. For example, compared to individuals with no affected relatives, the risk of vertebral fracture among men with one affected first-degree relative is threefold greater (OR: 2.9; 95% CI: 1.4–6.0) and is fourfold greater (OR: 4.4; 95%CI: 1.4–14.4) among those with two or more affected first-degree relatives. Furthermore, as estimated from both twin and family studies, the heritability of bone mineral density (BMD) ranges from 0.5 to 0.8. BMD is heritable in both younger and older individuals (including individuals well into the eighth decade of life), as well as in men and women of different ethnicities.

After determining that fracture risk and BMD are heritable, numerous studies have been performed in attempts to identify specific loci that influence these traits. A variety of study designs and analytical methods have been used, such as linkage analysis of families with a history of osteoporosis, families or sibling pairs drawn from the normal population, and sib pairs who are discordant for BMD values. Linkage analyses methods test for the co-segregation of a specific phenotype with a set of polymorphic genetic markers, and thus enable localization of a putative gene that may influence the specific trait. These linkage studies have revealed numerous loci that may influence BMD, of which the most important to date was the identification of LRP5, a gene that is involved in the Wnt-signaling pathway that plays a central role in controlling embryonic bone development and bone mass. Although numerous loci have been identified, there has been little consistency among these reports.

In addition to linkage studies, many genetic association studies have been performed. These studies test whether alleles or genotype frequencies differ among individuals with or without osteoporosis or whether mean BMD differs among individuals with different genotypes. Association studies can be performed using genotypes on candidate genes, that is, genes in specific biological pathways known to influence BMD, such as those coding for bone matrix proteins, steroid hormones, and regulators of local bone metabolism. Alternatively, association studies can be performed using data on genotypes across the entire genome. Examples of genes that have been robustly associated with BMD across multiple cohorts include: estrogen receptor-α (ESR1), LRP5, vitamin D receptor, and TGFBR3 (transforming growth factor, beta receptor III).

As described above, multiple environmental and genetic factors that influence fracture risk, osteoporosis, and/or BMD have been identified, but not all studies report consistent results for all of the risk factors. In part, these inconsistencies are attributable to the differences in the etiologies of BMD (a measure of bone strength) versus fractures (a measure of bone strength plus from trauma). Furthermore, effects of the known environmental factors and genes do not account for a large proportion of the population variation in risk of osteoporosis. In fact, effects of known genetic variants account for <10% of the estimated heritability of BMD. Because bone is a complex tissue, with multiple components, that changes over time, it is unclear which, if any, bone trait is a good measure (or surrogate) of osteoporosis and fracture risk or whether multiple measures are needed. Thus, other possible reasons for the above inconsistencies include interactions among the environmental (and genetic) risk factors, as well as possible differential effects on different aspects of bone metabolism and/or different bone compartments.

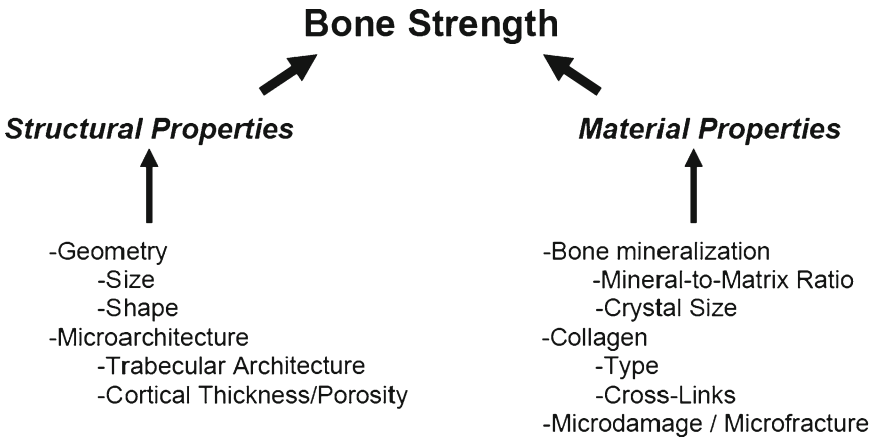

Fig. 138.1 The bone quality framework

138.1.3 Components of Bone Strength

Bone is a geometrically complex and composite material that has an array of mechanical properties; therefore, no simple phenotype is adequate to describe "bone strength." In fact, bone strength is determined by the overall quality of bone, such as bone size, cortical thickness, and trabecular microarchitecture (thickness, number, and connectivity of the trabeculae). Bone strength is usually defined as the "totality of features and characteristics that influence a bone's ability to resist fracture." As depicted in Fig. 138.1, bone strength comprises two components: structural properties and material properties. The structural properties of bone include microarchitecture (trabecular architecture and cortical thickness/porosity) and geometry (size and shape). The microarchitecture of bone is a composite of trabecular architecture (which represents the orientation, thickness, and spacing of the trabeculae, as well as the extent to which the trabeculae are interconnected) and cortical thickness and integrity.

The structural geometric properties of bone, such as the size, thickness, shape, and spatial distribution of bone mass in cross section, also have profound effects on bone strength and fracture propensity independent of BMD. For example, the ability of vertebral bodies to resist compressive forces is directly proportional to their cross-sectional area (CSA), a geometric property. Another important geometric measure is bulking ratio, an indicator of cortical bone instability. It is estimated as the ratio of the femoral neck width to the average cortical thickness. To further assess bone mechanical properties, investigators have also derived composite measures that integrate measures of bone architecture and geometry. One example of such a measure is strength strain index (SSI). It is calculated as the product of section modulus and volumetric cortical BMD normalized to the maximal physiological cortical BMD of human bones. SSI is well acknowledged in the bioengineering field to be a good surrogate measure of bone strength.

Finally, the material properties of bone include its mineral and collagen composition as well as the number, size, and localization of microdamage. Bone turnover (a bone remodeling process accompanied by removal of old bone and its replacement by new bone) rate is a function of the bone renewal process (modeling and remodeling) in which old or damaged bone is reabsorbed and new bone is created to replace it. Bone tissue is composed principally of inorganic bone apatite

crystals that mineralize an organic type I collagen matrix. The degree of mineralization, the material properties of the collagen matrix, crystal size, and the mineral-to-matrix ratio are all important for bone strength.

138.1.4 Assessment of Bone Strength

Considerable progress has been made in the recent years for development of noninvasive assessment of the skeleton, especially for many of the components of bone described above, which has enabled earlier detection of osteoporosis, as well as monitoring its progression and response to therapy. The capability now exists to evaluate the peripheral, central, or entire skeleton as well as the trabecular or cortical bone envelopes accurately and precisely, with the capacity to determine bone strength and predict fracture risk. A variety of methods are currently available to assess geometric and densitometric or even microarchitectural properties of bone: radiographic absorptiometry including both single and dual X-ray absorptiometry; quantitative computed tomography (QCT) including both standard and high-resolution QCT; quantitative ultrasound (QUS); and magnetic resonance imaging (MRI).

138.1.4.1 Key Facts of Radiographic Absorptiometry and DXA

Radiographic absorptiometry was the first quantitative technique to assess integral bone and it is restricted to measurements of appendicular bones, such as metacarpals, phalanges, or calcaneus, which are surrounded by a relatively small amount of soft tissue. Single X-ray absorptiometry (SXA) can be a valuable method in the diagnosis of osteoporosis because the machines used are portable, it is quick, results in low radiation exposure, and provides reasonable assessment of BMD at appendicular sites. It is still used in some studies. However, the precision is low and it is unable to assess bone density at bone sites, such as the hip, that are of major clinical concern.

Dual-energy X-ray absorptiometry (DXA), a two-dimensional measurement, is the most widely used modality for assessment of bone health. This method, which is mostly used for measuring BMD, is sensitive, but not specific, to prediction of fractures in individuals. Studies show that 50–70% of total bone strength can be attributed to aBMD; however, one meta-analysis reported a false positive rate of 15% while using aBMD when predicting hip fracture. The technique is attractive because it is noninvasive, is easily applied for both healthy individuals and patients, and the radiation dose is extremely small. Scanning times, which have been an impediment to its use in pediatric studies, have decreased substantially with newer technology. A further attractive feature is its ability to provide regional body composition analysis, such as body fat, fat-free mass, and bone mineral content for the total body, as well as subcompartments (e.g., legs). However, the DXA measurement device is expensive and not easily transportable. Furthermore, it only provides an overall measure of bone density, and is unable to assess bone health of different bone compartments, such as cortical versus trabecular bone. This latter limitation is especially critical because recent studies indicate that effects of age and other factors differ between cortical and trabecular bone. These differences may be due to the observation that the mineral contents and presumably the metabolism, of these two compartments, differ; for example, mineral tissue makes up 10–35% versus >90% of total tissue volume for trabecular and cortical bone, respectively. This inability to distinguish between bone compartments may explain some of the conflicting results regarding effects of genetic or environmental factors obtained from analyses of BMD in different populations.

138.1.4.2 Key Facts of Quantitative Computed Tomography (QCT)

Quantitative computed tomography (QCT), a three-dimensional imaging technology, can determine the true volumetric density (mg/cm^3) of both trabecular and cortical bone at different skeletal sites simultaneously, as well as measures of skeletal geometry, one of the other major components of bone strength (Fig. 138.1). For assessment of skeletal geometry, QCT imaging permits a direct measurement of vertebral and proximal femoral volumes and cross-sectional areas. The reliability of volume estimates based on projected areas (from radiographs or DXA images) is limited by inaccuracies in the use of simple analytic formulas to describe bone shapes and by errors in the projected areas themselves (caused by patient size or rotation, scoliosis, lordotic curvature, etc.). Thus, a two-dimensional view of a complicated structure does not provide an adequate estimate of its character. Because a volume is imaged, QCT scans may be reformatted along any axis, and geometry can be directly measured in a standardized view. QCT has several essential advantages over DXA; first, QCT measures BMD volumetrically (mg/cm^3) and is independent of bone size. By contrast, DXA provides a measure of areal BMD (g/cm^2) that is confounded by bone size differences. This confounding effect is best illustrated by a comparison with DXA measures of areal BMD in men and women: aBMD is greater in men versus women, but volumetric densities are similar. Thus, gender differences in vertebral bone mass and strength are due to greater bone size in men, not due to differences in volumetric density. A second major advantage of QCT compared with DXA is that it separately measures trabecular and cortical BMD (Fig. 138.2). Both cortical and trabecular BMD influence the mechanical integrity of bone. Measures of trabecular BMD may confer the highest risk for fracture and are more sensitive to changes in bone metabolism. By contrast, DXA yields a measure of integral BMD (i.e., cortical and trabecular) – a "confounded phenotype."

In clinical practice, QCT has been used to assess vertebral fracture risk and follow the progression of osteoporosis and other metabolic bone diseases. Moreover, due to the finer image quality, QCT-based bone measurements have been utilized to evaluate age-related bone loss, sex, and ethnic differences in bone density and geometry at different skeletal sites. However, as with DXA, the equipment to measure QCT is expensive and not easily movable and this limits some of its usefulness for large population-based studies.

138.1.4.3 Key Facts of Quantitative Ultrasound (QUS)

Several attractive features of QUS are low cost, portability, ease of use, and, most important, lower or zero dosage of radiation compared to DXA and QCT. Similar to QCT technology, QUS devices can assess trabecular and cortical bone compartments separately and also measure characteristics of bone strength independent of bone density. QUS measures ultrasound transmission velocity and ultrasound attenuation and both of these parameters are influenced by density and by bone microarchitecture. Because osteoporosis is characterized by decreased bone mass and deteriorated microarchitecture within bone tissue, composite measures of ultrasound transmission velocity as well as ultrasound attenuation may better reflect the bone strength and be closer correlated to clinic disease. However, poor precision and limited assessment of peripheral bone sites have limited the use of this technology as a first-line diagnostic tool in clinical practice.

138.1.4.4 Key Facts of Magnetic Resonance Imaging (MRI)

Magnetic resonance imaging (MRI) is a 3-D imaging method that uses magnetism, rather than ionizing radiation, to produce high-definition images of bone. It has higher resolution than either QCT

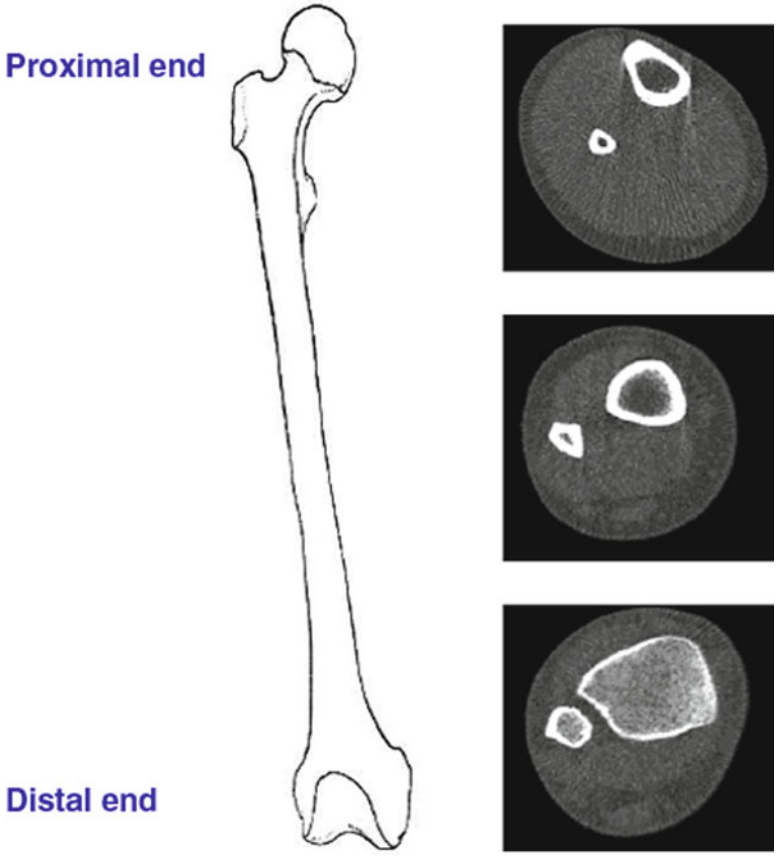

Fig. 138.2 Trabecular and cortical bone compartment measures by QCT. More trabecular bones (*shaded area*) at the distal end compared with more cortical bones (*lighted area*) at the proximal end of long bone

or QUS and produces a positive image of the interstitial space between trabeculae and a negative image of the bone matrix. Evidence from numerous clinical studies has shown that MRI-derived measurements of trabecular microarchitecture reflect the bone morphology changes across age and by disease status (Fig. 138.3). In addition, it successfully discriminates between patients with hip or vertebral fractures and healthy individuals. Despite the merits of MRI, there are two major drawbacks that have hindered the utilization of this technology: high cost and time-consuming procedures.

138.1.5 Dissect the Genetic and Environmental Determinants for Bones: Examples from Tobago Family Study

In this section, we present insights gained from the use of two bone-imaging methods, DXA and QCT. In particular, we present results on the genetic and environmental factors influencing bone architecture from the ongoing Tobago Family Study (TFS). The Tobago Family Study comprises eight multigenerational pedigrees with 471 individuals (283 women and 188 men) ranging in age

Fig. 138.3 Three-D reconstruction of bone microarchitecture by high-definition Micro-CT. *Left*: trabecular bone from healthy individual; *Right*: trabecular bone from osteoporotic individual (Source: http://www.sdu.dk/om_sdu/institutter_centre/klinisk_institut/forskning/forskningsenheder/ortopaedkirurgi/forskningsomraader/eksperimentel%20forskning/microct.aspx?sc_lang=en)

from 18 to 103 years (mean age = 43 years). These families represent a relatively random sample of the Tobago population and were recruited without regard for health outcome; the only criterion was that at least eight living, first-degree relatives were willing to participate in each family. Also, in general, men and women from Tobago have low levels of non-African admixture.

138.1.5.1 Example 1: Mean Bone Change by Age, Sex, Race, and Skeletal Compartments

The incidences of osteoporosis and osteoporotic fracture are known to be lower among individuals of African ancestry than among their Caucasian and Asian counterparts. Mean BMD is typically around 10% higher (about one standard deviation) among individuals of African ancestry versus other ancestral groups, and this difference is not explained by environmental covariates, including body size and physical activity. Furthermore, this difference is present at all ages and in both sexes. For example, Fig. 138.4a, depicts cross-sectional means of total hip aBMD obtained from DXA for men and women at different ages in the TFS, as well as published cross-sectional values for non-Hispanic African Americans and non-Hispanic European Americans in the US NHANES III study. As expected, aBMD decreases across age and men have higher bone density than women for all groups. Furthermore, mean aBMD at the hip was higher among men and women from Tobago versus non-Hispanic European Americans and non-Hispanic African Americans had intermediate values. The higher aBMD among the Tobago population versus African Americans is consistent with their higher average proportion of African ancestry (94% vs. 80%, respectively) based on genetic markers providing information on ancestry. Because 2-D DXA measures are available for many cohorts and some measures have been obtained longitudinally (rather than in cross section, as presented here), these data have been useful to assess age-related changes, as well as differences between genders, ancestral groups, and other environmental and genetic factors.

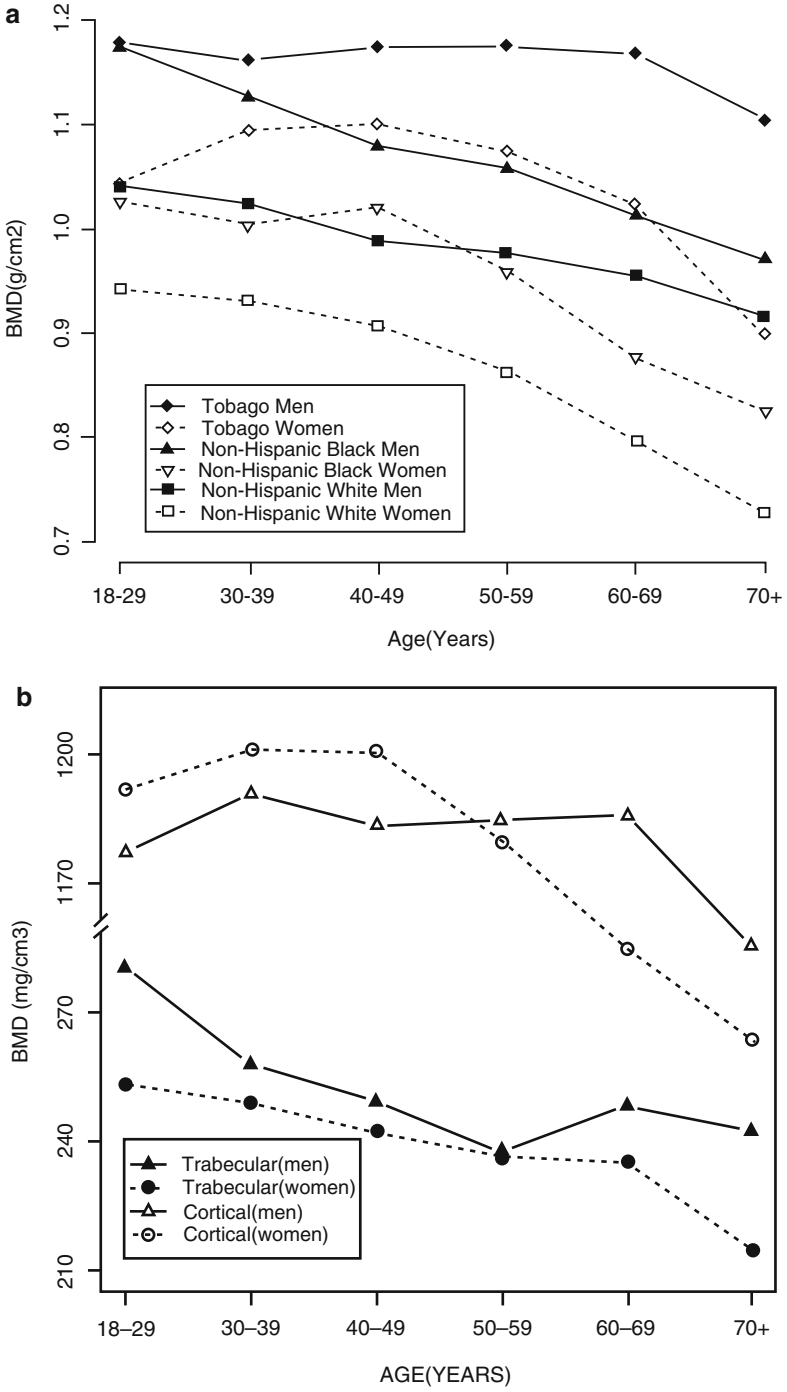

Fig. 138.4 (**a**) Age- and sex-specific means of total hip BMD among Tobagonians and US non-Hispanic whites and non-Hispanic blacks. (**b**) Trabecular and Cortical Mean BMD at Tibia by age and gender among Tobago family members

Table 138.1 Examples of environmental correlates for bone density phenotypes in Tobago family members [a, b, c]

	Age	*Gender*	*Weight*	*Smoking*	*Menopause status*	*Parity*
DXA Areal BMD (g/cm²)						
Lumbar spine	+ **		++ **		—— **	
Femoral neck	— **	+++ *	++ **		—— *	++ ^
Total hip	– *	++++ **	++ **		— *	
pQCT Volumetric BMD (mg/cm³)						
Trabecular, radius	— **	++++ **	++ **	—— ^	—— ^^	
Cortical, radius		– *	– *		— **	+ *
Trabecular, tibia	— **	++++ **	++ **	—— ^^		
Cortical, tibia	– **		– *		— **	++ **

[a] Symbols indicate positive (+) and negative (–) correlation. The strength of the correlation is indicated by the number of symbols: one symbol indicates less than 1% difference; two symbols, a 1–5% difference; three symbols, a 5–10% difference; and four symbols indicate a 10% or greater difference

[b] $^p < 0.10$, $^{^}p < 0.05$, $^*p < 0.01$, $^{**}p < 0.001$

[c] Code female as baseline

As described in the previous section, newer bone-imaging methods allow the assessment of subcompartments of bone, such as using cortical versus trabecular volumetric BMD. Figure 138.4b shows mean volumetric BMD (vBMD) of cortical and trabecular BMD at the tibia. As can be seen, mean trabecular vBMD was again higher in men than women at all ages and generally decreased with increasing age. By contrast, mean cortical vBMD was higher in women than in men until age 50 years, at which point, it decreased markedly in women, but remained fairly constant with advancing age in men, at least until the oldest age group (70+). The patterns observed among the Tobago population are very similar to those reported by Riggs et al. (2004) in US European Americans. These observations illustrate that different bone compartments may have unique features and that phenotypes measured by 3-D image techniques may be more useful for dissecting the underlying genetic and environmental factors.

138.1.5.2 Example 2: Identifying Environmental Factors Influencing BMD Phenotypes

We also mentioned previously that, in addition to age and sex, numerous environmental factors have earlier been reported to influence aBMD, although these results are not always consistent in different populations. In Table 138.1, we present results from an analyses of several environmental factors on measures of aBMD and vBMD obtained in the Tobago Family Study. In general, measures of aBMD and vBMD at different skeletal sites were higher in men than in women, decreased with increasing age, and increased with increasing body weight. Although aBMD and vBMD were measured at different skeletal sites, and, thus, a direct comparison is not possible, there are intriguing differences for other environmental factors. Smoking status was not significant at any aBMD site in the TFS study (although it is significant in some studies), however, it was correlated with cortical, but not trabecular vBMD. Likewise, these results indicate that parity has a strong effect on cortical vBMD, but is only significant for femoral neck aBMD and not total hip or lumbar spine. These results indicate that some environmental factors might only influence one bone compartment (trabecular or cortical) and that the inconsistent results across populations may reflect differences in the relative contribution of trabecular versus cortical vBMD to measures of aBMD (which is a combination of trabecular and cortical BMD).

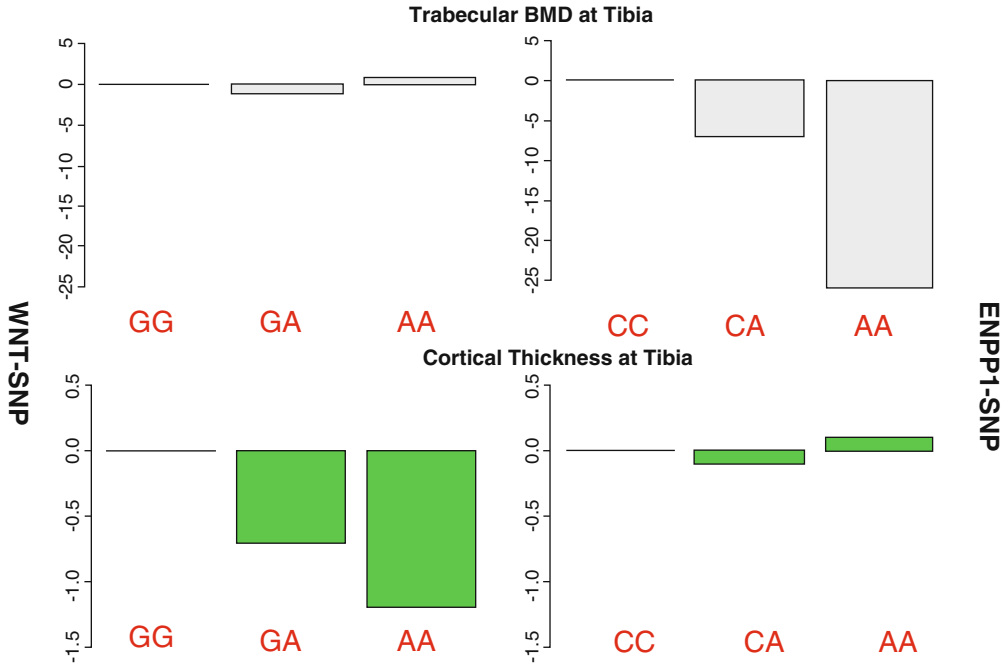

Fig. 138.5 Histogram of adjusted means by genotype for SNPs at WNT and ENPP1 genes. A/C/G/T represents nucleotides of purines (A/G) and Pyrimidines (C/T). *Upper left*: Mean of trabecular BMD by WNT SNP; *Upper right*: Mean of trabecular BMD by ENPP1 SNP. *Lower left*: Mean of cortical thickness by WNT SNP; *Lower right*: Mean of cortical thickness by WNT SNP

138.1.5.3 Example 3: Genetic Effects on Bone Phenotypes

In addition to assessment of environmental factors, analyses of genetic factors influencing different bone compartments (as measured by 3D imaging methods) may reveal insights regarding possible underlying mechanisms. As we described earlier, in general, heritability of aBMD measured by DXA ranges from 40% to 80% of the total population variation, and similar results were obtained for the TFS. However, using data on vBMD measured at the radius and tibia in TFS, heritability of trabecular vBMD was higher ($h^2 \sim 0.5$) than that of cortical vBMD ($h^2 \sim 0.25$). Subsequent analyses indicated that a common set of genes influenced trabecular (or cortical) vBMD measured at both skeletal sites, whereas, at least some of the genes that influenced trabecular vBMD differed from those that influenced cortical vBMD. Figure 138.5 presents specific examples of two genes that have differential effects on different bone compartments. Both genes are members of biological pathways that are involved in bone metabolism. As can be seen, a polymorphism in Wnt10b (one of 19 genes in wingless-type (WNT) family and part of the LRP5 pathway mentioned earlier) is significantly associated with cortical thickness, a measure of bone geometry, but not trabecular vBMD. By contrast, ENPP1 (ectonucleotide pyrophosphatase/phosphodiesterase 1) has significant association with trabecular vBMD, but not with cortical thickness.

In summary, using data from the TFS, we illustrate the use of 2D and 3D imaging methods to assess genetic and environmental factors that influence measures of bone strength. These results indicate that results of 2D imaging methods can be useful because many different populations have been assessed using these methods. However, analyses of data from 3D imaging methods indicate

that metabolism of different bone compartments may intrinsically differ; therefore, imaging technologies which can distinguish these different bone compartments are required for additional insights on the genetic and environmental architecture of bone strength. These results also indicate that single-bone phenotype is not sufficient to assess bone strength. Thus, it is possible these two types of phenotypes represent different characteristics of bone quality.

138.1.6 Application to Other Areas of Health and Disease

The 2-D and 3-D imaging technologies described above can be readily applied to studies of other health-related traits, such as obesity and sarcopenia (loss of muscle mass). Both obesity and sarcopenia are associated with increased risk of other diseases, including cardiovascular disease, diabetes, and osteoporosis, although the fundamental biological pathways by which this occurs are still unclear. Over the past few decades, a variety of genes and environmental factors that influence levels of obesity have been identified, even though much of this research has used body mass index (BMI), a relatively crude measure of obesity. Although BMI, measured as weight in kilogram/(height in meters)^2, takes into account both height and weight, it does not consider the lean-to-fat ratio. For example, two individuals can have the same BMI, but one could have more lean and the other more fat mass. Furthermore, many studies indicate that distribution of fat mass, such as abdominal versus hip fat, is associated with risk of chronic diseases, such as type 2 diabetes. Thus, use of 2D and 3D imaging methods, rather than BMI and waist circumference, should facilitate our understanding of environmental and genetic factors influencing obesity. In fact, more recent studies of visceral fat and intramuscular fat measurements (obtained by 3D methods) indicate that these measures are more highly correlated with risk of diabetes than is assessment of BMI alone. As with measure of BMD, improved definition of obesity again may lead to identification of specific genetic and environmental factors that influence these traits, as well as identification of individuals at risk.

Studies of sarcopenia, a disease associated with degenerative loss of skeletal muscle mass with aging, can be greatly improved by use of 2D and 3D imaging methods as well. Currently, many studies indirectly assess sarcopenia using measures of strength (such as leg strength or grip strength). Although such measures may be clinically important, the use of such a measure is similar to the use of fractures to assess osteoporosis. Studies of lower leg lean muscle mass (measured by DXA), together with measures of muscle attenuation (by CT scan), hold promise as potentially reliable surrogates for muscle quality.

In addition to the use of 2D and 3D imaging methods to assess genetic and environmental risk factors for osteoporosis, obesity, and sarcopenia separately, these methods can be used to assess the intrinsic connections among these body composition measurements. For example, bone strength and muscle mass decrease with increasing age, whereas fat mass increases. Furthermore, at younger ages, lean mass is the main predictor of BMD, presumably in part due to mechanical stresses, whereas, at older ages, fat mass is a better predictor of BMD. In addition to effects of age, Irwin et al. (2009) reported that active exercisers experienced significant decreases in percent body fat, increases in lean mass, and no change in BMD compared to random controls. Finally, evidence is accumulating that these three body compartments may be influenced by a similar set of genes, as well as unique sets of genes. Thus, the use of 2D or 3D imaging methods should greatly facilitate our understanding of the underlying mechanisms and interrelationships among osteoporosis, obesity, and sarcopenia. This knowledge should lead to identification of at-risk individuals and development of preventative strategies and treatment modalities.

Summary Points

- Osteoporosis is a complex disease, which is regulated by multiple risk factors including both environmental and genetic determinants and their interactions;
- Disentangling the effects of genetic and environmental factors on osteoporosis requires expertise in genetic epidemiology and related fields.
- Bone strength is the ability of bone to resist fracture and is composed of both structural and material properties.
- 2-D and 3-D imaging technologies provide different surrogate measures of bone strength, and each imaging method has strengths and weaknesses.
- Analyses of different components of bone strength, such as geometry versus bone architecture, indicate that genes and environmental factors may have differential effects on these components.
- Bone strength cannot be represented by any single measure of bone phenotype so far, but studies of the different components of bone strength may lead to better estimates of individual risk and treatment modalities.

Chapter 139
Body Composition and Lung Function

Mauro Zamboni, Andrea Rossi, Alessandra Zivelonghi, Giulia Zamboni,
and Francesco Fantin

Abstract A growing body of evidence indicates that excess body weight is associated with a wide range of health conditions, including respiratory diseases. Cross-sectional studies have demonstrated an inverse relationship between body mass index and pulmonary function evaluated by spirometry. Longitudinal studies have shown that increases in body weight can lead to a reduction in pulmonary function.

Although the influence of obesity on pulmonary function tests has been examined, there are limited studies that evaluate the influence of body fat distribution on pulmonary function tests in overweight and moderate obesity.

It has been previously shown that body fat distribution has an effect on pulmonary function. In particular, the excess of visceral fat has a negative effect on lung function and is inversely associated with chest wall compliance. A consistent negative association between waist circumference and pulmonary function has been demonstrated in normal weight, overweight and obese subjects, suggesting that the fat mass stored in the abdominal cavity, particularly visceral fat, most likely directly impedes the descent of the diaphragm leading to primarily restrictive respiration impairment.

An increased neck circumference has been suggested as a better sign of obstructive sleep apnoea than waist and BMI.

In the elderly the amount of body fat and a central pattern of fat distribution correlate negatively with lung function, whereas the amount of fat-free mass correlates positively with lung function. The age-related combination of fat free mass loss and fat gain, so called "sarcopenic obesity", may have additive negative effects on pulmonary function.

Abbreviations

FEV1	Forced expiratory volume in 1s
FVC	Forced vital capacity
FM	Fat mass
FFM	Fat-free mass
BMI	Body mass index
WHR	Waist hip ratio

139.1 Introduction

Obesity is a chronic disease and is associated with increased mortality.

Multiple health problems are common among the obese and include cardiovascular and metabolic diseases (e.g., non-insulin-dependent diabetes, ischemic heart disease, stroke, and dyslipidemia). Obesity is linked to a wide range of conditions including chronic obstructive pulmonary disease (COPD), asthma, obesity hypoventilation syndrome, pulmonary embolism, aspiration pneumonia, and obstructive sleep apnea (Chen et al. 2002). Fat distribution, more than excess of body fat itself, is linked to reduced lung function (Santana et al. 2001; Nishimura et al. 1995). Fat distribution is usually measured by waist circumference, sagittal abdominal diameter (SAD), and waist-to-hip circumference ratio (WHR). A high WHR is a proxy measurement for an excess of intra-abdominal fat. Body fat percentage, body fat mass, and fat-free mass, evaluated by DXA, and body fat distribution, evaluated by CT and MRI, are more commonly used in studies examining the effects of obesity.

In this chapter, we first describe the relationship between excess body weight and lung function. Second, we discuss the relationship between lung function and body fat distribution evaluated by anthropometry. Finally, we delineate the importance of the effects of age-related body composition changes on worsening of lung function.

139.2 Body Weight and Lung Function

A growing body of evidence indicates that excess body weight is associated with a wide range of health conditions, including respiratory diseases, such as chronic obstructive pulmonary disease (COPD) and asthma (Chen et al. 2002).

Cross-sectional studies have demonstrated an inverse relationship between body mass index (BMI; in kg/m^2) and pulmonary function tests (i.e., FEV1 and FVC) (Wise et al. 1998; Santana et al. 2001; Jones and Nzekwu 2006).

This is of particular importance since FEV1 and FVC are independent predictors of all-cause mortality (Schunemann et al. 2000) and a strong risk factor for cardiovascular disease, stroke, and lung cancer (Cook et al. 1994).

Longitudinal studies have shown that increases in body weight can lead to a reduction in pulmonary function (Nishimura et al. 1995). In an 8-year Italian longitudinal study, Bottai et al. evaluated BMI, spirometry, and carbon monoxide diffusing capacity in over 1,000 subjects from a general population (aged >24 years), observing that most of those who lost weight improved their lung function and those who gained weight reduced their lung function (Bottai et al. 2002) (Table 139.1).

Table 139.1 Key features of the relation between body composition and lung function in older adults

1. Cross-sectional and longitudinal studies have shown that body composition changes with aging, with an increase in fat mass and a decrease in muscle mass.
2. Body fat distribution also changes with age with visceral fat increase and subcutaneous fat decline
3. With aging, there is also loss of muscle mass, a process called sarcopenia, and an increase of the amount of fat inside and around muscles
4. Lung function has been shown to be inversely proportional to fat mass, but positively proportional to fat-free mass in the elderly
5. Sarcopenic obesity may have additive negative effects on pulmonary function

This table lists the key facts regarding relationships between body composition and lung function

A 10-year longitudinal study of middle-aged men in Northern Ireland showed that the decline in lung function was greater in those who had the largest increases in BMI over the study period. The rate of decline in FEV1 increased by 2.9 ml per year per unit increase in BMI over 10 years.

The detrimental effect of weight gain on lung function has been shown to be greater in men than in women, probably due to gender-related differences in fat distribution (Chen et al. 2007).

It must also be considered that a strong relation between underweight and weight loss and pulmonary function worsening has been observed. This is particularly significant in certain clinical conditions, such as COPD (Nishimura et al. 1995), and in the elderly (Tockman 1994). Actually, it should be considered that the relation between body weight and BMI with pulmonary function is not linear and that some important issues should be borne in mind when evaluating the relation between BMI and lung function. First, BMI does not allow distinguishing between fat mass and muscle mass, which have opposite effects on pulmonary function (Wise et al. 1998; Santana et al. 2001). Second, both weight and height are surrogate measures of body size and important predictors for pulmonary function measurements. Third, a unit of body weight or BMI is likely to have less fat mass for underweight persons and for men than for overweight persons and for women (Chen et al. 1993). In addition, body weight and BMI provide no information on the nature of body fat distribution that may play an important role in the association between obesity and pulmonary function (Chen et al. 1993).

139.3 Body Fat Distribution and Lung Function

Several studies have evaluated the relation between indices of body fat distribution and pulmonary function (Santana et al. 2001; Nishimura et al. 1995; Harik-Khan et al. 2001).

It is well known that body fat distribution is an important predictor of adverse health events, such as diabetes, hypertension, hyperlipidemia, and coronary events (Borkan et al. 1986). In central obesity, most of the fat deposits, both subcutaneous (SCAT) and visceral (VAT), are in the abdominal area (Fig. 139.1). It is well known that visceral fat deposits are more strongly correlated with cardiovascular risk than is the degree of adiposity (Després et al. 1990).

Truncal obesity determines a reduction of respiratory muscle strength and function, lung volumes, and peripheral airway size (Sugerman et al. 1997). Abdominal fat may also alter the pressure–volume characteristics of the thorax and restrict the descent of the diaphragm, thereby limiting lung expansion. Reduced ventilation at the lung bases can lead to the closure of peripheral lung units, ventilation-to-perfusion ratio abnormalities, and arterial hypoxemia, especially in the supine position (Caro et al. 1960). The expiratory reserve volume is also reduced and the work of breathing is increased (Caro et al. 1960) (Table 139.2).

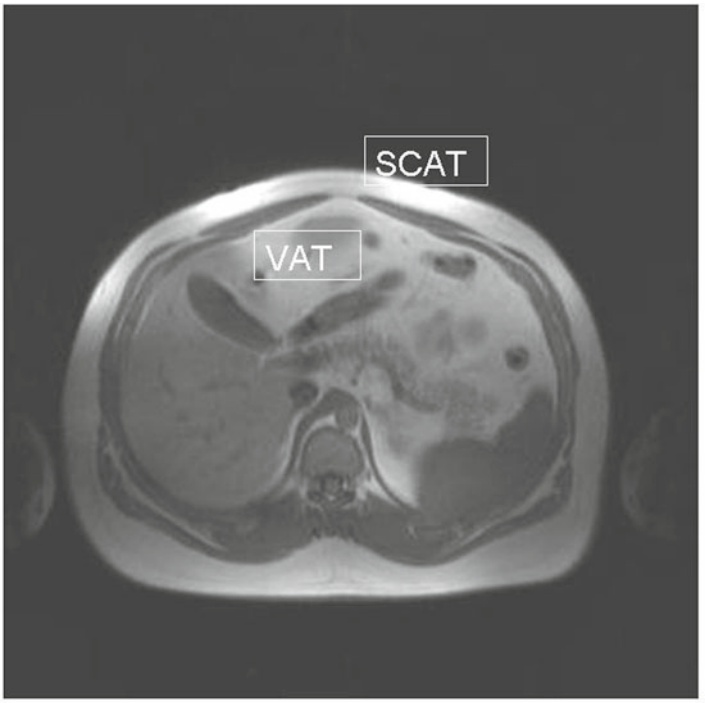

Fig. 139.1 Abdominal fat distribution evaluated by MRI. Transverse T1-weighted MRI image of the abdomen at L3 level, with subdivision of abdominal adipose tissue into subcutaneous adipose tissue (*SCAT*) and visceral adipose tissue (*VAT*)

Table 139.2 Key features of sarcopenic obesity

1. Sarcopenic obesity is a disordered form of body composition characterized by low muscle mass and high level of body fatness
2. Age-related increases in body fatness generally precede the onset of sarcopenia, which appears regardless of level of body fatness
3. The mechanism involved in sarcopenic obesity could be an increased production of TNF-alfa and leptin from adipose tissue, leading to progressive loss of muscle mass and gain in body fat (Roubenoff and Hughes 2000)
4. Prevalence of sarcopenic obesity increases with age, from about 2% to 10% from age 65 to 85 years (Morley et al. 2001)
5. Sarcopenic obesity is more strongly associated with disability and functional limitations than either obesity or sarcopenia (Morley et al. 2001)

This table lists the key facts regarding sarcopenic obesity

It has been shown, at least in obese subjects, that the amount of abdominal fat is inversely associated with chest-wall compliance (Nishimura et al. 1995; Jenkins and Moxham 1991). A consistent negative association between waist circumference and pulmonary function has recently been demonstrated in normal weight, overweight, and obese subjects, suggesting that FM stored in the abdominal cavity, particularly visceral fat, most likely directly impedes the descent of the diaphragm, leading to primarily restrictive respiration impairment (Jenkins and Moxham 1991).

In a cross-sectional study of 1,674 adults, waist circumference was negatively associated with FEV1 and FVC. On average, an increase in waist circumference of 1 cm was associated with a 13-ml reduction in FEV1 and an 11-ml reduction in FVC (Nishimura et al. 1995). Inverse associations

between indices of body fat distribution (i.e., sagittal abdominal diameter and waist circumference) and pulmonary function in men and women with BMI values >25 kg/m^2 were also demonstrated in a random sample of 2,153 healthy individuals with ages ranging from 35 to 79 years (Ochs-Balcom et al. 2006).

In the Baltimore Longitudinal Study of Aging (BLSA), the relation of WHR on FEV1 and FVC was examined in a population of 1,094 men and 540 women (18–102 years) showing that body fat distribution has independent effects on lung function that are more prominent in men than in women (Harik-Khan et al. 2001).

These findings have provided supportive evidence that abdominal adiposity is a better predictor of pulmonary function than weight or BMI.

139.4 Application to Other Areas of Health and Disease

139.4.1 Anthropometry and Obstruction Sleep Apnea Syndrome (OSAS)

It has also been shown that BMI is twice as strong as gender and fourfold stronger than age in predicting OSAS (Fig. 139.2) (Subramanian and Strohl 2004). However, a high amount of fat located in the chest, in the neck, as well as in the abdomen has been clearly shown to be a stronger predictor of OSAS than BMI (Subramanian and Strohl 2004). In a 30-year follow-up study, age, baseline waist circumference, and waist changes were the most powerful predictors of OSAS in old age, in obese as well as in normal-weight men (Carmelli et al. 2000).

An increased neck circumference has been suggested as a better sign of obstructive sleep apnea than other clinical indices and may be up to 77% sensitive and 82% specific for OSAS in patients referred to a sleep clinic (Davies et al. 1992). A prospective study in obese patients with symptoms suggesting sleep apnea showed that neck circumference is more useful as a predictor of obstructive sleep apnea than waist circumference and BMI (Hoffstein and Mateika 1992). Neck circumference (measured in centimeters) is adjusted if the patient has hypertension (4 cm is added), is a habitual

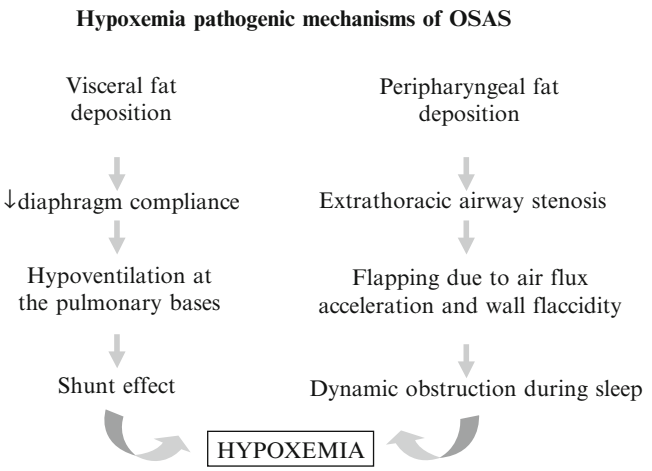

Fig. 139.2 OSAS pathogenic mechanism for Hypoxemia in visceral obesity. Mechanism responsible for respiratory disturbances in visceral obesity

Table 139.3 Key features of OSAS

1. The OSA syndrome is characterized by repeated partial or complete closure of the pharynx, gasping episodes, and sleep fragmentation (Bradley and Floras 2003)
2. Sleep-induced relaxation of the pharyngeal musculature is believed to be the cause of intermittent airway obstruction
3. The physiologic consequences of OSAS are repetitive bursts of sympathetic activity, hypoxia, hypercapnia, increased left-ventricular afterload, and acute hypertension (Bradley and Floras 2003)
4. The daytime hypersomnolence that can occur in obesity is a manifestation of OSAS
5. A person, who has obstructive sleep apnea, often is not aware of the apnea episodes during the night. Frequently, family members witness the periods of apnea

This table lists the key facts regarding Obstruction Sleep Apnea Syndrome

snorer (3 cm is added), or is reported to choke or gasp most nights (3 cm is added). A low clinical probability corresponds to an adjusted neck circumference of less than 43 cm, an intermediate probability (four to eight times as probable as a low probability) to a neck circumference of 43–48 cm, and a high probability (20 times as probable) to a neck circumference of more than 48 cm. Together with the consideration of the severity of symptoms, the clinical-probability estimate helps guide management (Flemmons 2002) (Table 139.3).

139.4.2 Body Composition and Lung Function in the Elderly

With aging, even in the healthy elderly population, a progressive decline in FEV1 and FVC has been observed, independent of smoking or environmental exposure (Enright et al. 1994; Burr et al. 1985). Worsening pulmonary function is clinically relevant because it is associated with increased morbidity and mortality rates (Kannel et al. 1983).

Several factors may contribute to age-dependent decline of lung function.

Cross-sectional and longitudinal studies have shown that body composition changes with aging, with an increase in fat mass and a decrease in muscle mass (Baumgartner et al. 1995).

Even without body weight changes, the amount of fat significantly increases with age (Prentice and Jebb 2001).

In men and women, in both normal weight and obese subjects, body weight tends to increase, peaking at about age 65 years in men and later in women, and then decreasing with further aging (Lissner et al. 1994).

Body fat distribution also changes with age, with visceral fat increase and subcutaneous fat decline.

Aging is also associated with a loss of muscle mass, a process called sarcopenia (Janssen et al. 2002), and an increase of the amount of fat inside and around muscles (Fig. 139.3) (Goodpaster et al. 2001). Both these two changes have been shown to be associated to an increased risk of physical functional decline and disability as well as to an increase in morbidity and mortality (Visser et al. 1998).

Maximal respiratory pressures, an index of the strength of inspiratory and expiratory muscles, decreases with age and is associated with handgrip and FFM (Enright et al. 1994).

Interestingly, in the few reports that investigated the association between the individual components of body composition (i.e., FM and FFM) and lung function, the latter has been shown to be inversely proportional to FM, but positively to FFM (Lazarus et al. 1998).

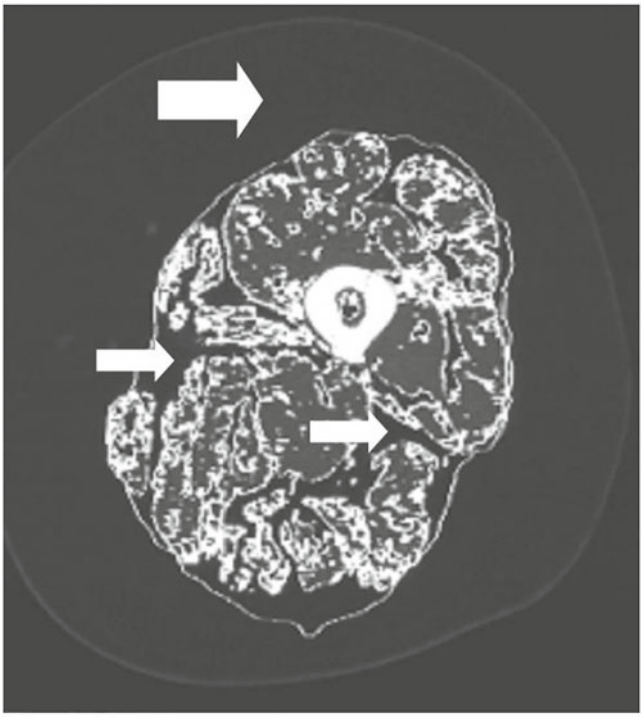

Fig. 139.3 Midthigh CT image of obese subject. Transverse unenhanced CT image obtained at the midthigh in an obese subject depicting subcutaneous (*large arrow*) and intermuscular adipose tissue (*small arrows*). The brighter pixels within the skeletal muscle tissue have attenuation values between 0 and 29 HU and represent low-density (high-fat) muscle. The *darker pixels* have attenuation values between 30 and 100 HU and represent high-density (low-fat) muscle

It may be possible that the loss in muscle and the gain in fat act synergistically to cause disability or metabolic disorders. Recently, the concept of sarcopenic obesity has been proposed (Zamboni et al. 2008) and its relation with physical impairment and disability has been investigated. The concept of sarcopenic obesity should help to understand the complexity of the relation between obesity and mortality and morbidity in the elderly. Sarcopenic obesity may be not recognized with the use of BMI, and, thus, its effect on mortality and morbidity is likely underestimated.

Previous studies have considered the role of body composition changes on lung function decline in the elderly (Santana et al. 2001; Enright et al. 1994; Lazarus et al. 1998; Wannamethee et al. 2005; Tockman 1994). Santana et al. have shown that body composition and fat distribution are associated with lung function in elderly men (Santana et al. 2001). In a population of 97 men aged 67–78 years with BMI ranging from 19.8 to 37.1 kg/m^2, they observed that the amount of body fat and a central pattern of fat distribution correlated negatively with lung function, whereas the amount of fat-free mass correlated positively with lung function (Fig. 139.4) (Santana et al. 2001). This finding has been recently confirmed in a longitudinal study involving 77 elderly men and women evaluated over a 7-year follow-up period, suggesting that the age-related combination of FFM loss and fat gain, so-called "sarcopenic obesity," may have additive negative effects on pulmonary function (Fig. 139.5) (Rossi et al. 2008).

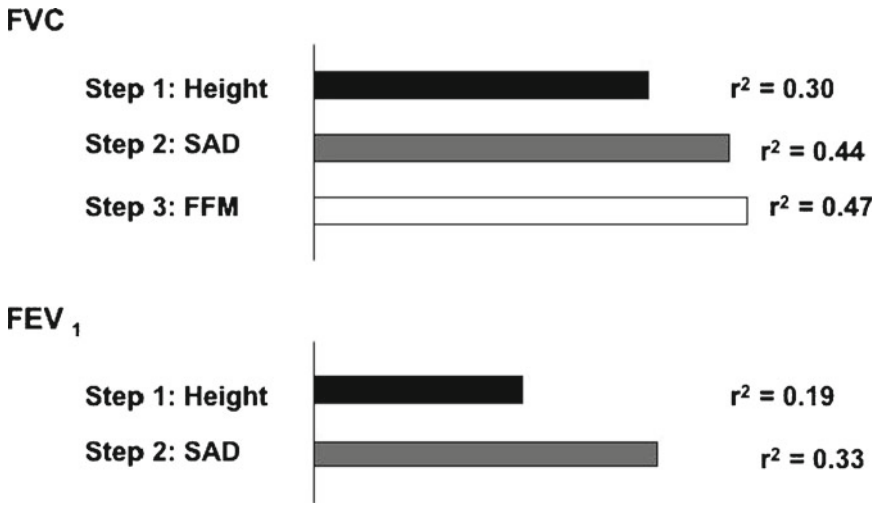

Fig. 139.4 Body composition predictors of lung function in the elderly. Stepwise multiple regression in a population of 97 men, aged 67–78 years with body mass indices (BMIs; in kg/m^2) ranging from 19.8 to 37.1, with use of age, anthropometric measurements, and body-composition variables as independent variables and ventilatory function indices (FEV1 and FVC) as dependent variables (Santana et al. 2001). *FEV1* forced expiratory volume in 1 s, *FFM* fat-free mass, *FVC* forced vital capacity, *SAD* sagittal abdominal diameter

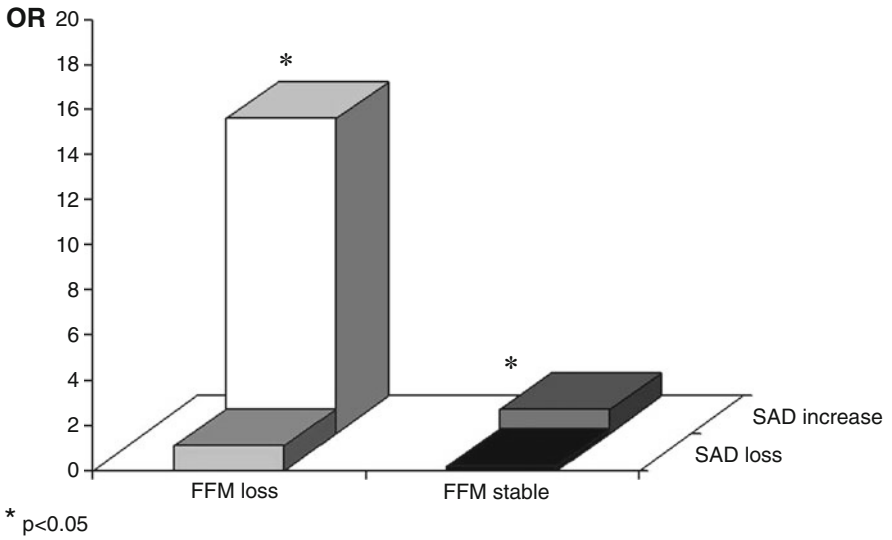

Fig. 139.5 Risk of worsening in FEV1 in the elderly population. Risk of worsening in FEV1 in the elderly population expressed as Odds Ratio (Rossi et al. 2008). *FEV1* forced expiratory volume in 1s, *FFM* fat-free mass, *SAD* sagittal abdominal diameter, *OR* odds ratio

Fig. 139.6 Sagittal abdominal diameter (*SAD*). Sagittal abdominal diameter evaluation with caliper

139.5 Practical Methods and Techniques

139.5.1 Sagittal Abdominal Diameter

Sagittal abdominal diameter (SAD) is defined as the shortest distance between the anterior and posterior trunk at the level of the iliac crest or lowest trunk site. In particular, the measurement is made between the xiphoid process and umbilicus, while the subject breathes softly (Fig. 139.6). The subject should be lying on a rigid surface.

Sagittal diameter can be measured with a Harpender caliper or a CT or MRI scan. Kvist and colleagues showed that sagittal abdominal diameter is highly correlated with visceral fat volume (Kvist et al. 1988) ($r = 0.93$). The caliper must have stability, robustness, and precision.

139.5.2 Neck Circumference

Neck circumference is measured in the midway of the neck, between midcervical spine and midanterior neck, to within 1 mm, with plastic tape. In men with a laryngeal prominence (Adam's apple), it must be measured just below the prominence (Ben-Noun L et al. 2001).

Summary Points

- A growing body of evidence indicates that excess body weight is associated with a wide range of health conditions, including respiratory diseases.
- Both cross-sectional studies and longitudinal studies have demonstrated an inverse relationship between body mass index and pulmonary function evaluated by spirometry.

- The excess of visceral fat has a negative effect on lung function and is inversely associated with the compliance of the chest wall.
- An increased neck circumference has been suggested as a better sign of obstructive sleep apnea than waist and BMI.
- Respiratory function may be affected by body weight, by weight change (both gain and loss), as well as by age-related changes in body composition.
- Age-related combination of fat-free mass loss and fat gain, so-called "sarcopenic obesity," may have additive negative effects on pulmonary function.
- Preventing weight gain, and, in particular, limiting the increase in visceral fat, may be important for reducing the negative effects of aging on lung function.
- In particular, clinicians should be aware that evaluation of body composition should be of clinical relevance even in pulmonary alterations.

Part XXII
Anthropometry in Special Conditions and Circumstances

Chapter 140
Psychosocial Correlates in the Context of Body Mass Index and Overweight

Helena Fonseca and Margarida Gaspar de Matos

Abstract The potentially serious physical and psychosocial consequences of overweight and obesity have made this condition one of the great contemporary public health issues. However, the earliest and most widespread consequences of adolescent obesity are of psychosocial nature. There is evidence that overweight and obesity in adolescence are associated with significantly lower levels of emotional well-being measures, body image dissatisfaction and social isolation.

Compared with normal weight peers, overweight and obese adolescents express concerns associated with weight more frequently, have a poorer perception of their own health, rate their life satisfaction as lower and are more involved in health compromising behaviours, such as chronic dieting and potentially harmful alcohol consumption. Growing evidence suggests that adolescents with chronic conditions other than obesity, are likely to engage in risky behaviours to at least similar, if not higher rates as their healthy peers, and alcohol has been recognized as the substance most frequently used by young people with a variety of chronic conditions, with little variation by diagnosis. Obesity seems to be similar to other chronic conditions of adolescence, especially in what concerns alcohol use and abuse.

Overweight and obese adolescents should, where possible, be reached with appropriate interventions addressing the broad spectrum of their psychological needs, enhancing their skill development for behavioural change, and providing support for dealing with potentially harmful behaviours.

140.1 Applications to Other Areas of Health and Disease

There is evidence that a variety of adverse psychosocial factors, including low self-esteem and body dissatisfaction are more common among overweight than among non-overweight teens. A vast number of associations between overweight and psychosocial factors have already been identified, including a poorer self-perceived health status and an increased difficulty in making new friends. Furthermore, when compared with their non-obese peers, overweight adolescents tend to have significantly lower levels of emotional well-being measures. Both potential social isolation and lower levels of emotional well-being may be detrimental to an optimal healthy development of overweight teens.

There is further evidence that overweight youth engage more in weight-control behaviours, both healthy and unhealthy, than their non-overweight peers, with unhealthy weight-control behaviours increasing with perception of body-weight increase. Because most clinicians do not regularly screen for unhealthy weight-control behaviours unless the adolescent is underweight, there is an urgent need to raise their awareness that they need to routinely screen for unhealthy weight-control behaviours when taking care of overweight youth. The design of health-promotion strategies would also benefit from the inclusion of this awareness.

As to date, scarce attention has been paid in surveys to the adolescents who have been excluded from analysis because of missing values for BMI. We know now that these adolescents tend to have poorer body image, poorer health behaviours and poorer social networks. Therefore, a potential bias in the results of studies that do not account for missing BMI may be introduced.

Strategies to prevent adolescent obesity and overweight must take into account a deeper knowledge of psychosocial issues in order to be able to delineate more effective programmes for assessing and treating overweight teens.

140.2 Introduction

In this chapter, the authors focus on behavioural and social correlates of body mass index (BMI) corresponding to overweight and obesity (≥85th and 95th percentiles, respectively) among adolescents.

Obesity results from a chronic energy imbalance such that the rate of energy intake exceeds the rate of energy expenditure. Evidence seems to suggest that in the twentieth century, high-fat food intake has increased and that, at the same time, energy expenditure has declined due to increasingly sedentary lifestyles (Martinez-Gonzales et al. 1999). It is known that obesity is greatly environmentally influenced and that a sedentary lifestyle and sustained physical inactivity may be the main risk factors. Elevated television viewing has already been identified as an important promoting factor for obesity in children. Thus, changes in physical activity and sedentary behaviour seem critical to treating adolescent obesity (Barlow and Dietz 2007).

In 2005, the International Obesity Task force estimated that one out of five European children was overweight (EU Platform 2005). The prevalence of paediatric overweight and obesity increases from north to south with values varying from 10% to 20% in northern Europe to 20–35% in southern European countries.

The potentially serious physical and psychosocial consequences of overweight and obesity have made this condition one of the great contemporary public health issues (Strauss and Pollock 2001; Ebbelling et al. 2002; Lobstein et al. 2004).

The most widespread consequences of adolescent obesity are psychosocial. Adolescence is a very unique and highly individual period in life where important biological and cognitive changes take place. It has been considered a critical developmental period when adolescents are adjusting to

physical changes, establishing their personal identity, seeking greater independence and increasingly relying on peer groups.

Obesity in adolescence carries with it negative connotations leading to important psychosocial problems, in addition to the medical complications (Dietz 1998). Several studies have shown clearly that obese adolescents become targets of early and systematic discrimination and they are ranked lowest as those with whom their peers would like to become friends (Strauss and Pollock 2003, Fonseca and Matos 2005, Fonseca et al. 2009a). Furthermore, they are more prone to develop a negative self-image that appears to persist into adulthood, and low self-esteem (Stunkard 1967). Obese adolescents with decreased levels of self-esteem demonstrated significantly higher rates of sadness, loneliness and nervousness and were more likely to engage in high-risk behaviours such as smoking or alcohol consumption (Strauss 2000). Goodman (Goodman and Whitaker 2002) showed that depressed adolescents are at increased risk for the development and persistence of obesity during adolescence. Other studies also suggested a positive association between depression in adolescence and BMI during adulthood (Pine et al. 2001). However, the nature of the relationship between obesity and mental-health conditions remain unclear.

With the objective of better understanding adolescent obesity, some psychosocial and lifestyle indicators were empirically investigated by the authors using the Portuguese Health Behaviour in School-aged Children (HBSC) data set (Matos et al. 2000, 2003, 2006). The interesting findings may help to better understand overweight adolescents and to what extent they may differ from their peers.

HBSC is a WHO collaborative study started in 1982, now including 41 countries and regions across Europe and in North America (Currie et al. 2008). Data collection occurs every four years. The overall goal of the study is providing evolving information on the health and health-related behaviours of young people as well as their social contexts. In Portugal, data have already been collected three times, in 1998, 2002 and 2006 and included, respectively, 6,903, 6,131 and 4,877 students who were attending the sixth, eighth and tenth grade, corresponding to 11, 13 and 15 years of age, on average. Schools were randomly selected from a national roster of public schools, stratified by region (five Education Regional Divisions). The sampling unit used in this survey was the classroom. In each school, classes were randomly selected in order to meet the required number of students for each grade, which was proportional to the number of same grade mates for each specific region, according to the data provided by the Ministry of Education.

BMI was calculated based on self-reported weight (kg)/height (m^2) using the questions: "How much do you weigh without clothes?" and "How tall are you without shoes?" Adolescents were categorised according to their BMI, based on the standard definition for overweight and obesity and the IOTF-recommended cutoff criteria (Cole et al. 2000).

Measures were defined as has been described in a previous analysis using the HBSC/WHO international survey data. A complete picture of previous uses of the items, their psychometric properties, and measures' validation, can be found in the international study report (Currie et al. 2004).

140.3 Physical Activity and Dieting

According to the research conducted by the authors, obese adolescents were less physically active compared to the non-obese (Fonseca and Matos 2005). Concerning dieting, both females and older teens were revealed to be more likely than males and younger teens to report dieting for weight loss (Fonseca et al. 2009a). Previous studies have already shown dieting to be a more common behaviour among overweight compared with non-overweight adolescents. A large percentage of self-reported overweight (38.0%) and obese (23.1%) adolescents reported not being on a diet because their weight

was fine. Even more striking was the high percentage of non-overweight adolescents (62.5%) reporting being on a diet. There is reason for concern if non-overweight youth are attempting weight loss, as the initiation of frequent dieting is a known risk factor for disordered eating (Patton et al. 1990).

140.4 Body Image

The authors assessed body image using three items: (a) an item measuring *perception of body weight*: "Do you think your body is (1) much too thin, (2) a bit too thin, (3) about the right size, (4) a bit too fat or (5) much too fat?" and (b) a question assessing *other people's perceptions* about one's appearance. Response options included: "they make positive comments," "they make negative comments" and "they do not make comments at all"; and (c) a six-item scale question assessing *body satisfaction/attitude towards appearance*: "Do you think you are (1) very good looking, (2) quite good looking, (3) about average, (4) not very good looking, (5) not at all good looking or (6) don't think about my looks?" Body satisfaction/positive attitude towards appearance was considered when options (1), (2) or (3) were chosen, and body dissatisfaction was considered when options (4) or (5) were chosen.

Identification of perceived body image was used as an interval variable (1–7), with a maximum value meaning a maximum of overweight and a minimum value meaning extreme thinness (Figs. 140.1 and 140.2).

Both obese and overweight adolescents were significantly more likely to report a negative attitude towards appearance and overweight teens were also more likely to report a wish to change something in their bodies (Fonseca et al. 2009a).

BMI, age, involvement in dieting and evaluation of one's physical appearance were found to be key explainers of body image among these adolescents and good predictors of the way these teens view themselves. As we can see in Table 140.1, BMI, involvement in dieting and evaluation of appearance were positively associated, while age was negatively associated (Fonseca and Matos 2005), which alerts us to the need for an early intervention that considers the age differences regarding this topic.

It has already been shown that early onset of obesity has an adverse effect on body image in adult life, and it has been suggested that early onset of obesity increases the risk of body dissatisfaction,

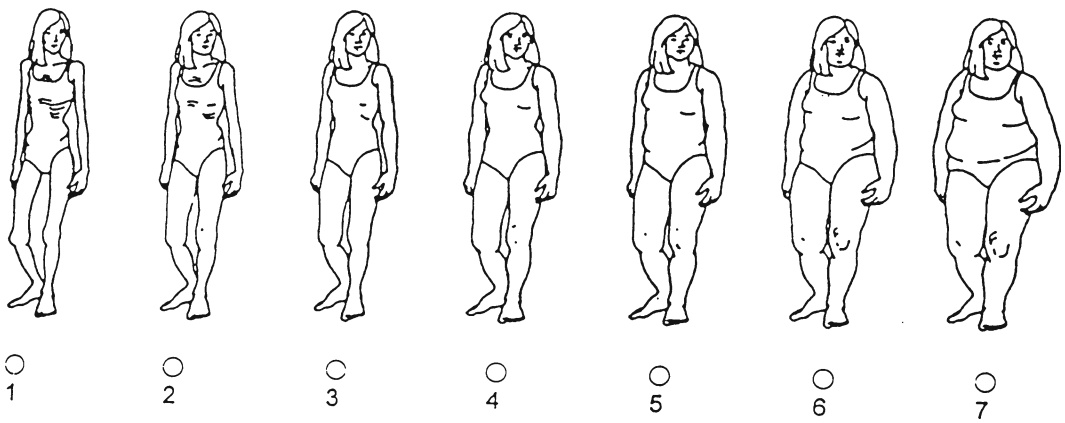

Fig. 140.1 Identification of perceived body image (females). Identification of perceived body image may be used as an interval variable (1–7), with a maximum value meaning a maximum of overweight and a minimum value meaning extreme thinness

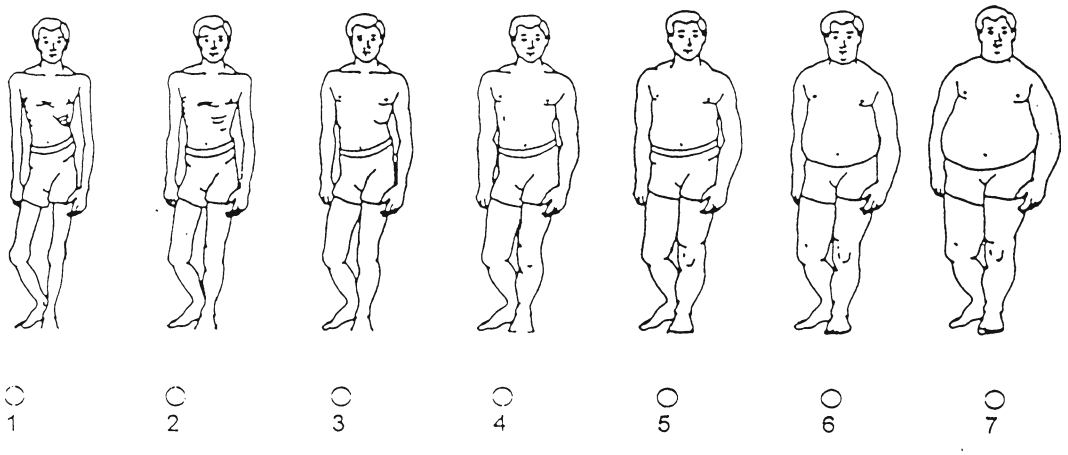

Fig. 140.2 Identification of perceived body image (males). Identification of perceived body image may be used as an interval variable (1–7), with a maximum value meaning a maximum of overweight and a minimum value meaning extreme thinness

Table 140.1 Perception of body image according to body silhouettes (multiple regression) (Reprinted from Fonseca et al. (2005), with permission)

	β	*t*	Significance
BMI	0.491	41.16	0.000
Gender	–0.019	–1.629	0.103 (NS)
Age	–0.413	–34.94	0.000
Physical appearance	0.032	2.718	0.007
Diet behaviour	0.110	9.40	0.000
Constant		32.04	0.000
			$r^2 = 0.349$

BMI, age, involvement in dieting and evaluation of one's physical appearance were found to be key explainers of body image among these adolescents, and good predictors of the way these teens see themselves. BMI, involvement in dieting and evaluation of appearance were positively associated, while age was negatively associated
NS not significant

which in turn impairs self-esteem (Wardle et al. 2002). It has also been shown that a higher BMI is associated with higher body-image dissatisfaction among adolescents, which may impact their psychosocial development in a negative way. The increased risk of body dissatisfaction among obese adolescents suggests another area of investigation into protective factors against overweight and obesity. These results also suggest that strategies to prevent adolescent obesity and overweight must take into account a deeper knowledge of psychosocial issues in order to be able to delineate more effective programmes for assessing and treating overweight teens.

140.5 Association with Psychosocial Factors

A vast number of associations between overweight and psychosocial factors have been identified, including a poorer self-perceived health status (Fonseca and Matos 2005).

Furthermore, when compared with their non-obese peers, overweight adolescents tended to have significantly lower levels of emotional well-being measures, reporting irritability and feeling nervous, more frequently (Fonseca et al. 2009a).

Both potential social isolation and lower levels of emotional well-being may be detrimental to an optimal healthy development of overweight teens.

Overweight adolescents further tended to report more difficulty in making new friends compared to their non-overweight peers (Fonseca et al. 2009a). Being attached to and accepted by the peer group is crucial to young people's development, and those who are not socially integrated are far more likely to exhibit difficulties with their physical and emotional health. Interaction with friends tends to improve social skills and strengthen the ability to cope with stressful events. On the contrary, isolation from peers can lead to feelings of loneliness and poorer emotional health. Interestingly, connection with friends has already been reported as being a protective factor against extreme weight-control behaviours among boys (Fonseca et al. 2002).

In summary, there is evidence that a variety of adverse psychosocial factors, including low self-esteem, body dissatisfaction and depressive symptoms are more common among overweight than among non-overweight teens.

140.6 Quality of Life and Life Satisfaction

To be overweight may represent a major psychosocial burden for an adolescent. Social stigma and marginalisation may, in fact, be a substantial challenge to their social and emotional well-being. A study of obese children and adolescents showed lower health-related quality of life compared with young people of a similar age who had cancer (Schwimmer et al. 2003) and was able to determine the large negative impact this chronic health condition may have on the adolescent.

One possible way of assessing life satisfaction is through the measurement technique known as the *Cantril ladder* with ten steps: the top of the ladder indicates the best possible life and the bottom the worst possible life (Cantril 1965). Adolescents who entered in the HBSC study were asked to indicate the step of the ladder at which they would place their lives at the moment (Fig. 140.3), by answering the question: "Here is the picture of a ladder: The top of the ladder '10' is the best possible life for you, and the bottom '0' is the worst possible life for you. In general, where on the ladder do you feel you stand at the moment?" Life satisfaction revealed to be higher among boys, decreased with progression in age and is lower among adolescents with a higher BMI.

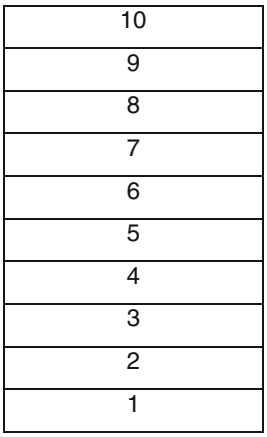

Fig. 140.3 Life satisfaction. Adolescents can be asked to indicate the step of a ladder at which they would place their lives at the moment (the *top* of the ladder indicates the best possible life and the *bottom*, the worst possible life). Overweight and obese adolescents tend to place themselves on a lower step compared with their non-overweight peers

140.7 The Concept of Obesity as a Chronic Condition

Growing evidence suggests that adolescents with chronic conditions other than obesity are likely to engage in risky behaviours to at least similar, if not higher rates, as their healthy peers (Sawyer et al. 2007), and alcohol has been recognised as the substance most frequently used by young people with a variety of chronic conditions, with little variation by diagnosis.

Many papers have been published about specific psychosocial factors associated with obesity in young people. Higher rates of health-risk behaviours, including smoking, among adolescents who diet (whether obese or not) have been reported by some authors. It has also been shown that overweight adolescents are more likely to engage in unhealthy behaviours, such as chronic dieting and binge eating.

Weekly drinking increases substantially in the general population between ages 13 and 15, and alcohol has already been recognised as the substance most frequently used by young people with a variety of chronic conditions. The exposure of obese adolescents to alcohol-consumption patterns associated with heightened risk of injury was studied by the authors who, based on the results of their research, have developed the concepts of the existing literature and propose that obesity is similar to other chronic conditions of adolescence, especially related to alcohol use and abuse (Fonseca et al. 2009a).

In the HBSC survey, alcohol use was assessed by the question: "How many times a week do you usually drink any alcoholic drink?" Response options included: "never," "less than once a week," "once a week," "2–4 days a week," "5–6 days a week," "once a day," "everyday" or "everyday, more than once," while alcohol abuse was assessed with the question: "Have you ever had so much alcohol that you were really drunk?" Response options included: "no, never," "yes, once," "yes, 2–3 times," "yes, 4–10 times" or "yes, more than 10 times."

Obese adolescents reported more regular drinking (drinking alcohol every day more than once) than their non-overweight peers (3.6% vs. 1.2%). They also reported having got drunk more than 10 times, significantly more often than non-obese teens (5.3% vs 2.4%) (Fonseca et al. 2009a).

140.8 Association with Unhealthy Weight-Control Behaviours

Recently, there has been growing attention in the literature to the tendency of different weight-related behaviours and disorders to simultaneously co-occur in the same individuals. Significantly higher percentages of overweight youth have been described to engage in binge eating and unhealthy weight-control behaviours than non-overweight youth (Neumark-Sztainer et al. 2002). Excessive weight-related concerns and behaviours have potentially serious consequences for adolescents in their impact on dietary intake, physical growth and psychosocial development and the development of disordered eating. Strong correlates of disordered eating have been found, including overweight status, low self-esteem, depression, suicidal ideation and substance use.

Concerns with weight, body shape and dieting with the purpose of losing weight are common among adolescents and have been suggested as risk factors for eating disorders. Although weight concerns are less common among males, these concerns are becoming more prevalent. Internalisation of the thin-ideal body image for girls in Western culture results in dissatisfaction with weight and shape, because the ideal body shape and weight are unattainable for most women. According to Stice's theory (Stice et al. 1996), one should expect overweight females to be more dissatisfied with their weight because they are far away from the ideal weight and shape. Thus, it is not surprising that several cross-sectional studies have reported a positive association between weight and engagement in bulimic behaviours. Moreover, family, peer and media pressures to be thin also increase or sustain

Table 140.2 Examples of healthy and unhealthy weight-control behaviours

Healthy weight-control behaviours	Unhealthy weight-control behaviours
Drink more water	Vomiting
Eat less sweets	Laxative use
Eat more fruits/vegetables	Diet pills/teas use
Drink less soft drinks	Smoking more cigarettes
Exercise more	Fasting/skipping meals

The different types of weight-control behaviours tend to present at different degrees, and some of them may be/become extreme

body dissatisfaction by repeatedly reminding women how far away they are from the ideal shape and weight. However, the development of eating disorders is even more complex and is believed to be related to personal factors, family and peer influences and sociocultural pressures.

Weight-control strategies may range from healthy behaviours, such as moderate dieting and exercise, to potentially harmful behaviours, such as vomiting, laxative or diet-pill use and skipping meals (Table 140.2). Correlates of unhealthy weight-control behaviours have been assessed using the Portuguese HBSC Portuguese data set (Fonseca et al. 2009b). The authors found that overweight youth and females engaged more in weight-control behaviours, both healthy and unhealthy than respectively their non-overweight peers and males. Moreover, UNWCB seemed to increase with perception of body-weight increase (Fonseca et al. 2009b).

The gender difference that was found may be understood because of the earlier growth spurt in females and the subsequent increase in percentage of body fat. Another possible explanation is the increased burden put on a girl's body image by society, which may lead to an increased concern about this topic. UNWCBs were also more prevalent among younger youth (13-year olds). Because the question regarding weight-control behaviour was not asked to the sixth graders (11-year-olds), the authors wonder whether they might start even earlier. It would be of interest to further investigate at what age UNWCBs tend to start.

Concrete thinking is still the dominant way of thinking during the first years of adolescence with important implications in behavioural competences. This may explain a higher involvement of younger youth in UNWCB, in an attempt to achieve a faster and more effective control of their weight.

It is well acknowledged that unhealthy weight-control behaviours are unlikely to be effective in weight control and may even inadvertently place youth at risk for further weight gain. Should overweight younger girls be targeted as a specific high-risk group for unhealthy weight-control behaviours? We envisage early adolescence as a window of opportunity for prevention in this regard.

In addition, UNWCBs were significantly higher among those who were dieting and among those who, although not being on a diet, considered they should be. It has already been shown from longitudinal research that the relative risk for dieters to develop an eating disorder is significantly higher than that for non-dieters after a 1-year period (Patton et al. 1990). The association found by the authors between dieting and UNWCB points in the same direction and may have important implications in clinical practice.

Alcohol and drug use have already been described as directly and significantly associated with disordered eating. The authors have further found in their research that UNWCBs were more prevalent among those reporting drinking everyday (Fonseca et al. 2009b). This correlation is understandable as risk factors tend to cluster. As far as we are aware of, a possible interaction between alcohol abuse and UNWCB had not been described in the literature so far. The implications of this potential interaction are huge for clinical practice: adolescents who are referred for alcohol abuse should start being screened for UNWCB and vice versa. The significant positive correlation found between healthy and unhealthy weight-control behaviours suggests that, when young people engage in weight-control behaviours, they try by all their means every kind of strategy, either healthy or

unhealthy. This knowledge may contribute to increase parents' and teachers' awareness for prompt identification of this kind of practices and adequate referral.

Obesity is a large public-health problem in adolescence; thus, a relatively large proportion of youth may be at risk for developing weight concerns and unhealthy weight-control behaviours. Unfortunately, most paediatricians do not regularly screen for unhealthy weight-control behaviours unless the adolescent is underweight. These findings support the need to raise awareness among clinicians that unhealthy weight-control behaviours are a quite common weight-control strategy. Because they are associated with both medical and psychological health risks, routine screening is warranted. Special attention needs to be directed towards youth at greatest risk for disordered eating, including overweight youth.

140.9 Gender Differences

Usually, females are more likely than males to report dieting for weight loss. Females also seem at increased risk regarding higher body dissatisfaction and lower satisfaction with life. Moreover, more weight-control behaviours, both healthy and unhealthy, have been described among females than among males. A better understanding of gender determinants of obesity may inform its prevention and treatment.

140.10 Methodological Considerations

Measuring health through self-reporting on a questionnaire such as HBSC has both strengths and limitations. Among the strengths, one should mention the fact of being standard, enabling comparisons between individuals and countries, noninvasive and ensuring anonymity. However, it limits the depth and coverage of measurements, as compared with qualitative methods. The cross-sectional nature of the study design does not enable us to draw conclusions about the direction of causality between overweight and obesity and the identified associated adverse psychosocial factors. Whether factors such as low self-esteem, poor body image, or even depression lead to obesity or whether obesity causes them, remains unclear. A third limitation is the high percentage (10.8%) of missing BMI values, which may introduce a potential bias. Associations between missing BMI values and a range of demographic, body image and emotional well-being variables have been studied that suggest that those subjects with missing values for BMI tend to have a poorer body image, poorer health behaviours and poorer social networks (Fonseca et al. 2009c). Missing values for BMI were significantly predicted by a younger age, sedentary lifestyle, having a poor body-satisfaction assessment, paternal absence, lack of friends of the opposite sex and poor perception of academic achievement. Implications for potential bias in the results of studies that do not account for missing BMI should be taken into account.

In most studies, pubertal indicators also lack not allowing to adjust for the timing of maturation. Adjustment for the timing of maturation is important, because overweight status in girls is strongly associated with earlier maturation while, for boys, early maturation is associated with a low BMI. Finally, the findings are based entirely on adolescents' self-reports and self-perceptions and biases. Although BMI is considered a reasonable measure with which to assess fatness in children and adolescents, once, subjective indicators of weight and height are used to obtain a BMI score biases in perception and reporting cannot be ruled out. Some authors have suggested that self-report could lead to a fairly good BMI rating, slightly underestimating the proportion of overweight adolescents, while others have questioned the reliability of this procedure.

140.11 Implications and Future Directions

Some of the adverse psychosocial factors that have been discussed throughout this chapter may help us to be more aware of the specific well-being concerns and behaviours among overweight youth. More consistent and comprehensive monitoring of health status, including life satisfaction, mental health and risk-taking behaviours would provide stronger evidence for clinical and preventive efforts that aim to mediate the effect of obesity on the lives of adolescents. The fact that overweight and obesity in adolescence appears to be associated with decreased life satisfaction should inform paediatricians and healthcare planners about intervention strategies and priorities.

A deeper understanding of the social aspects of growing up and becoming an adult being overweight is needed. How does the experience of being overweight as a teen impact one's capacity of engaging in age-appropriate social networks? Are efforts to develop a robust personal identity affected by the fact of being obese? Qualitative studies may help providing some insight into these important questions.

Since most obese adolescents remain obese as adults, this age group is a very important group to reach through preventive programmes addressing issues of health promotion, including body satisfaction, sociability, diet and sedentary lifestyles. One of the implications of this knowledge is the need for early identification, assessment and management of adolescents who exceed a healthy weight for height, gender and age, which would enable healthcare practitioners to start prevention and management of adolescent overweight and obesity earlier, thus decreasing the potential for associated medical and psychosocial problems.

Obesity prevention and treatment efforts might benefit from addressing the broad spectrum of the psychosocial implications of being overweight as a teen, enhancing skill development for behavioural change and providing support for dealing with potentially harmful behaviours, including exposure to alcohol consumption. A better understanding of determinants of obesity may further inform its prevention and treatment.

Health-promotion strategies should be able to enhance the capacity of overweight youth to negotiate the social demands of adolescence.

Summary Points

- Obesity in adolescence carries with it negative connotations leading to important psychosocial problems, in addition to the medical complications.
- A higher BMI is associated with higher body-image dissatisfaction among adolescents, which may impact their psychosocial development in a negative way.
- Overweight adolescents become targets of early and systematic discrimination, being more prone to develop a negative self-image and a low self-esteem.
- A vast number of associations between overweight and psychosocial factors have been identified, including an increased difficulty in making new friends and a poorer self-perceived health status.
- Furthermore, obese adolescents are at greatest risk for disordered eating. Because unhealthy weight-control behaviours are associated with important medical and psychological health risks, the clinician who cares for obese adolescents should routinely screen for unhealthy weight-control behaviours.
- As to date, scarce attention has been paid in surveys to those who are excluded from analysis because of missing values for BMI. Those who do not report their weight and/or height tend to have a poorer body image, poorer health behaviours and poorer social networks.

- Prevention and management of adolescent overweight and obesity should start earlier, thus decreasing the potential for associated medical and psychosocial problems.
- It is necessary to develop health-promotion strategies that enhance the capacity of overweight youth to negotiate the social demands of adolescence.

Chapter 141
Body Composition Studies in Critical Illness

Lindsay D. Plank

Abstract The systemic inflammatory response which is common to critically ill patients with major traumatic injury or severe sepsis precipitates a metabolic response which leads to rapid and marked derangements in body composition. Our laboratory, designed to measure total body protein (TBP), total body fat (TBF), total body and extracellular water (TBW and ECW), and total body potassium (TBK) in these patients while under the care of the intensive care unit (ICU), has characterized these derangements over a 3-week period from soon after admission to the ICU. Of the 33 patients studied, 21 were admitted to the ICU with blunt injury and 12 with peritonitis secondary to perforation of an abdominal viscus. Body composition assessments were carried out using in vivo neutron activation analysis, dual-energy X-ray absorptiometry, tritium and bromide dilution, and whole-body counting as soon as patients were haemodynamically stable. These measurements were repeated at regular intervals for 21 days. Massive TBP loss occurred which was derived principally from proteolysis of skeletal muscle in the early catabolic phase with later contribution from visceral organs. An aggressive approach to nutritional support of these patients ensured that TBF was unchanged over the course of the study. Trauma patients had retained >6 L and sepsis patients >12 L of resuscitative fluids, mainly in the extracellular compartment, by the time they were haemodynamically stable. After this time diuresis occurred, but in elderly patients (>60 years) the period of ECW expansion was markedly prolonged compared to younger patients (<40 years). The time course of changes in TBK, a measure of the cellular mass of the body, followed a very similar profile to that of TBP. The catabolic features of trauma and sepsis were very similar reflecting the impact of a systemic inflammatory response which is initiated by quite different insults.

141.1 Introduction

Critically ill patients in intensive care present formidable problems for the investigator interested in quantifying the body compositional changes associated with severe illness. All the standard methods for body composition measurement must be re-evaluated in view of the extreme compositional abnormalities seen in these patients. Since the early work of Cuthbertson (1945) it has been recognized that the metabolic sequelae of critical illness include massive erosion of body protein stores, expansion of the body water space, and consumption of body fat stores. Cuthbertson's work more than 60 years ago focused on injured patients and he showed that in the early phase after their injury these patients were in a hyperdynamic state, consuming protein and fat stores at a high rate, and conserving water and salt. This response is characteristic also of the patient admitted to the intensive care unit (ICU) with a severe infection. Indeed, patients surviving resuscitation after major trauma remain at risk of progressive organ failure and death from what appears to be an uncontrolled inflammatory process. This systemic inflammatory response is as if the patient is infected yet a septic cause is usually not identifiable. The term *systemic inflammatory response syndrome* (SIRS) was proposed by the expert consensus conference of the American College of Chest Physicians and the Society of Critical Care Medicine (Bone et al. 1992) to describe this generalized inflammatory process. This consensus meeting provided definitions of *SIRS*, *sepsis*, *severe sepsis*, and *septic shock* which have been widely accepted as they standardized terminology which previously lacked precise definition (Table 141.1). These conditions can be considered to form a continuum associated with increasing mortality, typically of the order of 50% for septic shock (Rangel-Frausto et al. 1995).

A number of scoring systems have been developed which grade the severity of critical illness and provide prognostic information. The *Acute Physiology and Chronic Health Evaluation* (APACHE) II score (Knaus et al. 1985) and its sequel APACHE III (Knaus et al. 1991) are most commonly utilized and take into account current biochemical and physiologic indices as well as age and co-morbidity. APACHE II scores, which are calculated within the first 24 h of admission, may range from 0 to 71 with higher scores indicating more severe disease and higher risk of death. For patients with traumatic injury the *Injury Severity Score* (ISS) (Baker et al. 1974) grades each injury, allocated to one of six body regions, on a scale of 1–5 (5 being life-threatening) and sums the highest scores (squared) for the three most severely injured body regions. Hence, ISS may range from 0 to 75.

Our studies of critically ill patients admitted to intensive care have enrolled patients with major trauma or severe sepsis.

Table 141.1 Key features of critical illness: trauma and sepsis

1. Characterized by a systemic inflammatory response or presence of systemic inflammatory response syndrome (SIRS)
2. SIRS describes an abnormal host response characterized by a generalized activation of the inflammatory reaction in organs remote from the initial insult
3. *SIRS* is manifested by two or more of the following:
   Temperature > 38°C or <36°C
   Heart rate > 90 beats/min
   Respiratory rate > 20 breaths/min
   White blood cell count > 12.0×10^9/L, <4.0×10^9/L, or > 10% immature forms (bands)
4. *Sepsis* denotes SIRS plus a documented infection (positive culture for organism)
5. *Severe sepsis* denotes sepsis associated with organ dysfunction, hypoperfusion abnormalities (e.g., lactic acidosis, oliguria, or an acute alteration in mental status), or hypotension
6. *Septic shock* denotes sepsis with hypotension, despite adequate fluid resuscitation, plus hypoperfusion abnormalities
7. *Multiple organ dysfunction syndrome* develops as the extreme manifestation of SIRS and is a consequence of the host response
8. These conditions form a hierarchical continuum associated with progressively higher mortality

This table lists key facts relating to critically ill patients with trauma or sepsis including useful definitions

141.2 A Body Composition Laboratory for Studies in Critical Illness

Since the early 1980s we have maintained a body composition facility designed for critically ill patients which is located within a short distance of the ICU. In this laboratory a compartmental analysis of the body is undertaken in which total body protein (TBP), total body fat (TBF), and total body water (TBW) are measured. TBP is further subdivided into skeletal muscle protein and visceral protein. TBW is also subdivided into extracellular water (ECW) and intracellular water. An estimate of cellular mass of the body is obtained by measurement of total body potassium (TBK). A hoist weighing system consisting of an electrically operated block and tackle attached to a load cell and to a frame that supports a canvas sheet on which the patient lies is used to transfer the patient from the bed to the scanning machines and the body weight is measured during the transfer. These measurements can be performed on patients soon after their admission to the ICU, once they reach haemodynamic stability at which time requirements for inotropic support have stabilized.

141.2.1 Total Body Protein

TBP is measured using prompt-gamma in vivo neutron activation analysis (IVNAA). A whole-body scanning technique is used where the patient is passed through two opposed neutron fields generated by ^{238}Pu/Be sources placed above and below the patient (Mitra et al. 1993). Gamma rays produced from the interaction of neutrons with nitrogen nuclei in the patient are detected using bilaterally placed sodium iodide crystals and suitable calibration allows estimation of total body nitrogen. TBP is calculated from total body nitrogen, by multiplying by 6.25 using the fact that nitrogen in the body is almost exclusively confined to protein at a mean level of 16%. Precision of 2.5% for TBP is achievable with this approach when dual scans of approximately 30 min each (depending on patient height) are used. We have assessed accuracy by scanning anthropomorphic phantoms composed of mincemeat and lard

Table 141.2 Accuracy and precision of the measurement of TBP in association with massive fluid overload

		Mass of protein by IVNAA (g)			
Mass of mincemeat phantom (kg)	Mass of protein by chemical analysis (g)	Normal hydration	Moderate fluid overload	Severe fluid overload	ANOVA[b]
43[b]	5,918 ± 126[c]	6,036 ± 54	6,017 ± 65	6,163±51	ns
		3.4% (2.1–4.8)[d]	4.2% (2.5–5.8)	3.4% (2.1–4.8)	
62[e]	8,624 ± 177	8,552 ± 65	8,640 ± 66	8,597±87	ns
		3.4% (2.3–4.6)	3.4% (2.3–4.5)	4.5% (3.0–6.1)	
75	10,348 ± 211	9,977 ± 80	10,176 ± 87	10,217±73	ns
		3.1% (1.9–4.4)	3.3% (2.0–4.6)	2.7% (1.6–3.8)	
87	11,744 ± 253	11,530 ± 106	11,382 ± 79	11,521±116	ns
		3.6% (2.1–5.0)	2.7% (1.6–3.8)	3.9% (2.3–5.5)	

Results are shown for mass of TBP measured by in vivo neutron activation analysis (IVNAA) and compared with chemical analysis in anthropomorphic phantoms prepared from mincemeat with and without additional fluid (Hill et al. 1993, Table 2, p. 8, Copyright © (1993) Springer, Heidelberg. With permission)

[e]This phantom received 20 IVNAA scans at each degree of hydration

with and without additional fluid to simulate the conditions that pertain in the patient situation. These phantoms contained a skeleton prepared from calcium phosphate. Each phantom was scanned 15 times in its entirety over approximately 2,000 s to give total counts of nitrogen. Administration of 3–6 L of physiological saline (depending on phantom size) provided moderate overhydration and 6–12 L, severe fluid overload. The results of this simulation (Table 141.2) indicate that accuracy of within 4%, compared to chemical analysis, was obtained and this was not compromised by high levels of fluid overload. Precision of between 2.7% and 4.5% was obtained, depending on phantom size.

141.2.2 Total Body Fat

A whole-body dual-energy X-ray absorptiometer (GE-Lunar model DPX+, Lunar Radiation Corporation, Madison, WI) is used to measure TBF. This technology partitions the body into TBF, fat-free soft tissue, and bone mineral. A fundamental assumption is that the soft tissue is normally hydrated (Pietrobelli et al. 1998) and the massive fluid changes experienced by the typical ICU patient may compromise the validity of the TBF measurements. We have assessed accuracy using the mincemeat and lard anthropomorphic phantoms of known fat content (measured by chemical analysis) and with different levels of over hydration (Table 141.3). It can be seen from the Table that precision for TBF was excellent (around 1.3%) while increasing degrees of fluid overload resulted in increased measured TBF. These increases do not exceed 2.5%. Increasing fluid overload is associated with reduction in the fat fraction to the extent predicted for normal saline by Pietrobelli et al. (1998).

141.2.3 Total Body Water

TBW is obtained by dilution of tritium-labeled water. However, it should be recognized that TBW measurements in critically ill patients are more difficult to obtain than in normal subjects or even the vast majority of sick patients. The fluid accumulation characteristic of ICU patients often includes

Table 141.3 Accuracy and precision of the measurement of TBF in association with massive fluid overload

		Mass of fat by DXA[a] (g)			
Mass of mincemeat phantom (kg)	Mass of fat by chemical analysis (g)	Normal hydration	Moderate fluid overload	Severe fluid overload	ANOVA[b]
43	11262 ± 97[c]	9805 ± 32	10184 ± 49	10125 ± 34	p<0.0001
		1.3% (0.8–1.8)[d]	1.9% (1.2–2.6)	1.3% (0.8–1.8)	
62[e]	16411 ± 140	14641 ± 36	14798 ± 37	15005 ± 36	p<0.0001
		1.1% (0.7–1.5)	1.1% (0.7–1.5)	1.1% (0.7–1.5)	
75	19691 ± 168	19518 ± 67	19777 ± 75	19926 ± 84	p<0.002
		1.3% (0.8–1.8)	1.2% (0.6–1.8)	1.6% (1.0–2.2)	

Results are shown for mass of TBF measured by dual-energy X-ray absorptiometry (DXA) and compared with chemical analysis in anthropomorphic phantoms prepared from mincemeat with and without additional fluid (Hill et al. 1993, Table 3, p. 9, Copyright © (1993) Springer, Heidelberg, with permission)

[e]This phantom received 20 DXA scans at each degree of hydration

collections of free fluid within body cavities (ascites, pleural effusions, intraluminal gut fluid, etc.) where mixing of isotope via the circulation is slow. Under these circumstances the period of isotope equilibration can be expected to be variably prolonged from the 2 to 3 h period sufficient in normally hydrated individuals. There may be loss of isotope in urine, nasogastric aspirates, and from fluid via surgical drains during this period of equilibration. In addition, the patients are all receiving IV fluids at moderate infusion rates. These fluids cannot be withheld over the period of isotope equilibration and by virtue of their non-instantaneous mixing with body water lead to a dilution effect in plasma water. Finally, the TBW itself may be changing during the period of isotope equilibration due to imbalance between gains and losses. Streat et al. (1985) addressed these issues and showed that after a 4-h equilibration time the volume of distribution was essentially constant after due consideration was taken of all losses and gains. By sampling of blood at 4, 5, and 6 h after injection of 3.7 MBq of tritiated water a measurement precision of 0.9% was achievable. A correction of 4% for non-aqueous hydrogen exchange is generally applied to the tritium dilution space in order to derive TBW. In the ICU situation, given the often quite massive fluid overload, it is likely that this correction is less than 4% and no correction was applied by Streat et al. (1985).

141.2.4 Extracellular and Intracellular Water

ECW is estimated by the dilution of sodium bromide provided as an intravenous injection of 50 mL of 5% solution. Bromide is distributed very similarly to chloride in the body (Wallace and Brodie 1939) and the "bromide space" is widely used as a measure of ECW volume. The advent of high-performance liquid chromatography as a very sensitive technique for assaying stable bromide (Miller et al. 1989) has effectively eliminated the need to use the radionuclide ^{82}Br which has an inconveniently short half-life (36 h). Bromide is known to penetrate some tissue cells, especially erythrocytes (Edelman and Leibman 1959; Pierson et al. 1978) and a correction needs to be applied for this. ECW can be determined using the formula (Bell et al. 1984):

$$\mathrm{ECW} = 0.90 \cdot 0.95 \cdot \mathrm{Br\ dose} / [\mathrm{Br}]_s$$

where 0.90 is the correction factor for intracellular penetration, 0.95 is the Donnan equilibrium factor for univalent anions, and $[Br]_s$ is the bromide concentration in protein-free serum ultrafiltrate after correction for the basal concentration. As for TBW estimation, equilibration appears to be complete after 4 h. However, it should be noted that a measurable increase in the bromide space beyond a rapid equilibration phase lasting a few hours may occur because of slow permeation of bromide into the CSF particularly (Moore et al. 1968; Pierson et al. 1978). ECW at the time of injection is calculated from the mean of three values derived from 4, 5, and 6 h serum samples by a manner exactly analogous to the method used for TBW. In trauma patients studied by Monk et al. (1996), the overall mean precision for the measurement of ECW varied from 6.9% when a single sample was taken to 4.0% when three samples were taken.

141.2.5 Skeletal Muscle Mass

Regional analysis of the whole-body DXA scanning images is used to estimate appendicular skeletal muscle mass using the method of Heymsfield et al. (1990). In this approach, the fat-free mass (FFM) of the limbs less the mass of wet bone of the limbs (1.82 × appendicular bone mineral content) is assumed to approximate limb skeletal muscle mass. Application of the method to critically ill patients requires a correction to the measured FFM (see below) to account for the deviation from normal hydration of lean tissue commonly seen in these patients. Total skeletal muscle mass is calculated from appendicular muscle mass by multiplying by 1.26, a factor established from the CT scanning of normal subjects (Wang et al. 1996). Protein content of total skeletal muscle is assumed to be 17% (Snyder et al. 1975).

141.2.6 Visceral Mass

Visceral tissue mass is derived from hydration-corrected whole-body FFM (see below) by subtracting the masses of wet bone and total skeletal muscle. The protein content of the visceral compartment is derived from TBP by subtracting the protein in skeletal muscle and the protein content of wet bone. The latter is assumed to be 26% of wet bone mass (Snyder et al. 1975).

141.2.7 Derivation of Hydration-Corrected Fat-Free Mass

Measured FFM (i.e., body weight – TBF) is composed of normally hydrated FFM (FFMn) plus additional fluid such that:

$$\mathrm{FFM} = \mathrm{FFMn} + \mathrm{TBW} - \mathrm{TBWn}$$

where TBW - TBWn represents the deviation of measured TBW from the water that accompanies FFMn. Rearranging this equation:

$$\mathrm{FFMn} = \mathrm{FFM}(1 - \mathrm{TBW}/\mathrm{FFM}) / (1 - \mathrm{TBWn}/\mathrm{FFMn})$$

where TBWn/FFMn is the ratio of TBW to FFM in healthy subjects, found to equal 0.73 in 176 healthy volunteers measured in our laboratory using the techniques described above. An analogous equation applies for hydration adjustment of the FFM of the limbs provided the measured whole-body hydration (TBW/FFM) applies also to the appendicular FFM.

141.2.8 Total Body Potassium

TBK is measured by analysis of the gamma spectrum emitted from naturally occurring K^{40} using a shadow shield counter (Beddoe and Zuidmeer 1986). This radioisotope, which is present in constant proportion (0.012%) in all natural potassium, emits penetrating gamma rays (1.46 MeV) which can be measured by radiation detectors placed around the body. With suitable calibration, the total mass of potassium can be estimated from the measured intensity of the emitted gamma radiation. Precision of better than 3% for this measurement in adults is possible with counting times of 15–30 min providing adequate shielding is provided to reduce natural background radiation levels (cosmic rays and radioactive contaminants in construction materials). Given that TBK is almost wholly (>97%) intracellular, changes in this quantity will tend to reflect changes in cellular mass. The relationship between TBK and body cell mass (BCM) can be determined based on the original assumptions of Moore et al. (1963). By assuming an average ratio for the intracellular K to intracellular N of 3 mmol K/g N and that one quarter of wet cell weight is protein, the BCM can be derived from TBK as follows:

$$\begin{aligned} \text{BCM} &= 6.25 \cdot 4 \cdot \text{TBK} / 3 \\ &= \text{TBK} \cdot 8.33 \end{aligned}$$

where no correction is made for extracellular potassium. However, the quantification of the BCM is dependent on the assumptions that it has an average K:N ratio of 3 in all states of sickness and health and that protein comprises 25% of cell mass even in intensive care patients. In the latter situation the model assumed above is unlikely to hold and it is preferable to assess changes in BCM by monitoring TBK directly.

141.3 Sequential Changes in Body Composition in Critically Ill Patients

We have conducted longitudinal studies of the changes in body composition that occur in critically ill patients with major trauma or severe sepsis. Patients were recruited for these studies soon after admission to the ICU and informed consent was obtained from the patient or, more usually, from their next of kin. As soon as they were haemodynamically stable (day 0), patients were transported to the laboratory for body composition measurements which were repeated 5, 10 and 21 days later. Major trauma patients were also measured on day 15. The criteria for the diagnosis of severe sepsis were those of the American College of Chest Physicians/ Society of Critical Care Medicine (ACCP/SCCM) consensus statement (Bone et al. 1992). Patients admitted to the ICU with major blunt trauma and an ISS ≥16 were eligible for the study. Twelve patients with generalized peritonitis secondary to perforation of an abdominal viscus completed the protocol. All underwent urgent surgery and were then treated in the ICU. Clinical details are given in Table 141.4. Complete clinical data and results of this study have been published elsewhere (Plank et al. 1998, 2000). Two of the 12 patients died (on postoperative days 24 and 28) but the other 10 survived and left hospital in a median time of 29.5 days. The median time from enrolment to the first body composition scan was 2 days (range 1-4 days). Twenty-one patients admitted to our ICU with major trauma completed the protocol. Eighteen sustained a major blunt head injury and three suffered blunt abdominal trauma. Clinical details are given in Table 141.4. The median time from enrolment to the first body composition scan was 3 days (range 0-5 days). Seven of the 21 patients developed septic complications while in the ICU.

Table 141.4 Characteristics of trauma and sepsis patients

	Trauma	Sepsis
Male/female	18/3	6/6
Age (year)	21 (16–70)	67 (25–76)
ISS	34 (16–59)	
APACHE II		21.5 (12–34)
Days on ventilator	6 (0–24)	9 (2–24)
Intensive care stay (days)	9 (2–26)	13 (3–29)
Hospital stay (days)	35 (12–78)	29.5 (12–120)

Results are medians (range). ISS: injury severity score, APACHE: acute physiology and chronic health evaluation

Demographic and clinical data of 21 patients with major blunt trauma and 12 patients with severe sepsis (With kind permission from Springer Science+Business Media: Sequential metabolic changes following induction of systemic inflammatory response in patients with severe sepsis or major blunt trauma, p. 631, Plank and Hill (2000), Table 1, © 2000 by the Société Internationale de Chirurgie)

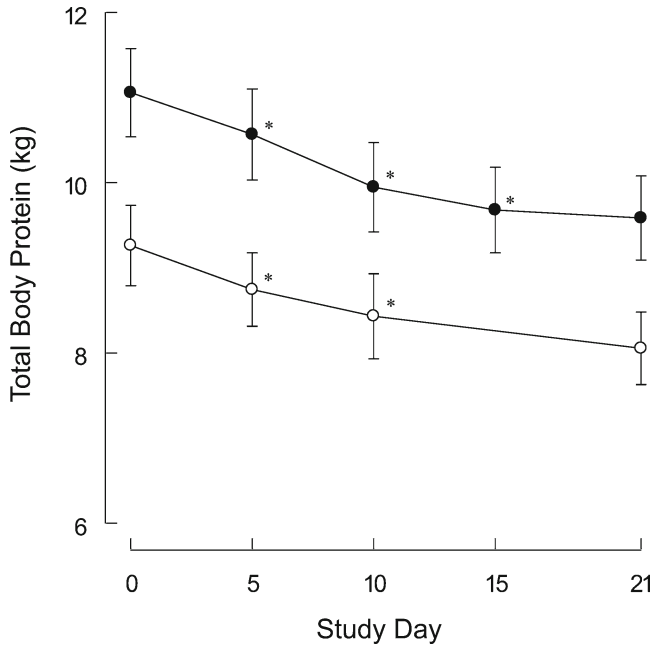

Fig. 141.1 Sequential measurements of total body protein (TBP) in trauma and sepsis. Total body protein in 21 patients with major trauma (*closed circles*) and 12 patients with severe sepsis (*open circles*) measured over a 21-day period after onset of illness (mean ± SEM). In both groups, 13% of the initial body protein was lost over the study period. * = a significant ($p < 0.05$) change from preceding measurement (With kind permission from Springer Science+Business Media: Sequential metabolic changes following induction of systemic inflammatory response in patients with severe sepsis or major blunt trauma, p. 631, Plank and Hill (2000), Fig. 1, ©2000 by the Société Internationale de Chirurgie)

141.3.1 Total Body Protein Changes

The trauma patients were younger and heavier than the sepsis patients and their absolute body protein stores higher**.** Total protein lost over the 21-day study period averaged 1.47 ± 0.20 (SEM) kg in the trauma patients ($p < 0.0001$) and 1.21 ± 0.13 kg in the sepsis patients ($p < 0.0001$) which for both groups amounted to 13% of day 0 TBP (Fig. 141.1). In both groups losses were greatest during the first 10 days, amounting to approximately 1.0% and 0.9% of TBP/day in trauma and sepsis, respectively.

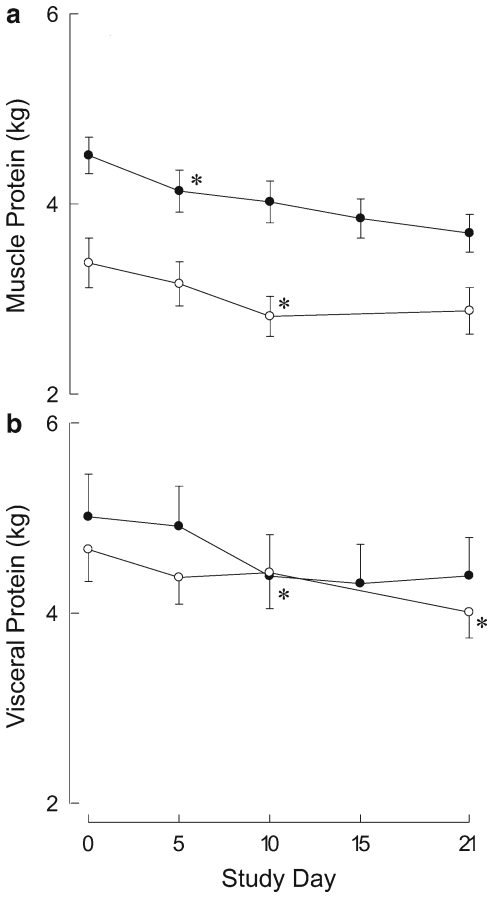

Fig. 141.2 Sequential measurements of skeletal muscle and visceral protein in trauma and sepsis. Skeletal muscle protein (**a**) and visceral protein (**b**) in 21 patients with major trauma (*closed circles*) and 12 patients with severe sepsis (*open circles*) measured over a 21-day period after onset of illness (mean ± SEM). Approximately 70% of the total protein lost over the first 5–10 days was derived form skeletal muscle. * = a significant ($p < 0.05$) change from preceding measurement

141.3.2 Changes in Skeletal Muscle and Visceral Protein

During the first 5 days of the study in the trauma patients and during the first 10 days in the sepsis patients, approximately 70% of the total protein lost came from skeletal muscle (Fig. 141.2). After these times a greater contribution to the protein lost was derived from visceral tissues.

141.3.3 Total Body Fat Changes

In both the trauma and sepsis patients TBF remained essentially unchanged throughout the 21-day study period (Fig. 141.3). The preservation of TBF stores reflects the results of aggressive enteral and/or intravenous feeding adopted with these patients as soon as clinically acceptable.

141.3.4 Total Body Water Changes

The changes in TBW that occurred over the 21-day study period are shown in Fig. 141.4 with estimated pre-illness values. Once haemodynamic stability had been reached (day 0), TBW began to return toward normal. In the trauma group, despite the mean value of TBW returning to the pre-trauma

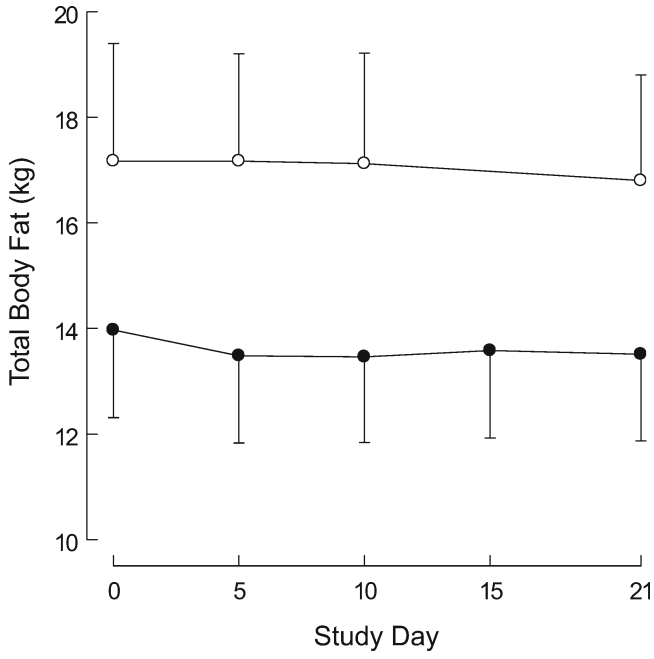

Fig. 141.3 Sequential measurements of TBF in trauma and sepsis. Total body fat in 21 patients with major trauma (*closed circles*) and 12 patients with severe sepsis (*open circles*), measured over a 21-day period after onset of illness (mean ± SEM). In both groups, TBF was preserved over the course of the study

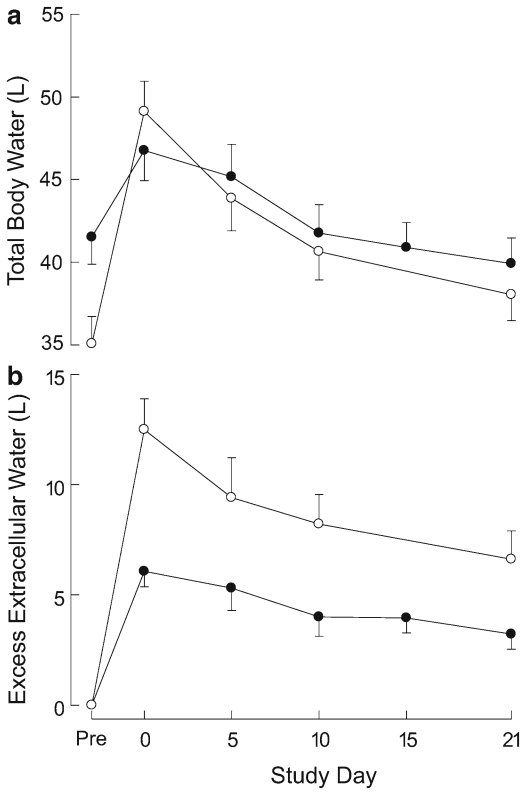

Fig. 141.4 Sequential measurements of TBW and excess extracellular water (ECW) in trauma and sepsis. Total body water (**a**) and excess ECW (**b**) in 21 patients with major trauma (*closed circles*) and 12 patients with severe sepsis (*open circles*), measured over a 21-day period after onset of illness with estimated pre-illness values (mean ± SEM). Total body water accretion is largely extracellular and amounts to >6 L in trauma and >12 L in sepsis at the end of the early resuscitation phase (With kind permission from Springer Science+Business Media: Sequential metabolic changes following induction of systemic inflammatory response in patients with severe sepsis or major blunt trauma, p. 632, Plank and Hill (2000), Fig. 2, © 2000 by the Société Internationale de Chirurgie)

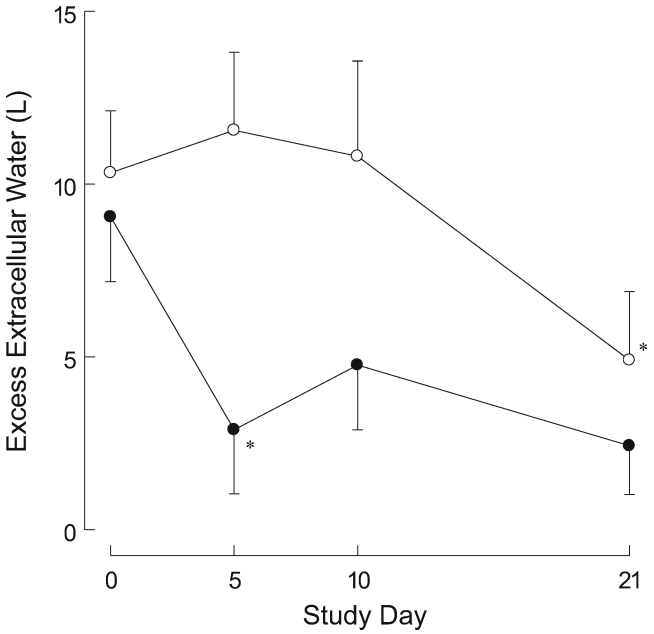

Fig. 141.5 Sequential measurements of excess ECW in young and elderly patients with sepsis. Excess ECW in 6 young (<40 years, *closed circles*) and eight elderly patients (>60 years, *open circles*) with severe sepsis, measured over a 21-day period after onset of sepsis (mean ± SEM) showing the prolonged period of fluid sequestration in the elderly patients. * = a significant ($p < 0.05$) change from preceding measurement (From Cheng et al. (1998). Copyright © (1998) American Medical Association. All rights reserved)

level by day 21, relative overhydration of the FFM was still present, indicated by the slightly elevated TBW:FFM ratio (0.74 ± 0.01). At day 21 in the sepsis group, this overhydration was more marked (0.77 ± 0.01) despite these patients having lost an average of 10.8 ± 1.4 L of water. These changes during and post-resuscitation can be largely accounted for by changes in ECW as shown in Fig. 141.4 where the excess over normal levels of ECW is shown. The volume of excess ECW accumulated was calculated from the difference between the measured ECW and the ECW predicted from the FFM of the patient corrected for abnormal hydration, using the ratio of ECW to TBW found in health, as described in detail elsewhere (Cheng et al. 1998). Over the first 2–3 days of resuscitation the trauma patients gained 6 L of fluid and the sepsis patients 12.5 L.

In elderly patients with sepsis (age > 60 years) the period of ECW expansion is more prolonged than in their younger counterparts (age < 40 years) and appreciable mobilization of the excess ECW does not occur for at least 10 days (Fig. 141.5). This highlights the need for close vigilance of elderly patients recovering from sepsis in terms of fluid balance and sodium restriction.

141.3.5 Changes in Total Body Potassium

Measurements of TBK over the 21-day study period in a subgroup of the trauma and sepsis patients decreased essentially in parallel with those of TBP (Fig. 141.6). The higher absolute TBK seen in the trauma group reflects the greater skeletal muscle mass in this group.

141.4 Applications to Other Areas of Health and Disease

In disease states where large fluid shifts occur, the simple 2-compartment model of body composition (TBF and FFM) is of limited value. In these conditions, which may include patients with end-stage renal or liver disease, heart failure patients, and those in the early postoperative phase after a

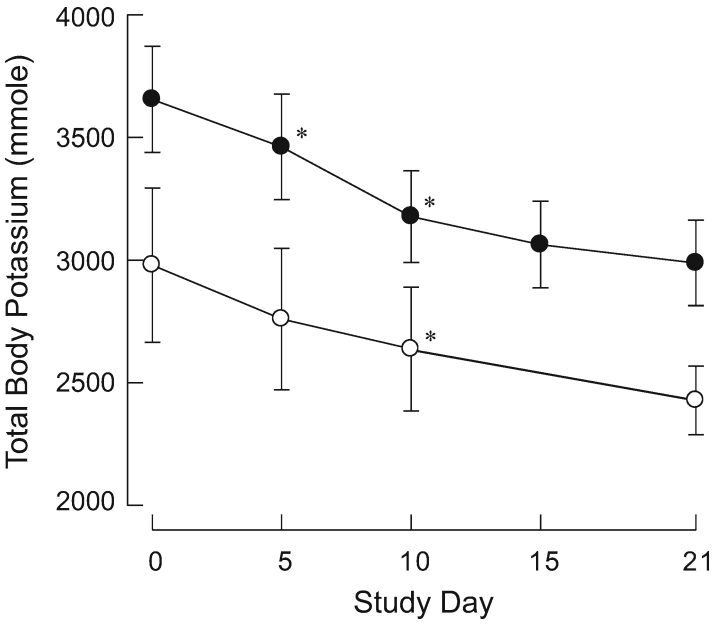

Fig. 141.6 Sequential measurements of total body potassium (TBK) in trauma and sepsis. Total body potassium in 18 patients with major trauma (*closed circles*) and 5 patients with severe sepsis (*open circles*), measured over a 21-day period after onset of illness (mean ± SEM). The changes in TBK track closely the changes in total body protein (TBP). * = a significant ($p < 0.05$) change from preceding measurement

major surgical operation, detailed compartmental analysis is invaluable for understanding the type and magnitude of the compositional derangements that occur. We have utilized such measurements to construct an energy balance where the changes in TBF, TBP, and total body glycogen (estimated from the other measured compartments), expressed as energy equivalents, over a defined time period for which accurate energy intake data was available, allows total energy expenditure to be calculated (Franch-Arcas et al. 1994). For predicting resting energy expenditure, equations which rely on body weight or FFM are unreliable in situations where fluid overload is present. In such cases, the measurement of body water spaces may allow correction of these compartments to "dry" or normally hydrated values. The availability of TBK as a measure most closely related to the energy-metabolizing "core" of the body provides an even more valuable approach to evaluating resting metabolic expenditure (Monk et al. 1996). Direct measurement of TBP has application for assessing response to therapies designed to promote anabolism in both critical illness and other catabolic conditions such as weight-losing cancer and liver disease.

Summary Points

- Body composition of critically ill patients with trauma or sepsis in the ICU is highly deranged.
- Massive proteolysis occurs, initially largely of skeletal muscle with contribution of visceral tissue as the clinical course progresses.
- The catabolic features of trauma and sepsis are very similar reflecting the impact of a systemic inflammatory response which is common to both groups of patients.
- The loss of body protein continues in the face of adequate nutrition support.
- Lipolysis is not evident when energy requirements are met by appropriate nutritional intake.

- Massive fluid overload is characteristic of these patients with 10 L of additional fluid not uncommon in the early resuscitation period.
- Diuresis of this fluid excess is more difficult in older than younger patients with a prolonged period of fluid sequestration evident in the former group.
- The time course of changes in TBK, a measure of the cellular tissue compartment of the body, follows a very similar profile to that of TBP.

Chapter 142
Anthropometry and Infectious and Parasitic Diseases

Pedro R.T. Romão, Francisco Martins Teixeira, Taysa Ribeiro Schalcher,
and Marta Chagas Monteiro

Abstract Anthropometric data are used to assess and predict performance, general health and survival of individuals and also can reflect the economic and social well being of populations. They are associated with the prognostic of several chronic pathologies such as risk of hypertension, diabetes mellitus, cardiovascular disease, arthritis and other diseases. Nutritional anthropometry is widely recognized as the measurements used to assess either physical growth or body composition. Some infections diseases suffer direct influence of anthropometric parameters and nutritional status, and also they may cause loss of appetite, malabsorption, increased catabolism that could exacerbate the malnutrition and further impaired immunity development. Several evidences indicate that chronic heavy infections represent a hidden risk factor for anemia in infants, growth retardation, delayed motor development, poor cognitive abilities and reduced school performance. Moreover, several studies suggest that the association between polyparasitism and malnutrition could be due either to direct effect of intestinal parasites on growth or to the effect of undernourishment on the immune response leading to an increased susceptibility to infection. Although the malnutrition has been classically associated with failure of immune response to eliminate the infectious agents due to increased frequency or sometimes severity of infections, children suffering several infections can die even with a very good nutritional appearance. In this chapter the authors have made some considerations about the association between parasitic and infectious diseases and alterations on anthropometric parameters.

142.1 Introduction

Anthropometry is a widely used, inexpensive, and noninvasive measure of the general nutritional status of an individual or a population group. It is used to assess and predict performance, general health, and survival of individuals and also can reflect the economic and social well-being of populations. Anthropometric data have been utilized and associated with the prognostic of several chronic pathologies. For example, individuals with large measures of subcutaneous adipose tissue are reported to be at increased risk for hypertension, diabetes mellitus, cardiovascular disease, arthritis, and other diseases. Moreover, anthropometry is widely used to measure general health in children. Although initially genetically programmed, both height and weight are strongly affected by social and environmental conditions, making growth a useful marker of health and living conditions.

Some infectious diseases directly influence anthropometric parameters, especially in developing countries, where parasitic infections are common and influence decisively the growth of children (Fig. 142.1). Nutritional anthropometry is recognized widely as an effective means of assessing nutritional status, especially at the level of the population, and the measurements taken are used to assess either physical growth or body composition. The former is a reflection of nutrient adequacy during development, the latter an indicator of the excess or deficit of energy and protein (Stenphenson et al. 2000a; Bethony et al. 2006). Protein-energy malnutrition is usually defined by low anthropometry, and the three indices commonly accepted based on height and weight measurements are height-for-age (HA), weight-for-age (WA), and weight-for-height (WH) and a value below the -2 standard deviation (SD) value (*Z*-score) or a fixed percent of median of the growth reference distribution as low or 'malnourished'. The main critic about nutritional anthropometry is the observation that a lower height and weight of children found in the studies in less-developed countries could be left to consider the children who show these characteristics due to its genetic profile (Stenphenson et al. 2000a; Bethony et al. 2006).

Malnutrition is estimated to cause about 12 million deaths of children less than 5 years annually. In association with infectious and parasitic diseases, it is the major obstacle to health in developing

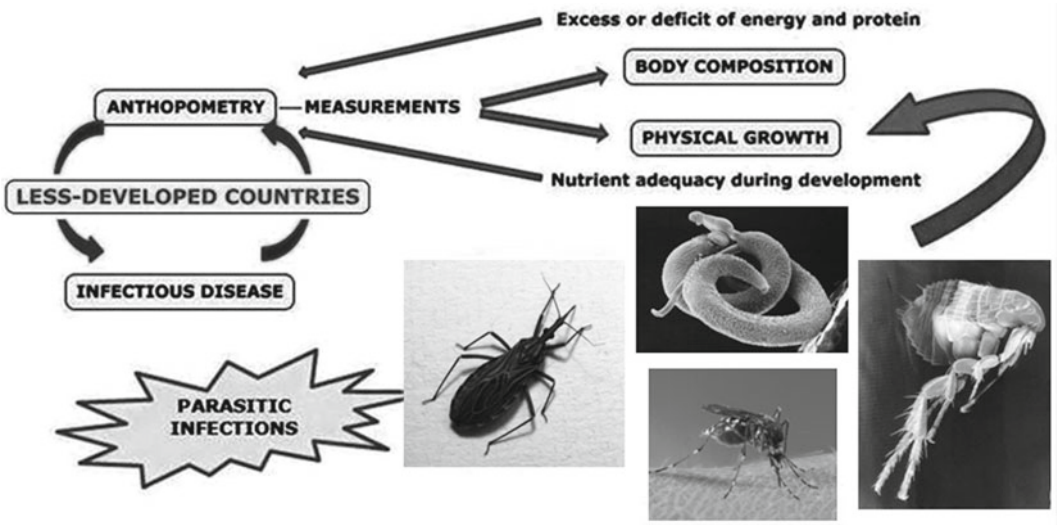

Fig. 142.1 Vicious circle of anthropometric measurement and infectious and parasitic diseases. The *circle* represents the relationship between anthropometric measures and diseases, especially parasitic infections common in children living in less developed countries, where malnutrition associated with poverty increases the chances of the individual to become sick because of the inability to fight against the infectious pathogens. There is a close relationship between the incidence of parasitic/infectious diseases and the level of intake of necessary nutrients for adequate development

countries, where the prevalence of parasitic infections is maximum before 5 years, reaching a relatively stable asymptote in adulthood. Protozoan and helminthic infections are widespread and antagonistic to certain aspects of intestinal physiology and thus of importance with respect to nutritional status in humans. In children of those countries, polyparasitism is very common, and frequently they are more heavily infected than the adults, being consequently more susceptible to suffer severe morbidity (Bethony et al. 2006) (Box 142.1).

It is important to point out that the host defense against the parasites depends on nutritional conditions and also that some infections may cause loss of appetite, malabsorption, and increased catabolism that could exacerbate the malnutrition and further impaired immunity development. Although the malnutrition has been classically associated with failure of immune response to eliminate the infectious agents, due to increased frequency or sometimes severity of infections, children suffering several infections can die even with a very good nutritional appearance. The explication to this remains speculative. Anthropometrical parameters truly represent nutritional status, and a worse nutritional status always increases severity of infections. In this chapter, the authors have discussed some parasites and infectious diseases that influence or can be influenced by the nutritional status and the importance of anthropometric analysis in this area of knowledge.

142.1.1 Amebiasis

Entamoeba histolytica infection remains an important cause of morbidity and mortality mainly in countries where malnutrition has high prevalence and the sanitation infrastructure and health educations are not adequate. Recently, it was demonstrated that IFN-α production, a Th1 cytokine involved in the protection against several infections, is linked to nutritional status and predicts susceptibility of children to *E. histolytica* (Table 142.1). The authors showed that peripheral blood mononuclear

Box 142.1 Highlights of the interplay among anthropometry and immunity to infectious and parasitic diseases

Thymus Size and Health

- The thymus is responsible for T-cell differentiation.
- In infancy, its size has been considered a strong and independent risk factor for mortality.

Immunological findings in small-for-gestational age and low-birth-weight infants and in elderly of the developing world

- Increased risk of death in the immediate postpartum period, thymic atrophy, prolonged impairment of cell-mediated immunity, reduced number and proliferative response of T-lymphocytes to mitogens, and deficient phagocyte functions are common in small-for-gestational age and low-birth-weight infants.
- In developing countries, the elderly present a higher risk of acquiring infectious diseases due to the cumulative effects of immunosenescence and malnutrition.

Immunological findings during nutrient depletion

- Nutritional deficiency is commonly associated with parasitic infections and a significantly impaired development, differentiation, and activation of the immune system. It can affect immune-cell trafficking, phagocytosis, cytokine production, and immune effector function, favoring infections and body energy consumption.

This box lists the immunological findings in special conditions related to anthropometry

cells of children with both weight-for-age *Z*-score (WAZ) and height-for- age *Z*-score (HAZ) <–2 produce less IFN-γ when stimulated *in vitro* with antigen-soluble amebic extract, indicating the importance of nutritional status for parasite control (Haque et al. 2007).

142.1.2 Giardiasis

In relation to giardiasis, data showed that children infected with different species of *Giardia* (*G. lamblia, G. intestinalis*, or *G. duodenalis*) present more significant deficit in height-for-age (HAZ), weight-for-height (WHZ), weight-for-age (WAZ), and mid-upper-arm circumference for age (MUACZ) than uninfected children (Table 142.1). Furthermore, giardiasis causes iron-deficiency anemia, micronutrient deficiencies, malnutrition, and growth retardation in children (Silva et al. 2009). It is recognized that *G. lamblia* infection may destroy the brush borders of enterocytes and impair the activity of mucosal enzymes, causing carbohydrate and lipid malabsorption. The pharmacological treatment of giardiasis is able to improve significantly the body-weight gain and fat-free mass of children.

142.1.3 Leishmaniasis

Leishmaniasis is ranked as one of the most neglected parasitic diseases and has strong links with poverty. It remains a major public health problem despite the vast amount of research on *Leishmania* pathogens, which cause a spectrum of diseases ranging from self-healing cutaneous lesions to

Table 142.1 Association between anthropometry and different parasitic diseases

Disease	Anthropometric variables[a]	Reference
E. histolytica[b] (diarrhea/ dysentery)	There is positive correlation among IFN-α production by PBMC, HAZ, and WAZ has been described. Low levels of IFN-α was associated with risk of *E. histolytica* diarrhea/dysentery in children from Dhaka, Bangladesh	Haque et al. (2007)
Giardiasis	Children infected with *Giardia lamblia* have lower means of HAZ, WHZ, WAZ, and MUACZ than uninfected children. Giardiasis causes iron-deficiency anemia, micronutrient deficiencies, malnutrition, and growth retardation in children, which can be ameliorated by the treatment	Carvalho-Costa et al. (2007) Silva et al. (2009)
Cutaneous and Mucosal Leishmaniasis	Plasmatic levels of selenium, zinc, and iron were decreased in patients with cutaneous leishmaniasis, probably in response to immunoregulatory cytokines; ML and CL are more frequent in patients with malnutrition	Machado-Coelho et al. (2005) Kocyigit et al. (2002)
Visceral Leishmaniasis	Deficit in WAZ and HAZ scores; hypoalbuminemia; inversion of the albumin/globulin ratio; decreased body mass index and mid-upper-arm circumference-for-height; low weight at birth; lower value of *Z*-scores for total and free insulin-like growth factor (IGF-I) and for IGF-binding-protein 3 were associated with a higher chance of developing active visceral leishmaniasis	Gomes et al. (2007) Maciel et al. (2008)
Malaria	Stunted and underweight and wasted African children had a more than twofold higher risk of dying by malaria	Müller et al. (2003)
Malaria in Pregnant Women	Fetal growth retardation in weight and length present from 30 weeks' gestation; placental or peripheral parasitemia at delivery were associated with reduced newborn weight, length and head circumference, wasting and stunting	Kalanda et al. (2005)

[a] Available parameters linked to higher risk of described disease

[b] Etiologic agent more frequently associated with diarrhea and dysentery

Abbreviations: *HAZ* Height-for-age *Z*-score, *IFN-γ* Interferon-gamma, *IGF-I* Insulin-like growth factor, *MUACZ* Mid-upper-arm circumference for age, *PBMC* Peripheral blood mononuclear cells, *WAZ* Weight-for-age *Z*-score, *WHZ* Weight-for-height *Z*-score

progressive and often fatal disease. It is known that the nutritional status might influence the outcome of *Leishmania* spp. infection, especially in children aged less than 5 years. In this context, the prejudicial interaction between malnutrition and the development of cutaneous, mucocutaneous, and visceral diseases has been described, but it is more evident in patients with the classical form of visceral disease, which is characterized by fever, hepatosplenomegaly, pancytopenia, hypoalbuminemia, and hypergammaglobulinemia (Machado-Coelho et al. 2005; Gomes et al. 2007).

An important reduction in plasma levels of selenium, zinc, and iron was observed in patients with cutaneous leishmaniasis, probably in response to immunoregulatory cytokines (Table 142.1). Furthermore, in a study carried out in southeast Brazil using a total of 2,820 patients diagnosed with American cutaneous leishmaniasis, data found that individuals with mucosal leishmaniasis (ML) presented 3.4 times more chances of being malnourished than patients with cutaneous lesions (CL). ML occurred 4 times more frequently in patients with malnutrition than in well-nourished individuals (Machado-Coelho et al. 2005).

In relation to visceral leishmaniasis (VL), in a *Leishmania chagasi* endemic area of Brazil, a decrease in body mass index (BMI) and mid-upper-arm circumference for height was observed in children with VL, and a decreased birth weight was associated with a higher chance of developing severe disease (Table 142.1). In addition, higher albumin concentrations and birth weight protected

against disease. In another study, also conducted in endemic area for VL in Brazil, it was found that children with active form of disease presented more pronounced weight loss and a deficit in WAZ and HAZ compared with oligosymptomatic, asymptomatic patients and non-infected children. Serum albumin levels also were significantly reduced in children with active (2.7 ± 0.22 g/dl) or oligosymptomatic (2.97 ± 0.34 g/dl) VL compared with asymptomatic (4.22 ± 0.07 g/dl) and control (4.36 ± 0.03 g/dl) children, indicating that VL can affect the nutritional condition of patients. It is important to comment that the deficit in height and weight was not a risk factor to infection by *Leishmania* in that geographic area. Moreover, the serum ferritin concentration in the active VL group was 11, 18.6, and 22.7 orders of magnitude higher compared with oligosymptomatic, asymptomatic and control individuals, respectively (Gomes et al. 2007). Insulin-like growth factor (IGF-I) production is regulated by nutritional status. It was demonstrated that, in patients with active form of VL or oligosymptomatic patients, the levels of IGF-I and also its ligand IGF binding-protein 3 (IGFBP3) were significantly reduced in relation to controls or asymptomatic patients (Table 142.1). IGF-I is mainly produced in the liver (Gomes et al. 2007). Thus, it is possible that the cytokine-induced inflammation can decrease IGF-I production by liver cells, since its biosynthesis is inhibited by mediators, such as TNF-α, IL-1, and IL-6, which are produced in the course of VL. On the other hand, the alterations in liver induced by those inflammatory cells may impair the production of IGF-I and IGFBP3. Overall, these results suggest that, in leishmaniasis, malnutrition is likely to occur previous to infection (cutaneous and visceral leishmaniasis) impacting on the outcome of disease, and also to be reinforced at least during visceral form of disease, since a marked reduction in fat reserves and muscle mass related by TNF-α production occurs.

142.1.4 Malaria

The relationship between malnutrition and malaria is an unsolved and complex issue. *Plasmodium falciparum* infection may cause malnutrition, whereas malnutrition itself may modulate susceptibility to malaria. There is no direct association between malnutrition and malaria mortality, but stunted, underweight, and wasted African children had a more than twofold higher risk of dying than non-malnourished infected children (Table 142.1). Although children living in an endemic area of malaria showed clinical symptoms of disease during the first 10 years, the effect of malaria on nutritional status appears to be greatest only in the first 24 months, suggesting that, subsequent to infection, children aged under 2 years became underweight or stunted (Nyakeriga et al. 2004). Moreover, in a study carried out with pregnant women in Chikwawa District, Southern Malawi, a rural area endemic to malaria, the mean birth weight, length, and head circumference were significantly lower in babies of mothers with placental or peripheral *P. falciparum* parasitemia at delivery. Furthermore, univariate analysis showed that placental and/or peripheral presence of parasite was associated with wasting and stunting (Kalanda et al. 2005). These alterations could be due to placental insufficiency, leading to intrauterine growth restriction.

142.1.5 Tuberculosis

About one-third of the world's population carries the bacterium that causes tuberculosis, *Mycobacterium tuberculosis*, and roughly 10% of these people will go on to develop the disease. Because drug courses can last for a year or more, most people do not complete their treatment, and the growth of resistance is therefore inevitable.

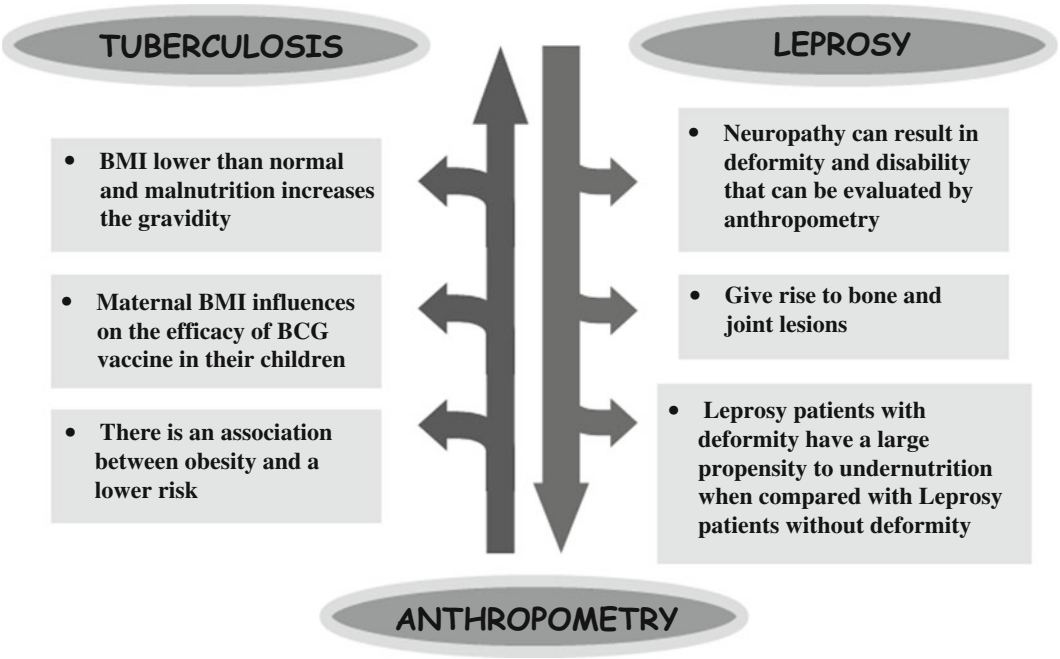

Fig. 142.2 Relationships among anthropometry, tuberculosis, and leprosy. Anthropometric measurements influence the prognosis of infection caused by *Mycobacterium tuberculosis*. However, in relation to leprosy, an opposite effect has been observed, and the disease and the degree of deformity have a decisive influence on the anthropometric parameters

A better understanding of the relationship between the tubercle bacilli and our body is probably an important issue for the discovery of new interventions seeking for solutions to problems that arise when we interact with this pathogen. Although there are many studies about the morbidity and mortality of tuberculosis at a worldwide level, many researchers continue to look for answers about the metabolic, physiological, and immunological processes involved in the control of the infection and in a positive prognostic for the host or in the spread of the pathogen in the body and dissemination of disease, occasioning many times the death of the patient.

In terms of anthropometric characteristics, the BMI invariably has been associated to mortality. One value of BMI lower than normal represents an increase in the risk when it refers to tuberculosis. Moreover, malnutrition is associated with higher incidence and increase in the gravidity of the clinical status of tuberculosis, according to radiographic visualization of lungs of infected individuals (van Lettow et al. 2004).

Important items that have been monitored and are the focus of recent research on the effectiveness of current vaccine used against tuberculosis and the search for new strategies for vaccination. The *Mycobacterium bovis* BCG vaccine presents efficacy that can range from 0% to 80%, depending on the geographic region evaluated. One of the possible explanations for this variation could be the maternal anthropometric characteristics (Moore et al. 2004). This speculation comes from studies that showed a negative correlation between the immune response of children and adolescents against mycobacterial antigens and the BMI of their mothers (Fig. 142.2). Furthermore, the antenatal and postnatal environments show a decisive influence in the capacity to mount a protective immune response against tuberculosis (Table 142.2). The season of birth can be important to a subsequent effective response against *Mycobacterium tuberculosis*. In countries where there are well-defined seasons with periods of wet and dry weather, there is a decrease in energy intake and available food

Table 142.2 Different aspects of anthropometric measures in relation to tuberculosis and leprosy

Tuberculosis		Leprosy	
Moderate to severe malnutrition in patients with tuberculosis is a risk factor associated with early death	Bernabé-Ortiz (2008) Van Lettow et al. (2004)	Given that individuals may be cured and yet suffer lifelong deformities and disability, the number of individuals with nerve damage would be a better indicator for elimination of leprosy	Greve et al. (1994)
Birth weight, prenatal undernutrition, and postnatal environment have influence on vaccination against tuberculosis	Moore et al. (2004)	Computerized podometric evaluation of the insensible feet of leprosy patients showed a close relation between points of increased pressure and areas with deficient sensation	Greve et al. (1994)
Micronutrient supplementation to patients with active tuberculosis and HIV improves their health by increasing $CD4^+$ count, increasing their weight, and improving the efficacy of their drug treatment	Swaminathan et al. (2008)	BMI and mid-upper circumference have been demonstrating that cured leprosy patients with residual deformity have a larger propensity to undernutrition than cured leprosy patients without deformity	Diffey et al. (2000)
There is an association between obesity and a lower risk to become infected by tubercle bacilli. A cholesterol-rich diet accelerates bacteriologic sterilization in pulmonary tuberculosis.	Pérez-Guzmán et al. (2005)	The inclusion of nutritional-status evaluation by anthropometry as part of the initial screening of leprosy patients prior to instituting socioeconomic rehabilitation has been proposed as a strategy that can help in the prioritization of these patients	Vaz et al. (2001)

This table summarizes important published data concerning anthropometric measurements and their influence on the risk of infected people to be sick, on immune response, and point out that, in untreated *Mycobacterium leprae*-infected patients, the disease impacts on the nutritional status and also on quality of life, promoting deformities and disability

from the previous harvest in the wet seasons. In the same way, the wet season represents the time in which there is a higher demand for female exhaustive labor in agriculture. Consequently, the variations of available food and increased daily efforts in the life of mothers influence the birth weight of their children and the response of these children to the prophylactic action of BCG vaccine against tuberculosis.

Weight loss is one of the fundamental signs both in HIV-positive and HIV-negative tuberculosis patients. Malnutrition and wasting are associated with tuberculosis and HIV infection. Coinfection with one pathogen may potentially exacerbate the wasting that occurs in the other (van Lettow et al. 2004). Since HIV-infected adults with pulmonary tuberculosis had significantly low micronutrients and BMI, this subgroup may potentially benefit from nutritional interventions. Several studies have revealed that micronutrient supplementation to patients with active tuberculosis and HIV improves their health by increasing CD4 T-cells' count, increasing their weight, and improving the efficacy of their drug treatment, in addition to decreasing opportunistic infections (Table 142.2).

Tuberculosis and leprosy show different aspects about association with anthropometry. For tuberculosis, the great majority of research works has established a relationship of the effects of anthropometry, especially weight and height represented by BMI, with the gravity of disease. The risk of mortality has a negative correlation with anthropometric indicators of nutritional status. For leprosy, it is the inverse, as many studies have observed an influence of the disease on anthropometric measurements (Fig. 142.2). It is important to note that tuberculosis, as much as leprosy, remains a serious threat to public health in less developed countries (Diffey et al. 2000; Walker and Lockwood 2007).

Although obesity has association with diabetes and cardiovascular-associated diseases, which represent predisposing factors to the increase of incidence of tuberculosis, it is important to note that there is an association between obesity and a lower risk to become infected by tubercle bacilli (Pérez-Guzmán et al. 2005). Both clinical and experimental studies have shown that a cholesterol-rich diet helps the host against infection by tuberculosis (Table 142.2).

Endogenous reactivation is becoming a major source of tuberculosis disease among the older generations. Although treatment of latent infection is a possible strategy against this endogenous reactivation, the decision to is not always easy to make in a high-prevalence setting, especially in view of the limitations in the currently available diagnostic and treatment tools. The cost-effectiveness of such screening is likely to be improved if BMI can be taken into consideration. Aggressive measures may also be indicated against elderly malnutrition to reduce the risk of reactivation of tuberculosis, and nutritional supplementation in this regard. It may therefore be worthwhile to explore the potential impact of ongoing changes in our body build on the future tuberculosis trend.

142.1.6 Leprosy

Leprosy has plagued human populations for thousands of years and puzzled scientists since the identification of its etiological agent, *Mycobacterium leprae*, by Hansen in 1873. Ancient texts describe the existence of leprosy in China, India, and Egypt in around 600 BC, and skeletal remains bearing hallmarks of the disease have been found in Egypt (Monot et al. 2005). The disease causes skin lesions and neuropathy. Secondary complications of the neuropathy can result in deformity and disability, with skin, mucosal, eye, and nerve involvements (Diffey et al. 2000). Computerized podometric evaluation of the insensible feet of leprosy patients showed a close relation between points of increased pressure and areas with deficient sensation. The use of this anthropometric type of evaluation may be an important instrument in preventing plantar ulcers, because we can see the exact point of increased pressure. This fact is confirmed by qualitative analysis that demonstrated the coincidence between plantar ulcers and points of increased pressure (Greve et al. 1994).

The maintenance of the treatment with the multidrug therapy is a fundamental strategy to reduce the current socioeconomic problems of the leprosy. After introduction of multidrug treatment, there was an expressive decrease in leprosy incidence that was also more restricted to very young and very old patients. Leprosy remains a stigmatizing disease. However, multidrug therapy has led to the understanding that leprosy can be effectively treated before disability. Since 1985, 14 million individuals have received multidrug therapy (Walker and Lockwood 2007).

Some of the most important problems associated with leprosy are the disability and the difficulties in the socioeconomic rehabilitation of patients. Leprosy continues to give rise to bone and joint lesions, which may ultimately become crippling (Fig. 142.2). This has, in fact, been listed as a priority area for leprosy program planners. Moreover, when some authors compare leprosy patients, with or without deformity, these problems become still more expressive (Monot et al. 2005; Walker and Lockwood 2007). Anthropometric parameters, such as BMI and mid-upper arm circumference, have

demonstrated that cured leprosy patients with residual deformity and their household members have a greater propensity to undernutrition than cured leprosy patients without deformity (Table 142.2). Surprisingly, many of the household members of cured leprosy patients with deformity who presented this greater propensity were not sick but only infected by *Mycobacterium leprae*, since, despite 90% of the people who maintain contact with these patients become infected, only 8% will be sick.

The inclusion of nutritional-status evaluation by anthropometry as part of the initial screening of leprosy patients prior to instituting socioeconomic rehabilitation has been proposed as a strategy that can help in the prioritization of these patients. This is important because, when economic resources are limited the processes of rehabilitation need to be addressed in those most in need (Table 142.2). In much of Asia and Africa, the focus on elimination as a target has resulted in inappropriate programs with the sole purpose of reducing the number of cases on the treatment register, instead of improving the quality and effectiveness of leprosy services. In spite of the effectiveness of the available treatment, many patients develop deformity, especially those related to the impairment of the peripheral nervous system. Once those individuals are cured and yet suffer lifelong deformities and disability, the number of individuals with nerve damage would be a better indicator for control of leprosy (Greve et al. 1994).

142.2 Geohelminths and Anthropometry

The geohelminths are among the most common etiologic agents of human infections and often occur together within the same host. Geohelminth infections occur predominantly in the developing countries of the tropics and subtropics areas, where it is estimated that there are currently one billion people infected. The geohelminths include the common whipworm, *Trichuris trichiura*; the large intestinal roundworm, *Ascaris lumbricoides*; and two species of hookworms, *Ancylostoma duodenale* and *Necator americanus*. Hookworms and *Ascaris* inhabit the small intestine, whereas *Trichuris* is a parasite of the colon. They can live in the gastrointestinal tract for up to several years (Stephenson et al. 2000a).

Intestinal parasitic infections remain a serious public global health problem. Although the predictors of stunting are multifactorial, intestinal parasitic infections, notably helminthic infections, are acting as factors associated to low nutritional status, along with sanitary and socioeconomic conditions to increase morbidity and mortality in children and various other functional consequences, including impaired cognitive development and impaired growth (Stenphenson et al. 2000a). In Brazil, intestinal diseases caused by protozoan and helminthic parasitism (Fig. 142.3) and infectious diseases (Fig. 142.4) still lead to great number of death annually (Ferreira et al. 2006; Buschini et al. 2007).

The World Health Organization now recommends that, in areas where infections are endemic (prevalence of 20–30%) and anemia is prevalent, hookworm control (using chemotherapy) needs to be included in strategies designed to improve the health, development, and nutritional status of girls and women. Intestinal parasite infections can be controlled with anthelmintic drugs in conjunction with education and improvement of sanitary conditions. Intervention studies have shown that infection with as few as ten roundworms is associated with deficits in growth and physical fitness in school-aged children and those moderate whipworm infections can cause growth retardation and anemia. Fortunately, many of the growth and nutritional deficits caused by these infections are reversible with the use of anthelmintics. For example, the treatment of intense infections with whipworm has shown a positive impact on anthropometric parameters and iron status of schoolchildren

Source: Ministry of Health, Division of Health Surveillance, Mortality Information System (MIS) and demographic base of the Brazilian Institute of Geography and Statistics (http://tabnet.datasus.gov.br/cgi/deftohtm.exe?idb2008/c17.def)

and preschool children. However, although control strategies relying on targeted delivery of benzimidazole anthelmintic are generally effective at eliminating adult worms, reinfection occurs quickly, and frequent treatments may be necessary for sustained improvement in the health of at-risk populations.

Epidemiologic evidence in many different countries has shown that for *Ascaris* and *Trichuris*, heavy infections will occur predominantly among school-aged children and, hence, a window period of susceptibility to morbidity from these parasites during childhood. For hookworm, heavy infections

also can occur during childhood but, probably, increasing intensity occurs more commonly with age. Evidence indicates that chronic heavy infections with geohelminths represent a hidden risk factor for maternal iron-deficiency anemia and fetal growth retardation, anemia in infants, growth retardation, delayed motor development, poor cognitive abilities, reduced school performance, and an impaired immune response (Stephenson et al. 2000b; Bethony et al. 2006). In several studies, the association between polyparasitism and malnutrition can be due either to the direct effect of intestinal parasites on growth or to the effect of undernourishment on the immune response, leading to an increased susceptibility to infection.

142.2.1 Trichuriasis

The common whipworm *Trichuris trichiura* occurs where fecal contamination occurs on warm and damp soil; it affects an estimated 800–1,000 million individuals worldwide. Children with *Trichuris* colitis have numerous systemic sequelae that are similar to those caused by other kinds of inflammatory bowel disease. Growth retardation is a prominent feature, and it is proportional to the intensity of chronic infection. The basis by which whipworms impair physical growth during childhood is unknown. Among the mechanisms proposed are direct intestinal protein losses, anorexia and increased catabolism resulting from TNF-α production, and reduced host circulating levels of IGF-I (Cooper et al. 1997; Duff et al. 1999; Drake and Bundy 2001) (Table 142.3). Even less well known are the mechanisms by which *Trichuris* impairs cognition and school performance (Drake and Bundy 2001).

Several studies showed that *T. trichiura* infection may contribute to vitamin A and zinc deficiencies caused by reduced retinol and zinc intake, respectively, due to anorexia and/or vomiting, malabsorption, and increased requirement and loss due to diarrhea. On the other hand, the zinc deficiency is associated with increased susceptibility toward gastrointestinal nematodes, likely through a weakening of the gut epithelial barrier, allowing greater penetration and establishment of the larval stages as well as a profound impairment of the gut immune response. Heavy *Trichuris* infections cause iron-deficiency anemia and growth retardation, both of which are associated with poor cognition and low school performance (Stephenson et al. 2000a, b; Drake and Bundy 2001; Bethony et al. 2006) (Table 142.3).

142.2.2 Ancylostomiasis

The two major species of hookworms are *Ancylostoma duodenale* and *Necator americanus*, and more than 700 million people worldwide are infected with hookworms. The adult hookworms attach via their buccal capsule to the intestinal mucosa, rupture capillaries, and feed on blood. The pathogenesis of hookworm infection is mainly a consequence of the blood loss, which occurs during attachment and feeding. In a large number of developing countries, hookworms are the leading cause of iron-deficiency anemia, hypoproteinemia, and growth delay, which is proportional to worm burden (Table 142.3). During heavy infections, sufficient blood (and plasma protein) loss can result in depletion of host iron and protein reserves, leading to physical and mental retardation and sometimes deaths in children, as well as adverse maternal–fetal outcomes. The processes of growth retardation and deficits in attention and intellectual development that occur during chronic, heavy hookworm infections in childhood are possibly due to the development of clinical iron deficiency (Hotez et al. 2004, 2005; Bethony et al. 2006) (Table 142.3).

Table 142.3 Harmful effects of the association between helmintic infections and malnutrition. Association between malnutrition and different helmintic infections

Pathogen/disease	Nutritional variables[a]	References[b]
Trichuris trichiura Trichuriasis	Can lead to intestinal protein losses, anorexia and increased catabolism resulting from host tumor-necrosis-factor production, and reduced host circulating levels of insulin-like growth factor I Contribute to vitamin A and zinc deficiencies caused by reduced retinol and zinc intake, respectively Heavy infections cause iron-deficiency anemia and growth retardation, both of which are associated with poor cognition and impair school performance	Bethony et al. (2006) Drake and Bundy (2001) Stephenson et al. (2000a) Stephenson et al. (2000b) Cooper et al. (1997)
Ancylostoma duodenale *Necator americanus*	Hookworms can lead to iron-deficiency anemia, hypoproteinemia, and growth delay, which is proportional to worm burden	Bethony et al. (2006) Hotez et al. (2005) Hotez et al. (2004) Stephenson et al. (2000a)
Ancylostomiasis	Chronic heavy hookworm infections in childhood with clinical iron deficiency can lead to processes of growth retardation and deficits in attention and intellectual development Hookworm infection can cause levels of undernutrition that are greatest among younger children and decrease with the age	
Ascaris lumbricoides Ascariasis	The Ascariasis contributes to impairment of growth and cognitive development in children by; different ways: 1. I impairing host nutrition by causing malabsorption of protein, lactose, fat, and some fat-soluble vitamins, including vitamin A, through a process of villous atrophy; 2. Producing a battery of peptide serine protease inhibitors that *in vitro* can block the action of pancreatic trypsin, chymotrypsin, and elastase; and 3. Causing different degrees of intestinal mucosal epithelial cell damage, because they can elicit mechanical damage and lumen obstruction if they reach the biliary tree or become entangled and matted into a bolus of worms.	Payne et al. (2007) Bethony et al. (2006) Stephenson et al. (2000a) Ferreira et al. (2006) Buschini et al. (2007)

This table summarizes the effects of parasite infections on nutritional status and anthropometric parameters, such as deficient growth and deficits related to biochemistry functions and cognitive development

[a] Possible consequences in nutritional status with the presence of described disease

[b] Recent works which discuss the issues

142.2.3 Ascariasis

Ascaris lumbricoides (roundworm) infects 0.8–1.2 billion people worldwide, and it is the major cause of disease burden, especially in developing countries, with an estimated loss of from 1.2 to 10.5 disability-adjusted life years per infected person. The role of *A. lumbricoides* in determining malnutrition has been extensively studied. *A. lumbricoides* infection, even in the absence of obvious symptoms of disease, can impair linear growth. Data showed higher prevalence of stunting and underweight among high-school children infested by *A. lumbricoides*. This persistent intestinal parasitic infestation seemed to be associated with physical growth retardation and low nutritional indices, such as height-for-age Z score (HAZ) and weight-for-age Z score (WAZ).

Ascariasis may affect growth in different ways, depending on its long-term effects (Table 142.3). Several studies showed that large parasite burdens in ascariasis can lead to intestinal obstruction and

also to decreased appetite and food intake. It was demonstrated that adult *Ascaris* worms impair the absorption of vitamin A and fat, leading to nutritional deficiencies, whereas vitamin A deficiency may reduce the immune response to intestinal parasites, leading to higher worm burdens. Furthermore, there is substantial evidence that ascariasis contributes to impairment of growth and cognitive development in children and thus has important long-term consequences if not prevented or treated (Stephenson et al. 2000a; Payne et al. 2007).

In summary, the *A. lumbricoides* infection may lead to the following disease classification: (1) reversible growth faltering in children and/or reduced physical fitness in children and adults, which lasts for the duration of the infection; this deficit in health is recovered completely once the individual loses the infection; (2) permanent growth retardation, which is a lifelong consequence of infection, occurring only in children; this deficit might be recovered, but only partially, even if the individual loses the infection completely; (3) clinically overt, acute illness (such as intermittent abdominal pain or discomfort, nausea, anorexia, or diarrhea) of short duration and mild-moderate severity, sufficient for the infected individual to seek medical attention; (4) acute complications (including intestinal obstruction and its complications, biliary or pancreatic disease, appendicitis, and peritonitis) of sufficient severity for the affected individual to be hospitalized; and (5) mortality caused by acute complications (5% case fatality rate) (Stenpheson et al. 2000a; Bethony et al. 2006; Payne et al. 2007).

142.3 Applications to Other Areas of Health and Disease

Anthropology is one of the interdisciplinary scientific fields that is gaining much attention since it can have applications in many different areas of knowledge. Its use is not restricted directly to the assessment of nutritional status or indirectly to indicate either a state of immune incompetence or susceptibility to disease. In many chapters of this hand book, the reader can come across many different applications including the study of human development, fetal growing, and diagnostic comprehension of genetic, cardiovascular, hematological diseases, and others.

Infectious and parasitic diseases are mostly endemic in underdeveloped and developing countries, including Brazil, a tropical developing country, where many infectious diseases including tuberculosis, leprosy and leishmaniasis present high incidence (Table 142.4). Hence, we need to consider that some infectious agents including parasites can persist chronically in the human body without provoking a strong host response. In fact, many patients remain well in spite of the infection. Conversely, patients with heavy infection or those in the initial infective stage may have symptoms. Frequently, parasites degenerate and die in human tissues. By contrast, some parasites live for a long time in the human body, from several years to decades and produce chronic inflammation. Furthermore, many patients have repeated and cumulative infections. Because of persistent or lifelong exposure to para-

Table 142.4 New cases of infectious diseases in Brazil by year, 2000–2007

Disease	2000	2001	2002	2003	2004	2005	2006	2007	Total
Tuberculosis	81,182	73,771	77,493	78,596	77,678	76,741	71,870	72,179	609,510
Leprosy	43,196	45,646	49,149	51,680	50,271	49,145	44,764	41,367	375,218

sites and their excreta, cancer may develop. For example, hepatocellular carcinoma or bladder cancer develops in patient with schistosomiasis. Some parasitic diseases that affect the lungs and urinary bladder will be discussed in the appropriate sections of individual parasitosis. Some parasites reach the peritoneal space during their migratory life cycle and they inadvertently reside there and produce inflammatory reaction.

Infection intensity is a key factor to understand the morbidity of the patients; although light infections are often asymptomatic, heavy infections cause an array of morbidities, including dietary deficiencies and delayed physical and cognitive development. In this way, chronic heavy infections represent a hidden risk factor for anemia in infants, growth retardation, delayed motor development, poor cognitive abilities, reduced school performance, and an impaired immune response.

Infection, inflammation, or increased oxidative stress may also increase catabolic loss of certain nutrients. For example, infection with most microorganisms leads to activation of macrophages and neutrophils by microbial products or by pro-inflammatory mediators produced by damaged cells. The release of the pro-inflammatory cytokines, such as tumor necrosis factor (TNF)-alpha and interleukin (IL)-1beta and IL-6, result in induction of the systemic acute-phase response. This response will lead directly to responses by the central nervous system (e.g., induction of fever and production of cortisol to down-regulate inflammation) and the liver, which includes the increased production of positively regulated acute-phase proteins (e.g., C-reactive protein or CRP) and the decreased synthesis of other proteins, which results in decreased serum retinol concentration and serum iron and zinc concentrations. The decreased serum retinol concentrations during infection could lead to decreased tissue concentrations of vitamin A. It is unclear whether these reductions in the serum micronutrient concentrations lead to decreased transport to target tissues.

Additionally, parasitic infections contribute to iron-deficiency anemia and nutritional deficiencies. Micronutrient deficiencies may be produced by infectious diseases in one of the following five ways: (1) decreasing food intake (anorexia); (2) impairing nutrient absorption; (3) causing direct micronutrient losses; (4) increasing metabolic requirements or catabolic losses; and (5) impairing transport to target tissues.

Thus, serious acute infections, particularly those that involve the gastrointestinal tract, impair linear growth. Chronic infections can also impair linear growth. Opportunistic infections may have accounted for diminished growth in some, but not all, children. For example, *Helicobacter pylori* can cause a chronic bacterial infection of the stomach and duodenum and, in some cases, can cause gastric or duodenal ulcer disease. Acute and chronic infections may impair linear growth due to micronutrient deficiency. For example, diarrhea and acute respiratory infections have been associated with the development of vitamin-A deficiency.

Summary Points

- There is a strong relationship between malnutrition, severity of infections, and infant mortality, especially in developing countries where parasitic infections are common.
- Undernutrition is not necessarily caused by inadequate food intake. There are malnourished people in rich countries, for example, patients receiving long-term care and those hospitalized.
- There is a negative correlation among anthropometric parameters, immune-response development, and health. Poor nutrition can lead to reduced immunity, increased susceptibility to disease, and impaired physical and mental development.
- Nutritional status of the host can be modified by increased demands of the parasites or by specific effects, for example, mucosal mechanical obstruction, blood loss, and others. Hence, chronic and uncontrolled infections can increase malnutrition status creating a continuous cycle of malnutrition and infection.

- Geohelminths may alter food intake, digestion and absorption of nutrients, and increased catabolism due to production of cytokines, such TNF-α, IL-1, and IL-6. These parasites can also lead to intestinal protein losses, deficiencies of vitamin A, zinc, and iron, anemia, hypoproteinemia, and growth retardation.
- Some parasites, such *Ascaris lumbricoides*, may affect growth in different ways, and may impair host nutrition by causing malabsorption of protein, lactose, fat and some fat-soluble vitamins, including vitamin A and also by direct mechanical damage and lumen obstruction.
- There is a prejudicial association between malnutrition, low values of anthropometric measures, and the outcome of cutaneous, mucocutaneous, and visceral diseases, but this is more evident in patients with the classical form of visceral disease.
- Lower BMI value represents an increased risk to tuberculosis. A negative correlation among anthropometric indicators of nutritional status and mortality by tuberculosis has been found.
- Leprosy continues to give rise to bone and joint lesions which may ultimately become crippling. Computerized podometric evaluation of the insensible feet of leprosy patients showed a close relation between points of increased pressure and areas with deficient sensation.
- Anthropometric parameters, such as BMI and mid-upper-arm circumference, have indicated that cured leprosy patients with residual deformity have a greater propensity to undernutrition when compared to cured leprosy patients without deformity.

Key Features

Table 142.5 Key features of parasitic and infectious diseases

1. Parasitology is the study of parasites and their relationships with their hosts.
2. Parasitism is a relationship in which the parasites physiologically depend on the host.
3. Infectious diseases are caused by pathogenic microorganisms, such as bacteria, viruses, parasites, or fungi; the diseases can be spread, directly or indirectly, from one person to another.
4. Unsanitary living conditions, poor nutrition, low education and economic levels, inadequate public health politics, and compromised immune response of people contribute to the high prevalence of parasitic and infectious diseases in tropical and subtropical countries.
5. Nutritional status influences the immunological defense against infectious and parasitic diseases.
6. Malnutrition plays an important role in susceptibility to infections.
7. The World Health Organization has considered malaria, leishmaniasis and leprosy as major human tropical diseases.

This table lists the key features of parasitic and infectious diseases including the concepts of parasitism, infectivity and their relationship to other areas of knowledge, and the importance of nutritional status and anthropometric parameters to efficient defense by the host

Chapter 143
Body Composition in Spinal Cord Injured–Paraplegic Men

Yannis Dionyssiotis

Abstract Spinal cord injury-induced paraplegia causes an extreme and sudden immobilization of the lower limbs. The effects of spinal cord injury in paralyzed areas are well documented. Immobility leads to a changing pattern of loading in the paralyzed areas, which respond by alteration in structure. Subjects lose muscle mass and bone and gain fat mass, especially in the lower limbs. In addition, studies have shown that the demineralization and the deterioration of body composition are more severe in the sublesional regions of the subjects and in tetraplegics compared with paraplegics. Clinical studies also indicated that neurological injuries are associated with the development of a rapid and severe osteoporosis that is not only due to a compromised biomechanical function but also could have a central nervous system origin. In this chapter, factors influencing body composition in paraplegia and rehabilitation intervention are also discussed.

Abbreviations

BMC	Bone mineral content
BMD	Bone mineral density
BMI	Body mass index
DEXA	Dual energy X-ray absorptiometry
FM	Fat mass
FFM	Fat free mass
LM	Lean mass
NLoI	Neurological level of injury
SCI	Spinal cord injury
pQCT	Peripheral quantitative computed tomography

143.1 Introduction

Human body composition measurement to quantify nutritional and health status has become important as evidence accumulates identifying relative body fat as a significant predictor of mortality (Seidel et al. 1996; Bender et al. 1998; Van Der Ploeg et al. 2003).

Spinal cord injury (SCI) causes immobilization associated with profound changes in the body composition in spinal cord injured (SCI) patients. There is loss of lean tissue mass (LM) and bone, but gain in fat mass (FM), and regional changes. The potential risks involved with these changes in body composition have implications for the health of the SCI individual (Jones et al. 1998). Disorders such as carbohydrate intolerance, insulin resistance, lipid abnormalities, and heart disease occur prematurely and at a higher prevalence in the SCI population and may be related to adverse changes in body composition that result from immobilization and skeletal muscle denervation from SCI (Spungen et al. 2003).

Body mass index (BMI, kg/m2) was used in many studies as a surrogate measurement of obesity. It is a very simple measurement of fat requiring only the measurement of height and weight; however it does not distinguish the individual components of weight. The applicability of conventional BMI cut-off values is questioned (Buchholz 2005; McDonald et al. 2007). According to the literature, several studies have shown that anthropometric measures tend to underestimate fat percentage when compared with able bodied individuals. BMI is an insensitive marker of obesity in subjects with SCI and measuring fat with BMI in chronic paraplegic patients is not enough to determine a subject's body fat percentage (Olle et al. 1993).

Fat free mass (FFM) is often used to standardize or index physiological variables, such as resting metabolic rate and strength (Van Der Ploeg et al. 2003). Skeletal muscle is the main component of FFM, representing 50% of the non-fat component in the total body (Clarys et al. 1984; Modlesky et al. 2004). In the assessment of nutritional status, disease risk, danger of illnesses, physical function, atrophic effects of aging and muscle-wasting diseases, the exact quantification of the amount of skeletal muscle is important (Forbes 1987; Mojtahedi et al. 2008).

A decline in bone mineral density (BMD) and bone mineral content (BMC) has been detected radiologically in the paralyzed limbs of patients as early as 6 weeks after SCI. The dramatic reduction in BMD or BMC has been well documented in chronic SCI patients. Bone loss generally involves the pelvis and lower extremities in paraplegic patients, while in tetraplegic patients the upper extremities are also involved. SCI patients display a specific form of demineralization characterized by an exclusively sublesional topography in which the head of tetraplegics (upper and lower body paralysis) and the upper limbs of paraplegics (lower body segment paralysis) are preserved (Jiang et al. 2006).

143.2 Imaging Techniques

Changes in body composition in SCI patients can be assessed with various techniques including isotope-labelled water (Jones et al. 1998), total body potassium counting (Lussier et al. 1983; Spungen et al. 1992), anthropometric measures (Bulbulian et al. 1987), hydrodensitometry (Lussier et al. 1983; Sedlock 1990), dual photon absorptiometry (DPA) (Spungen et al. 1992; Changlai 1996) and dual energy X-ray absorptiometry (DEXA) (Jones et al. 1998). However, some of these methods are not particularly suitable for use in the SCI population.

The hydrodensitometric model was regarded as the "gold standard" for body composition assessment. This model partitions the body into two compartments of constant densities (FM: 0.9007 g/cm3 and FFM: 1.100 g/cm3) and assumes that the relative amounts of the FFM components [water, protein, protein, bone mineral (BM), and non-BM] are fixed (Brozek et al. 1963; Van Der Ploeg et al. 2003).

Hydrodensitometry is clearly inappropriate for individuals who deviate from these fixed and/or assumed values (e.g., children, elderly, and obese), and its application is therefore somewhat limited (Womersley et al. 1976; Schutte 1984; Lohman 1986; Fuller et al. 1996).

Recently, DEXA has gained acceptance as a reference method for body composition analysis (Mahon et al. 2007; LaForgia et al. 2009). Originally designed to determine bone density, DEXA technology has subsequently been adopted for the assessment of whole body composition and offers estimation rapidly, non-invasively and with minimal radiation exposure (Van Der Ploeg et al. 2003; Dionyssiotis et al. 2008). DEXA also has the advantage of being a three-compartment model that quantifies: (1) bone mineral density and content (BMD, BMC), (2) FM and (3) lean mass (LM), half of which is closely correlated with muscle mass and also yields regional as well as total body values (Rittweger et al. 2000).

143.3 Pathophysiological Context

Complete SCI causes inactivation and consequently unloading of affected skeletal muscle (Van Der Ploeg et al. 2003). Studies performed on the skeletal muscle in paraplegics following SCI indicate marked changes in muscle morphology and in metabolic and contractile properties, and on the plasticity of the muscle in the present condition. Disuse was thought to be the mechanism responsible for the skeletal muscle atrophy in paraplegics, but muscle fibres following SCI begin to change their functional properties early post injury. It is evident that other co-factors such as spasticity and microvascular damage, contribute to the induction of the marked morphological and enzyme histochemical changes seen in the paralyzed skeletal muscle (Scelsi 2001). Small fibers, predominantly fast-twitch muscle, and low mitochondrial content have been reported years after injury in cross-sectional studies. These data have been interpreted to suggest that human skeletal muscle shows plasticity (Castro et al. 1999).

Actually, little is known regarding the nature and time frame of the influence of complete SCI on human skeletal muscle, because in cross-sectional studies, different groups of few subjects have been examined and the data was analyzed on different time periods in the chronic phase of paralysis. Muscle fibre cross-sectional area (CSA) has been suggested to decline from 1 to 17 months after injury and thereafter to reach its lowest point. Conversion to type II fibres has been suggested to occur between 4 months and 2 years after injury, resulting in even slow-twitch muscle becoming predominantly fast twitch thereafter (Castro et al. 1999). Metabolic enzyme levels in skeletal muscle might be expected to be reduced after SCI because of inactivation. In support of this contention, succinic dehydrogenase (SDH) activity, a marker of aerobic-oxidative capacity, has been reported to be 47–68% below control values in fibres of tibialis anterior muscle years after injury (Scelsi 2001). Conversely, force loss during repetitive contractions evoked by surface electrical stimulation (ES) of skeletal muscle in humans does not appear to be altered within a few months of injury (Shields 1995), but it is greater a year or more after SCI (Hillegass and Dudley, unpublished observations). The greater fatigue, when evident, has been partially attributed to lower metabolic enzyme levels (Scelsi 2001).

Muscle atrophy in paraplegics is of the central type and depends on the disuse and loss of upper connections of the lower motor neuron, sometimes associated with the loss of anterior horn cells

and trans-synaptic degeneration. The last alteration may be responsible for the denervation changes seen in early stages post SCI. In the later stages of paraplegia (10–17 months post SCI), diffuse muscle atrophy with reduction of the muscle fascicle dimension is associated with fat infiltration and endomysial fibrosis. In all stages post SCI, almost all patients showed myopathic changes, such as internal nuclei, fibre degeneration and cytoplasmic vacuolation due to lipid accumulation (Scelsi 2001).

The mechanisms that underlie bone loss after SCI remain poorly elucidated and controversial. Disuse may play an important role, but factors that are independent of mechanical loading of the skeleton also appear to be important. Possible influential non-mechanical factors may include poor nutritional status, disordered vasoregulation, hypercortisolism (either therapeutic or stress-related), alterations in gonadal function, endocrine disorders, and neural factors (Jiang et al. 2006).

Mechanical stress is one of the determinants of BMD, bone morphology and bone strength. Osteocytes embedded in the bone matrix respond to the mechanical load and to changes in bone metabolism (Doty 1981; Cowin et al. 1991; Lanyon 1993).

The gap junction of the long processes of osteocytes plays an important role in transmitting the mechanical load through intracellular signal transmitters (cAMP and cGMP) and extracellular signal transmitters (PGE2, IGF-I, IGF-II, and TGF-b) to induce bone formation by osteoblasts and inhibition of bone resorption by osteoclasts, or a combination of the two (Rodan et al. 1975; Palumbo et al. 1990; Duncan 1995; Jiang et al. 2006). Therefore, disuse accelerates bone resorption, leading to fragile bones. Sympathetic nervous system (SNS) dysfunction after SCI is attributable to loss of supraspinal control that occurs with disruption of spinal cord pathways (Teasell et al. 2000).

Maintenance of homeostasis within the body is a function of the autonomic nervous system and is interrupted when central nervous system (CNS) communications are interrupted. With high-level spinal cord injuries the SNS is disproportionately involved when compared with the parasympathetic nervous system. In a complete high-level SCI, functioning in the isolated spinal cord below the lesion becomes independent of supraspinal control and has been termed “decentralization” of the SNS (Claus-Walker and Halstead 1982; Karlsson et al. 1998).

Today there is clinical evidence that the sympathetic regulation of bone does exist in humans and plays a clinically important role in diseases characterized by excessive sympathetic activity (Schwarzman 2000). SCI is a dynamic process that is related to alterations in both the central and peripheral SNS. Also, changes in the autonomic nervous system are proposed to cause attrition of SCI bone, via changes in vascular tone and flow (Levasseur et al. 2003).

Sympathetic denervation in SCI may cause arteriovenous shunts and a slowdown of intraosseous blood flow, thus increasing bone resorption. Anatomically, in SCI above the mid-thoracic SNS outflow is crucial to the development of clinical features of SNS dysfunction. It has been observed that the higher the level of the SCI, the greater the degree of clinical manifestations of SNS dysfunction (Teasell et al. 2000).

Vascular modifications below the neurological lesion play a role in the bone resorption after SCI by inducing a local modification of the endosteal surface. The decrease of gas exchanges and blood could promote osteoclast formation because of local hyper pressure, thus accelerating bone resorption (Chantraine et al. 1979).

This clear predominance of bone demineralization in the highly vascularized metaphyseal–epiphyseal areas of the long bones constitutes an additional argument. However, there is indeed a significant local vascularization at the level of these areas, which would be particularly affected by a secondary intramedullary blood stasis due to the sublesional vasomotor disorder (Teasell et al. 2000).

143.4 Methodological Considerations

143.4.1 Paraplegia Related Alterations in Lean Mass, Fat Mass, and Body Mass Index

143.4.1.1 Body Mass Index (BMI) in Spinal Cord Injury – Paraplegia

Similar body mass indices were found between paraplegics and controls, although there were significant decreases in the lean muscle mass of the paraplegics (<16%). The analysis of body composition with DEXA has also revealed large increases in fat in people who do not appear obese, yet they carry large amounts of fat tissue and in the group of paraplegic subjects FM was 47% higher (Jones et al. 2003). Furthermore, where authors performed research on the usage of the BMI in anthropometric measurements, the conclusion was that BMI, widely used as an obesity measurement tool, is not capable of distinguishing the weight components among people, so that the fat percentage is degraded in the paraplegic population in comparison to the control group (Bulbulian et al. 1987) (Fig. 143.1).

In a study which investigated a chronic paraplegic population, BMI values were statistically decreased compared to controls (Dionyssiotis et al. 2008), while others found no significant difference in relation to controls (Maggioni et al. 2003; Mamoun et al. 2004). Moreover, BMI values in both paraplegics and controls were below values considered to indicate obesity (BMI > 27.8) (Statement NIOSH/CDC, 1987; Schulte et al. 2007; Dionyssiotis et al. 2008). This finding may be acceptable for the control group examined, but raises questions regarding the paraplegics. Literature has shown that paraplegics are obese (Kocina 1997). Nevertheless, there are studies which demonstrate the usefulness of BMI as an indicator of obesity in body composition in people with SCI (Gupta et al. 2006). However, these studies included both tetraplegics and middle-aged people, unlike the Greek study which included relatively young individuals (Dionyssiotis et al. 2008). The latest studies show that the criteria of BMI are not effective in assessing obesity in people with SCI (McDonald et al. 2007) (Figs. 143.2 and 143.3).

As with the healthy population, BMI values are positively correlated with obesity in the SCI population. This emerged from a study, conducted by whole body DEXA Norland X-36, only when the

findings of total fat in paraplegics were correlated with BMI. Employing whole body DEXA Norland XR-36, it was found that the total FM was statistically, significantly higher for any given BMI value in paraplegics compared with controls (Dionyssiotis et al. 2008), a finding that strongly supports the studies held by the whole body DEXA Hologic QDR-2000 method (Spungen et al. 2000, 2003).

The studies illustrated statistically, significantly higher total FM and fat percentages for any given unit of BMI in paraplegics in comparison to controls. Increased fat per BMI unit was found in a

study, also by the above authors, of monozygotic twins, one with SCI compared with the non-SCI co-twin (Spungen et al. 2000). Adjustments in classifications of normal, overweight, obese, and morbid obesity by BMI are needed for persons with SCI (Groah et al. 2009).

In addition, in an analysis between paraplegics with high and low neurological level injuries (NLoIs), a lack of statistically significant differences in BMI was highlighted. However, when data from the analysis undertaken in areas measured by whole body DEXA were compared in the same patients, there were differences between paraplegics with high and low NLoI. This finding is new and reinforces those views on the inaccuracy of BMI usage in the analysis of body composition of paraplegics (Dionyssiotis 2008; Dionyssiotis et al. 2008).

BMI of the male paraplegic group was slightly greater than that of the male tetraplegic group (25.2 vs. 24.7 kg/ m2; $p < 0.01$). The proportion of overweight or obese was comparable between men with SCI and that observed in men in the US general population. Distribution of BMI by level of injury was similar, with 37.5% and 40.5% of the male tetraplegic and male paraplegic groups, respectively, falling into the recommended BMI range. Approximately 50% in each male group were overweight by BMI, and 12.5% and 10.8%, respectively, were classified as obese. Overall, when compared with the general population-observed distribution by BMI, a greater proportion of men with SCI fell into the desirable BMI range and fewer fell into the obese category (Groah et al. 2009).

No differences were found in BMI between paraplegics in the acute phase of injury and control. This finding is in accordance with other studies reported in chronic paraplegic patients and controls, in which despite the same BMI, the body composition and the distribution of fat and FFM were altered in patients with SCI, with the FFM being statistically, significantly lower in paraplegic

Table 143.1 Regional (*upper and lower limbs*) and total body composition results in controls vs. total paraplegic group

		Control group $n = 33$	Paraplegics $n = 31$	
Whole body DEXA	Parameters	Mean value ± SD	Mean value ± SD	*p*-Value
Upper limbs	BMC, g	449.88 ± 57.3	465.15 ± 65.71	N.S
	Lean, g	6,570.21 ± 1,498.81	6,082.03 ± 1,615.13	N.S
	Fat, g	2,025.32 ± 874.04	2,316.87 ± 1,500.12	N.S
Lower limbs	BMC, g	1,213.84 ± 149.37	886.26 ± 178.81	< 0.0005
	Lean, g	19,692.73 ± 3,242	11,094.3 ± 2,174.64	< 0.0005
	Fat, g	6,909.91 ± 2,497	8,203.3 ± 3,433.02	N.S.
Total body	BMC, g	3,322.7 ± 302.84	3,016.74 ± 368.38	0.001
	Lean, g	56,655 ± 8,781.05	42,211.2 ± 6,509.2	< 0.0005
	Fat, g	19,015.8 ± 6,553.84	23,071.8 ± 9,485	0.001

Values of measured parameters (bone mineral content (BMC), lean and FM) in paraplegics and controls using whole body DEXA in upper and lower limbs and total body composition (Reprinted (modified and translated) from Dionyssiotis 2008)

patients in total body composition and in the lower, but not the upper limbs. As far as the FM is concerned, it was statistically, significantly higher (kilograms and %) in the total body composition in the upper and lower limbs (Maimoun et al. 2006) (Table 143.1).

These findings show that using the BMI does not contribute substantially in determining the body composition of paraplegics, but that it shows a lower percentage of fat in this population – a finding that agrees with other studies and shows that the anthropometric measurement with BMI in paraplegics underestimates fat in body composition when measurements are compared with healthy subjects (Jones et al. 1998).

143.4.1.2 Total Body Composition Alterations

The body composition is significantly altered during the first 6 months after the injury according to studies conducted in paraplegics who noticed remarkable muscle atrophy between the first and the third month after injury, without further loss until the following 6 months (Rossier et al. 1991; Uebelhart et al. 1995; Baldi et al. 1998; Castro et al. 1999). The corresponding percentages were 10.7% in the lower limbs and 5% in the total body composition in six young paraplegic men, while the LM increased by 19.6% in the upper limbs. In a perspective study of 1 year, muscle mass is dramatically diminished during the first months after the injury in the lower limbs (in 15 weeks), while in the same time period the fat content tended to increase. The total lean muscle mass is reduced by approximately 9.5% within 6 months, while the lean muscle mass of the lower limbs is reduced by 15.1% within a year after the injury. Nevertheless, authors phrased that LM is better preserved in patients who develop spasticity (Wilmet et al. 1995) (Fig. 143.4).

In another study the population of paraplegics was estimated with DEXA and furthermore anthropometric skinfold measurement was performed. The anthropometric measurement underestimated significantly the FM in the paraplegics' population. The total and regional body composition (FM; fat-free mass, FFM) was estimated in 13 SCI patients and total FM was found to be significantly higher and LM lower in comparison to the controls. In the group of paraplegics the regional FM was higher in the lower limbs and the trunk (Maggioni et al. 2003).

In active paraplegic men FM was found to be 16–24% compared to 15% for normal men (Kocina 1997). In chronic paraplegics who had suffered injury 2 years earlier, the amount of skeletal muscle in the FFM of the soft tissue was studied at the mid-shaft of the femoral bone using a magnetic resonance

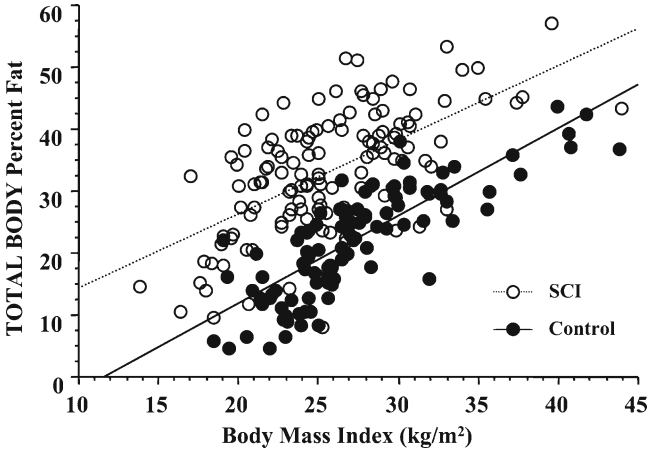

Fig. 143.4 The relation of total body percent fat with body mass index (BMI) for spinal cord injured and controls. Relationship of total body percent fat with BMI for the spinal cord injury (SCI) and control groups (SCI: $r = 0.60$, $p < 0.0001$, control: $r = 0.81$, $p < 0.0001$). The subjects with SCI had, on average, a 13 ± 1% increase in percent fat for any given BMI compared with the control subjects (Reprinted from Spungen 2003. With permission)

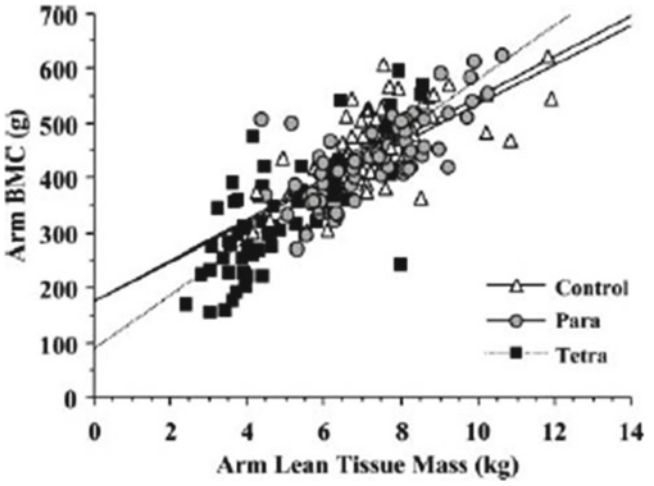

Fig. 143.5 The relation of arm bone mineral content (BMC) with arm lean tissue mass for tetraplegics (tetra), paraplegics (para) and controls. Relationship of arm BMC with arm lean tissue mass for Tetra, Para, and control (Tetra: $r = 0.76$, $p < 0.0001$; Para: $r = 0.73$, $p < 0.0001$; control: $r = 0.73$, $p < 0.0001$). There were no significant interaction effects or slope differences among Tetra, Para, and control groups (Reprinted from Spungen 2003. With permission)

imaging (MRI) technique and with DEXA and compared with similar normal population. Muscle mass and fat-free soft tissue mass were statistically, significantly lower in paraplegics, but the paraplegic group showed a lower ratio of muscle to fat-free soft tissue mass tissue in relation to controls (Modlesky et al. 2004). Using the MRI technique, an 18–46% loss was observed in the thigh surface in complete paraplegics in the acute phase of 6 weeks, with an additional loss of about 8–15% during the next 18 weeks (Castro et al. 1999). The percentage of FM in subjects with low paraplegia was comparable to controls at 20%, although in higher NLoI, the rate of fat ranged from 30% to 36% in 37 SCI patients studied using radioisotope methodology (Nuhlicek et al. 1988). In 133 men with chronic SCI, 13 ± 1% more fat per unit of BMI and higher values of FM in paraplegics' upper limbs and lower rates of LM were found compared with controls (Spungen et al. 2003) (Fig. 143.5).

Table 143.2 Arms' measured parameters in controls and paraplegic groups

Whole body DEXA parameters		Control group $n = 33$ Mean value ± SD	High Paraplegics $n = 16$ Mean value ± SD	Low Paraplegics $n = 15$ Mean value ± SD	*p*-Value
ARMS	BMD, g/cm^2	0.76 ± 0.11	0.66 ± 0.10	0.76 ± 0.12	0.008
	BMC, g	449.88 ± 57.3	454.86 ± 68.10	476.13 ± 63.53	0.391
	Lean, g	6.570 ± 1.499	6.150 ± 1676	6.007 ± 1.602	0.451
	Fat, g	2.025 ± 874	1.951 ± 962	2.658 ± 1839	0.186

Values of measured parameters BMC, BMD, lean and FM) in both paraplegic groups and controls using whole body DEXA in the upper limbs (Reprinted (modified and translated) from Dionyssiotis 2008)

The strong influence of the duration of injury to both the lower limbs and body composition study has been reported in a study of monozygotic twins where one brother had complete paraplegia and his twin brother was normal. The reduction in LM was as greater as longer the duration of the paralysis (Spungen et al. 2000, 2003).

A statistically significant decrease of 26% in total muscle mass in paraplegics compared with controls was found within 5 years of injury. Moreover during the same period in paraplegics the total amount of fat was statistically, significantly increased by 21% (Dionyssiotis 2008). Similarly, others found that the total muscle mass decreases by about 9.5% within 6 months, while the muscle mass of the lower limbs is reduced by 15.1% 1 year after the injury (Wilmet et al. 1995). The increased rate of fat by 29% which was found in the Greek study of paraplegics with a low NLoI (Dionyssiotis 2008) is substantially similar to a former study (increased rate of fat in paraplegics 20%) of a group of paraplegics that also included high paraplegics (Nuhlicek et al. 1988). The difference is due to the participation of high paraplegics in their study which reduced the percentage. In a mixed paraplegic population (complete and incomplete paraplegics) the percentage of LM, but not absolute LM, in the upper limbs of paraplegics was significantly lower than controls, suggesting that the higher amount of absolute FM in paraplegics was responsible for this result (Spungen et al. 2003). In contrast, the Greek study of the analysis of LM and FM in paraplegics' upper limbs and controls did not show any significant differences (Dionyssiotis et al. 2008). However, when paraplegics were analyzed according to the NLoI, values of fat in high paraplegics' upper limbs were similar to controls and lower in comparison with values of fat in the low paraplegics group. However these results were not statistically significant. In the same study further investigation of the relationship of muscle mass in both upper limbs of paraplegic groups revealed that the high paraplegics have 2% more muscle mass than the low paraplegics. Also, the corresponding relationship concerning the fat revealed a decrease in fat by 26.6% in the upper limbs of the high paraplegics compared with the low paraplegics. Taking into consideration that the upper limb is only theoretically a non-weight bearing bone in paraplegics, an explanation of this finding could be that high paraplegics are trying to overcome their handicap through an arm overuse (high mechanical forces) reducing regionally adiposity and inducing LM. So the question is if the higher FM values in low paraplegics' arms are responsible for the higher values in BMD (Dionyssiotis 2008; Dionyssiotis et al. 2008) (Table 143.2).

In a prospective 1-year study it was seen that LM is better preserved in patients who develop spasticity (Wilmet et al. 1995). Other authors also reached the same conclusion as Gorgey and Dudley 2003. The latter study included patients with incomplete SCI. This conclusion, however, has been questioned by other researchers and has not been verified by studies involving patients with complete paraplegia (Eser et al. 2005). Spasticity does not constitute a maintaining factor of the

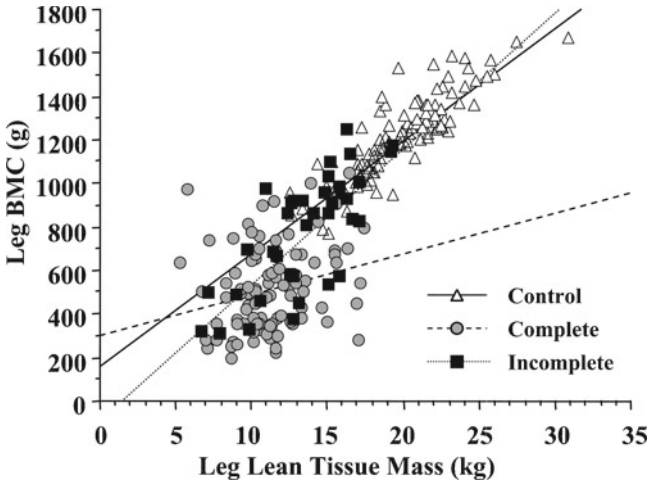

Fig. 143.6 Relationship of leg BMC with leg lean tissue mass for those with complete or incomplete SCI and controls. Relationship of leg BMC with leg lean tissue mass for those with complete (an absence of sensory or motor function below the neurological level, including the lowest sacral segment) or incomplete (sensory or motor function below the neurological level, including the lowest sacral segment) spinal cord injury (SCI) and controls (complete: $r = 0.25$, $p < 0.01$; incomplete: $r = 0.74$, $r < 0.0001$; control: $r = 0.86$, $p < 0.0001$). Those in the complete group had significantly less BMC per unit of lean tissue mass than the other two groups (slopes: complete = 0.061 vs. incomplete = 0.553 and control = 0.747; $p < 0.01$) (Reprinted from Spungen 2003. With permission)

muscle system and we believe that the importance of neurogenic damage is highlighted, so that either the myopathic muscle does not recognize stimuli due to its degeneration or it recognizes them incorrectly (Dionyssiotis 2008) (Fig. 143.6).

In addition, the strong influence of the duration of injury to the lower limbs and body composition has been reported in monozygotic twins, where one brother had complete paraplegia and his twin brother was normal (Spungen et al. 2000). The authors concluded that the longer the duration of paralysis, the greater the decrease in muscle mass. In the group of high paraplegics a strong relationship between duration of paralysis and both total body and upper limbs fat was found (Spungen et al. 2003). Despite the similar paralytic effect on body composition and the similar duration of paralysis in both paraplegic groups of this study, the explanation of that strong correlation may be due to the outcome of higher frequency of standing and increased mobilizing in the group of low paraplegia and the possible use of gait orthoses and standing frames that results in increased energy consumption and obesity reduction. Nevertheless, this explanation is simplistic considering the complex pathophysiology with regard to hormonal influences, the injury and the neurogenic factor in body composition of paraplegics (Dionyssiotis 2008).

143.4.2 Spinal Cord Injury Induced Paraplegia and Bone

SCI always results in substantial and rapid bone loss. In SCI patients, the demineralization predominates on the long bones of the lower limbs. The most affected sites are the trabecular metaphyseal–epiphyseal areas of the distal femur and the proximal tibia (Jiang et al. 2006). The predominant finding of SCI on bone is a large loss of bone during the first year of injury due to disuse osteoporosis, predisposing to an increased prevalence of fractures (Spungen et al. 2003). An ongoing demineralization

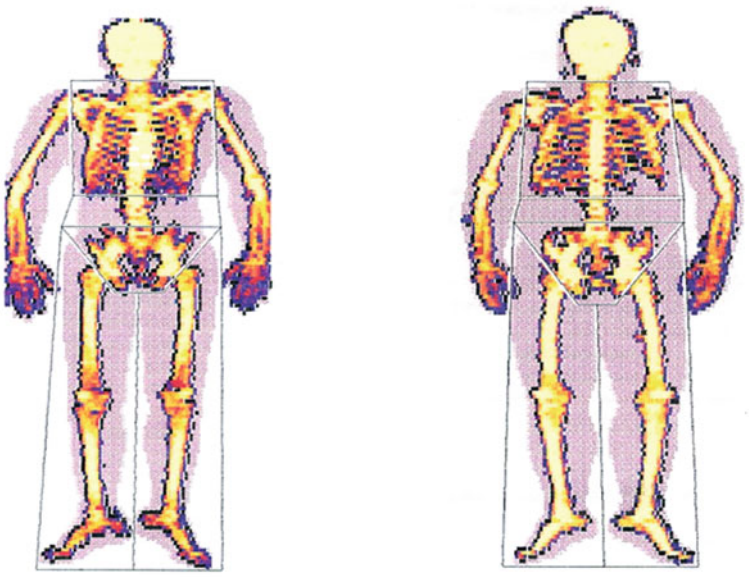

Fig. 143.7 Whole body Norland XR-36 in paraplegic (*left*) vs. control subject and values of the measured parameters. Whole body and regional distribution of fat mass (FM), lean mass (LM), BMC and BMD from paraplegic subject Thoracic 12 (*left picture*) and healthy man using whole body DEXA Norland X-36 and values of measured parameters (Reprinted from Dionyssiotis 2008)

in the tibia was demonstrated 3 years after trauma (Biering-Sörensen et al. 1988) and a progressive bone loss in SCI over 12–16 months prior to stabilizing (Lazo et al. 2001) (Fig. 143.7).

Duration of paralysis, related loss of bone in the lower limbs of monozygotic twins with chronic paraplegia in comparison with their able-bodied co-twins is also reported (Bauman et al. 1999). A longitudinal study of 15 acute SCI patients revealed that BMD in the calcaneus and proximal tibia was decreased by 7.5% and 5.3% in 6 weeks after injury, respectively (Warden et al. 2002). Cancellous bone is more affected than cortical bone after SCI. In a prospective study, six acute tetraplegics were followed up for 12 months, and the trabecular and cortical BMDs of the tibia were found to be decreased by 15% and 7%, respectively (Frey-Rindova et al. 2000). In a cross-sectional study (Dauty et al. 2000) of 31 SCI patients more than 1 year after injury, a significant demineralization at the distal femur (-52%) and the proximal tibia (-70%) was demonstrated and this is in accordance with the findings of other authors (Biering-Sorensen et al. 1990; Finsen et al. 1992). Similarly, in another cross-sectional study of eight SCI patients, a reduction of 35.3% in BMD of the tibial trabecular bone occurred within the first 2 years after SCI, whereas there was only a 12.9% reduction in tibial cortical bone (de Bruin et al. 2000). Bone loss in the proximal tibia of acute SCI patients is about 5.3–15%, whereas in chronic SCI patients a range of 15–52% was reported (Biering-Sorensen et al. 1990; Demirel et al. 1998; Dauty et al. 2000; Warden et al. 2002).

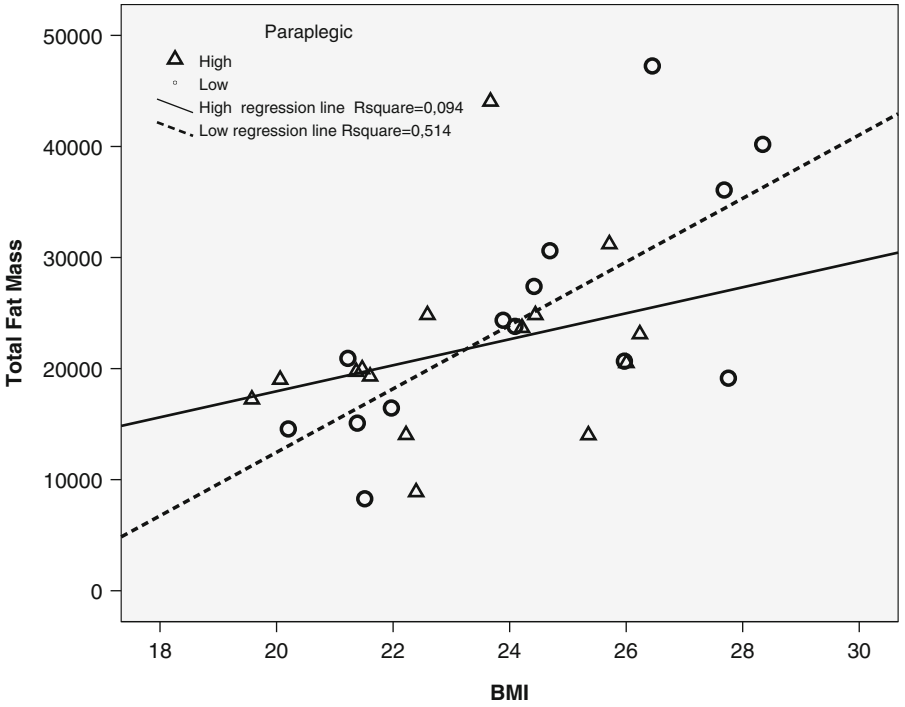

Fig. 143.8 The relation of total FM with BMI for paraplegics with high and low levels of injury. Relationship of total FM with BMI for paraplegic subjects (high paraplegics above thoracic (T) seven neurological level of injury (NLoI) vs. low paraplegics T8-T12 NLoI. According to the level of neurological injury during analysis between paraplegic subjects no statistically significant differences in BMI were found. When we correlated data from the analysis undertaken in body composition measured by the method of whole body DEXA we found strong correlation of total FM with BMI only in low paraplegic group. This finding is new and reinforces those views on the impossibility of use of BMI in the analysis of body composition of paraplegic subjects (Reprinted (modified and translated) from Dionyssiotis 2008)

143.4.3 Factors that Appear to Influence Bone in SCI Individuals

1. The level of the lesion and thus the extent of impairment of motor and sensory functions may be taken into account first, because tetraplegics are more likely to lose more bone mass throughout the skeleton than paraplegics (Tsuzuku et al. 1999). A reduction of lower limb BMC in chronic paraplegics vs. controls was found independently of the NLoI. Lower limb BMC was negatively correlated with the duration of paralysis in the total paraplegic group, but after investigation according to the NLoI this relationship was due to the strong correlation of high paraplegics leg BMC with the duration of paralysis, meaning that the NLoI determines the extent of bone loss (Dionyssiotis et al. 2009). However, similar severity of demineralization in the sublesional area was shown between paraplegics and tetraplegics, and the extent of the bone loss may be variable (Demirel et al. 1998; Tsuzuku et al. 1999; Dauty et al. 2000) (Fig. 143.8).
2. In addition, in those SCI individuals with complete lesions (an absence of sensory or motor function below the neurological level, including the lowest sacral segment) bone loss is more severe than subjects with incomplete lesions (partial preservation of motor and/or sensory function(s) below the neurological level, including the lowest sacral segment) (Garland et al. 1992; Demirel et al. 1998; Sabo et al. 2001). In a cross-sectional study of 11 patients with complete SCI and 30

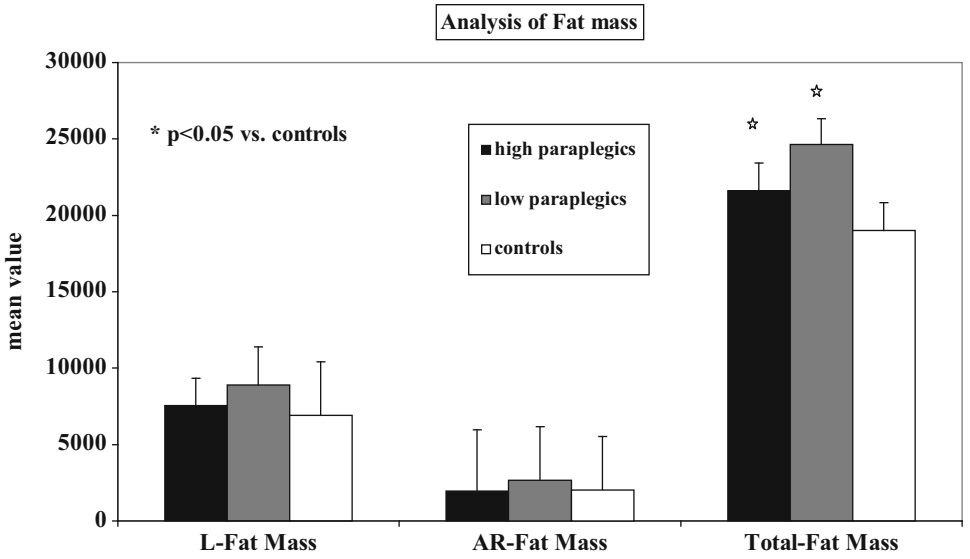

Fig. 143.9 Fat mass analysis in the two paraplegic groups and controls in upper limbs region (AR-FM), lower limbs region (L-FM) and total body composition (Total – FM). Fat mass analysis in the two paraplegic groups and controls in legs, arms and total body. Analysis of FM in paraplegics' arms and legs vs. controls did not show any significant differences. Total body fat value was statistically significant increased in paraplegic subjects 23,071 ± 9,485 vs. 19,015.± 6,553 in controls ($p = 0.05$) (Reprinted (modified and translated) from Dionyssiotis 2008)

patients with incomplete SCI, more significant osteopenia was observed in patients with complete SCI than in patients with incomplete SCI (Demirel et al. 1998).

3. Inconsistent results have been reported regarding the effect of muscle spasms on BMD in SCI patients. Those with spasticity were found to have higher BMD when compared with flaccid individuals (Demirel et al. 1998), and a significant correlation between the degree of spasticity measured with modified Ashworth scale and BMD was reported. Thus, it was concluded that spasticity may be protective against bone loss in SCI patients (Eser et al. 2005). Conversely, other investigators have not established a correlation between BMD and muscle spasticity (Panin et al. 1971; Gross et al. 1987; Biering-Sorensen et al. 1990; Wilmet et al. 1995; de Bruin et al. 2000) (Figs. 143.9 and 143.10).
4. Studies also emphasize the contribution of aging to bone loss in complete SCI patients. Moderate correlation between age and femoral BMD was observed in a cross-sectional study of 30 patients with SCI of 1-year duration or less (Kiratli et al. 2000). On the other hand, bone loss in eight pairs of identical male twins with SCI of duration ranging from 3 to 26 years appeared to be independent of age (Bauman et al. 1999; Wood et al. 2001)
5. Muscular loading of the bones has been thought to play a role in the maintenance of bone density. The ability to stand or ambulate itself does not improve BMD and does not prevent osteoporosis after SCI, although exercise increases site-specific osteogenesis in able-bodied individuals (Kunkel et al. 1993). There was only one study demonstrating that standing might reduce the loss of trabecular bone after SCI. In this prospective study of 19 acute SCI patients, the patients involved in early loading intervention exercise lost almost no bone mineral, whereas the immobilized patients lost 6.9–9.4% of trabecular bone (de Bruin et al. 1999) (Fig. 143.11).

Muscles rather than body weight achieve the greatest loads on bone (Frost 1987). It is difficult to translate in vivo bone strains from animal work to a gross loading environment for humans.

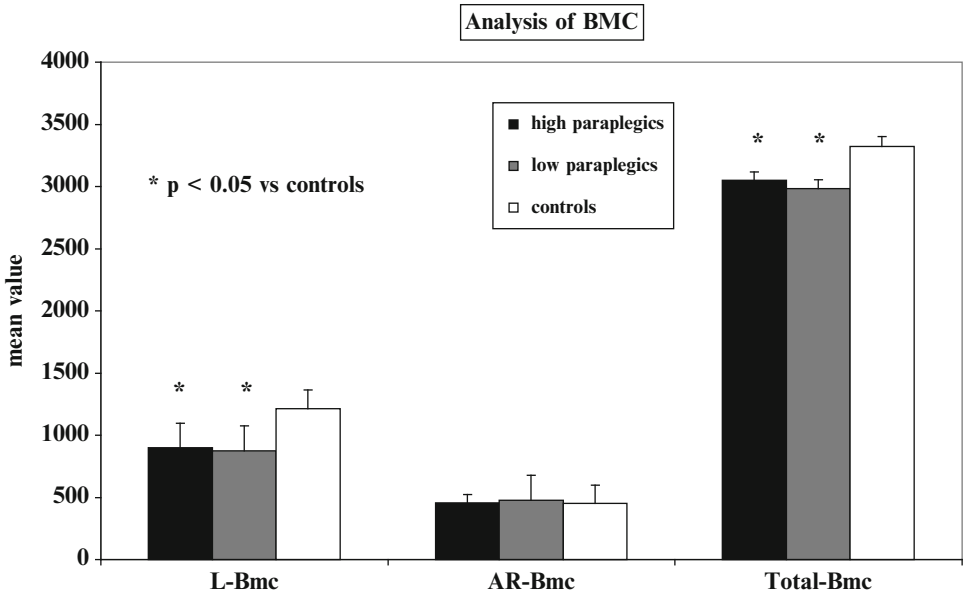

Fig. 143.10 Analysis of bone mineral content (BMC) in the two paraplegic groups and controls. Analysis of BMC in high and low level paraplegics and controls. A statistically significant reduction was observed in BMC in total body composition (3,016 ± 368 vs. 3,322 ± 302, $p = 0.001$) and paraplegics' lower limbs (886 ± 178 vs. 1,213 ± 149, $p < 0.001$) in comparison with able-bodied males (Reprinted (modified and translated) from Dionyssiotis 2008)

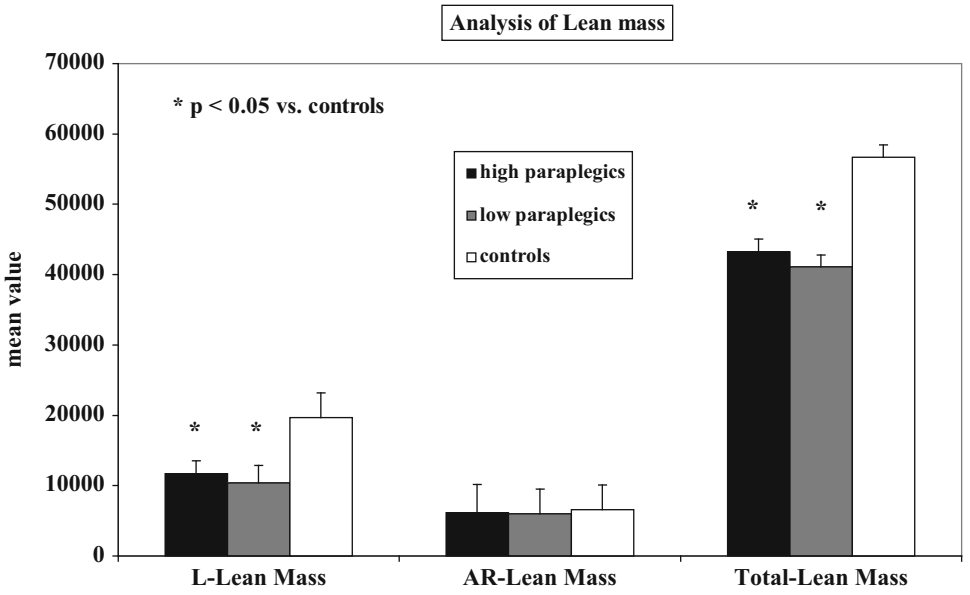

Fig. 143.11 Analysis of lean mass (LM) in the two paraplegic groups and controls. Analysis of LM in high and low level paraplegics and controls. A statistically significant reduction in total LM ($p < 0.001$) in paraplegics' total body and lower limbs composition in comparison with able-bodied males (42,211 ± 6,509 vs. 56,655 ± 8,781 and 11,094 ± 2,174 vs. 19,692 ± 3,242, respectively) was observed (Reprinted (modified and translated) from Dionyssiotis 2008)

However, the pioneering work in animal models (Frost 1988) suggests that if the active–resistive standing exercise can indeed transmit loads at an appropriate frequency and strain-rate, compressive loads approaching 240% body weight may have the potential to be osteogenic (Frost 1990, 1995).

Functional electrical stimulation (FES) cycling (Ragnarsson et al. 1988) and quadriceps muscle training (Belanger et al. 2000) have been able to increase force-generating capability and to improve muscular endurance with training after SCI (Ragnarsson et al. 1988). Conversely, cycling with FES has been reported to induce only small improvements in BMD (Bloomfield et al. 1996; Mohr et al. 1997) as well as having no effect (Leeds et al. 1990; BeDell et al. 1996) on lower extremity BMD measurements in individuals with SCI. Additionally, neither passive standing, ambulation with long-leg braces, nor ambulation with FES have yet to exhibit any improvement in lower extremity BMD in chronically injured subjects (Sloan et al. 1994; Needham-Shropshire et al. 1997). The subject population of previous BMD studies were comprised almost exclusively of individuals with chronic rather than acute SCI. These interventional BMD studies may have utilized sub-threshold mechanical stimuli. The use of relatively low bone loading regimens is not unexpected due to the extensive atrophy of chronically paralyzed muscle (Shields 2002, 2007) and concerns of fracture which have been reported to occur with physical interventions (Valayer-Chaleat et al. 1998; Frey-Law and Shields 2004).

6. The duration of paralysis has also been shown to affect the degree of bone loss in the sublesional areas (Lohman 1986; Modlesky et al. 2004). Studies report inverse relationships between the duration after injury with lower limb percentage-matched BMD and trunk percentage-matched BMD (Clasey et al. 2004). In addition upper limb FM and lower limb BMD were correlated with the duration of paralysis in total paraplegic group, but after investigation according to the NLoI (NLoI). This association was due to the strong correlation of high paraplegics' lower limbs BMD with the duration of paralysis. The explanation of this strong correlation could possibly be that despite the similar paralytic effect on bones in all paraplegic patients and the similar duration of paralysis in the two paraplegic groups, this difference is possibly a result of higher incidence of standing in the group of low paraplegics and direct effect of loading lower limbs and walking with orthoses. The association of the duration of paralysis with parameters below and above the NLoI raises the question of the existence of a hormonal mechanism as an influential regulator in paraplegics' body composition (Dionyssiotis et al. 2008).
7. The role of leptin: the hormone leptin is secreted by fat cells and helps regulate body weight and energy consumption (Fruhbeck et al. 1998). The amount of leptin in the circulation is positively correlated with the percentage of fat in people (Maffei et al. 1995). In paraplegics, when compared with healthy subjects, higher levels of leptin have been found, possibly due to greater fat tissue storage (Bauman et al. 1996). Leptin activates the sympathetic nervous system (SNS) through a central administration. The disruption of the sympathetic nervous system may modify the secretion and activity of the leptin, because the sympathetic preganglionic neurons become atrophic in high paraplegics (Elias et al. 1998; Correia et al. 2001). The irritation thus, below the NLoI, from the leptin is disturbed. In addition, extensive obesity is known to reduce lipolytic sensitivity (Haque et al. 1999; Horowitz et al. 1999; Horowitz and Klein 2000). Given that in a high level of neurological paraplegia there is a problem of disorder of the autonomic nervous system, and in combination with the existence of scientific evidence, that the hormone leptin activates the sympathetic nervous system through central control, it was formulated that the closure <of paths> of the central nervous system disrupts the effect of leptin and possibly increases the risk of obesity in paraplegic patients with high-level injury (Krassioukov et al. 1999; Jeon et al. 2003).

However, after separation of SCI subjects into those with an injury above or below Thoracic (T) 6, leptin levels were significantly higher in the former group. T6 appears to be the lowest level of injury in most patients with SCI to develop autonomic dysreflexia. With SCI above the level of T6, there is reduced SNS outflow and supraspinal control to the splanchnic outflow and the lower-extremity blood vessels. Multiple regression analysis showed that serum leptin levels in men with SCI correlated not only with BMI but also with the neurologic deficit. This finding supports the notion that decentralization of sympathetic nervous activity relieves its inhibitory tone on leptin secretion, because subjects with tetraplegia have a more severe deficit of sympathetic nervous activity (Wang et al. 2005).

143.4.4 Steady State After Injury

Is there a time after injury where bone loss ceases? Some authors reported that approximately 2 years after SCI, a new steady state level between bone resorption and formation would be re-established (Chantraine et al. 1986; Biering-Sorensen et al. 1990), whereas others (de Bruin et al. 2005) found that there was no sign of a new steady state in bone formation in the lower extremities 2 years after the SCI. Using peripheral quantitative computed tomography (p QCT) has been shown that different parameters reach the steady state at different time and levels in the same bone (Dionyssiotis et al. 2009). It still remains controversial whether or not a new steady state of bone remodelling is re-established after SCI.

143.4.5 Effect of Paralysis in Bones Above and at the Neurological Level of Lesion

There is no demineralization of the upper limbs in paraplegics. On the contrary, a minor increase of BMD (6%) in the humerus was reported in a cross-sectional study of 31 male chronic paraplegics 1 year post injury. With reliance on the upper limbs to provide movement for activities of daily living in the SCI population, this area could be subjected to greater site-specific loading, and thus increasing osteogenesis, than in the corresponding able-bodied population. At the lumbar spine, the trabecular bone demineralization remains relatively low compared to the cortical bone demineralization of long bones (Dauty et al. 2000). Normal (Chantraine et al. 1986; Biering-Sorensen et al. 1988; Kunkel et al. 1993) or even higher than normal (Ogilvie et al. 1993) values of BMD in the lumbar spine have been reported, a phenomenon which is named dissociated hip and spine demineralization (Leslie and Nance 1993). One reason for preservation of bone mass in the vertebral column is because of its continued weight-bearing function in paraplegics. In a cross-sectional study of 135 SCI men, BMD in the lumbar spine was found to be stable with an insignificant decline in the tetraplegic population at 1 ± 5 years post injury in the 20–39-year age group, whereas in the 40–59-year age group and the 60+-year age group, bone mass in the lumbar spine remained unchanged or even increased with age (Szollar et al. 1997). However, several factors may affect the results of BMD measurement: lumbar spine arthrosis, bone callus, vertebral fracture, aortic calcification, osteosynthesis material, etc. Degenerative changes in the spine may be the most possible reason to give falsely higher values of BMD (Dauty et al. 2000). An interesting question is why we do not see osteoporotic vertebral fractures in SCI patients to the extent it occurs in post-menopausal osteoporotic women or senile osteoporotic men?

143.5 Conclusion

Another critical question that arises is how best to proceed programmatically to promote optimal body weight and composition to reduce disease risk. Typical management options include dietary change, physical activity, and pharmacologic options. First-line self-management is often dietary changes for improved weight control and disease prevention. To achieve benefits, many individuals with SCI would have to follow stringent diets with lower total energy intake and an emphasis on nutrient-rich foods (Groah et al. 2009).

143.6 Applications to Other Areas of Health and Disease

Paraplegia related alterations of body composition are very important. Not only fractures because of bone loss but other diseases such as coronary heart disease, non-insulin-dependent diabetes mellitus and lipid abnormalities exist in paraplegics with higher prevalence. The increased fat percent in the body and the immobilization play a significant role in these diseases. Research about body composition in paraplegia is very important to quantitate and monitor body composition changes and to modify our therapeutic interventions in this specific population.

Summary Points

- Healthy BMI values often underestimate body fat in men with spinal cord injury and may mask the adiposity.
- BMI and total body fat were interrelated in SCI, as in the control population, but the line was shifted to the left, indicating that total body fat mass and percent were significantly greater at any given unit of BMI in persons with SCI than in controls.
- Upper limbs' analysis according to the neurological level of injury unmasked similar fat values in high paraplegics and controls vs. higher values in low paraplegics.
- Spasticity did not defend skeletal muscle mass and bone. This result supports the concept that after spinal cord injury the myopathic muscle could not recognize correctly the stimulation because of the neurogenic injury.
- Studies indicated marked atrophy of paralyzed muscles after spinal cord injury suggesting a preferential atrophic response in the antigravity muscles. One explanation is that paraplegics mostly transfer much of the weight-bearing demands of daily activities to their upper extremities. This reduced the weight-bearing of the affected paralyzed muscles triggering a cycle of added muscle atrophy and acts synergistically with the continuous catabolic action caused by the neurogenic factor.
- Spinal cord injury induces bone loss in paraplegics. A decline in bone mineral density as well as bone mineral content is expected in paralyzed segments.
- The duration of paralysis is positively correlated with the degree of bone loss. Duration of paralysis is positively correlated with total fat mass in total paraplegic group. This correlation was found to be stronger for high paraplegics in specific regions (upper limbs) and in total body composition.
- While it is possible that different stimuli are necessary to cause adaptations in muscle and bone after SCI, it is also possible that osteoporosis, unlike muscle atrophy, is essentially irreversible

once established. Prevention rather than treatment may have the greatest potential to alleviate this significant SCI complication.

- Muscles and bones are related tissues. Strategies that help paraplegics to bear weight, to stand or walk therapeutically should be added early in the rehabilitation program to gain benefits according to muscles and bones.

Key Points

Table 143.3 Key points of Spinal Cord Injury (SCI) induced paraplegia

Key points in body composition in SCI – paraplegia
Body mass index values often underestimate body fat in men with spinal cord injury
Subjects lose muscle mass and bone and gain FM especially in lower limbs
Osteoporosis is essentially irreversible once established
Paraplegia related alterations are associated with unloading but also could have a central nervous system origin
Spasticity did not defend skeletal muscle mass and bone
Important issues in paraplegia related changes in body composition

Chapter 144
Anthropometry of Head Circumference, Limb Length and Dementia

Jae-Min Kim, Robert Stewart, Il-Seon Shin, and Jin-Sang Yoon

Abstract Recent research findings suggest that dementia in late life may have its origin in early life. Head circumference (HC) and limb length are recognized to be determined at least in part by factors operating in childhood and remain stable into late life; these measurements may, therefore, be valuable proxy markers for early life environment particularly, it appears, early life nutrition. In this chapter, we review the research evidence for relationships between specific attained anthropometric measures – HC, leg length (LL), arm span and height – and other markers of early life environment, followed by associations between these measures and cognitive outcomes in later life (cognitive impairment and dementia). Smaller HC has been found to be associated with adverse cognitive outcomes including dementia and has been assumed, in this respect, to be a marker of brain "reserve." However, shorter LL and arm span have also been found to be associated with dementia and cognitive impairment. Shorter standing height measured both in early/mid and late life has found to be associated with adverse cognitive outcomes including dementia; however, due to the impact of spinal curvature and kyphosis on trunk length that occur with advancing age, limb length is a more reliable indicator of earlier stature. Several studies have suggested that associations between anthropometric measures and cognitive outcomes are modified by gender or apolipoprotein E genotype. Overall, for the prediction of disorders such as dementia, HC and limb length provide potentially important proxy information on childhood environment and are very cheap, easy, and quick to measure in epidemiological research.

144.1 Introduction

There has been a growing research interest in associations between the early life environment and late life cognitive impairment. Educational level (Stern et al. 1994; Evans et al. 1997), area of residence (Hall et al. 2000; Yano et al. 2000), parental occupation (Kaplan et al. 2001; Wilson et al. 2005) and household size in childhood (Moceri et al. 2001; Borenstein et al. 2005) have been found to be potentially important in the etiology of dementia. One possible explanation is that an adverse early life environment might affect maturation of the brain (Dekaban 1978), and increase vulnerability to later neurodegeneration. However, one of the weaknesses of research in this area is that information on the quality of the early life environment can only be evaluated by individuals' reports, which are clearly subject to recall bias in the context of a disorder, which impairs memory. Furthermore, it is very difficult in late life interviews to ascertain childhood nutritional status, a risk factor for dementia of particular potential interest.

Anthropometric measures such as HC and limb length have received recent research attention as proxy markers for early life environment, which may be particularly useful for dementia research because: (1) these involve direct measurement and are, therefore, not affected by recall bias; (2) they can be applied very easily, cheaply and quickly and (3) measurement error can be potentially minimized. The review of the literature carried out for this chapter aimed to clarify the evidence for associations with early life environment and cognitive outcomes in late life. For these purposes, we focused on HC, LL, arm span and height as the anthropometric measures most frequently investigated. After outlining the significance of early life environments as etiological factors for late life cognitive impairment and dementia, HC and limb length in adulthood are briefly discussed as proxy markers for early life environment. This is followed by reviews on the four most used anthropometric measures at late life with respect to dementia: HC, LL, arm span and height. Finally information is presented on modification effects of gender and apolipoprotein E e4 allele (apo E4) on these measures.

144.2 Early Life Environment and Late Life Cognition or Dementia

There has been growing interest on the early life environments as etiological factors for late life cognitive impairment and dementia. This hypothesis was based on the assumption that structural and functional brain capacity is developed mainly in childhood and adolescence (Schmand et al. 1997) and may have an influence on later cognitive outcomes. The mechanism underlying the protective effect of increased brain capacity has been hypothesized in terms of "cognitive reserve": that is, the ability of individuals with increased reserve to cope with more advanced brain pathology, so that

they remain free of dementia symptoms for longer than those with less reserve (Stern et al. 1992). Level of education has been considered as one of the major determinants or markers of cognitive reserve at early life and "cognitive reserve" theory arose from the well replicated observation that higher education is associated with lower risk of dementia (Stern et al. 1994; Evans et al. 1997). The neuronal activation associated with educational exposure has been suggested as enhancing synaptic complexity, neuronal reserve and resistance to harmful insults on cognition (Garibotto et al. 2008). Cognitive reserve theory is supported by observations that higher education in people who develop dementia is associated with evidence of more advanced underlying disease: namely, more severe brain changes (Stern et al. 1992) and worse prognosis (Wilson et al. 2000).

Other early life factors found to be associated with dementia also relate to adverse home situations. Parental manual occupation and lower education, representing lower familial social class, were associated with an increased risk of dementia (Kaplan et al. 2001; Wilson et al. 2005). Higher number of sibling size, which has been found to predict final educational attainment (Downey 2001), has also been found to be associated with dementia (Moceri et al. 2001; Borenstein et al. 2005). Rural childhood residence, where less educational opportunities can be expected, was associated with later development of dementia (Hall et al. 2000; Yano et al. 2000). Childhood undernutrition, known to be correlated with lower household socio-economic level, has been suggested to be associated with reduced brain synaptogenesis and complexity of dendritic branching (Dobbing 1984), which might account for later associations with risk of dementia: that is, that the early life environment may not only modulate later ability to compensate for slowly progressing neurodegenerative disorders (i.e. affecting age of onset of the clinical dementia syndrome), but also may affect the brain's underlying vulnerability to pathology (i.e. affecting the absolute risk of dementia). This is supported by a finding from a cohort of elderly Nuns that linguistic ability (derived from pieces of writing submitted on entering the order in early adult life) was negatively associated with Alzheimer pathology at postmortem, regardless of intervening dementia diagnosis (Snowdon et al. 1996).

However, an important weakness of studies which seek to characterize the childhood environment much later in life is the necessary reliance on individual's self-reported information, and the problem of recall bias when cognition disorders (generally affecting memory even in mild "preclinical" cases) are the focus of the research. This is particularly the case for more complex aspects of early life environment such as nutritional status.

144.3 Head Circumference and Limb Length as Proxy Markers for the Early Life Environment

Recently some anthropometric measures have been received research attention as proxy markers for early life environment. Head circumference has attracted particular interest, for obvious reasons, in dementia research. The cranial vault approaches maximum proportions by age 7 and, therefore, HC measurements in adulthood largely reflect brain growth in the early years of life (Gale et al. 2003). Active and substantial neuronal growth also occurs in that period. However, it can also be importantly reduced by undernutrition, and effects of nutritional restriction at key stages in development may be less amenable to later catch-up, thereby giving rise to effectively permanent deficits to brain structure and/or function (Dobbing 1984). Smaller HC measured in late life has been found to be associated with lower educational level and childhood rural residence (Kim et al. 2008a, b), and is also known to be highly correlated with intracranial volume (Jorgenson et al. 1961).

Within general epidemiology, the use of limb length measurements in adulthood as proxy markers for childhood exposures has been present for some time, particularly LL (Gunnell 2002).

Like skull circumference, skeletal growth progresses in parallel with maturation of the brain (Ho et al. 1980), and LL has been found to be highly correlated with HC in elders (Kim et al. 2008a). Longitudinal studies have found that LL measured in childhood is strongly associated with socioeconomic status (Gunnell et al. 1998). A British birth cohort study suggested that attained adult LL was particularly associated with diet in infancy, especially breast feeding and energy intake at age 4, whereas trunk growth was more strongly associated with later childhood stressors such as parental separation (Wadsworth et al. 2002). Adverse childhood socioeconomic circumstances have been found to be associated with shorter LL in both younger and older adults (Kim et al. 2003; Webb et al. 2008). Studies of arm span or demispan have shown similar results to those with LL (Kim et al. 2003; Jeong et al. 2005), although the number of reports are less. Total height, on the other hand, appears less valuable than limb length as proxy marker for early life environments. Adult height has been found to be associated with adverse childhood socioeconomic status (Webb et al. 2008), while height in late life failed to reflect this (Schooling et al. 2008). This is likely to be due to intervening risk of spinal curvature and kyphosis with advancing age which mean that total height becomes less strong a marker of earlier stature (Bannerman 1997). Limb length, on the other hand, is much less affected by these processes and remains a better marker even into advanced old age.

Overall, HC and limb length have been found to be determined in childhood and remain stable into late life and, therefore, are potentially valuable proxy markers for early life environments, particularly early life nutrition, with the following advantages in late life epidemiological research: (1) they remove the risk of recall bias, (2) they can be applied very easily, cheaply and quickly, and (3) measurement errors can be minimized, particularly for LL.

144.4 Head Circumference and Late Life Cognition

Studies on the associations between HC and cognitive outcomes including dementia and Alzheimer disease (AD) are listed and their characteristics are summarized in Table 144.1. Eight of 14 studies listed were carried out in the USA, although the ethnicity of the participants was diverse including those with Caucasian, Hispanic, African and Asian backgrounds. Most used data from community-based surveys apart from one case control study. The method for measuring HC was almost identical across the studies that it was measured by placing a plastic tape over the eyebrows and passing it around the head above the eyebrows and over the most posterior protuberance of the occiput. The mean HC ranged 55.9–58.5 cm in men and 54.2–55.7 cm in women. Outcomes included cognitive function (measured by various tests), dementia and AD. Three studies were prospectively designed and, therefore, cognitive decline and incident AD were considered as outcomes.

The first study found no association between HC and AD. However, it was reported that smaller HC was associated with poorer cognitive function in AD cases, but not in non-cases (Graves et al. 1996). However, the remainder found significant associations between smaller HC and worse cognitive function (Reynolds et al. 1999; Gale et al. 2003; Kim et al. 2008b), increased risk of cognitive decline (Gale et al. 2003), increased prevalence of dementia or AD (Schofield et al. 1997; Mortimer et al. 2003; Kim et al. 2008a; Llibre Rodriguez et al. 2008; Mortimer et al. 2008; Scazufca et al. 2008) and increased incidence of AD (Borenstein Graves et al. 2001; Borenstein et al. 2005). Some effect modification has been reported with two studies finding that the associations were stronger, and/or only significant, in women (Schofield et al. 1997; Kim et al. 2008a) or in the presence of the apo E4 (Borenstein Graves et al. 2001; Borenstein et al. 2005; Kim et al. 2008b). One case-control study reported negative results, in that the association between smaller HC and AD was no longer significant after adjustment for age and education (Espinosa et al. 2006).

Table 144.1 Studies on the associations between head circumference (HC) and cognitive outcomes

Source	Country/ethnicity	Study type	Sample number	Mean HC	Cognitive outcomes	Evaluation methods	Comments
Graves et al. (1996)	USA/Japanese American	Community based cross-sectional	1985	Median 55.7 cm	Cognitive function, AD	CASI, NINCDS-ADRDA	Smaller HC was associated with poorer cognitive function in AD cases, but not in non-cases nor with probable AD
Schofield et al. (1997)	USA/White, African American, Hispanic	Community based cross-sectional	649	Men 56.9 cm, Women 54.7 cm	AD	NINCDS-ADRDA	Smaller HC was associated with AD, statistically significant in women but not in men
Reynolds et al. (1999)	USA	Community based cross-sectional	825	Men 58.5 cm, Women 55.7 cm	Cognitive function	MMSE	Every 1 cm increment in HC was associated with a reduction of 20% in the risk of low MMSE score in non-demented elderly
Borenstein Graves et al. (2001)	USA/Japanese American	Prospective cohort	1869	55.9 cm	Incident AD	NINCDS-ADRDA	Small HC predicted earlier onset of AD in the presence of apo E4
Tisserand et al. (2001)	Netherlands/ unknown	Community based cross-sectional	818	Men 58.0 cm, women 55.5 cm	Cognitive function	GIT, Stroop tests, WLT, MMSE	HC was related to tests on intelligence, global cognitive function, and information processing speed, but not memory in non-demented elderly
Gale et al. (2003)	UK/unknown	Retrospective cohort	215	At birth 34.7 cm, adult 57.3 cm	Cognitive function and decline	AH4 test, Wechsler Memory Scale	Adult but not at birth HC was associated with higher cognitive performance and less cognitive decline
Mortimer et al. (2003)	USA/Caucasian female	Prospective cohort	294	Mode 54–55 cm	Dementia	Nonstandard criteria	Combination of small HC and low education increase the risk of dementia
Borenstein et al. (2005)	USA/Japanese American	Prospective cohort	1859	55.8 cm	Incident AD	NINCDS-ADRDA	Small HC was associated with incident AD in the presence of apo E4
Espinosa et al. (2006)	USA/unknown	Case control	1051	Men 57.8 cm, Women 55.3 cm	AD	NINCDS-ADRDA	AD patients had significantly smaller HC compared to controls, but it was no longer significant after adjustment
Kim et al. (2008a)	Korea/Korean	Community based cross-sectional	916	Men 55.9 cm, Women 54.2 cm	Dementia, AD	DSM-IV	Smaller HC was independently associated with dementia and AD, but only in women

The associations between smaller HC and adverse cognitive outcomes have been supported by neuroimaging findings. Smaller intracranial brain volumes measured directly by magnetic resonance imaging have been found to be associated with worse cognitive function in healthy elderly (MacLullich et al. 2002), with AD (Wolf et al. 2004), and with and increased risk of cognitive decline in people with AD (Mori et al. 1997).

In summary, smaller HC has been found to be associated with a range of adverse cognitive outcomes including dementia in late life. This may reflect its role as a component of brain reserve, possibly even through spatial restrictions imposed by smaller intracranial volume on brain size and function. However, final brain size and HC are at least in part determined by genetic makeup and may be associated with other aspects of brain development besides simple size limitations. Measurement and consideration of parental HC might be useful to control for genetic determinants in the future although this presents substantial logistic challenges. It is also important to recognize that the associations between HC and cognitive outcomes could be modified by demographic or genetic factors.

144.5 Leg Length and Late Life Cognition

Studies on the associations between LL and cognitive outcomes including dementia and AD are listed and their characteristics summarized in Table 144.2. The six studies identified were from various countries with diverse ethnicities. All studies involved analysis of community-based survey data. For measuring LL, five studies applied iliac crest height (from the uppermost part of the iliac crest to the ipsilateral lateral malleolus in standing position) and one study used knee height (from sole of the foot to the anterior surface of the thigh, with the ankle and knee each flexed to a 90° angle). Two studies were prospectively designed. Cognitive outcomes included cognitive function and decline, prevalent/incident dementia and/or AD.

The first study of LL and dementia was from South Korea. It was reported that shorter LL was associated with dementia and AD, but the association was only significant in women after adjustment for age and education (Kim et al. 2003). The same study group recently reported similar results, and also found the associations were independent of HC despite a significant correlation between LL and HC (Kim et al. 2008a). A larger prospective study from the USA subsequently found similar results in that the associations between shorter LL and incident dementia and AD were also only significant in women, although a formal test for statistical interaction did not reach statistical significance (Huang et al. 2008). A prospective study from the UK with African-Caribbean population reported that shorter LL was significantly associated with cognitive impairment, but not with cognitive decline (Mak et al. 2006) and found no gender modification. A recent study from Brazil also found an association (Scazufca et al. 2008), while another from Cuba found no significant association after adjustment for age, education and family history of dementia (Llibre Rodriguez et al. 2008).

In summary, shorter LL has found to be associated with dementia and cognitive impairment mirroring the findings for HC. It is possible that both HC and LL are proxy measures for the same underlying risk factors. However, the association between LL and dementia was not accounted for by HC in one analysis (Kim et al. 2008a), so it is also possible that LL is associated with specific early-life stressors and has an independent causal pathway. Similar to the results of HC studies, gender modification of the associations between LL and dementia have been reported in a few studies. As with HC studies, genetic or familial confounding, although unlikely, has not been ruled out.

144.6 Arm Span and Late Life Cognition

Analyses of associations between arm span and cognitive outcomes including dementia and AD are listed and their characteristics are summarized in Table 144.3. These studies have been less frequent than those of HC or LL with only three detected to date: two from South Korea and one from the USA. All studies analyzed community-based survey data: two cross-sectional and one prospective. For measuring arm span, demispan (the distance from the sternal notch to the middle finger tip along the outstretched arm) was usually used. Cognitive outcomes included cognitive function, and prevalent/incident dementia and AD.

The first study of arm span and dementia was from Kwangju, South Korea, and found that shorter arm span was associated with dementia and AD. The association, in common with that for LL, was only significant in women after adjustment for age and education, although a test for gender interaction did not reach statistical significance (Kim et al. 2003). The second study was from Jeonbuk province in South Korea and a different sample. This also found that shorter arm span was associated with cognitive impairment and dementia, although with no gender interaction (Jeong et al. 2005). A recent prospective study from the USA found significant associations between shorter arm span and both dementia and AD in both men and women (Huang et al. 2008).

In summary, shorter arm span has found to be associated with adverse cognitive outcomes including dementia. These results were consistent with those of HC and LL, although with less obvious gender interactions. In the Kwangju sample, arm span was very highly correlated with LL (Pearson's correlation coefficient = 0.73) (Kim et al. 2003). Arm span may, therefore, also be a proxy measure for early life environment, although this has not been formally investigated.

144.7 Height and Late Life Cognition

Studies of associations between height and cognitive outcomes are listed and their characteristics summarized in Table 144.4. Of the five studies identified to date, two used historical cohort study designs with adult height as an exposure, two were community-based cross-sectional studies and one was a case control study. Cognitive outcomes included cognitive function, and prevalent dementia and AD.

The first analysis of adult height and late life cognitive function was carried out on data from a Japanese American population and found a "dose dependent" association between shorter height measured in 1965–1968 and cognitive impairment 3 decades later (Abbott et al. 1998). In a recent larger study from Israel, height measured in midlife was associated with prevalent dementia and AD, again in a dose dependent pattern (Beeri et al. 2005). A cross-sectional survey from Kwangju, South Korea using sitting height as an exposure reported different findings, in that shorter sitting height was associated with prevalent dementia, but lost significance after adjustment for age and education (Kim et al. 2003). However, another South Korean study in a different sample reported significant associations between shorter height and both cognitive impairment and dementia (Jeong et al. 2005). A recent case-control study from the USA found that shorter height was associated with AD in men, while it was only significantly associated with AD in the absence of apo E4 in women (Petot et al. 2007).

In summary, shorter standing height measured both in mid- and late-life has been found to be associated with adverse cognitive outcomes including dementia. However, sitting height in late life was not independently associated with dementia (Kim et al. 2003), which suggests that limb length may explain most of the standing height associations with trunk length compromised as a measure in late life because of spinal curvature and kyphosis, as mentioned earlier (Bannerman 1997).

Table 144.3 Studies on the associations between arm span and cognitive outcomes

Source	Country/ethnicity	Study type	Sample number	Mean arm span	Cognitive outcomes	Evaluation methods	Comments
Kim et al. (2003)	Korea/Korean	Community based cross-sectional	746	Men 83.4 cm, women 76.4 cm	Dementia, AD	DSM-IV, NINCDS-ADRDA	Shorter arm span was associated with dementia and AD, only significant in women
Jeong et. al. (2005)	Korea/Korean	Community based cross-sectional	235	Men 83.1 cm, women 76.2 cm	Cognitive function, dementia	MMSE, DSM-IV	Shorter arm span was associated with cognitive impairment and dementia
Huang et al. (2008)	USA/unknown	Prospective cohort	2798	86.6 cm	Incident dementia and AD	DSM-IV, NINCDS-ADRDA	Shorter arm span was associated with higher risks of dementia and AD

Table 144.4 Studies on the associations between height and cognitive outcomes

Source	Country/ethnicity	Study type	Sample number	Mean height	Cognitive outcomes	Evaluation methods	Comments
Abbott et al. (1998)	USA/Japanese American men	Retrospective cohort	3733	163.5 cm	Cognitive function	CASI	Adult short height was associated with late-life cognitive impairment
Kim et al. (2003)	Korea/Korean	Community based cross-sectional	746	Sitting height, men 74.0 cm, women 66.1 cm	Dementia, AD	DSM-IV, NINCDS-ADRDA	Shorter sitting height was associated with both dementia diagnoses, but lost significance after adjustment
Beeri et al. (2005)	Israel/unknown	Retrospective cohort	1881	168.1 cm	Dementia, AD	DSM-IV, NINCDS-ADRDA	Adult short height was associated with late life dementia and AD
Jeong et al. (2005)	Korea/Korean	Community based cross-sectional	235	Men 163.2 cm, women 148.2 cm	Cognitive function, dementia	MMSE, DSM-IV	Shorter height was associated with cognitive impairment and dementia
Petot et al. (2007)	USA/unknown	Case-control	580	Men 174.4 cm, women 161.4 cm	AD	NINCDS-ADRDA	Shorter height was associated with AD in men. In women, it was associated with AD only in the absence of apo E4

CASI Cognitive Abilities Screening Instrument; *AD* Alzheimer disease; *DSM-IV* Diagnostic and Statistical Manual of Mental Disorder 4th edition; *NINCDS-ADRDA* National Institute of Neurological and Communication Disorders and Stroke-Alzheimer's Disease and Related Disorders Association criteria for the diagnosis of AD; *MMSE* Mini-Mental State Examination; *apo E4* apolipoprotein E e4 allele

For this reason, associations between skeletal dimensions and cognitive outcomes may be obscured in older people if the former are limited to standing height, and limb lengths are more suitable in these age groups as markers of dementia risk.

144.8 Gender Modification

Several studies have reported modification by gender of associations between anthropometric measures and cognitive outcomes. With respect to HC, the associations between smaller HC and dementia and/or AD were significant only in women in two studies. One study was from the USA with diverse ethnicities, such as white, African-American and Hispanic (Schofield et al. 1997), and the other study was from South Korea (Kim et al. 2008a). Therefore, this phenomenon was found in various ethnicities. Possible explanations include the following: (i) The correlation between HC and intracranial volume has been found to be less strong in men (Willerman et al. 1991), so that differential misclassification might have occurred. (ii) There may be gender differences in vulnerability to stressors occurring during the period of brain maturation that sex hormones may have a role in brain development and early vulnerability (MacLusky and Frederick 1981). iii) Additionally there were particular characteristics in the South Korean study. That is, different early life social conditions for male and female children of the older generation in that country (possibly in common with other East Asian countries) should be considered. Male gender preference was highly prevalent at the time when the participants were growing up, due to strongly held Confucian patriarchal traditions in Korea. It was, therefore, common practice for parents to provide education and/or nutrition preferentially to male children, particularly in families with lower socio-economic status (Kim et al. 2008a). However, this does not explain similar findings emerging from US cohorts (Schofield et al. 1997) where gender preference is unlikely to have been so pronounced.

In terms of limb length, shorter LL and arm span were significantly associated with dementia and AD only in women in a Korean sample (Kim et al. 2003). Shorter LL was significantly associated with incident dementia and AD only in women, while shorter arm span was significantly associated with them in both genders in a US sample. Possible explanations include the following: (1) Health states in adult or late life could mediate the associations. Shorter limb length has been found to be associated with cardiovascular disease in adulthood (Han et al. 1997; Davey Smith et al. 2001). Higher overall cardiovascular mortality in men might possibly account for a later gender difference through differential survival. (2) Skeletal growth terminates approximately 2 years earlier in women compare to men, and may. Therefore, be more closely related to brain maturation and the early life environment. (3) The male gender preference hypothesis raised above for associations with HC could also applied to those with limb length.

In summary, there is some evidence to suggest that there might be gender differences in the relationships between these markers of early life status and risk of dementia. As well as methodological issues, this may reflect different causal pathways or different strengths of association between anthropometric measures and underlying brain vulnerability. However, replication has frequently been incomplete and further research is required.

144.9 Modification by Apolipoprotein E Genotype

Three studies of HC have reported modification by the presence/absence of the apo E4. A US cohort study of Japanese Americans found that small HC predicted earlier onset of AD more strongly in the presence of apo E4 (Borenstein Graves et al. 2001). A follow-up study of the same cohort also found

that small HC was associated with incident AD more strongly in the presence of this allele (Borenstein et al. 2005). Recently a South Korean study also found that smaller HC was associated with poorer cognitive function only in the presence of apo E4 (Kim et al. 2008b). Interestingly, the participants of all three studies were of East Asian ancestry, while studies of HC and dementia in other populations have not mentioned apo E interaction.

These data suggest that effects of adverse early life environments on the development of poorer cognitive outcomes may be strengthened in the presence of this genetic vulnerability marker. Gene–environment interactions may be an important consideration, but require further replication.

144.10 Applications to Other Areas of Health and Disease

The associations between these anthropometric measures and cognitive impairment may have a neuroendocrinological basis, which might link the findings to those from other disorders. Particularly, growth hormone (GH) levels are associated with both anthropometry and cognitive function: (1) cognitive impairments have been found in GH deficient men (Deijen et al. 1996); (2) GH replacement therapy has been found to improve cognitive function in adults with childhood-onset GH deficiency (Deijen et al. 1998) and (3) binding sites for GH are found in various brain areas, particularly in hippocampus, a brain structure affected at an early stage in AD (Van Dam et al. 2000). Sex hormones are also potentially linked with both anthropometry and cognition: Specifically, decreased LL has been found to be associated with later menarche (dos Santos Silva et al. 2002), and lower early life cognitive function has been found to be associated with earlier menopause (Richards et al. 1999).

Summary Points

- Recent research findings suggest that risk of dementia in late life may be substantially influenced by early life factors.
- Early life environmental factors relevant to this issue include education, parental occupation, sibling size and rural/urban living area. However, this information acquired in late life may not be accurate because of recall bias.
- Childhood nutrition, one of the variables on early life environments, is an important factor for the risk of dementia. However, it is very difficult to estimate previous childhood nutritional status directly in later life.
- There have been accumulating evidence that HC and limb length are determined substantially in childhood and remain stable into late life and, therefore, they could be reliable proxy markers for early life environment particularly in terms of early life nutrition.
- Smaller HC has been found to be associated with adverse cognitive outcomes including dementia in late life, hypothesized as a component of brain reserve.
- Shorter LL has also been found to be associated with dementia and cognitive impairment.
- Shorter arm span has found to be associated with adverse cognitive outcomes including dementia.
- Shorter standing heights measured both in adult and elderly has found to be associated with adverse cognitive outcomes including dementia.
- Several studies have reported that associations between anthropometric measures and cognitive outcomes are more prominent in women. If genuine, these might reflect differences in the risks for or causal pathways to dementia particularly in the aspects of early life environment and nutritional status.
- Some studies of HC and dementia have reported that the associations were stronger in the presence of the Apo e4 allele, but more replication is needed.

Key Features

Table 144.5 Key facts on early life environments and dementia

1. Adverse environments in early life are associated with increased risk of dementia and cognitive impairment in late life
2. These factors include education, parental occupation, household size, living area
3. There are indirect evidences suggesting associations between early life nutrition and cognitive development which may influence risk of dementia much later in life.

Table 144.6 Key facts on anthropometry of HC, limb length and dementia

1. As well as genetic influences, HC and limb length have important environmental determinants in childhood and remain stable from adolescence/early adulthood into late life
2. Smaller head size and shorter limb length are proxy markers for lower early life socio-economic status: for LL particularly reflecting nutrition in infancy
3. Both factors have been associated with adverse cognitive outcomes including dementia
4. There have been several reports that these associations are modified by gender or apolipoprotein E4 genotype

Chapter 145
Anthropometry in Special and Selective Conditions and Circumstances: Anthropometry as Measure of Risk in COPD Patients

Ernesto Crisafulli, Stefania Costi, and Enrico M. Clini

Abstract In the last decade, Chronic Obstructive Pulmonary Disease (COPD) has been redefined and newly approached not only as an airway-disease condition, but as a multi-component disease including extra-pulmonary manifestations, such as peripheral muscle weakness and malnutrition.

The evaluation of body composition (as a part of nutritional assessment) fairly integrates the simple body mass index (BMI) measure by measuring the individual's active metabolism (fat free mass, FFM). Indeed, BMI and FFM are both parameters correlated with many COPD-strong outcomes. In several epidemiological studies of COPD population admitted to both in- or outpatient rehabilitation programmes, the estimated prevalence of weight loss ranges from 17% to 53%. Nonetheless, weight reduction, together with FFM depletion, is a common feature in emphysema as well as in chronic bronchitis.

A nutritionally depleted patient is usually defined by a BMI of ≤ 20 kg/m^2. Several studies aimed at evaluating the prognostic value of BMI in COPD patients have documented that BMI ≤ 25 kg/m^2 and weight reduction of >3 kg/m^2 are strong predictors of mortality. Moreover, other studies confirmed that FFM and measurement of the cross-sectional area of muscle mass (mid-thigh and mid-arm) also correlate to survival rates.

In future research, studies looking at other anthropometric, metabolic and functional factors able to predict the long-term survival should be welcomed in patients with other diseases, such as pulmonary fibrosis, similarly leading to chronic respiratory failure.

Abbreviations

AMA	Arm muscle area
BCM	Body cell mass
BIA	Bioelectrical impedance analysis
BMI	Body mass index
BODE INDEX	Body mass index (B), obstruction (O), dyspnea (D) and exercise endurance (E)

CI	Confidence interval
COPD	Chronic Obstructive Pulmonary Disease
ECW	Extracellular water
FEV_1	Forced Expiratory Volume in the first second
FFM	Fat free mass
FFMi	FFM index
FM	Fat mass
HR	Hazard ratio
HRQL	Health related quality of life
IBW	Ideal body weight
ICW	Intracellular water
LTOT	Long term oxygen therapy
LVRS	Lung volume reduction surgery
MAC	Mid-arm circumference
MAMC	Mid-arm muscle circumference
NETT	National Emphysema Therapy Trial
$PaCO_2$	Arterial Carboxide Pressure
PaO_2	Oxygen Arterial Pressure
PEmax	Maximal Expiratory Mouth Pressure
RR	Relative risk
TBW	Total Body water
TSF	Triceps skinfold thickness
VO_2 %/Kg	Percentage of oxygen consumption for kilogram

145.1 Introduction

Chronic Obstructive Pulmonary Disease (COPD) is no longer considered a disease affecting the airways, but a multi-component disease with several systemic consequences.

Even if the dysfunctional characteristics of COPD, such as flow obstruction and expiratory limitation, are still considered as the cardinal features for intervention strategies, recent evidence suggested that COPD be considered a complex disease including extra-pulmonary manifestations, such as peripheral muscle weakness and malnutrition.

Abnormalities in body composition and alteration in body weight (i.e. loss in body mass and/or muscle wasting) are highly prevalent in the advanced stages of this illness. The extra-pulmonary manifestations of COPD are probably linked to several chemical mediators of inflammation which in turn have direct effects on muscle performance and composition. This characteristic may strongly complicate the whole clinical management of the disease.

In this chapter we will review the main aspects dealing with measures of body composition and nutritional status in COPD and their likely significance in clinical practice (Table 145.1).

Table 145.1 Key points of nutritional measure in COPD

- Nutritional status should be always integrated as a measures of health in patients with COPD
- Both BMI and FFM provide useful and integrated information to the individual's nutritional status
- Change in body mass is fairly related with change in prognosis in COPD individuals

This table lists the main features and evidence related to the likely significance of assessing body measure in patients suffering from COPD

145.2 Assessment of Body Composition and Nutritional Status in COPD: Methods and Techniques

The complexity of COPD as a disease, including extra-pulmonary manifestations, has frequently recalled the clinical features of peripheral muscle weakness and malnutrition (Table 145.2).

The terms "malnutrition" and "cachexia", meaning nutritional depletion and wasting of body mass, have frequently been reported in the clinical history of COPD. Weight loss may have multiple causes, including a reduction in dietary intake, the effect of the increased energy cost of breathing due to the abnormal respiratory mechanics and the effects of chronic systemic inflammation. Muscle wasting is an important systemic manifestation, since the loss of more than 40% of metabolically active tissue causes death. The imbalance between protein synthesis (anabolism) and protein breakdown (catabolism), leads to hyper-metabolism and may be the consequence of mild systemic inflammation in COPD.

Systematic nutritional assessment is nowadays considered as an essential component of any integrated management of COPD patient. The measurement of the body weight only is certainly useful as a screening tool in the first step of nutritional evaluation, but this measurement does not provide qualitative data regarding body composition; thus, it cannot be sufficient to describe the patients' nutritional status.

In order to study this topic in depth, body composition should be analysed to detect malnutrition by focusing the assessment on the body cell mass (BCM), which represents the active metabolic contractile tissue. The imbalance between the fat mass (FM) and the fat free mass (FFM) is a marker of body composition alteration which, in patients with low FFM, represents malnutrition. Nonetheless, body composition alterations are not necessarily associated with change in body weight.

Several studies stated that measuring FFM allows muscle wasting to be detected, whilst the FFM index (FFMi), calculated as FFM/height^2, further characterizes nutritional depletion. FFM has a strong relationship with pulmonary diffusing capacity in these patients. To date, there is no guideline that dictates criteria to categorize FFM or FFMi; consequently, clinicians usually dichotomize these parameters by using the cut-off value suggested by Schols and colleagues, which is equal to 15 kg/m^2 for women and 16 kg/m^2 for men (Schols et al. 1993).

Muscular tissue depletion, as demonstrated by a reduction in FFM, is significantly associated with selective atrophy of type II muscle fibres (see Fig. 145.1) (Gosker et al. 2002). The atrophy of these fibres – which are efficient for short bursts of speed and power and use both oxidative and anaerobic metabolism – drives the impairment of the skeletal muscles of patients with COPD. It has been clearly demonstrated that it occurs very frequently in severe hospitalized patients, as well as in outpatients with moderate to severe airflow obstruction. From a clinical point of view, loss of FFM in COPD is associated with impairment in respiratory muscle strength, although a partial contributor

Reduction of TSF
Reduction of mid-thigh and mid-AMA

This table summarizes the most typical changes of body and muscle characteristics in the malnourished COPD patient
FFM fat free mass; FM fat mass; TSF triceps skin fold thickness; AMA arm muscle area.

to the weakness of these muscles is undoubtedly the mechanical disadvantage owing to hyperinflation and the changes in chest wall shape. FFM depletion is also responsible for other important clinical manifestations of COPD such as peripheral muscle weakness (Engelen et al. 2000), impairment in exercise capacity and general worsening of health status. Indeed, alteration in body composition, independent of weight loss, seems to be an important predictor of worsening the perceived Health Related Quality of Life (HRQoL) (Mostert et al. 2000). Interestingly enough, normal-weight COPD patients with low FFM always report lower level of HRQoL as compared with underweight patients with normal FFM. Table 145.3 summarizes body and nutritional abnormalities, which can affect COPD patients with muscle depletion.

From a practical point of view, assessment of FFM can be obtained using different techniques, including hydro-densitometry and isotopic dilution with the deuterium and sodium bromide method. These techniques provide the values of intracellular (energy-exchanging part) and extracellular (role of support and transport) water compartments by measuring the total (TBW) and the extracellular (ECW) body water. The intracellular water (ICW) is detected as the difference between TBW and ECW. This method is complex and cannot be used on a wide scale. So far, this method has been used in a group of clinically stable COPD patients (Baarends et al. 1997) to show that the ECW/ICW ratio

was similar in normal weight and underweight individuals. However, this ratio increased in patients with low FFM, thus showing that the intracellular compartment, which relates to muscles and other tissues, was even more depleted than expected.

An easier method to assess FFM is bioelectrical impedance analysis (BIA). A low intensity alternate electric current is applied through electrodes to the ankle and the wrist, and the resistance opposed by the body tissues to its flow is then measured. FFM is then indirectly calculated from this measurement, since the resistance opposed by the FM to the electric current flow is higher than the impedance of the FFM. BIA is highly reproducible in patients with COPD. The only fluctuation detected is a slightly higher resistance and a consequently lower estimated FFM in the fasting state. Several algorithmic rules have come from different patient populations to calculate FFM by way of BIA, but attention has to be paid to choose an algorithm that is appropriate for the population studied.

Schols and colleagues specifically applied both the above-mentioned techniques in patients with COPD (Schols et al. 1991), demonstrating an excellent association between the impedance and the deuterium dilution results in estimating FFM.

Finally, the real nutritional status can also be estimated by skinfold anthropometry. The measurement of skinfold thickness can be taken at four body sites, specifically on the triceps brachii, on the biceps brachii, over the subscapular area, or on the suprailiac area. This measurement is a simple and widely used method to assess FM. Total FM is estimated using equations or tables, and FFM is obtained by subtracting FM from body weight. Triceps skinfold thickness (TSF) and mid-arm circumference (MAC) can be used to calculate mid-arm muscle circumference (MAMC), which estimates muscle mass as:

$$\mathrm{MAMC} = \mathrm{MAC} - (\pi \mathrm{TSF}) .$$

Alternatively, arm muscle area (AMA) can be calculated as:

$$\mathrm{AMA} = \mathrm{MAMC}^2 / 4\pi .$$

It should be recognized that this method is based on the assumption that the measured fat layer represents a constant fraction of total body fat. However, this is no longer true in elderly subjects where FM is predominantly located in the central and internal parts of the body. Thus, in patients with COPD the measurement of skinfold thickness tends to underestimate FM while overestimating FFM, when compared with the deuterium dilution method (Schols et al. 1991).

In two studies (Hunter et al. 1981; Schols et al. 1991), TSF was <90% of the standard in 62% and 76% of COPD patients and MAMC was <90% of the standard in 50% and 53%, respectively. The AMA was 79% of the standard in outpatients and 62% of standard in patients with acute respiratory failure. Despite its well-known limitations, this method may suggest depletion of both FM and FFM in COPD population.

For a long time, study results have reported differences in anthropometry and nutritional status that are significantly linked to two specific patterns of body composition, which correspond to the clinical subtypes of COPD. These phenotypes are the emphysematous type (*pink puffer)* and the chronic bronchitic type (*blue bloater*). It is well recognized that the emphysematous patient is more breathless, has marked hyperinflation and frequently manifests a major degree of weight loss. In contrast, the bronchitic patient has more severe central cyanosis with no marked weight loss; in fact this type is often overweight and occasionally manifests weight loss in the terminal phase of the disease. Recent data indicate that these two clinical subtypes of COPD are associated with different levels of impairment of skeletal and respiratory muscles, as a consequence of different manifestations of metabolic alterations.

A previous paper (Openbrier et al. 1983) clarified the differences in the anthropometric characteristics between the two clinical subtypes of COPD, highlighting that somatic depletion is particularly

evident in pink puffer compared to blue bloater patients. Moreover, in the emphysematous patient group, the authors found a strong correlation between the degree of airflow obstruction (FEV_1, forced expiratory volume in the first second) and the somatic depletion ($r = 0.699$, $p < 0.001$) as well as the single-breath lung diffusing capacity ($r = 0.605$ $p < 0.019$). Unfortunately, this study included only 18 patients, 14 with emphysema and 4 with chronic bronchitis and, consequently, was not powered to detect a clinically significant difference, if any, in the outcome analysed.

In a more recent paper, Engelen and colleagues (2000) have shown that whole body and extremity FFM were lower in both the emphysematous and chronic bronchitis patients compared to controls, but the trunk FFM was lower than in controls only in emphysematous patients. Therefore, FFM as calculated at the extremities seems to be similar in the two COPD phenotypes, whereas trunk FFM is not. In both groups, however, absolute skeletal muscle function and muscle function per kilogram of whole body FFM were lower than in healthy people, with no difference in the two clinical subtypes. The authors have concluded that wasting of extremity FFM is associated with skeletal muscle weakness and is unrelated to the COPD subtype, although marked differences in whole body composition can be demonstrated between the emphysematous patients and the patients suffering from chronic bronchitis.

145.3 Body Mass as Outcome Measure and Prevalence of Weight Loss in COPD Patients

During the last decade, the influence of the BMI on different epidemiological and functional aspects of COPD has become an area of increasing interest in research. In order to consider body weight as a valuable outcome in COPD, the relationship between body weight and other common COPD-related parameters has been studied. The measurement of height, weight and weight changes provides an initial assessment of the nutritional condition of the patient. However, clinicians should remember that some degree of weight change frequently occurs in patients with severe respiratory failure, due to fluid retention.

Physicians usually make use of two simple and well-known methods to compare the weight of the patient with the physiological values. The first approach compares actual body weight, calculated by the Metropolitan Insurance Company tables, to the Ideal Body Weight (IBW) as derived from height, size and sex. Nutritional depletion occurs when body weight is less than 90% of the IBW (Metropolitan Life Insurance Company 1983).

The second approach uses the Body Mass Index (BMI) or *Quetelet Index*, which is easily calculated by dividing the patient's weight in kilograms by the patient's height in squared meters (kg/m^2). In vivo measurements have demonstrated that the BMI formula is a valid gauge of change in body mass.

On the basis of BMI, patients can be categorized as underweight, normal weight, overweight and obese. The US Department of Agriculture and the Department of Health and Human Services, in a report called *Nutrition and Your Health*, proposed a BMI between 18.5 and 24.9 kg/m^2 as a healthy weight target, while underweight people are characterized by a BMI lower than 18.5 kg/m^2 and overweight and obese people have a BMI greater than 25 and 30 kg/m^2 respectively (US Department of Agriculture and US Department of Health and Human Services 2000). However, the same report states that a BMI above or below the healthy range may actually correspond to a healthy status and, conversely, having a BMI which falls inside the healthy range may not necessarily mean being healthy, because the body composition may be abnormal even in the presence of a physiological BMI. Therefore, the assessment of body composition should always integrate the calculation of BMI.

This assessment is particularly relevant in specific clinical conditions, such as cachexia or muscle wasting, where the weight loss is distributed dissimilarly between FFM e FM. In fact, in cachexia most of the weight loss behave to FFM, the active metabolic contractile tissue, whereas in muscle wasting the loss of BCM and FM are balanced. Thus, cachexia is always accompanied by muscle wasting, but muscle wasting does not always lead to cachexia (Vandenbergh et al. 1967; Wilson et al. 1989; Schols et al. 2005).

Moreover, measurement of body weight, BMI and nutritional status can be defined by involuntary weight loss, when a loss of 10% during the previous 6 months is categorized as severe malnutrition.

A close relationship between poor muscle condition, reflected by a reduction in the actual body weight or a low BMI, and a reduction in the maximal aerobic capacity has been observed in several studies. Furthermore, reduced body mass has an independent negative effect on muscle aerobic capacity in COPD patients, as manifested by a decrease in maximal oxygen consumption, a reduction in the lactate threshold and a slowing down of the oxygen consumption kinetics.

Many studies concerning the prevalence of low body weight in COPD individuals with different disease severities have been performed by using diverse methods to detect the underweight condition.

Schols and colleagues (1993) reported data on the prevalence of the underweight condition and body composition in a group of 255 patients, consecutively admitted to a pulmonary rehabilitation programme. Their results indicate that the depletion of body weight, associated with a reduction in FFM detected by the MAMC measurement, was most pronounced in moderate to severe stable COPD. In particular, a reduction in the actual body weight (<90% of IBW) was present in 46% of patients suffering from chronic hypoxemia, while a prevalence of nutritional alteration was found in 27% of normoxyemic patients with severe COPD (FEV_1 between 35 and 50% of predicted) and in 41% of patients with very severe airflow obstruction ($FEV_1 < 35\%$).

Another study (Braun et al. 1984) showed that the prevalence of nutritional depletion affected 27% out of the 60 outpatients with COPD referred to rehabilitation. Moreover, the measurement of the triceps skinfold was below 60% of standard in one-third of patients. In this study, the body weight is related to the FEV_1, the lung diffusing capacity and the percentage of oxygen consumption per kilogram, at rest (VO_2%/kg).

Furthermore, three very substantial recent epidemiological studies which involved a large number of people with COPD in China (Zhong et al. 2007), the Netherlands (Vermeeren et al. 2006), and Latin America (Montes de Oca et al. 2008) provided data on the prevalence of weight loss.

The Chinese study collected data from 25,627 subjects of whom 8% were COPD and found that the percentages of patients with a BMI < 18.5 kg/m^2, between 18.5 and 23.9 kg/m^2, between 24 e 27.9 kg/m^2 and >28 kg/m^2 were 21%, 9.5%, 6% and 5.4% respectively (significant trend, $p < 0.001$).

The COSMIC study in the Netherlands, which involved 39 outpatient centres and 389 moderate to severe stable COPD patients, resulted in 27% prevalence of nutritional depletion (pre-defined by a BMI ≤ 21 kg/m^2 and/or FFMi ≤ 15 and ≤ 16 kg/m^2 for females and males respectively). Moreover, weight depletion as assessed by the BMI (18% vs. 10%, respectively, $p < 0.01$) and the FFMi (40% vs. 20% $p < 0.001$) was significantly prevalent in females rather than in males (see also Fig. 145.2). No difference between depleted and non-depleted COPD patients has been recorded in FEV_1% of predicted value, in perceived dyspnoea, and in disease-specific health status measured by the St. George's Respiratory Questionnaire.

The Latin America data from the PLATINO study (Proyecto Latino-americano de Investigacion en Obstrucción Pulmonar), which involved 759 COPD patients and 4,555 subjects without, showed that, a higher proportion of underweight (6% vs. 2.9%) and normal weight (31% vs. 24.5%) categories were present among COPD. The proportion of overweight was similar in the two groups

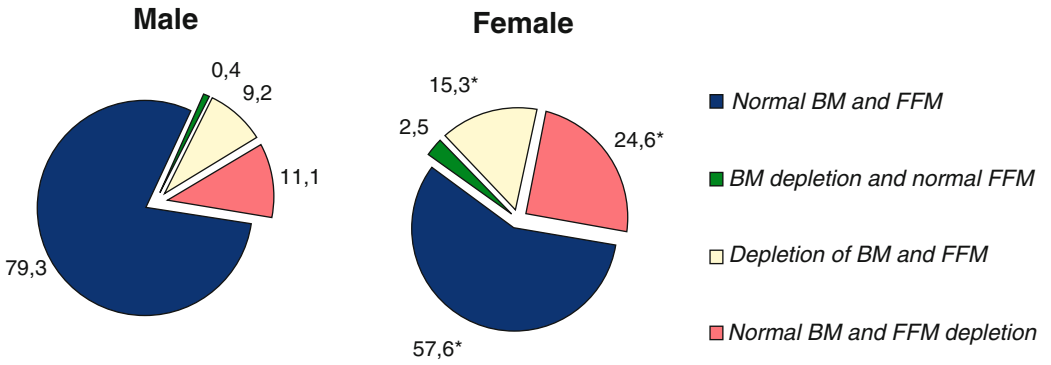

Fig. 145.2 Prevalence of different depletion categories stratified by gender. Gender may partially influence the distribution of different categories of depletion in COPD patients. Results are expressed as percentage. *$p < 0.05$ (between males and females) (Modified and adapted from Vermeeren et al. 2006)

(39.9% vs. 41%), whereas obese individuals were lower among COPD (23% vs. 31.4%). Factors associated with lower BMI in men with COPD were older age, current smoking and a severe or very-severe degree of the disease. In women with COPD, current smoking and a lower level of education were associated with lower BMI, whereas dyspnoea and wheezing were associated with higher BMI.

In a prospective observational study Mazolewski and co-workers (1999) aimed at defining the incidence and the clinical meaning of nutritional deficiencies in patients with COPD. They studied 51 end-stage emphysematous patients who had undergone video-assisted thoracoscopic surgery for lung volume reduction and found that the BMI was below the normal range in 53% of the population. The important clinical consequence of their analysis is that 26% of the patients with low BMI required prolonged ventilatory support for more than 24 h, compared to the 4% of the patients with a normal BMI. This data was also associated with a different length of stay in hospital (15.9 vs. 11.8 days) in the two groups.

On the other hand, data from one of the most famous epidemiological studies (the so called Copenhagen City Heart Study – CCHS) (Vestbo et al. 2006) did not show a higher prevalence of underweight patients among 1,898 COPD patients studied, when compared to healthy people. This result was confirmed even when considering the sub-groups of severe patients or women. In addition, the pattern of distribution of FFM was different as compared to BMI. In the whole cohort of patients, 83.8% had normal or high BMI and a FFMi above the 10th percentile, as referred to the cut-off values (14.62 and 17.05 kg/m^2 in women and men, respectively). In addition, 13.1% of the cohort showed normal or high BMI and a FFMi below the 10th percentile, 0.7% had a low BMI and a FFMi above the 10th percentile, and 2.4% had a low BMI and a FFMi below the 10th percentile. Thus, a higher proportion of subjects with low FFMi had a normal BMI compared to subjects that matched low FFMi with low BMI.

The results from CCHS controvert findings by Schols and colleagues (1993) but discrepancies between populations can be explained by some differences in the sources of patients examined. In particular, Vestbo and colleagues identified COPD people by way of a population survey, whereas Schols and co-workers included COPD patients in their study after a complete assessment performed before their referral for inpatient rehabilitation programme. Importantly, the Dutch study demonstrated differences in body composition even in the early stages of COPD, when patients are not generally considered to have associated muscle wasting.

145.4 BMI, Weigth Change and Nutritional Status as Predictors of Survival in COPD

In patients with end-stage COPD, the underweight condition has been investigated so far as a negative predictive factor of survival. A study of Vandenbergh and co-workers (1967) observed that 5-year mortality was higher in COPD patients who lost weight (80%) in contrast to those whose weight was stable (50%).

Other studies, using both prospective and retrospective design, then examined and confirmed the relationship between the nutritional status, as assessed by weight, height and BMI, and the increased risk of mortality in COPD (see also Fig. 145.3).

Wilson and co-workers (1989) retrospectively analysed a cohort of 779 male patients with moderate to severe COPD and normal values of oxygen arterial pressure (PaO_2), by using the data available from the National Institutes of Health Intermittent Positive Pressure Breathing Trial. By way of a Cox proportional hazards model they found that a significant borderline association ($p = 0.055$) exists between the body weight, expressed as a percentage of the IBW, and survival with the strongest correlation in men with moderate airflow obstruction. In fact, from their analysis, 25% of the patients examined turned out to be underweight (weight < 90% IBW) and, in the sub-group of patients with a FEV_1 of less than 35% of predicted, 51% were undernourished as compared with 20% in the less severely obstructed patients ($FEV_1 > 47\%$ of predicted). Thus, it seems that the severity of airway obstruction is associated with an increased risk of under-nutrition. However, since different studies provide different conclusions about the relationship existing between nutritional status, mortality and severity of airflow obstruction, more research is still needed for an agreed-upon definition and accurate assessment of the nutritional status.

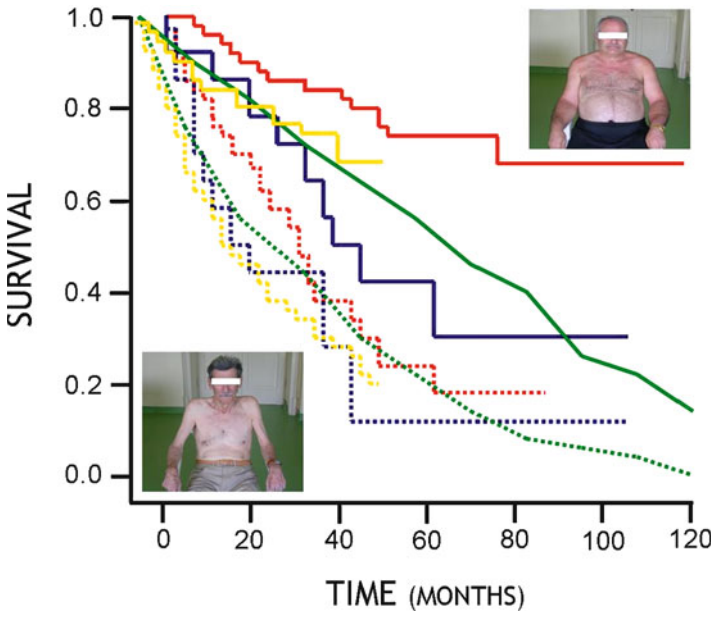

Fig. 145.3 Survival in COPD of different body mass. Graph displays the Kaplan-Meyer survival curves from underweight (BMI ≤ 20 kg/m², *Modify as lines, and photo bottom left*) and normal/ overweight (BMI ≥ 25 kg/m² *Modify as lines, and photo top right*) COPD phenotypes (Modified and adapted from Budweiser et al. 2007, Schols et al. 1998, Chailleux et al. 2003 and Marti et al. 2006).

Two subsequent retrospective studies, investigating different COPD populations, provided evidence of a relationship between low BMI and mortality, independent of the FEV_1. In a cohort of 348 severe Canadian COPD subjects including patients with hypoxemia and recruited for a study regarding the effectiveness of the negative pressure ventilation, Gray-Donald and colleagues (1996) found that 18% of patients were underweight and that the poor nutritional status, detected as a low BMI, and the use of home supplementation of oxygen were strong predictors of death, independently associated with reduced survival in a follow-up that lasted 3–5 years. Degree of airway obstruction (FEV_1), maximal expiratory mouth pressure (PEmax), age, smoking status and gender were factors not associated with survival.

A relevant retrospective study of Schols and co-workers (1998) in 400 COPD stable patients under rehabilitation, and without any nutritional support therapy, demonstrated that body weight is a significant prognostic factor in COPD. The authors found that survival decreased significantly in both underweight and normal weight patients when compared with those who were overweight and obese ($p < 0.0001$). Furthermore, a multivariate analysis which investigated the risk of death, showed that the BMI (Relative Risk (RR) 0.928 with 95% Confidence Interval, CI 0.894 to 0.963, $p < 0.0001$) together with age ($p < 0.0001$) and low PaO_2 ($p < 0.05$) were significant independent predictors of increased mortality. After stratification of the COPD population by BMI quintiles, a threshold equal to 25 kg/m^2 was identified as the cut-off value below which the mortality risk increased significantly.

A subsequent study by Landbo and co-workers (1999) prospectively investigated a cohort of 2,132 Danish patients with COPD (1,218 men and 914 women). The prevalence of nutritional depletion, defined as patients with BMI < 20 kg/m^2, was higher in females (15.5% vs. 5.1% in males) and the RR of death, adjusted for smoking, chronic mucus hyper-secretion, FEV_1 and gender, was significantly increased in underweight subjects, in contrast to overweight and obese patients. This result was particularly evident in the sub-groups of patients with moderate and severe airway obstruction (see Fig. 145.4).

However, when analysing the COPD-related cause of mortality, patients with BMI < 20 kg/m^2 showed a RR equal to 3.34 (95% CI 1.94–5.83) in men and 2.45 (95% CI 1.42–4.22) in women, compared to patients with BMI ≥ 30 kg/m^2 (RR 0.60 with 95% CI 0.29–1.25 in men, and 0.34 with 95% CI 0.12–0.97in women). These findings suggest that abnormal eating habits, either manifested as obesity or cachexia, increases all-cause mortality in mild to moderate COPD patients. Similar results were found for COPD-related causes of death, with the strongest association in the sub-group of patients with severe COPD (RR of 7.11 with 95% CI 2.97–17.05 in patients with low BMI as compared with those with high BMI). The authors then concluded that low BMI is an independent risk factor for mortality in subjects with COPD and that the association is strongest in subjects with severe COPD.

More recently, the study of Budweiser and co-workers (2007) which involved 188 COPD patients with chronic hypercapnic respiratory failure (FEV_1 31.0% of predicted, arterial carboxide pressure ($PaCO_2$) equal to 56.3 mmHg) and under home mechanical ventilation, did confirm the negative role of baseline BMI (Hazard Ratio – HR 5.07 with 95%CI 2.92–8.20, $p < 0.0001$), together with lung residual volume, and blood gases to predict mortality. Similar to the study by Schols (Schols et al. 1998), authors found that a weight gain and a consequent increase in the BMI to the level of 25 kg/m^2 is associated to improved survival at the 5-year follow-up.

Two other recent studies were conducted (Chailleux et al. 2003; Marti et al. 2006) to detect factors that predict survival in patients with COPD with chronic hypoxiemic respiratory failure and the need for Long Term Oxygen Therapy (LTOT) for a minimum of 18 h/day. The first study in temporal order investigated a cohort of 4,088 severe COPD patients, with both chronic bronchitis and/or emphysema, requiring domiciliary LTOT. This study analysed data collected from the *Observatoir*

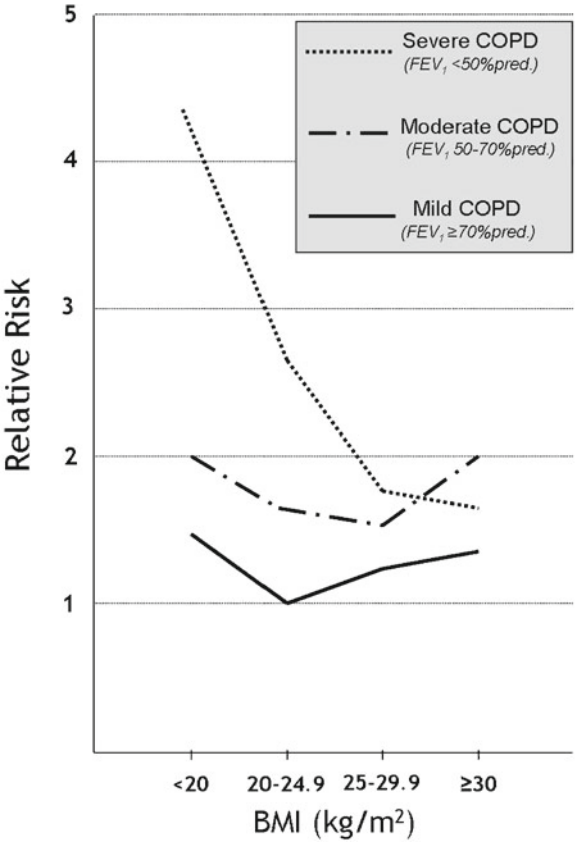

Fig. 145.4 Relative risk (RR) for all-cause mortality in COPD patients. Graph displays the risk of all-cause mortality in COPD patients with different degree of airway obstruction. Taken the reference risk at 1 in the phenotype with BMI 20–24.9 and Mild obstruction, the risk increases according to the decrease in BMI, especially in the most severe individuals (Modified and adapted from Landbo et al. 1999)

de la Association Nationale pour le Traitement a Domicile de l'Insuffisance Respiratoire Chronique, a national French database. Authors assessed the prognostic value of nutritional depletion on the rates of survival and hospitalization and found that the prevalence of malnutrition, defined as a BMI < 20 kg/m^2, was around 23% in men and 30% in women and that BMI is a risk factor for mortality independent of age, FEV_1, PaO_2 and gender. The 5-year survival rates were 24%, 34%, 44% and 59% for patients with BMI values < 20 kg/m^2 (95% CI 21–27), 20 ≥ 24 kg/m^2 (95% CI 32–36), 25 ≥ 29 kg/m^2 (95% CI 41–48) and ≥ 30 kg/m^2 (95% CI 53–64), respectively. The RR of death, using a BMI ≥ 30 kg/m^2 as the reference value, was 40% greater in the sub-group of patients with BMI 25 ≥ 29 kg/m^2, 80% in those with BMI 20 ≥ 24 kg/m^2, and 140% in those with a BMI < 20 kg/m^2. Again, the best prognosis among COPD under domiciliary LTOT was observed in overweight and obese individuals. Moreover, this study demonstrates that low BMI is the most powerful predictor of duration and rate of hospitalisation, independent of baseline blood gas levels and respiratory function. Indeed, the mean time spent in hospital was 29,6 ± 40,4 days/year in patients with BMI < 20 kg/m^2 versus 17,5 ± 30.1 days/year in those with BMI ≥ 30 kg/m^2. This result further corroborates the clinical significance of BMI as an outcome measure in COPD.

The other study by Marti and colleagues reported data from a retrospective Spanish study in 128 severe COPD (126 males), treated with LTOT and admitted in a tertiary teaching hospital, aimed at evaluating outcomes which can predict reduction in survival. This retrospective design reported data in the cohort in a time frame of 10 years. Based on the correlation analysis, BMI <25 kg/m^2, the number of co-morbid conditions, as assessed by the Charlson index, age ≥ 70 years and presence of cor pulmonale were positively associated with all-cause mortality. Low BMI and presence of

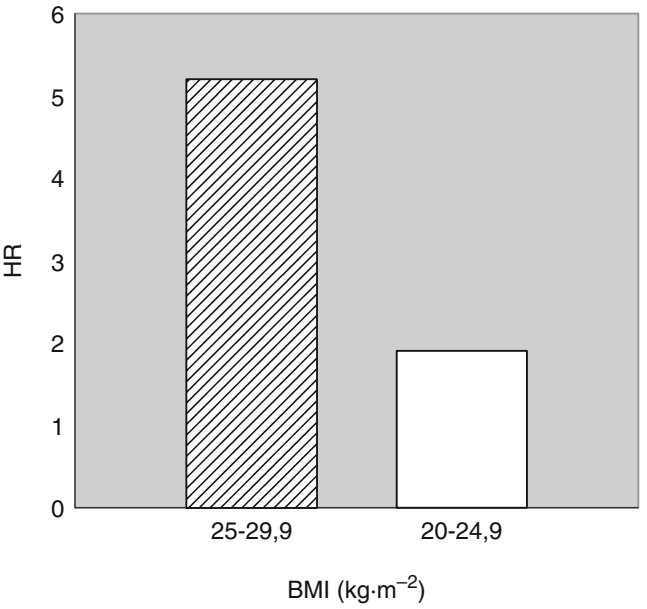

Fig. 145.5 Relative risk for all-cause mortality in the most severe COPD patients. Bars display the risk of all-cause mortality (as assessed by hazard ratio – HR) in the categories of both BMI 25–29.9 and BMI 20–24.9 among very severe COPD patients undergoing domiciliary long-term oxygen therapy (LTOT) (Modified and adapted from Marti et al. 2006)

co-morbidities still remained the only significant predictive factors associated with death when the analysis was restricted to respiratory mortality. In particular, BMI 20 ≥ 24.9 kg/m^2 or <20 kg/m^2 had a increased risk for all-cause mortality (see Fig. 145.5) and for respiratory cause of death (HR 2.07 with 95%CI 1.42–5.07, and 4.95 with 95%CI 2.04–12.01, $p < 0.01$).

In order to evaluate the additional prognostic importance of weight change, Prescott and colleagues (2002) reported data on unselected population of COPD (n = 1,612) participating in the CCHS over 15 years. They confirmed the role of baseline BMI to predict survival. In particular, they studied the mortality rate due to COPD taking the sub-group of patients with a BMI 20 ≥ 24.9 kg/m^2 as the reference value, and found that the RR of death was reduced by 34% and 28% in the sub-groups of patients with BMI between 25 ≥ 29 kg/m^2 and ≥30 kg/m^2 respectively. Not surprisingly, the risk increased by 68% in those COPD with BMI < 20 kg/m^2. They also performed an analysis that investigated the relationship between weight change in BMI units (e.g. for a subject 170 cm tall, 1 unit change in the BMI is equal to 3.89 kg.) and mortality, taking 1 kg/m^2 as the reference value of change in the BMI; a gain between 1 to 3 kg/m^2 or >3 kg/m^2 was associated with a mortality risk reduction by 17% and 5% respectively, whereas a reduction in BMI units between 1 to 3 kg/m^2 or >3 kg/m^2 increased this risk by 31% and 114% ($p < 0.001$) respectively. These findings suggest, after adjusting for age, smoking habits, baseline BMI, and lung function, that weight loss > 3 BMI units would be associated with a significantly higher mortality risk in COPD patients.

Martinez and coworkers (2006) explored the factors predicting mortality in patients with a narrow specific emphysema phenotype and candidate to LVRS inside the National Emphysema Therapy Trial (NETT). A total of 609 patients with severe airflow obstruction and hyperinflation were evaluated for risk factors such as markers of emphysema detected by CT scan, demographic, clinical and physiological data, BMI and changes of the modified BODE index (Celli et al. 2004), which is considered one of the most sensitive outcome predicting risk of death in COPD populations, where the higher the score, the higher the risk. Interestingly enough, in this study, as shown in the above-mentioned study on BODE index by Celli, the BMI, when taken as a single outcome measurement, did not show any significance to predict death. Indeed, taking the 60% of BMI distribution as a reference value, the upper quintile distribution of values (= mean BMI > 28 kg/m^2) showed a HR of 0.86

(95%CI 0.62–1.21, $p = 0.40$) whereas the lower quintile distribution of values (= mean BMI <21.4 kg/m^2) showed a HR of 1.32 (95%CI 0.98–1.78, $p = 0.06$). However, it is worth noting that the modified BODE index score has been shown to be a valid independent predictor of survival in these patients with severe emphysema. Taking the values of BODE between 1 and 6 as a reference category, BODE score 7 ≥ 10 showed a HR of 1.48 (95%CI 1.07–2.05, $p = 0.02$), meaning a significant increase in the risk of mortality in COPD patients with BODE index score above 6. It is difficult to draw a definitive interpretation from this apparent discrepancy of results; the lack of significance of BMI alone in predicting survival might depend on the particular population of severe COPD here included. On the other hand, it is likely that a multi-component index such as the BODE (which also includes BMI) might better reflect the power of prediction in the same population. For sure, further research will clarify this aspect.

Finally, even if BMI alone has been demonstrated to be a valid factor correlated to mortality risk in COPD, three other studies underlined the additional predictive role of body composition and muscle mass area.

To assess the association between FFM and mortality, Schols and coworkers (2005) studied 412 patients with moderate to severe COPD over 5 years. They stratified their cohort into three different pre-defined categories according to different patterns of tissue-depletion: low BMI with normal or above-normal FFMi (semi-starved), low FFMi with normal or above-normal BMI (muscle atrophy) and low BMI with low FFMi (cachectic). While the first two categories were equally distributed among stages of the disease, a higher prevalence of cachexia (29% in men and 27% in women) was seen in the sub-group of patients more severe COPD. Furthermore, while patients with muscle atrophy and cachexia reported similar and worst survival rate, the group of semi-starved (or no impairment) had significantly higher rate of survival. Thus, patients with low FFM had greater mortality risk than all the others, and FFM appears to be a better independent predictor of survival with respect to the BMI and the FM (RR 0.90, 95% CI: 0.84–0.96, $p = 0.003$). Therefore, this study supports the need to include assessment of body composition, as an important marker of disease severity, in COPD staging and phenotyping.

Two recent prospective studies (Marquis et al. 2002; Soler-Cataluña et al. 2005) aimed to assess the prognostic value of muscle mass depletion in severe COPD concluded that, in addition to the prognostic role of BMI level, measurement of the muscular cross-sectional area and the circumference of the mid-thigh as measured by means of the usual CT scan method, may also have a significant role in predicting the patient's survival.

145.5 Applications to Other Areas of Health and Disease

Weight loss and muscle wasting are recognized as critical features that may have an adverse impact on the natural history of COPD patients, influencing both morbidity and mortality. Several studies have documented that BMI ≤ 25 kg/m^2 is a strong predictor of mortality in these patients. The role of low body weight as a determinant of poor survival in COPD patients could be linked to several factors, such as respiratory and peripheral muscle weakness. However, it is still possible that the progressive decline in BMI as shown in patients with COPD, is a marker of advanced disease corresponding to a currently unknown factor also responsible for the decline in pulmonary function.

Recent findings indicate that the assessment of body composition and nutritional status provide additional information compared to BMI alone and help in categorizing COPD patients.

Future research will need to systematically integrate the body composition measure in the whole assessment of COPD patients. Furthermore, a similar approach and assessment should be investigated

even in patients other than COPD, such as idiopathic pulmonary fibrosis. Indeed, in respiratory diseases characterized by lung fibrosis, we still do not know which anthropometric, metabolic or functional factors can predict the long-term outcomes. In addition, all those respiratory conditions leading to chronic respiratory insufficiency might include in their assessment and phenotyping description, some of the body composition parameters which could also be used to identify who are most likely at risk of death.

Therefore, a more extensive knowledge on this topic could then help clinicians to identify patients at risk who may benefit more from life-sustaining interventions, such as domiciliary oxygen.

Summary Points

- Chronic respiratory diseases, COPD in particular, often present with extra-pulmonary manifestations, of which malnutrition and concomitant muscle wasting are most important
- The evaluation of body mass (BMI) and composition (FM and FFM) is an essential part of COPD patient's assessment, and these measures fairly correlate with strong outcomes such as long-term survival
- Several methods of increasing complexity may indirectly (skinfold thickness, MAC or muscle-circumference) or directly (hydro-densitometry, isotopic dilution, BIA) provide information on the FFM status in COPD
- BMI reduction already reflects poor muscle condition and correlates with individual's reduction in maximal aerobic capacity. A cut-off of ≤ 21 kg/m^2 is nowadays considered a threshold limit of nutritional depletion in COPD patients. FFM evaluation, however, may further inform about this status, being the cut-off of ≤ 14.62 kg/m^2 in men and of ≤ 17.05 kg/m^2 in women the threshold of normality
- Longitudinal change of an individual's BMI may variably predict the risk of subsequent survival in the COPD population. Anthropometry can therefore help to detect clinical aspects of COPD patients which are essential in defining specific phenotype and in addressing further interventions

Conflict of Interest Declaration All the authors declare to have no actual and potential conflicts of interest.

Chapter 146
Anthropometry in Congenital Adrenal Hyperplasia

Henrik Falhammar, Anna Nordenström, and Marja Thorén

Abstract Congenital adrenal hyperplasia (CAH) is a monogenic disorder of the adrenal cortex with cortisol deficiency and androgen excess affecting anthropometric parameters throughout the entire life. Glucocorticoids are the mainstay of therapy and anthropometry is vital in judgment and adjustment of the treatment. Treatment involves a difficult balance, in which both over- and under-substitution will result in an increased risk of short final height. Hence, the majority of patients with CAH have attained a final height below their potential. However, improvements in management have resulted in more patients reaching their target height. Earlier, obesity was common in CAH. Nowadays the situation may have improved, weight in these patients does not differ from that in the general population. However, the shorter stature of CAH patients results in an elevated body mass index (BMI) in most reports on both children and adults, and patients aged >30 years may have a higher waist to hip ratio. BMI may give an unreliable estimate of body fat in CAH since, females in particular may experience high androgen levels leading to increased muscle mass. Moreover, owing to the exposure to raised androgens during fetal life, many girls and women with CAH show more gender-atypical behavior regarding choice of profession and leisure time interests with increased physical activity as a consequence. These individuals may then show an elevated BMI as a result of increased muscle (lean) mass, but without increased fat mass. On the other hand, in overtreatment with glucocorticoids, lean mass may be low and BMI may underestimate fat mass. Dual energy X-ray absorptiometry (DXA) provides a more accurate and reliable way of measuring fat and lean mass in males and females affected by CAH. DXA has demonstrated increased fat mass in CAH, but sometimes also, especially in women, increased lean mass.

Other anthropometric characteristics of females with CAH are a lower ratio of the length of the index finger to the ring finger compared to female controls of the same ethnicity, indicating a more masculine-typical ratio. The virilization of external genitals seen predominantly in classic CAH includes a longer clitoris than normal unless operated upon. Benign testicular adrenal rest tumors are common and in about one third of patients may reach a size large enough to become palpable.

In conclusion, anthropometry is a central part of the management of CAH; however, due to the special features of CAH, the interpretations of anthropometry may differ.

146.1 Introduction

Congenital adrenal hyperplasia (CAH) is a monogenic disorder of the adrenal cortex with cortisol deficiency and androgen excess affecting anthropometric parameters throughout life (Table 146.1). Glucocorticoids are the mainstay of therapy and anthropometry is vital in the judgment and adjustment of the treatment (Table 146.2). Height, weight, and different measurements of fat and lean mass

Table 146.1 Key features of monogenic disorders

1. A disease controlled by a single defective gene
2. Considered to be relatively rare, however, the global prevalence at birth is about 1/100
3. Over 10,000 human diseases are considered to be monogenic
4. Inherited (passed on from one generation to another) in a simple pattern
5. Inheritance patterns for monogenic disorders are usually autosomal dominant, autosomal recessive, or X-linked
6. CAH is considered to be one of the most common monogenic disorders inherited in an autosomal recessive pattern

This table lists the key facts of monogenic disorders including its frequency and inheritance
CAH congenital adrenal hyperplasia

Table 146.2 Key features of congenital adrenal hyperplasia

1. CAH is potentially fatal because of cortisol deficiency if not correctly diagnosed and treated promptly with glucocorticoids
2. Girls with CAH are born with different degrees of virilization of external genitalia (ambiguous genitalia) due to elevated prenatal androgens, except in the mild non-classical variant
3. Females exhibit clitoral hyperplasia if not previously subjected to surgery
4. A high risk of not obtaining target height, that is, most individuals will not reach their target height as it is very difficult to obtain the optimal glucocorticoid dose
5. Increased central obesity
6. Increased fat mass, but also sometimes, especially in older women, increased lean mass
7. Decreased index-to-ring finger ratio

This table lists the key facts of congenital adrenal hyperplasia (CAH) focusing on anthropometric features of CAH

are measured regularly in individuals with CAH. A large number of studies have been published on children and young adults with CAH; however, the majority is quite small. By contrast, studies including older adults with CAH are rare. This chapter will commence with an overview of the pathophysiology and clinical presentation of CAH, followed by a more detailed description of the different results found in anthropometric measurements in children and adults affected by CAH. Moreover, suggestions on how, which and when anthropometric measurements should be performed will be given.

146.2 Overview of Congenital Adrenal Hyperplasia

CAH occurs due to total loss or impairment of one of the five steroidogenic enzymes in the adrenal cortex responsible for cortisol production. The most common impairment, 21-hydroxylase deficiency, accounts for approximately 95% of all cases. The enzyme 21-hydroxylase controls the synthesis of cortisol and aldosterone (Fig. 146.1), and mutations in the cytochrome P450 (*CYP21A2*) gene will determine the degree of deficiency, with a generally good correlation with the phenotype. For a more extensive review, see White and Speiser (2000) and Merke and Bornstein (2005). Classical CAH due to a 21-hydroxylase deficiency is divided into salt-wasting (SW) and simple virilizing (SV) types. In SW CAH, both cortisol and aldosterone production are severely impaired, while in SV CAH mainly cortisol is affected. Via lack of negative feedback to the pituitary gland and the hypothalamus, low serum cortisol levels will stimulate corticotropin (ACTH) and corticotropin-releasing hormone (CRH) production. ACTH stimulates both adrenal growth and adrenal androgen production, the latter being the reason why females with classic CAH are born with virilized external genitalia (Table 146.3). Non-classic (NC) CAH exhibits milder symptoms of androgen excess, and females do not have virilized external genitalia at birth. Patients with NC CAH show no obvious cortisol and aldosterone deficiency. The symptoms and signs in female NC CAH may be indistinguishable from those found in polycystic ovary syndrome (PCOS) with oligomenorrhea, hirsutism,

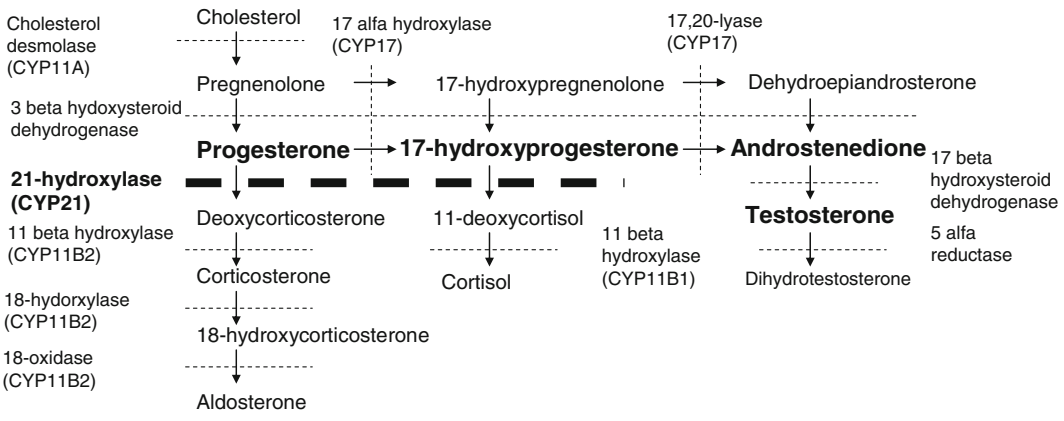

Fig. 146.1 Steroid biosynthetic scheme in the adrenal cortex. The pathways of cortisol, aldosterone, and androgens with their steroid precursors are shown. The different enzymes involved in steroid synthesis are included. The enzyme 21-hydroxylase is most frequently affected in congenital adrenal hyperplasia and is highlighted together with precursors and androgens usually being elevated in this condition

Table 146.3 Key facts of virilization

1. Development of male sex characteristics in females or increased male characteristics in boys before pubertal time
2. In females, the signs are:
   (a) facial hair and increased body hair (hirsutism);
   (b) accelerated growth and bone maturation;
   (c) acne;
   (d) deepening of the voice;
   (e) male-pattern baldness; and
   (f) increased size of clitoris (hypertrophy): in newborn girls, 'scrotalization' of the labial skin, and different degrees of fusion of the labiae, forming a common urogenital sinus, can be found
3. Caused by excess androgen production, that is, testosterone and similar hormones or intake of androgens, namely, use of anabolic steroids
4. CAH is one of the most common causes of virilization

This table lists the key facts of virilization including signs and causes

infertility, and ovaries with increased stroma and multiple follicles (Falhammar et al. 2008). Males with NC CAH are usually found through family studies or because of symptoms of premature pubarche and acne (Merke and Bornstein 2005; Falhammar et al. 2008).

Patients with the salt-losing form of CAH are typically diagnosed during the first weeks of life, while SV CAH has been diagnosed as late as 15 years of age and NC CAH at 6–32 years of age, but occasionally at a very late age (Falhammar et al. 2007a; Falhammar and Thorén 2005). Males with SV or NC CAH are sometimes diagnosed later than females with SV or NC CAH. During the last decades, a number of countries have initiated neonatal screening programs with 17-hydroxyprogesterone, detecting predominately classic CAH due to 21-hydroxylase deficiency. In the Swedish program, one out of 10,500 children is affected (Thilén et al. 1998). Similar frequencies have been found in other populations with an overall incidence of one in 15,000 newborns for classic CAH (White and Speiser 2000; Merke and Bornstein 2005). However, a few geographically isolated populations have a higher incidence of classic CAH, the highest being the Yupik Eskimos in Alaska with an incidence of one in 280 (Merke and Bornstein 2005). In contrast to classic CAH, NC CAH due to 21-hydroxylase deficiency is considered to be the most frequent autosomal recessive genetic disorder in man, with 0.1% of the general Caucasian population affected and higher frequencies in Hispanics and Yugoslavs (1–2%) and in Ashkenazi (Eastern European) Jews (3–4%) (White and Speiser 2000).

Compared to 21-hydroxylase deficiency, the other forms of CAH are rare. The incidence of 11-beta hydroxylase deficiency is about one out of 100,000 in the general population (White and Speiser 2000). This variant of CAH exhibits elevated levels of the steroid precursors deoxycorticosterone (DOC) and 11-deoxycortisol (Fig. 146.1). DOC is a strong mineralocorticoid, and the affected patients show not only virilization but also decreased serum potassium and a raised blood pressure. CAH due to 3-beta-hydroxysteroid dehydrogenase deficiency is even rarer, and females may have only mild virilization of the external genitalia while males exhibit ambiguous genitalia (undermasculinization). Levels of dehydroepiandrosterone and 17-hydroxypregnenolone are elevated (Fig. 146.1).There are more rare variants of CAH, but, in this chapter, we will primarily refer to 21-hydroxylase deficiency when discussing CAH.

Since the introduction of glucocorticoid treatment in the 1950s, these medications have remained the mainstay of treatment in CAH, supplementing the cortisol deficiency and suppressing the ACTH production and leading to restrained androgen production. All patients with CAH due to a 21-hydroxylase deficiency display some degree of aldosterone deficiency, which is, however, clinically apparent only in the SW and SV forms. Fludrocortisone, a mineralocorticoid, is usually added as well, since it may reduce the glucocorticoid dose needed. Unfortunately, supraphysiological doses of

glucocorticoids are often required to suppress the adrenal androgens, and the hypercortisolemia carries the risk of such adverse effects as short stature in adulthood, obesity, insulin resistance, elevated liver function tests, osteoporosis, and fractures (Falhammar et al. 2007a,b, 2009).

146.3 Anthropometry at Birth

In healthy infants, boys are larger at birth than girls in terms of birth weight, length, and head circumference. Infants with CAH have been studied in order to determine whether or not this difference is caused by prenatal exposure to androgens.

Data on birth weight are not entirely consistent. Two studies including 92 and 101 subjects, respectively, demonstrated significantly higher weights compared to reference populations (Jääskelainen et al. 1997; Balsamo et al. 2006), whereas, in one study of 89 children, a modest decrease was found (Völkl et al. 2006). Furthermore, differences in birth weight between classic and non-classic (NC) CAH cases have been found. In an Italian study of infants at 38–41 weeks of gestation ($n = 101$), patients with the classical forms were significantly heavier than the NC patients, the mean weight in females being 3.4 ± 0.4 versus 3.2 ± 0.7 kg and in males 3.5 ± 0.4 versus 3.2 ± 0.7 kg. NC patients were in turn not different from controls (Balsamo et al. 2006). An increased birth weight (+ 0.8 SDS) was also displayed in Finnish infants with early diagnosed, that is, severe forms of CAH, compared to infants with less severe forms (+ 0.2 SDS) diagnosed later during childhood (Jääskeläinen and Voutilainen 1997). Moreover, differences between the two classical forms have also been demonstrated in that patients with the more severe SW form weighed less than those with the milder SV form (Balsamo et al. 2006).

Birth length is increased in infants with CAH and has been reported to be + 0.38 and + 0.39 SDS in females and males, respectively (Völkl et al. 2006). In the latter study, the severity of the disease was not indicated. Balsamo et al. reported that birth length was significantly higher in classic CAH than in NC CAH. In females, the mean birth length was 50.3 ± 1.5 cm in classic CAH and 49.8 ± 2.1 cm in NC CAH. The corresponding means in males were 51.2 ± 1.7 and 49.7 ± 2.1 cm. It has been reported that the *CYP21A2* genotype was positively correlated with gestational length in girls but not in boys (Gidlöf et al. 2007). Gestational age may therefore contribute to the differences seen in birth weight and length.

It is a well-known fact that androgens stimulate skeletal maturation and growth of muscle mass and reduce fat mass. It is likely that the differences in birth length and birth weight, although modest between healthy and CAH infants as well as between classic and NC CAH ones, are attributable to dissimilarities in prenatal adrenal androgen exposure. Possible impacts of other hormonal differences, such as in hydrocortisone concentrations, remain to be explored.

146.4 Postnatal Growth and Final Height

The majority of patients with CAH attain a final height (FH) below their height potential. Treatment in CAH is a difficult balance, where both over- and undersubstitution will result in an increased risk of short FH. Overtreatment with glucocorticoids will result in a decreased growth rate and short stature. On the other hand, undertreatment will result in an androgen excess and growth acceleration and also advanced bone maturation and early epiphysis closure and therefore a short FH. The trend over time has been to use lower doses of hydrocortisone (the preferred glucocorticoid until FH has been achieved), which has resulted in a better FH for individuals with CAH (Hoepffner et al. 2008).

146.4.1 Growth

Growth is a sensitive tool for assessing hormonal control in CAH.

Undiagnosed and untreated patients with milder forms of CAH, that is, SV, who are able to survive past the neonatal period, or NC show an increased growth velocity. Typically, the growth acceleration is obvious from age 3–6 and is accompanied by other symptoms of androgen excess, such as adult/apocine sweating, acne, and pubic hair. It is more common that boys are not diagnosed, as they generally do not demonstrate ambiguous genitalia, and they are often described as big and strong with good muscles. The accelerated bone age results in premature closure of the epiphysis and therefore short stature. The early closure of the growth plate may compromise limb growth even more, resulting in a relatively long trunk (high sitting height) (Young et al. 1989).

Interestingly, several reports indicate that growth velocity and possibly bone maturation either do not seem to be affected or are only moderately affected by excess androgens during the first 12–18 months of life (Claahsen-van de Grinten et al. 2006; Thilén et al. 1995).

146.4.2 Final Height

A meta-analysis of height outcome in 561 CAH patients from 18 centers showed an overall mean weighted FH of -1.37 SDS (no trend for when the articles were published was found). Patients with an early diagnosis had a better outcome (–1.11 SDS) than those with a late diagnosis (–1.61 SDS), and females had a better outcome than males (–1.24 vs. –1.57 SDS). Final height SDS minus target height SDS calculated for all the 204 patients for whom target height (TH) was available gave –1.21 SDS. There was a good correlation between early diagnosis and compliance and FH (Eugster et al. 2001). However, there are contradictory reports concerning the positive effect of early diagnosis on FH, which may reflect different treatment policies. Longer lasting synthetic glucocorticoids as well as high doses of hydrocortisone result in a risk of overtreatment and a shorter FH (Bonfig et al. 2007; Balsamo et al. 2003). This may be the explanation for the conflicting reports as to which form of CAH has the most compromised FH: SW (Trinh et al. 2007) or SV (Balsamo et al. 2003; Manoli et al. 2002). Hence, patients with good hormonal control have been reported to be taller (Trinh et al. 2007; Eugster et al. 2001). In a Swedish survey of 61 women with CAH, the majority of whom had received slightly supraphysiological glucocorticoid doses, the mean FH was 160 cm as compared with 167 cm in controls, and there was no difference in height between older and younger patients (Falhammar et al. 2007a).

It appears that patients with CAH predominantly lose height potential during the first year of life and during puberty. Therefore, it is important to keep the glucocorticoid doses as low as possible throughout childhood and especially during these vulnerable periods (Van der Kamp et al. 2002; Bonfig et al. 2007; Manoli et al. 2002; Girgis and Winter 1997). The addition of mineralocorticoid substitution in patients with SW CAH is also beneficial for reaching TH by reducing the demand for glucocorticoids (Balsamo et al. 2003). Moreover, FH is also dependent on the timing of puberty and hormonal control. Pubertal growth has been reported to be early by, on the average, 2 years (Hargitai et al. 2001) and possibly early in boys (especially with SW) and timely in girls (Trinh et al. 2007; Bonfig et al. 2007). The pubertal growth spurt is reported to be diminished to different extents in both (Hargitai et al. 2001; Stikkelbroeck et al. 2003a; van der Kamp et al. 2002; Manoli et al. 2002).

Body proportions have been reported to be within the normal range in CAH, with the exception of one patient (out of three studied) with the NC form and late diagnosis (Young et al. 1989).

146.5 Weight

Obesity was previously considered to be a common side effect of glucocorticoid treatment in patients with CAH. With time, the management of this therapy has improved. In more recent reports, no difference in weight was found in either adult males or females compared to controls (Stikkelbroeck et al. 2003b; Falhammar et al. 2007a). Similar results have been reported in children (Isguven et al. 2008). In a Swedish study, females with CAH aged 30 years or more were, however, 8 kg heavier than females with CAH aged 18–29 years, while there was no significant difference between younger and older age-matched female controls (Table 146.1) (Falhammar et al. 2007a). This could possibly indicate that patients with CAH (at least female ones) increase their weight more during aging, compared with the general population.

146.6 Body Mass Index

Although weight does not differ between patients with CAH and controls, the shorter stature in patients results in an elevated body mass index (BMI) according to the majority of reports (Stikkelbroeck et al. 2003b; Jääskeläinen and Voutilainen 1996; Isguven et al. 2008), but not all (Cameron et al. 1995), in both children and adults with CAH. However, in the recent Swedish study mentioned above where adult females with CAH were compared with age- and sex-matched controls, only the patients with CAH ≥30 years of age exhibited an elevated BMI, whereas younger adult patients with CAH had BMIs similar to those of controls (Falhammar et al. 2007a) (Table 146.1). The BMI range was, however, wide in both patients and controls (18–48 kg/m^2 and 18–40 kg/m^2). In patients, 11% were even underweight (BMI <19.9 kg/m^2), 56% were normal (BMI 20–24.9 kg/m^2), 18% were overweight (BMI 25–29.9 kg/m^2), 8% were obese (BMI 30–39.9 kg/m^2), and 5% were extremely obese (BMI ≥ 40 kg/m^2). Thus, patients with obesity (BMI ≥30) were a minority (18%).

To avoid adult obesity, the management from infancy and onward is extremely important. Overtreatment during infancy, with high doses of glucocorticoids, was reported to increase the risk of obesity in childhood despite adequate treatment for several years thereafter (Knorr et al. 1988). Prepubertal children had increased BMIs also when growth was not negatively affected. In normal children, BMI increases rapidly to a peak in infancy, and then reverses before increasing again later in childhood. An early age for this rebound is considered a reliable indicator of future adult obesity. Children with CAH were reported to have an earlier adiposity rebound by, on the average, 3 years compared with the normal population, and BMI SDS was greater than 1 in all but one patient in spite of no change in height SDS (Cornean et al. 1998).

Contributing factors predisposing to obesity in childhood are glucocorticoid dosing, bone age delay, and parental obesity. The relative risk of obesity, defined as BMI >2 SDS, was reported to be 4.86 in children and adolescents with obese parents (Völkl et al. 2006).

146.7 Anthropometric Estimations of Body Fat

146.7.1 Body Circumferences

Measurements of body circumferences have not been reported widely in CAH. Visceral obesity is an established risk factor for cardiovascular disease and type 2 diabetes, and waist circumference and the waist-to-hip ratio are established anthropometric measurements used for estimating truncal fat.

We reported similar waist circumferences in both younger (18–29 years) and older (30–63 years) female patients with CAH and age- and sex-matched controls (Falhammar et al. 2007a). The waist-to-hip ratio was, however, elevated in the older women with CAH compared to controls. Both in adult females with CAH and in controls, the waist-to-hip ratio was increased in the older compared with the younger group (Table 146.4). We have found similar results in adult males with CAH.

In a study of eight boys and nine girls affected with CAH aged 1.6–10.5 years, waist, hip, upper arm, and femur circumferences were increased compared to controls (Isguven et al. 2008). The waist-to-hip ratio was, however, increased in girls, while it was decreased in boys.

146.7.2 Skinfold Thickness

Another simple measure that correlates with body fat, skinfold thickness has occasionally been used in studies of individuals with CAH. At least in children, skinfold thicknesses have been demonstrated to be increased at all locations measured (biceps, triceps, subscapula, suprailiac, and femur, and the sum of all) compared to controls (Isguven et al. 2008). Prepubertal children had increased skinfold thickness also when growth was not negatively affected (Cornean et al. 1998).

146.8 Limitations of Anthropometric Measurements for Assessment of Body Fat in Adults with CAH

BMI can be unreliable as an estimate of body fat, especially in people with CAH. If undiagnosed or poorly controlled, especially females with CAH will experience high androgen levels, leading to muscular hypertrophy (Fig. 146.2). Moreover, probably due to the exposure to raised androgens during fetal life, girls and women with CAH show more gender-atypical behavior regarding choice of profession and leisure time interests than controls (Frisén et al. 2009). In fact, 74% were interested in rough sports (100% in the most severe genotypes), such as ice hockey and soccer. These individuals may display an elevated BMI due to increased muscle (lean) mass but no increased fat mass. Conversely, in physically very inactive patients or in those on severe overtreatment with glucocorticoids (exogenous Cushing's syndrome), lean mass may be low and BMI may underestimate fat mass. Hence, a more reliable method of estimating body fat, but also lean mass, is needed in combination with anthropometric measurements in individuals with CAH.

146.8.1 Dual-Energy X-Ray Absorptiometry

Dual-energy X-ray absorptiometry (DXA), which has been used in some studies on CAH patients (Cameron et al. 1995; Stikkelbroeck et al. 2003b; Falhammar et al. 2007a), provides a fairly accurate, reliable, and simple way of measuring fat and lean mass in males and females affected by CAH. Unfortunately, not all DXA machines can measure body composition because DXA equipment is used primarily for bone measurements and to enable measurements of fat and lean body mass additional software is necessary. In addition, the whole body must be measured and not just the central parts, which is the case with some DXA machines used solely for bone measurements.

Table illustrating anthropometry, body composition (by DXA), and blood pressure measured in female patients with congenital adrenal hyperplasia and age-matched controls <30 and ≥30 years of age (mean ± SEM or median and range). Body-composition data were calculated in 24 patients and 26 controls <30 years and in 32 patients and 34 controls ≥30 years. Fat mass and lean body mass data are adjusted for body height (kg/m^2) (From Falhammar et al. (2007a), Copyright 2007, The Endocrine Society)

Body composition data were calculated in 24 patients and 26 controls younger than 30 year and in 32 patients and 34 controls 30 or older. Fat mass and lean body mass data are adjusted for body height (kg/m^2)

NS not statistically significant ($P \geq 0.05$); BP blood pressure

[a] Comparison between patients and controls younger than 30 year

[b] Comparison between patients and controls at least 30 year old

[c] Comparison between patients younger than 30 and 30 year old or older

[d] Mann-Whitney U test; χ^2, with Yates correction

[e] Percentage of total body mass

[f] Percentage of total truncal mass

[g] The three patients on antihypertensive medication were excluded

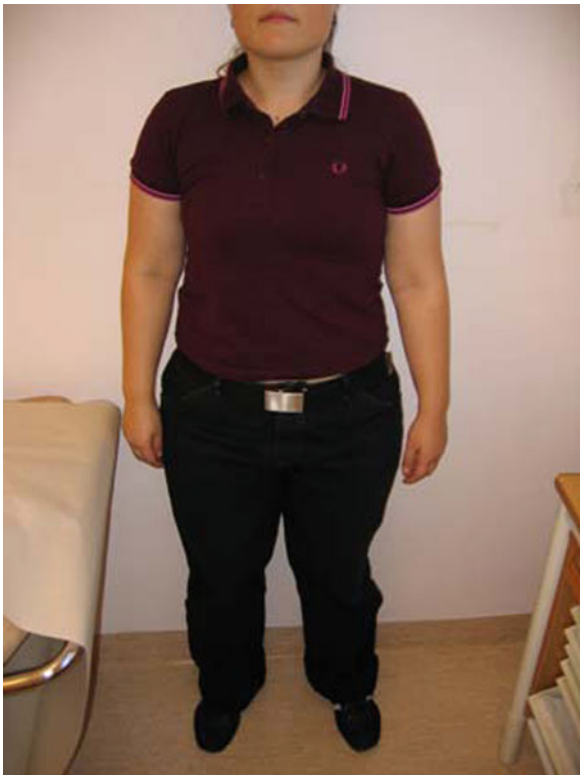

Fig.146.2 An adult woman with CAH. This figure illustrates a short woman with classic CAH, poor compliance to glucocorticoid medication, and signs of muscular hypertrophy. Her serum testosterone was markedly elevated (16 nmol/L; reference interval in adult females 0.3–3.0 nmol/L, in adult males 10–30 nmol/L)

Cameron et al. investigated the total fat-to-lean ratio in male and female children, adolescents, and young adults with CAH, aged 8–32 and found a higher ratio in patients with CAH than in their controls (Cameron et al. 1995). Stikkelbroeck et al. assessed male and female patients 17–25 years of age and found an increased total fat mass, but not lean mass, in patients with CAH compared to age- and sex-matched controls, especially when adjusted for the shorter height in CAH patients (Stikkelbroeck et al. 2003b). By contrast, we found no difference with respect to controls in adult females with CAH under 30 years of age in either total or regional fat or lean mass (Table 146.4). Surprisingly, in the older patients with CAH (≥30 years of age), total and arm lean mass adjusted for height were found to be elevated, whereas different measurements of fat mass did not differ from age-matched controls. Moreover, older women with CAH demonstrated more fat and lean mass than younger women (Table 146.4). Both the younger and older cohorts were modestly overtreated with glucocorticoids as evidenced by suppression of adrenal androgens (Fig. 146.3). It cannot be ruled out, though, that some of the older patients may have been undertreated in the past with ensuing stimulation of muscle mass by elevated adrenal androgens. However, in both women with CAH and their controls, the strongest correlation between total lean mass adjusted for height turned out to be fat mass adjusted for height (Fig. 146.4). This correlation was even stronger if only older women with CAH were studied.

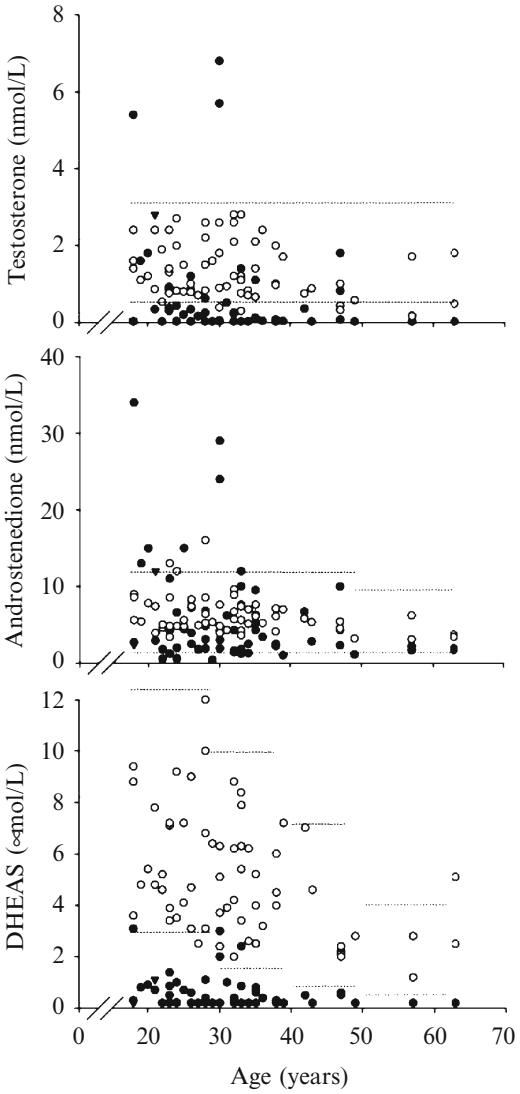

Fig.146.3 Serum androgens in adult women with congenital adrenal hyperplasia and controls. Figure illustrating different androgen levels in women affected by CAH (congenital adrenal hyperplasia) and age- and sex-matched controls. (●) CAH women, those on antiandrogen excluded. (▼) CAH women on antiandrogen. (○) Controls. $P < 0.001$ between CAH women and controls in all comparisons. Reference limits for the different androgens and different age intervals are indicated by *dotted lines* (From Falhammar H et al. (2007a). Copyright 2007, The Endocrine Society)

146.8.2 Bioelectrical Impedance Analysis

Bioelectrical impedance analysis is a noninvasive, inexpensive method of measuring total body fat. Body-fat percentage using bioelectrical impedance analysis was significantly elevated in children with CAH compared to controls (27.3% vs. 11.5%) (Isguven et al. 2008). However, when available, DXA measurements are preferred due to the possibility of measuring regional fat and lean mass distribution.

146.9 Shoe Size

Shoe sizes, as a measurements of foot length, have been demonstrated to be smaller in young adult males with classic CAH than in healthy controls (40.6 ± 1.5 vs. 43.9 ± 1.0; $P < 0.001$), probably reflecting their shorter stature by 12.1 cm compared to controls (Stikkelbroeck et al. 2003b).

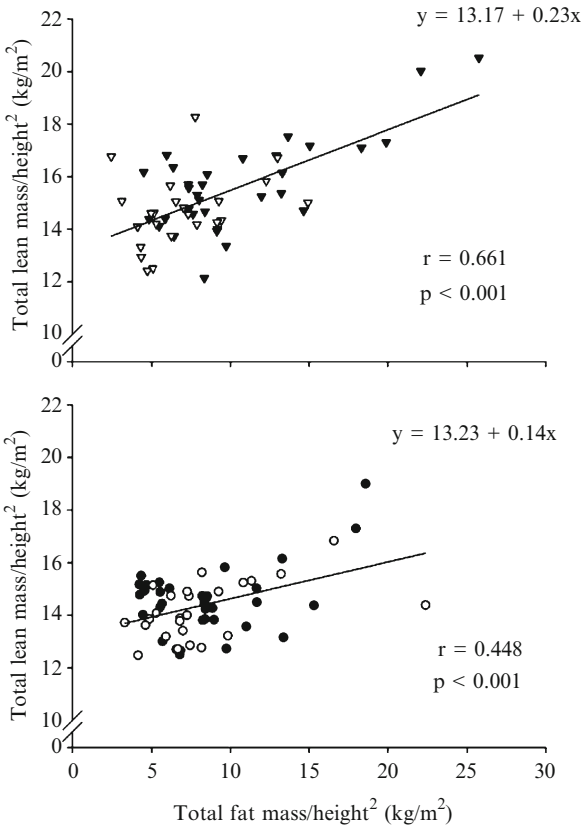

Fig.146.4 Correlation between total lean mass/height^2 and total fat mass/height^2 in adult women with congenital adrenal hyperplasia. Figure illustrating correlation between muscle (lean) mass and fat mass, both adjusted for the shorter height in individuals with CAH (congenital adrenal hyperplasia). (▼) CAH women ≥30 years old. (▽) CAH women <30 years old. (●) Controls ≥30 years old. (○) Controls <30 years old (From Falhammar H et al. (2007a). Copyright 2007, The Endocrine Society)

146.10 Ratio of the Second and Fourth Finger Length

Since first published in 1875, males have consistently been demonstrated to have, on average, a lower ratio of the length of the index finger to the ring finger (2D- to-4D ratio) than females (McIntyre 2006). As early as the end of the first trimester of gestation, this sex difference can be found. Constant means of the 2D-to-4D ratio for males and females have been reported from at least 2 years of age through adulthood. It can be assumed that the sex difference in the 2D-to-4D ratios is a result of androgen status. Hence, the 2D-to-4D ratio has been suggested as a marker of intrauterine androgen exposure.

Since females with CAH are exposed to high intrauterine levels of androgens, they have been considered to be a model for testing the hypothesis that prenatal androgens can affect the 2D-to-4D ratio. If the hypothesis is correct, these females should display a smaller 2D-to-4D ratio than healthy women.

In one study, the 2D-to-4D ratio was measured on both hands in females with CAH (aged 7–44 years) and control females (aged 12–44). Females with CAH exhibited lower 2D-to-4D ratios, indicating more masculine-typical ratios compared to female controls, although the difference did not reach statistical significance on the left hand (Fig. 146.5). No differences between females with CAH and female controls were found in the absolute length of any of the four fingers measured (Brown et al. 2002).

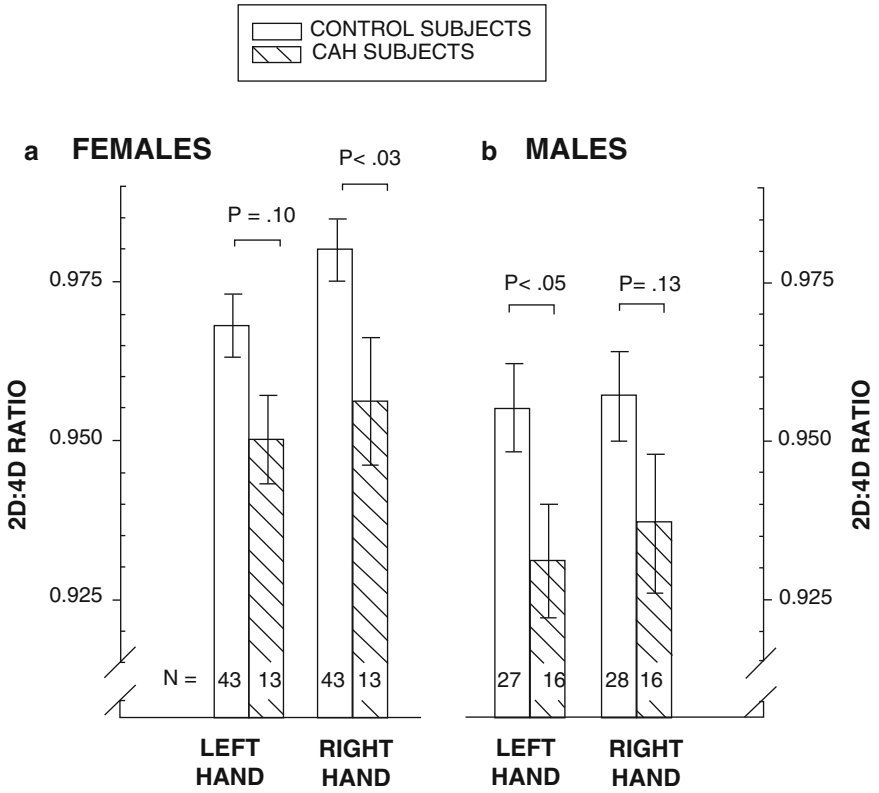

Fig.146.5 Ratios of the length of the index finger to the ring finger (2D-to-4D ratio) in females and males. Figure illustrating finger ratios in CAH individuals and controls. (**a**) Mean finger-length ratios of females with CAH and control females for both the *left* and *right* hands. Females with CAH have a significantly smaller 2D:4D on the *right* hand than do female controls. (**b**) Mean finger-length ratios of males with CAH and male controls for both the *left* and *right* hands. Males with CAH have a significantly smaller 2D:4D on the *left* hand compared with male controls. *Error bars* represent standard errors of the means; all *P* values are two-tailed (Reprinted from Brown et al. (2002), Copyright (2002), with the kind permission of Elsevier)

Males with CAH (aged 5–21 years) and male controls (aged 9–34) were also studied. Interestingly, in males affected by CAH, the 2D-to-4D ratio was smaller on both the left and the right hands compared to unaffected male controls. However, this did not reach statistical significance on the right hand. In addition, to adjust for a putative genetic influence, six male relatives without CAH were recruited to act as a further control group for six of the males with CAH. When the related unaffected males were compared to their male relatives with CAH, the latter displayed smaller 2D-to-4D ratios on both the left and right hands. The significance was far higher than when the males with CAH were compared with unrelated male controls. Hence, individuals with CAH demonstrate smaller 2D-to-4D ratios than controls, and this supports the hypothesis that intrauterine androgens affect the 2D-to-4D ratios. However, in adults, the correlation between sex and the right-hand 2D-to-4D ratio is quite low, with an approximately 60% overlap between males and females in a homogeneous population. Moreover, in a mixed-race population, race accounts for more variation in the 2D-to-4D ratio than sex. Populations of African descendents have lower 2D-to-4D ratios at all ages, but considerable differences have also been reported among ethnic groups usually considered to be racially comparable (McIntyre 2006).

146.11 Clitoral Size

Newborn girls with classic CAH present with virilized external genitalia, including varying degrees of clitoral hypertrophy, 'scrotalization' of the labial skin, and different degrees of posterior fusion of the labiae majorae, thus forming a common urogenital sinus of varying length. Genital surgery is usually performed to create female-looking genitalia. A number of different procedures have been used for surgery of clitoral hypertrophy. Historically, clitoral amputation was commonly performed, but due to the increased awareness of the importance of the clitoris for sexuality in females, more sophisticated techniques have been developed. Nowadays, a great deal of effort is made to provide a satisfactory cosmetic result without surrendering sensation and vascularity of the clitoris by modern methods of genital surgery, which include sparing as much as possible of the dorsal nerves.

Nordenskjöld et al. reported on 62 adult women with CAH, 62% of whom had had some kind of clitoroplasty performed (Nordenskjöld et al. 2008). The length of the clitoris was correlated with the surgical intervention and, unless amputated, it was longer than a normal-sized clitoris. In those not operated upon, the mean length was 28.8 mm (range 10–50 mm), which is considerably longer than normal (normal-sized clitoris, 16 ± 4.3 mm). A normal-sized clitoris was found in 17 women (six not operated upon). In eight women, the clitoris was small (defined as <11.5 mm) (four amputated, one not operated upon). In 36 women, the clitoris was larger than normal (defined as >20.5 mm) and 17 of them had had no clitoral surgery performed.

146.12 Testicular Adrenal Rest Tumors

The adrenals and testicles are developed in close vicinity during fetal life, and adrenal cells are present in normal testicles. Due to the increased ACTH levels in CAH, these cells can be stimulated and grow so as to result in benign testicular tumors typically located in the rete testis, causing obstruction of the seminiferous ducts and impaired fertility. Previously, testicular adrenal rest tumors were considered rare in CAH; however, new data have changed that perception. Stikkelbroeck et al. demonstrated one or more testicular tumors in 16 (94%) of the 17 males with CAH, examined by ultrasonography (Stikkelbroeck et al. 2001). In only six males (35%) were the tumors palpable. These findings are in agreement with our own experience.

146.13 Application to Other Areas of Health and Disease

Individuals with CAH demonstrate many special features which have to be accounted for when comparing with controls. For example, adult males and females affected by CAH are, on the average, considerably shorter than age- and sex-matched controls, which makes many comparisons incorrect if not adjusted for the difference in height. Moreover, in diseases with high or low androgen exposure, especially in females, this could render approximations of BMI as a measurement of obesity incorrect as the proportion of muscle mass is being under- or overestimated. DXA measurements using special software for body composition are therefore a more satisfactory technique. However, it is not just the present or the total lifetime exposure to androgens that is of importance. In fact, the intrauterine androgen exposure may be even more important as it affects the development of the brain and results in a more masculinized behavior. The change in behavior and interests may be of importance for future selection of work and leisure activities affecting muscle-mass development.

An indirect method of assessing intrauterine androgen exposure is to measure the 2D-to-4D ratio. Disorders of increased androgen exposure during fetal life include, apart from CAH, androgen-producing tumors in the mother, androgen intake by the mother, and girls with male co-twins. Disorders of decreased androgen exposure during fetal life include Turner syndrome (in which exposure to androgens and estrogen is exceptionally low as a result of undifferentiated gonads), complete androgen insensitivity syndrome (CAIS, 46 XY karyotype; testicles are developed but do not descend and testosterone levels are normal to high, but the phenotype is female due to malfunctioning androgen receptors), etc. Some of the anthropometric and other features of CAH could also be due to long-term exposure to supraphysiological doses of glucocorticoids. Long-term exposure to supraphysiological doses of glucocorticoids is also seen in Addison's disease, pituitary insufficiency, in some patients with bronchial asthma, in patients with rheumatologic, hematologic, nephrologic, dermatologic, and neurologic diseases, along with patients after different kinds of organ transplantation. Endogenous exposure to glucocorticoids can be seen in Cushing's syndrome.

146.14 Guidelines

In CAH growth, both height and weight measurements are the most powerful tools we have for assessing the effect of treatment at follow-up during childhood and adolescence.

We recommend that weight and height be measured at every visit, which should occur every 3 months to yearly, depending on the age of the patient and the severity of CAH.

As in many other conditions, BMI is not the optimal tool for estimating body fat. Waist circumference and the waist-to-hip ratio are better techniques for estimating, at least, central obesity. DXA measurement of body composition with adjustments for height constitutes a more advanced method which is quite in widespread use. However, if not available, bioelectrical impedance analysis or skinfold thickness measurements could be alternatives.

In adults, a waist and hip circumference measurement should be done yearly, and, we believe, a DXA scan for body composition, if available, should be done at least every 5 years, and usually bone mineral density is measured at the same time. If DXA measurements of body composition are not available, alternative methods might be used, such as skinfold thickness or, preferably, bioelectrical impedance analysis. The results of these anthropometric measurements should be used primarily to adjust the glucocorticoid dose, and also for implementing lifestyle changes.

The ratio of the length of the index finger to the ring finger can be used as an estimate of intrauterine androgen exposure, although mainly at the group level.

Summary Points

- Individuals affected by CAH are exposed to high intrauterine levels of androgens, that is, male hormones. There is a good genotype-to-phenotype correlation. Females are born with different degrees of virilization of the external genitalia (ambiguous genitalia) depending on the severity of the disease with, among other things, clitoral hyperplasia, and both males and females require glucocorticoid supplementation in most cases for survival.
- Increased androgen levels during childhood lead to increased growth and also to accelerated bone age and therefore compromised final height.
- Supraphysiological glucocorticoid doses may lead to short stature in adulthood, obesity, insulin resistance, high liver function test level, osteoporosis, and fractures.

- Many patients with CAH will demonstrate central obesity and other indices of increased body fat mass, but at least women aged ≥30 years with CAH will also demonstrate increased muscle mass. Waist-to-hip ratio and DXA measurements with body- composition assessments are good techniques for estimating fat and muscle mass.
- Measuring the second-to-fourth finger ratio may be a way to estimate prenatal androgen exposure. The ratio is usually decreased in both males and females with CAH compared to the general population.

Chapter 147
Changes in Anthropometric Measures in Systemic Lupus Erythematosus

Chi Chiu Mok

Abstract Systemic lupus erythematosus is a chronic multi-systemic autoimmune disease that predominantly affects women of reproductive age. Despite the emergence of novel therapeutics, the main stay of systemic lupus erythematosus treatment remains systemic glucocorticoids. High-dose or long-term glucocorticoid administration is associated with bone demineralization and a profound change in body composition. Chronic use of glucocorticoids in children and adolescents retards growth velocity and leads to short adult body height. Although elevation of proinflammatory cytokines as a result of disease activity, imbalanced nutrition, lack of physical activity due to musculoskeletal complications, avoidance of sunshine and hormonal disturbances may contribute to a loss of lean body mass and bone mineral content, the chief mechanism for a change in fat distribution, abdominal obesity, loss of muscle mass and growth retardation in patients with systemic lupus erythematosus is glucocorticoid therapy. This chapter summarizes data on measurement of fat and lean body mass in patients with systemic lupus erythematosus and its relationship with bone mineral density.

Abbreviations

Apo A1	Apolipoprotein A1
Apo B	Apolipoprotein B
ATPIII	Adult Treatment Panel III
BMI	Body mass index
DXA	Dual energy X-ray absorptiometry
HDL	High density lipoprotein
hsCRP	High sensitivity C-reactive protein
IGF-1	Insulin growth factor 1
IL-6	Interleukin-6
NCEP	National Cholesterol Education Program
SLE	Systemic lupus erythematosus
TNF-α	Tumor necrosis factor α

147.1 Introduction

Systemic lupus erythematosus (SLE) is an autoimmune disease that mainly affects women of reproductive age. The disease may affect multiple organs and systems, with new clinical features developing at different time points of the disease course, which is characterized by periods of exacerbation and remission. The clinical manifestations of SLE are heterogeneous and no two patients are exactly alike. A recent cluster analysis (To et al. 2009) of the clinical features of 1082 SLE patients who were observed longitudinally for 8 years identified three patterns of clinical manifestations – predominant musculoskeletal and dermatological features (best prognosis), predominant and serious renal disease associated with higher mortality and heterogeneous clinical manifestations involving multiple systems.

Because of the clinical and immunological heterogeneity of the disease, the course and prognosis of SLE is largely unpredictable. Although certain environmental factors such as medications, ultraviolet light, hormonal changes and administration of exogenous estrogens have been implicated for triggering disease flares, no identifiable causes can be found in the majority of cases (Mok and Lau 2003). Patients with major organ involvement, recurrent disease relapses and refractory disease manifestations are associated with a poorer prognosis. There is still no cure for this chronic, disabling and potentially fatal disease, although newer medications are able to reduce the risk of disease flares with lower incidence of toxicities.

Management of SLE depends on the nature, severity and reversibility of organ manifestations, and their underlying pathology. Mild manifestations of SLE such as arthritis and dermatological disease usually respond to topical corticosteroids, sun-screening and antimalarials. Systemic glucocorticoids and more aggressive immunosuppressive treatment are indicated for major organ manifestations such as glomerulonephritis and neuropsychiatric disease. Despite the emergence and availability of newer immunosuppressive and biological agents such as mycophenolate mofetil, tacrolimus, rituximab, belimumab and abatacept (Mok 2010), glucocorticoid-based regimens remain the mainstay of treatment for SLE, both for initial and maintenance therapy.

However, the use of glucocorticoids is associated with a number of short-term and long-term adverse effects, some of which are related to the dosage and duration of administration. Long-term use of glucocorticoids is a major cause of organ damage in SLE. According to one observational study, the cumulative prednisolone dose was significantly associated with the development of osteoporotic fractures, symptomatic coronary artery disease and cataract in patients with SLE (Zonana-Nacach et al. 2000). In addition to chronic glucocorticoid therapy, renal insufficiency, premature menopause, avoidance of sun exposure, disabling arthritis and myopathy, the use of other medications such as anticoagulants and anticonvulsants also contribute to low bone mass and increased risk of fragility fractures in SLE patients (Lee and Ramsey-Goldman 2005). Other well recognized side effects of glucocorticoids are increase susceptibility to infections, reduction of growth velocity in children, proximal myopathy, impaired glucose tolerance, hypertension, hyperlipidemia, mood disorders and avascular bone necrosis.

147.2 Glucocorticoids and Body Composition

Glucocorticoid therapy induces the classical cushingoid body phenotype which comprises central obesity, prominence of dorsal, temporal, and supraclavicular fat pads and moon face and thin limbs. The pathophysiology is not fully understood, but lipid mobilization in the adipose tissues with redistribution of fat in the abdominal viscera appears to be the main mechanism (Bjorntorp 1997).

Lipid mobilization depends on both lipolysis and re-esterification of free fatty acids in the adipose tissues. In the presence of insulin, glucocorticoids inhibit catecholamine-induced lipolysis but promote the lipolytic effect of growth hormone (Ottosson et al. 2000). Moreover, glucocorticoids reduce re-esterification in adipose tissues by inhibiting glucose transport, leading to an increase in circulating free fatty acids (Divertie et al. 1991). The density of glucocorticoid receptor seems to be higher in intra-abdominal (visceral) than in subcutaneous adipose tissues (Rebuffe-Scrive et al. 1985) and this may explain the regionally specific effects of glucocorticoids, depending on the degree of perturbation on lipid accumulation and mobilization in various body sites. Adipose tissue biopsies from patients with Cushing's syndrome showed enlargement of abdominal fat cells with low lipolytic but high lipoprotein-lipase activity, which may explain the accumulation of fat in the abdomen after glucocorticoid exposure (Rebuffe-Scrive et al. 1988).

Besides inducing a centripetal body fat redistribution, glucocorticoids also lead to an increase in body weight (and hence body mass index) because of their stimulatory effect on appetite. In some individuals, particularly children, more generalized instead of central obesity develops after glucocorticoid treatment (Yanovski and Cutler 1994). Moreover, glucocorticoids increase protein catabolism which results in loss of proximal muscle mass. Thus, the use of high-dose or long-term glucocorticoids is the main cause for the reduction of bone mineral density and change in body composition observed in patients with SLE.

Long-term glucocorticoid treatment alters the pulsatility and secretion of growth hormone by increasing the somatostatin inhibitor tone (Simon 2007). Glucocorticoids also decrease the expression of growth hormone receptors on hepatocytes, leading to lower insulin growth factor-1 (IGF-1) mRNA levels (Mehls et al. 1993). In vitro studies have also shown that glucocorticoids may exert direct inhibitory effects on the growth plates by inhibiting chrondrocyte proliferation and transcription of the growth hormone receptor, resulting in decreasing production of IGF-1 (Jux et al. 1998). Administration of glucocorticoids in children and adolescents may lead to retardation of growth velocity and short adult height. The severity of growth retardation depends on the age at the time glucocorticoid treatment, severity of the underlying diseases and duration and dose of glucocorticoids received (Shamir et al. 2007).

147.3 Anthropometry and Body Composition in SLE

In addition to the untoward effects of chronic glucocorticoid administration, disease-specific factors may also contribute to a change in anthropometric measures and body composition in patients with SLE. Though uncommon, chronic active arthritis similar to that of rheumatoid arthritis is a problem in a subset of SLE patients. Chronic arthritis leading to joint deformity and disuse atrophy may lead to a loss in lean body mass. The levels of cytokines such as tumor necrosis factor (TNF)-α and interleukin (IL)-6 are elevated in patients with active SLE compared to normal controls (Gomez et al. 2004; Chun et al. 2007). There is evidence that elevated TNF-α levels is linked to the loss in fat-free mass in disease states such as rheumatoid arthritis (Walsmith et al. 2004). IL-6 stimulates formation and activity of the oesteoclasts and is unfavorable for bone mineral density (Manolagas 1995). Moreover, TNF-α and IL-6 may also contribute to growth retardation and hence short adult height in children by inhibiting IGF-1 transcription via the growth hormone receptors and/or chrondrocyte proliferation in the growth plates (Shamir et al. 2007). On the other hand, insufficient physical activity due to chronic joint problem, imbalanced nutrition, lack of outdoor activity to avoid sunshine and hormonal disturbances as a result of active SLE and its treatment may also result in a change of fat and lean body mass and loss of bone mineral content.

Table 147.1 Summary of studies on body composition in patients with systemic lupus erythematosus

	Kipen et al. (1998)	Kipen et al. (1999)	Lilleby et al. (2007)	Mok et al. (2008)
Study design	Cross-sectional	Longitudinal	Cross-sectional	Longitudinal

BMD bone mineral density; *BMC* bone mineral content

Besides measuring bone mineral density, the dual energy X-ray absorptiometry (DXA) scan enables precise measurement of body composition in terms of fat-free and fat body mass by passing photons of two levels of energy through the body (two-compartment model) (Deurenberg-Yap et al. 2001). Fat-free body mass can further be broken down into lean soft tissue mass and bone mineral content (three-compartment model). A number of cross-sectional and longitudinal studies have demonstrated the substantial effect of glucocorticoids on body composition in patients with various medical diseases including SLE (Azcue et al. 1997; Formica et al. 1997; Kipen et al. 1998). In most of these studies, an increase in fat body mass but a reduction in lean body mass and bone mineral content was reported.

There are much fewer studies which specifically target body composition in patients with SLE (Table 147.1). Kipen et al. (1998) performed a cross-sectional DXA study on the body composition of 82 predominantly Caucasian female SLE patients, 30 of whom were post-menopausal, with a median duration of menopause of 8.5 years. The median age of these patients was 41 years and the median SLE duration was 7.1 years. Seventy percent of these patients had been exposed to glucocorticoids at some stage of their disease but only 39% patients had damage scores as measured by the SLE damage index, indicating that this sample of patients had relatively mild disease manifestations. The median cumulative dose of corticosteroids received by the patients was 12.8 g and the median body mass index was 24 kg/m^2. There were no control subjects in this study. Using univariate linear regression analysis, it was demonstrated that a reduced fat-free mass was significantly associated with higher damage scores, a history of exposure to corticosteroids and increasing age. In a stepwise multiple linear regression model, fat-free body mass was significantly associated with total body, lumbar spine and femoral neck bone mineral density. Thus, older SLE patients with more serious disease that warrants systemic glucocorticoid treatment and more organ complications are more prone to a loss in fat-free mass and bone mineral density.

Twenty-eight SLE patients who participated in this study were followed longitudinally for serial changes in body composition and bone mineral density (Kipen et al. 1999). The mean age of this

cohort of patients was 34.4 years and the mean follow-up duration was 3.2 years. Seventeen (61%) patients were exposed to corticosteroids during the observation period and the mean daily dose of prednisolone was 12.0 mg. Over the 3-year follow-up period, a significant increase in body mass index and fat-free body mass was observed in these patients. In patients who were exposed to corticosteroids, only the increase in fat-free mass was statistically significant. A stepwise linear regression analysis showed that disease activity of SLE was associated with an increase in body mass index and fat body mass. In contrast, exercise was associated with an increase in fat-free mass. Older age at baseline and smoking were unfavorable factors for the change in whole body bone mineral density.

Lilleby et al. (2007) studied the body composition and lipid and lipoprotein levels in 68 childhood-onset patients with SLE and compared those with 68 age- and gender-matched healthy controls. The mean age of the SLE patients was 26.2 years and the mean SLE duration was 10.4 years. The mean body mass index was 23.8 kg/m^2. Corticosteroids were used in 93% of these patients and the mean duration of corticosteroid use was 36 months. This cross-sectional case-control study demonstrated that SLE patients had significantly higher percentage total body fat but lower lean body mass than healthy controls. The cumulative dose of corticosteroids was found to be independently associated with the percentage total body fat in a multivariate regression model. Disease activity score of SLE, physical activity and dietary intake was not associated with body fat. Compared to controls, patients with SLE had lower high density lipoprotein (HDL) cholesterol and apolipoprotein A1 (apo A1) levels, but a higher mean apo B/apo A1 ratio.

Recently, we also studied the serial changes in body composition and bone mineral density over 6 months in 29 SLE patients who were treated with high-dose glucocorticoids for various disease manifestations (Mok et al. 2008). The mean age of this cohort of patients was 39.7 years. Eight-three percent of these patients were women and 29% of them were postmenopausal. The mean duration of SLE was 80.1 months. Fourteen patients (48%) were glucocorticoid-naive. The mean maximum daily dose of prednisolone administered was 32.9 mg and the mean cumulative prednisolone dose in 6 months was 2.7 g. Except for calcium supplement and vitamin D, none of these patients had ever received bisphosphonates or other anti-osteoporotic medications.

After 6 months' glucocorticoid treatment, a significant drop in bone mineral content of the trunk (–5.0 ± 2.2%; $p = 0.04$) and the whole body (–1.2 ± 0.4%; $p = 0.002$) compared to baseline was observed in our cohort of patients. Moreover, the bone mineral density of the hip (–1.7 ± 0.6%; $p = 0.006$) and the whole body (–0.7 ± 0.3%; $p = 0.01$) also dropped significantly. The fat mass of the trunk (+14.5 ± 4.1%; $p = 0.001$) and the limbs (+10.0 ± 3.2%; $p = 0.004$) of the patients increased significantly, which was associated with a non-significant drop in lean mass of the trunk (–3.3 ± 1.8%; $p = 0.08$) and limbs (–0.8 ± 2.4%; $p = 0.75$) (Figs. 147.1 and 147.2). The fat content (% fat) of the trunk and whole body also increased significantly from baseline to month 6. The changes in whole body bone mineral content correlated significantly with age and changes in total fat body mass but not with lean mass, sex, body mass index, smoking, cumulative prednisolone dose or changes in bone mineral density. In this prospective study, it was demonstrated that in patients with SLE, high-dose glucocorticoid treatment led to an early and rapid drop in bone mass, which was more serious in older patients and correlated with an increase in body fat. Table 147.2 summarizes the essential findings of these studies.

147.4 Abdominal Obesity and Metabolic Syndrome in SLE

Patients with SLE are prone to premature atherosclerosis. This is caused in part by an increased prevalence of traditional vascular risk factors and other disease- or treatment- related factors such as antiphospholipid antibodies, chronic glucocorticoid therapy and elevation of inflammatory markers

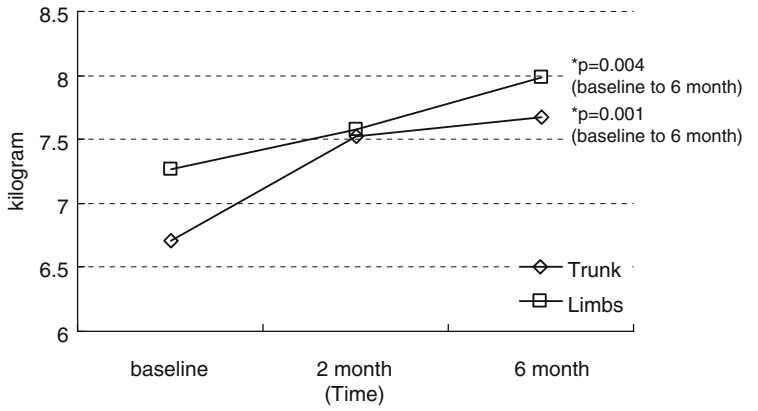

Fig. 147.1 Changes in fat mass of the trunk and limbs in SLE patients receiving high-dose glucocorticoids

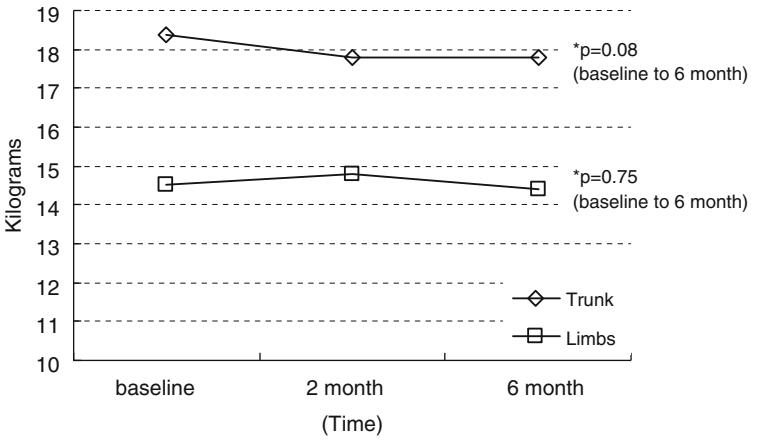

Fig. 147.2 Changes in lean mass of the trunk and limbs in SLE patients receiving high-dose glucocorticoids

Table 147.2 Summary of the findings in studies involving body composition in systemic lupus erythematosus

	Study design	Study duration	Findings
Lilleby et al. (2007)	Case-control	–	SLE patients had significantly higher body fat content but lower lean body mass than age-matched healthy controls. In SLE patients, the cumulative glucocorticoid dose was independently associated with body fat content
Kipen et al. (1999)	Longitudinal	3.2 years	Significant increase in body mass index and fat-free body mass in SLE patients was noted. There was also increase in fat body mass, but the change was not significant. Disease activity of SLE was associated with an increase in body mass index and fat mass. Physical exercise was associated with an increase in fat-free mass. Older age at baseline and smoking were unfavorable factors for a drop in whole body bone mineral density
Mok et al. (2008)	Longitudinal	6 months	Significant drop in bone mineral content (total body, trunk) and bone mineral density (total body and hip) after high-dose glucocorticoid treatment was demonstrated. Body fat mass and fat content also increased significantly. Drop in total body bone mineral content correlated with increasing age and increase in fat mass

SLE systemic lupus erythematosus

and cytokines such as high sensitivity C-reactive protein (hsCRP), homocysteine, IL-6 and TNFα (Mok 2006). The metabolic syndrome is a constellation of risk factors that increase the risk for type II diabetes mellitus and cardiovascular and cerebrovascular diseases. These risk factors include abdominal obesity, atherogenic dyslipidemia, elevated blood pressure and insulin resistance (Grundy et al. 2005). A number of case control studies have reported an increased prevalence of the metabolic syndrome in SLE patients of different ethnic backgrounds (Chung et al. 2007; Bultink et al. 2008; Negron et al. 2008; Sabio et al. 2008; Bellomio et al. 2009; Vadacca et al. 2009; Mok et al. 2010) (Table 147.3).

The interplay among disease activity, treatment, obesity, metabolic syndrome and atherosclerosis is complex and intriguing. Disease complications such as renal impairment and glucocorticoid treatment lead to increased prevalence of impaired glucose tolerance, hypertension, dyslipidemia and visceral obesity, which in turn increases the incidence of metabolic syndrome in SLE patients. On the other hand, as a result of active SLE proinflammatory cytokines such as TNFα and IL-6 reduce the activity of insulin, inhibit insulin receptor autophosphorylation and signal transduction, thereby promoting insulin resistance and leading to hyperglycemia, compensatory hyperinsulinemia and dyslipidemia (Pereira et al. 2009). In patients with visceral obesity, hypertrophic adipocytes and the accumulation of macrophages in abdominal fat may be a source of production of proinflammatory cytokines that aggravate the degree of insulin resistance (Sidiropoulos et al. 2008).

Abdominal obesity, defined as a waist circumference of >102 cm in men and >88 cm in women by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III), is one of the criteria for the diagnosis of the metabolic syndrome (Grundy et al. 2005). In Asians, the criterion for abdominal obesity is modified to >90 cm in men and >80 cm in women (Heng et al. 2006). In various case-control studies, an increase in waist circumference or proportion of patients meeting the central obesity criteria of the metabolic syndrome is demonstrated in patients with SLE. This is summarized in Table 147.3. Central obesity predisposes individuals to the metabolic syndrome and increases the risk of cardiovascular diseases. Thus, screening for central obesity and the metabolic syndrome may help identify a subset of patients in whom more rigorous control of vascular risk factors is warranted.

147.5 Summary and Clinical Implications

The take-home messages of this article are summarized in Table 147.4. There are very few case-control or prospective studies in the literature regarding body composition in patients with SLE. Although chronic arthritis and elevation of cytokines as a result of disease activity may contribute to a loss of lean body mass, the chronic use of systemic glucocorticoids is the main cause for a change in body composition in patients with SLE. Glucocorticoid use leads to a redistribution of body fat to the trunk and an overall increase in fat body mass. Central obesity is associated with insulin resistance and predisposes individuals to the metabolic syndrome. Although the increase in body weight may be beneficial for bone mineral density in the long-run because of its stimulatory effect on osteogenesis as a result of the corresponding increase in mechanical stress mediated by mass gravitational load on the skeleton, the overall effect of glucocorticoids on bone mineral density is negative. Glucocorticoids inhibit osteoblastogenesis, increase apoptosis of osteoblasts and suppress the activity of the osteoblasts, leading to a decrease in bone formation. Glucocorticoids also contribute to osteoporosis by prolonging the life span of the osteoclasts and hence enhancing bone resorption, reducing gastrointestinal absorption of calcium, increasing renal excretion of calcium and suppressing sex hormone production (Mazziotti et al. 2006). Patients with SLE have an early and rapid loss

Table 147.3 Summary of studies on central obesity and metabolic syndrome in systemic lupus erythematosus

Authors, year	Number of patients	Ethnicity	Mean age (years)	Sex	Waist circumference, cm	BMI, kg/m^2	Prevalence of the metabolic syndrome
Chung et al. (2007)	102	67% Whites	42	91% women	48% with high waist circumference	28 (24.1–33.2)	29.4%
Bultink et al. (2008)	141	70% Whites	39	All women	Not stated	25 ± 6	16%
Negron et al. (2008)	204	Hispanic	43.6	96.1% women	91% with high waist circumference	31.4 ± 6.5	38.2%
Sabio et al. (2008)	160	Spanish	30.9	89% women	86.3±13.5; 36% with high waist circumference	25.9 ± 5.3	20%
Bellomio et al. (2009)	147	Argentinian	37.2	89% women	49% with high waist circumference	Not stated	28.6%
Vadacca et al. (2009)	50	Whites	Not stated	All women	79 (64–118)	24.2	28%
Mok et al. (2010)	123	Chinese	47.9	93% women	37% with high waist circumference	17% with BMI ≥27 kg/m^2	16.3%

Values were expressed as mean ± standard deviation; brackets contain the upper and lower range of values
BMI body mass index

Table 147.4 Take-home messages

1.	Chronic glucocorticoid therapy leads to an increase in total body fat in patients with systemic lupus erythematosus
2.	High-dose glucocortioid contributes to an early and rapid drop in total bone mass despite an increase in fat mass in systemic lupus erythematosus
3.	Chronic glucocorticoid therapy is associated with catabolism of the skeletal muscles and a loss in lean body mass
4.	Chronic glucocorticoid therapy in childhood patients with systemic lupus erythematosus contributes to growth retardation and short adult height
5.	Bisphosphonates, calcium supplement and vitamin D should be routinely prescribed in patients with systemic lupus erythematosus receiving glucocorticoid therapy. The use of glucocorticoids should be judicious, with the adoption of lowest possible dose and duration of therapy that is adequate for the control of disease activity. Early institution of glucocorticoid-sparing agents should be considered
6.	Patients on chronic glucocorticoid therapy should be advised on a well-balanced diet and encouraged to perform weight-bearing exercises
7.	Systemic lupus erythematosus patients should be regularly screened for abdominal obesity and metabolic syndrome. More rigorous control of vascular risk factors is warranted in these patients
8.	Recombinant growth hormone treatment may be considered in selected children with systemic lupus erythematosus who receive long-term glucocorticoids

of total bone mass after treatment with high-dose glucocorticoids despite a significant increase in total fat mass and body mass index (Mok et al. 2008). Therefore, bisphosphonates should be routinely prescribed to SLE patients who are about to receive glucocorticoid therapy in order to alleviate the loss in bone mineral density. More vigorous preventive strategies are warranted in older patients receiving high-dose glucocorticoids and in those patients with early and more profound gain in body fat after glucocorticoid treatment. Central obesity and the metabolic syndrome should be screened so that more aggressive control of traditional vascular risk factors is warranted.

In addition to a deleterious effect on bone mineral density, the chronic use of glucocorticoids is also associated with an increase in protein catabolism in the skeletal muscles. This leads to a loss in lean body mass which is demonstrated in case-control studies (Kaji et al. 2006; Foster et al. 2004). SLE patients on chronic glucocorticoid therapy should be encouraged to perform weight-bearing exercises to strengthen their muscles and help improve their bone mineral density. The use of glucocorticoids in SLE patients should be judicious, with the adoption of the lowest possible dose that is adequate for the control of disease activity. Baseline and interval monitoring of bone mineral density should be undertaken during the course of glucocorticoid therapy. Glucocorticoid-sparing immunosuppressive agents should be considered early in the course of treatment to allow tapering of glucocorticoids.

Long-term glucocorticoid treatment in childhood and adolescence is associated with stunted growth and short adult height. In addition to the above measures, recombinant human growth hormone treatment may be considered in selected patients, in close collaboration with endocrinologists and pediatricians (Simon 2007).

147.6 Future Perspectives and Research Agenda

As emphasized in this review, the number of studies is too small to provide a clear view on the predisposing factors for a deleterious change of body composition in patients with SLE. Prospective studies involving larger cohorts of patients are needed in the future. Perhaps the changes in various parameters of body composition can be studied as a secondary end-point in multicenter randomized controlled trials of newer biological agents for the treatment of SLE. Moreover, the inter-relationship

Table 147.5 Research agenda

1. Prospective studies with larger cohorts of risk factors for deleterious changes in body composition in patients with systemic lupus erythematosus
2. Relationship among cytokines, hormones, lipid profile, body composition, central obesity and the metabolic syndrome in systemic lupus erythematosus
3. Interventional studies on the change in lean and fat body mass in patients with systemic lupus erythematosus e.g. exercise, hormonal therapy
4. Recombinant growth hormone therapy in high-risk pediatric patients with systemic lupus erythematosus receiving chronic glucocorticoid treatment
5. Newer glucocorticoid receptor agonists with fewer adverse effects on bone metabolism

among cytokines, hormones, lipid profile, change in body composition, central obesity and the metabolic syndrome in SLE patients has to be studied in more details. Interventional studies, such as the effect of exercise and hormonal replacement therapy on the change in lean and fat mass, quality of life, psychological well being and bone mineral density in patients with SLE receiving stable doses of gluccocorticoids, should be considered as one of main topics in future research agenda. Recombinant growth hormone therapy in children receiving long-term glucocorticoid for their SLE and who are at risk of short stature should be further explored. Finally, glucocorticoid receptor agonists with fewer side effects related to lipid and bone metabolism should be developed (Table 147.5).

Summary Points

- Elevation of cytokines due to disease activity, chronic arthritis leading to disuse atrophy, lack of physical activity, hormonal disturbances, avoidance of sunshine and imbalanced nutrition may contribute to a loss of lean body mass and bone demineralization in patients with SLE.
- The main cause for a profound change in body composition and low bone mineral density in SLE patients is chronic glucocorticoid treatment.
- Long-term glucocorticoid therapy leads to fat redistribution, increase in fat body mass, loss in muscle and lean body mass and reduction in bone mineral content.
- Central obesity and insulin resistance predisposes SLE patients to the metabolic syndrome and increased risk of atherosclerosis and cardiovascular complications.
- Glucocorticoid treatment in children and adolescents retards growth velocity and leads to short body height.
- Calcium, vitamin D and bisphosphonates should be routinely prescribed to patients with SLE who receive glucocorticoids. Abdominal obesity and the metabolic syndrome should be regularly screened, and more rigorous control of vascular risk factors is warranted. Recombinant human growth hormone may be considered in selected children who receive chronic glucocorticoid treatment.

Key Facts About Systemic Lupus Erythematosus

- Systemic lupus erythematosus (SLE) is a multisystemic autoimmune disease of unknown etiology that predominantly affects women of the childbearing age.
- SLE is clinically and immunologically heterogeneous.
- The main stay of treatment of SLE is systemic glucocorticoids, particularly for major and serious organ manifestations.

- Active disease with persistent elevation of cytokines, long-term use of glucocorticoids and disease-related complications such as renal disease predispose SLE patients to central obesity, insulin resistance and increased prevalence of traditional vascular risk factors, which in turn contributes to accelerated atherosclerosis and increased risk of cardiovascular complications.
- Chronic elevation of proinflammatory cytokines, the presence of the antiphospholipid antibodies and chronic renal insufficiency also increases the risk of premature atherosclerosis and vascular thrombosis in patients with SLE.

Chapter 148
Anthropometric Measurement-Based Estimates of Body Water in Children on Peritoneal Dialysis

B.Z. Morgenstern

Abstract Total body water (TBW) is a critical body component in healthy children and those with disease, particularly those with kidney failure. There are gold standard methods to measure TBW directly, but they are expensive and cumbersome. Some require exposure to ionizing radiation. The ability to accurately and precisely estimate TBW from anthropometric data offers an opportunity to be more cognizant of TBW. Such estimates have been published and updated over the past 50 years, and are reviewed. They each perform well in the subjects in which they were developed, but do not seem to work as well when applied to different populations. An aggregate approach may be the most precise way to estimate TBW based upon anthropometric measures.

Estimating TBW, accepted to also be the volume of distribution of urea, in patients on dialysis is also emphasized. The measure of dialysis adequacy, *Kt*/*V* requires the ability to estimate or measure *V*, which is essentially TBW. For patients on peritoneal dialysis, *V* must be estimated to determine *Kt*/*V*. TBW estimating formulas developed in healthy children do not perform well at all in children on peritoneal dialysis. Formulas to estimate TBW in children on PD have been developed. They have been validated in a separate cohort of children. Still, these formulas are not precise in children who are at the extremes of hydration or degree of body fat. The ideal approach to estimate TBW in children on PD is yet to be determined.

Abbreviations

BIA	Bioimpedance analysis
BSA	Body surface area
CKD	Chronic kidney disease
D_{FFM}	Density of fat free mass
DEXA	Dual energy X-ray absorptometry
DXA	Dual X-ray absorptometry
HD	Hemodialysis
Ht	Height
Kt/*V*	Clearance × time/volume of distribution: a number used to dialysis treatment adequacy
PD	Peritoneal Dialysis

TBW Total body water
Wt Weight

148.1 Introduction

Many chapters of this text have already established the importance of an understanding of body compartments in the greater understanding of human physiology, pathophysiology and in therapeutics. An ability to either measure or rapidly estimate with reasonable accuracy total body water (TBW) can have practical applications relating to parenteral fluid therapy (Winters 1973) or dialysis (AJKD 2006; Wells 2008). Previous chapters have described the various methods currently available to directly measure TBW (El-Bishti 1981, 1996; Davies 1997; Thomas 1998). These include the measurement of distribution of 'heavy' water (either D_2O or H_2O^{18}), bioimpedance analysis (BIA), and estimates from anthropometrically determined fat mass. The accepted 'gold standard' for measurement of TBW is the use of heavy water. Although not difficult to perform and free from radiation exposure, studies using heavy water are time consuming and costly. BIA is an accepted method, but there are some important caveats to performing studies in this manner, and sizable variations in the results are seen when compared with the heavy water (Thomas 1998). Given the logistical hurdles associated with the application of precise techniques, it is not surprising that estimates of TBW based upon simple and reliable body measures have been sought.

148.2 Key Facts Regarding Total Body Water Estimates in Children (Table 148.1)

148.3 TBW Estimates in Healthy Children

Estimates of TBW in children based upon body size have been published many times over the past half-century (Edelman 1952; Mellits 1970; Morgenstern 2002; Chumlea 2005; Wells 2005; Sen 2009). The degree of precision seems to decrease over time, likely due to secular trends in fatness seen over the same time period (Wells 2005). These prediction equations, as one might predict, are age and sex dependent. They tend to include basic measures only, specifically height and weight, and do not usually include anthropometric measures used to estimate fat mass. Not surprisingly, they tend to be most inaccurate at extremes of obesity, where the weight of the fat mass, which contains less water, obscures the estimates of TBW. As discussed in other chapters, sex differences become more pronounced after puberty, when lean body mass in males tends to increase more rapidly than in females and fat mass increases more rapidly in females.

Table 148.1 Key facts regarding estimates of total body water in healthy children based upon anthropometric measures

TBW can be estimated for populations of healthy children based upon simple anthropometric measures.
TBW estimates relative to body size have changed over the past three decades, likely due to a secular increase in adiposity.
TBW is most accurately estimated by using an aggregate value based upon multiple estimating formulas.
TBW linearly relates to body surface area via the anthropometric parameter height × weight.

Key facts regarding estimates of total body water in healthy children based upon anthropometric measures

Until the end of the twentieth century, the most widely accepted estimating equations for TBW were those of Mellits and Cheek (Mellits 1970). These are linear equations developed from studies of normal, healthy, and non-obese children and young adults. The equations are:

$$\text{Boys,} \quad \text{ht} < 132.7\ \text{cm} = -1.927 + (0.465 \cdot\ \text{wt}) + (0.045 \cdot\ \text{ht})$$
$$\text{Boys,} \quad \text{ht} > 132.7\ \text{cm} = -21.993 + (0.406 \cdot\ \text{wt}) + (0.209 \cdot\ \text{ht})$$
$$\text{Girls,} \quad \text{ht} > 110.8\ \text{cm} = 0.076 + (0.507 \cdot\ \text{wt}) + (0.013 \cdot\ \text{ht})$$
$$\text{Girls,} \quad \text{ht} > 110.8\ \text{cm} = -10.313 + (0.252 \cdot\ \text{wt}) + (0.154 \cdot\ \text{ht})$$

It can be seen that the breakpoints (where the slope of the relationships between height, weight, and TBW changed) differed for boys and girls (by 21.9 cm of height). There is no clear age dependence in the data, but the breakpoints can be viewed as a surrogate for age.

The original data of Mellits and Cheek were based upon studies performed on 236 children. Morgenstern et al. (2002), identified an additional 101 children who had TBW measures reported in the literature, including 71 infants. They reanalyzed the pooled TBW results and developed a series of estimates which were again age and sex based. Their equations were:

$$\text{Infants} \quad 0-3\ \text{month}\,(n=71)\text{TBW} = 0.887 \cdot\ (\text{Wt})^{0.83}$$
$$\text{Children} \quad 3\ \text{months to}\ 13\ \text{years}\,(n=167):$$
$$\text{TBW} = 0.0846 \cdot\ 0.95^{[\text{if female}]} \cdot\ (\text{Ht} \cdot\ \text{Wt})^{0.65}$$
$$\text{Children} > 13\ \text{years}\,(n=99):$$
$$\text{TBW} = 0.0758 \cdot\ 0.84^{[\text{if female}]} \cdot\ (\text{Ht} \cdot\ \text{Wt})^{0.69}$$

Not surprisingly, these equations fit better for TBW estimates in infants, but did not otherwise perform better than the equations of Mellits and Cheek (Morgenstern 2002). It should be noted that sex was not reported in 45% of the infants identified in their literature search, but, statistically, it did not impact the precision of the estimate when included in their model. Likewise, length also had no statistical impact on TBW in infants.

Subsequently, three additional reports have been published that assess the accuracy of anthropometric-based estimates of TBW. The most recent report of Sen et al. (2009) (Fig. 148.1) demonstrated that the estimates based upon the equations published by Morgenstern were more precise than those published by Mellits and Cheeks in a population of South Asian children. It is possible that the two prediction equation sets (those of Mellits and those of Morgenstern) worked well because both of those data sets were based upon measures in children from the 1970s and 1980s. Children in that era may have had the same degree of adiposity as children from South Asia have currently.

Two papers from more Western populations (as compared with the South Asian population in Sen's paper), where the secular increase in adiposity is more pronounced, did not demonstrate very precise performance by either set of prediction equations (Chumlea 2005; Wells 2005). The Chumlea study subjects were from southwestern Ohio in USA (the Fels study), whereas those of Wells were from Cambridge in the UK.

Chumlea (Chumlea 2005) developed the following series of estimating equations:

$$\text{Boys}: \text{TBW} = -25.87 + 0.23\,(\text{stature}) + 0.37\,(\text{weight})$$
$$\text{Girls}: \text{TBW} = -14.77 + 0.18\,(\text{stature}) + 0.25\,(\text{weight})$$

In their cross-validation analysis, these equations yielded a pure error mean of 3.6 liters for boys. In these children, the Morgenstern equations led to a pure error of 8.15 L, whereas the equation of Mellits yielded a pure error of 4.73 L. In girls, the Chumlea's model's pure error was 2.43 L, Morgenstern's was 5.76 L, and Mellits 2.87 L. The authors do not mention whether they evaluated a (ht × wt) parameter in their modeling.

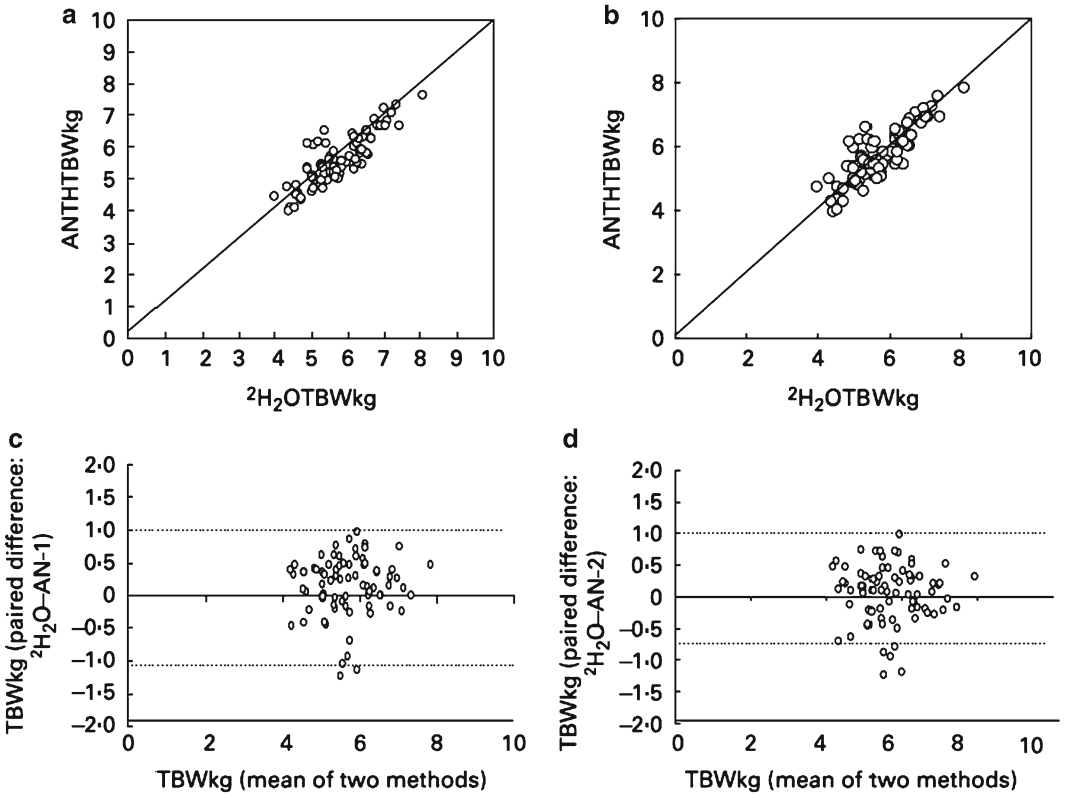

Fig. 148.1 Comparison of two TBW-estimating formulas. (**a** and **b**) TBWkg: Individual data points comparing values derived by the reference method (Deuterium water (D_2O)) with the anthropometric estimating equations plotted along the 'line of identity'. ANTHTBWkg = TBW in kg derived by the Mellits and Cheek equations on the left graph and the Morgenstern and Mahoney on the right graph. $2H_2O$TBWkg = TBW measured by D_2O. (**c** and **d**) Bland–Altman plots of the difference in each participant between TBW derived by D_2O and the estimating formula plotted against average of the TBW by D_2O and each estimating formula. D_2O – Mellits and Cheek (graph on *left*): mean difference = 0.15, SD = 0.44, $p = 0.005$, D_2O – Morgenstern and Mahoney (graph on *right*): mean difference = 0.05, SD = 0.45, $p = 0.372$ (Adapted from Sen (2009). With permission)

Wells et al. (2005) reported on TBW measures on 672 subjects from 1990 to 2003. They evaluated the equations of Mellits and Morgenstern (but not those of Chumlea, as the papers appeared within months of each other) and an older prediction equation reported by Friis-Hansen (1957a, b). They also found that no equations performed well, again presumably due to increased adiposity in the study population. Average differences were 11.5% for Friis-Hansen, 4.0% for Mellits, and 7.0% for Morgenstern. Errors >15% were seen in 40% of subjects for Friis-Hansen, 14% for Mellits, and in 17% for Morgenstern. The overestimation was approximately twice as high in infancy. The Friis-Hansen and Mellits equations showed greater bias in girls.

Wells et al. reported their own prediction equations (Wells 2005), the difference between males and females being that females have, on average, 470 mL less TBW than boys of equal size and age. Again, the authors do not report on any effort to evaluate the (ht × wt) parameter:

$$\text{Boys}: \ln\text{TBW} = -2.952 + (0.551 \cdot \ln(\text{wt})) + (0.796 \cdot \ln(\text{ht}) + (0.008 \cdot \text{age(years)})$$

$$\text{Girls}: \ln\text{TBW} = -2.952 + (0.551 \cdot \ln(\text{wt})) + (0.796 \cdot \ln)\text{ht}) - 0.047 + (0.008 \cdot \text{age(years)})$$

One paper, from Quiterio et al. (2009), has compared two of the more contemporary prediction models presented above. The authors evaluated these models in 188 adolescent athletes. They not only compared the prediction equations of Wells and Morgenstern, but also evaluated prediction equations based on DXA, bioimpedance spectroscopy, and bioimpedance analysis. Using equations of Wells and Morgenstern, they observed large biases, wide limits of agreement, and significant trend lines, which made both estimate equations less valid than the other methods in predicting TBW in adolescent athletes.

The equations developed by Morgenstern overestimated TBW in the athletes. Quiterio et al. agreed with Wells (Wells 2005) that prediction equations derived in children from earlier generations systematically overestimate TBW measurements in contemporary infants and children, since children have become heavier and fatter, which altered the relation between anthropometry and TBW. They also postulated that the overestimation of TBW values from equations of Morgenstern might be related to the fact that the athletes were taller and heavier than the subjects evaluated by Morgenstern.

By contrast, using the Wells equations significantly underestimated TBW values. Quiterio et al. did not expect this result, as the athletes were heavier and taller than the nonathletes studied by Wells. The authors hypothesized that because the prediction equations used were developed in nonathletic children and adolescents, who were presumably normally hydrated, they may have had a different fat-free mass density (D_{FFM}) than the athletes they studied. They demonstrated that there is a significant association between D_{FFM} and the mean errors between non-reference methods and deuterium dilution values, for almost all methods.

They concluded that TBW estimates compared to a gold standard method were most accurately predicted using TBW calculated from the specific constants of fat-free mass hydration using DXA measures of fat-free mass. Bioimpedance analysis and bioimpedance spectroscopy were found to be valid and nonbiased, but revealed wide limits of agreement and therefore poor accuracy. Unfortunately, the 'best' predictor, DXA, requires exposure to ionizing radiation, which limits its ability to be used repetitively.

With regard to the ability to predict TBW based upon simple anthropometric measures, the issue remains unresolved. A meta-analysis combining all the data on TBW published after 1990 might be beneficial. As a part of that analysis, an assessment of the utility of a (Ht × Wt) parameter would be critical. Morgenstern (Morgenstern 2002, 2006) (Fig. 148.2) demonstrated a strong linear relationship between log-transformed TBW and log-transformed (Ht × Wt). Many estimates of body surface area, especially that of Mosteller (Mosteller 1987; Modha 2009), contain some variation on the parameter (Ht × Wt). There is some compelling logic that TBW might be more tightly associated with body surface area than height or weight independently, irrespective of the impact of other variables, such as adiposity and D_{FFM}.

Perhaps the ultimate solution to developing reasonable estimates of TBW in healthy children will be to take the approach advocated by Wells (Wells 2009) and use the 'wisdom of crowds'. In their elegant studies on 196 children, the standard error of the estimates was smallest with the lowest mean bias (0.11 L), when they used an aggregate prediction model composed of 12 different equations. This aggregate approach may be the optimal way to arrive at reasonably precise estimates for individual subjects (Fig. 148.3).

148.4 TBW Estimates in Children on Peritoneal Dialysis

The estimate of TBW in patients with chronic kidney disease (CKD) is an example wherein a special population serves as an exemplar of the greater whole. Patients with CKD are assumed to have disorders of hydration, but these can result in either excess or reduced levels of hydration. Even more specifically, patients on dialysis may manifest greater extremes of over- or under-hydration. In addition,

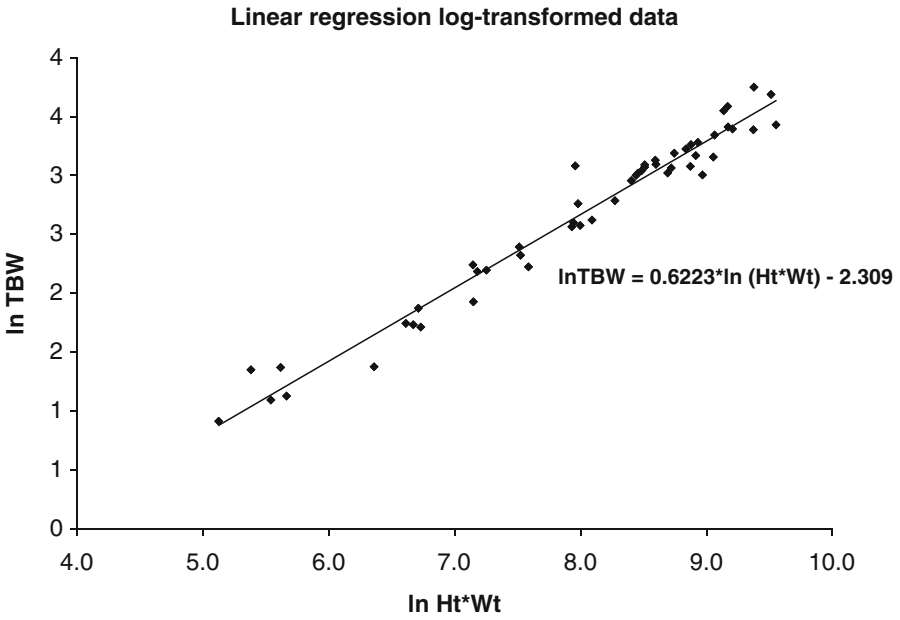

Fig. 148.2 Linear regression of log-transformed TBW versus the Height × Weight (Ht*Wt) parameter in children on peritoneal dialysis. Data not previously published, but used to develop formulas in (Morgenstern 2006)

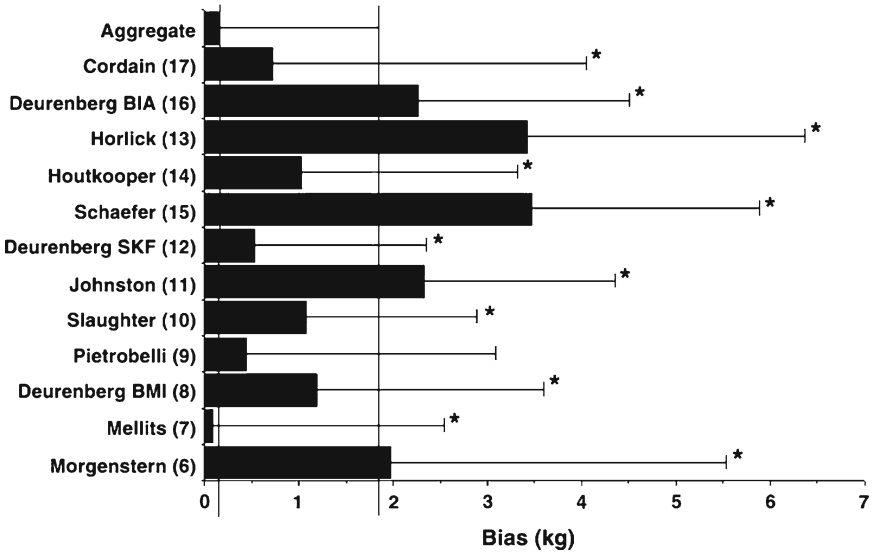

Fig. 148.3 Bias in fat-free mass or fat-mass estimates in 196 children. Mean (+SD) bias in fat-free mass or fat mass in 196 children, calculated as the predicted value minus the measured value. The bias in fat-free mass has the opposite sign of that in fat mass. The graph compares 12 individual predictions with the aggregate average of those 12 predictions. The vertical lines represent the mean bias and the mean bias +1 SD, for the aggregate prediction. All mean biases were expressed as positive values. *Asterisks* denote bias that is significantly greater than the aggregate bias. *BIA* bioelectrical impedance analysis; *SKF* skinfold thickness (Adapted from Wells (2009). With permission)

Table 148.2 Key facts regarding peritoneal dialysis (PD)

- PD is the commonest form of dialysis used on children with end-stage kidney disease.
- PD is uses the principles of diffusion and convection to remove water and solutes across the peritoneal membrane.
- PD requires the placement of a soft catheter into the peritoneal cavity and the use of balanced electrolyte solutions. Water is removed from patients by using hypertonic solutions.
- The optimal volume of fluid to place into the peritoneal cavity of a child is one that is estimated using the child's surface area.
- Dosing of dialysis modalities (hemodialysis and PD) is based upon the concept of the removal of urea from total body water. The expression is *Kt*/*V*, where K is the clearance of urea, t is the time of dialysis and *V* is the volume of distribution of urea, which is accepted to be total body water.
- Computer modeling to determine *Kt*/*V* in hemodialysis generates a value for *V* and for the urea generation rate. In PD, calculation of *Kt*/*V* requires a robust estimate of V, hence the importance of accurately estimating total body water in patients on PD.

Key facts regarding peritoneal dialysis for those unfamiliar with this treatment modality

dialysis dose is commonly measured by urea removal, reported as *Kt*/*V*, where *K* is the clearance of urea in mL/min, *t* is the time of the treatment, and *V* is the volume of distribution of urea. Urea is generally accepted to distribute in TBW; hence, it is critical to correctly estimate TBW in order to measure urea removal. Adequacy of a dialysis therapy is based upon achieving a target *Kt*/*V* (AJKD 2006) (Table 148.2).

There are two forms of maintenance dialysis: hemodialysis (HD) and peritoneal dialysis (PD). Hemodialysis is a very efficient process and leads to the simultaneous and relatively rapid removal of both urea and water. Classical urea kinetic modeling will solve for both *V* and the urea generation rate. Newer, simplified versions of kinetic modeling require that an estimate of *V* be performed (Dumler 2004). Some measurement techniques developed for HD can report a *Kt*/*V* result without the need to measure or estimate *V* separately (Sternby 1998). For PD patients, on the other hand, measurement of *Kt*/*V* requires a measurement or an estimate of *V*, which is, as noted above, TBW.

Efforts to estimate TBW in PD patients (the *V* of the expression, *Kt*/*V*) have been ongoing for over a decade. The importance of this measure has been highlighted (Tzamaloukas 1996; Morgenstern 2001). There continues to be some controversy as to the optimal formula to use to estimate TBW in adults on PD. The National Kidney Foundation KDOQI™ Guidelines for Peritoneal Dialysis in adults recommend the use of TBW estimates from either the formulas or Watson or Hume (AJKD 2006). When evaluated in adults on PD, these estimating formulas did not perform well, but were more accurate than a simple estimate of 0.58 × wt (Woodrow 2003).

Direct measurement of TBW in children with CKD and on dialysis has been performed with bioimpedance analysis (Bradbury 1995, 1996; Wuhl 1996). In patients on PD, however, controversy exists as to whether or not the dialysate in the abdominal cavity impacts the impedance measures (Rallison 1993; Aufricht 1995). Limits of agreement between directly measured TBW and that estimated by bioimpedance analysis in children with CKD and particularly those on dialysis are still quite wide.

There are somewhat more data available for the TBW estimates in children on PD. The KDOQI™ Guidelines for PD in children recommend the formulas developed by Morgenstern et al. (2006). These formulas were developed from direct measures of TBW in children using D_2O or H_2O.[18] A total of 64 children aged 1 month to 23 years on maintenance PD in either Germany or the USA was studied. The same statistical analysis that was applied to the healthy children reevaluated by Morgenstern (Morgenstern 2002) was used on these data. A tight linear correlation existed between the log-transformed TBW and log-transformed (ht × wt): $r^2 = 0.96$, $p < 0.0001$. When back transformed, the following estimating equation was identified:

$$\mathrm{TBW} = 0.11 \cdot \left(\mathrm{HtWt}\right)^{0.61}$$

Somewhat greater precision, not surprisingly, was found when sex-specific equations were generated, and an additional weight factor was added:

$$\text{Boys}: \text{TBW} = 0.10 \cdot \left(\text{HtWt}\right)^{0.68} - 0.37 \cdot \text{ weight}$$

$$\text{Girls}: \text{TBW} = 0.14 \cdot \left(\text{HtWt}\right)^{0.64} - 0.35 \cdot \text{ weight}$$

In a validation cohort, TBW was predicted with a mean difference of 0.001 (±2.5, SD) L. The prediction was weakest in children who were at extremes of hydration status. A preliminary version of these formulas (Morgenstern 2001) was validated by Mendley (Mendley 2005) in 14 children on PD. Of the TBW estimates, including formulas based on bioimpedance analysis, the formulas of Morgenstern in children on PD (Morgenstern 2006) had the smallest root mean squared error, and the least skewing. Interestingly, DEXA-derived values based on an age-adjusted hydration constant yielded results closest to measured TBW.

The relationship between body surface area and TBW could be explored in this model, since TBW and BSA are both dependent on (ht × wt). This led to the following simple linear equations being derived, using the Mosteller (Mosteller 1987) BSA equation:

$$\text{Boys}: \text{TBW} = 20.75 \cdot \text{ BSA} - 3.88$$

$$\text{Girls}: \text{TBW} = 16.96 \cdot \text{ BSA} - 1.57$$

Even more than for TBW estimates based upon anthropometric measures for healthy children, the need for accurate and precise estimates in children on PD is critical. The formulas of Morgenstern still have fairly large limits of agreement in individual children, even though they apply well to a population. Additional components to these estimating equations will need to be developed to improve their performance. These additional components, especially for the children on PD, will need not only to account for adiposity, but will also need to include a measure of the degree of over- or underhydration.

148.5 Applications to Other Areas of Health and Disease

As noted earlier in this chapter, there are a number of uses for precise yet simple estimates of total body water. These areas specifically include the provision of parenteral fluid therapies to healthy children, for example, when they are to undergo surgery, and to ill children, especially those with dehydration, a major cause of morbidity and mortality. The evaluation of the pharmacokinetics of medications is also dependent on assessment of TBW.

In the areas of kinesiology and performance, especially as they relate to body composition and optimizing muscle output in competitive sports, it is equally important to understand TBW and to be able to use TBW estimates to determine changes in lean body mass.

Summary Points

- Estimation of TBW in healthy children has implications related to medication dosing and fluid therapies.
- TBW can be reasonably estimated for populations of healthy children based upon simple anthropometric measures.
- TBW estimates relative to body size have changed over the past three decades, likely due to a secular increase in adiposity.

- TBW is likely most accurately estimated by using an aggregate value based upon multiple estimating formulas.
- TBW may linearly relate to body surface area via the anthropometric parameter height × weight.
- TBW in children on peritoneal dialysis directly impacts measures of delivered dialysis dose.
- TBW in children on peritoneal dialysis can be estimated from anthropometric measures using formulas that differ slightly from those that apply to healthy children.
- In children on PD, a linear relationship still exists between height × weight, TBW, and body surface area.

Chapter 149
Anthropometry and Body Composition in Chronic Kidney Disease Patients not on Dialysis

Vincenzo Bellizzi, Biagio Di Iorio, and Luca Scalfi

Abstract Chronic Kidney Disease (CKD), characterized by complex metabolic derangements is burdened by changes in nutritional status during the entire course of the disease. Overt malnutrition is usually observed in the late stages of CKD, but a decrease of body cell mass and other changes in body composition, for instance over-hydration, may occur early, even with no evidence of weight loss. The effects of alteration in nutritional status and body composition on clinical outcome are critical; protein-energy wasting by itself can worsen renal function and prognosis, being also strictly related to cardiovascular risk. On the other hand, some studies, but not all, have indicated that in CKD patients not yet on dialysis there is an inverse relationship between higher body mass index and some hard outcomes, such as mortality and cardiovascular events. In addition, body mass index seems to be a predictor of the onset of CKD in the general population; a possible association with waist circumference or waist-to-hip ratio has been described, as well. Thus, a challenge for nutritionists and nephrologists is to identify early changes of nutritional status in CKD patients in order to improve the patient's prognosis. International guidelines advise to assess nutritional status on a regular basis, but indications for CKD patients not yet on dialysis have been much less defined than those for dialysis patients. In addition, assessment of nutritional status in CKD requires multiple measurements and different techniques should be used concurrently. Anthropometry represents a first level assessment tool with some limitations because of the possible influence of an over-hydration state; although not very sensitive in detecting minor changes in body composition, it remains useful if associated with other nutritional tools. Among these, bioimpedance analysis (BIA) should be considered because it is very easy to perform at the bedside and can detect changes of body fluids in the early stages of CKD, such as blunted over-hydration in absence of clinically detectable edema. Thus, anthropometry and BIA should be used concurrently in the evaluation of nutritional status in CKD patients.

Abbreviations

BCM	Body cell mass
BIA	Bioimpedance analysis
BMI	Body mass index

149.1 Introduction

149.1.1 Classification of Chronic Kidney Disease

The current classification of severity for chronic kidney disease (CKD) is mainly based on functional criteria referring to both a marker of renal function (glomerular filtration rate = GFR) and a marker of kidney damage (proteinuria), thus overcoming the cause of disease; such CKD staging system incorporates all the old, vague definitions of kidney diseases such as *chronic renal failure*, *chronic renal insufficiency*, *pre-dialysis, and pre-end-stage renal disease* (Eckardt et al. 2009). CKD stages 1 and 2 define conditions of kidney damage (as revealed by proteinuria) with normal GFR (≥90 mL/min/1.73 m^2) or slightly reduced GFR (89–60 mL/min/1.73 m^2), whereas CKD stages 3, 4, and 5 describe conditions of moderate-to-severe reduction of GFR (respectively, 59–30, 29–15, and <15 mL/min/1.73 m^2), independently of proteinuria; stage CKD-5D refers to CKD-5 patients with end-stage renal disease (ESRD) requiring dialysis treatment, while the suffix 'T' is used for all CKD stages in kidney-transplant recipients. Such a classification based on the severity of disease has the major advantage to allow a better definition of patient's prognosis. Nonetheless, the question whether additional factors associated with prognosis, such as body weight, should be included in the classification of CKD remains to be addressed.

Table 149.1 Key points of Chronic Kidney Disease – CKD

1. The primary function of the kidney is to maintain the body electrolytes and water balance and to eliminate the waste products of protein catabolism.
2. Additional major functions of the kidney are the regulation of acid–alkali balance and the production/activation of several hormones (erythropoietin; renin; and vitamin D).
3. Chronic kidney disease is characterized by a progressive and definitive decline of all renal functions, irrespectively of the underlying disease.
4. As a consequence of renal function impairment, hypertension, anemia, electrolyte disturbance, metabolic derangement, and body water imbalance are common clinical features in CKD.
5. Changes of body composition (water, free-fat mass, etc.) occur early during CKD and the onset of malnutrition is not unusual, mainly in advanced CKD.
6. Severe loss of renal functions is incompatible with life and needs renal functional replacement with either dialysis or transplantation.

This table points out the key factors of chronic kidney disease, including major renal functions and consequence of renal function loss
CKD chronic kidney disease

Table 149.2 Key points of nutritional nomenclature in CKD

1. Different terms are commonly used for the same nutritional condition or the same term is used for different nutritional conditions in CKD.
2. On behalf of the International Society of Renal Nutrition and Metabolism, an expert panel reviewed basic terminology related to nutritional problems in CKD.
3. Malnutrition was considered as a confusing and ambiguous term because it may indicate both undernutrition and overnutrition.
4. The terms protein–energy wasting and cachexia were recommended.
5. Protein–energy wasting was defined as the state of decreased body stores of protein and energy fuels (that is, body protein and fat masses), often associated with diminished functional capacity related to metabolic stresses due to CKD and refers to very different degrees of nutritional depletion.
6. Cachexia refers to a very severe form of protein–energy wasting, often associated with profound psychological, metabolic, and immunological disorders, which develops as a serious complication of CKD and carries a very poor prognosis; and almost no therapies for its treatment are approved.

This table points out the complex issue of nutritional nomenclature in CKD and describes which terms have to be considered ambiguous or should be recommended according to international experts (Fouque et al. 2008)
CKD chronic kidney disease

149.1.2 Metabolic and Nutritional Derangements in Chronic Kidney Disease

Metabolic and nutritional abnormalities represent major features of uremic syndrome. Retention of excretory products and metabolic wastes due to loss of renal function induces the accumulation of toxic metabolites, which, in turn, generate changes in both cellular metabolism and volume and/or electrolyte composition of body fluids. Moreover, severe kidney disease is associated with abnormalities of various hormones which are directly related to the loss of renal parenchyma and contribute to the derangement of several metabolic pathways. In addition, the decrease of lean body mass due to a net protein catabolism, and eventually associated with weight loss, may occur in renal patients even when they are clinically stable and without metabolic acidosis. Also, complex alterations of carbohydrate metabolism take place early in CKD, leading to insulin resistance independently of the presence of diabetes. Furthermore, dyslipoproteinemia and dyslipidemia can also arise in the initial phases of CKD. Altogether, these major metabolic changes occurring in early and advanced stages of the disease may substantially affect body composition and nutritional status.

Table 149.3 Causes of metabolic and nutritional derangements in CKD

- Anorexia
  - Uremia (i.e., *wasting toxins*)
  - Depression
  - Gastrointestinal intolerance
- Hyper-catabolism
  - Increase of catabolic hormones (*PTH and glucagon*)
  - Resistance to anabolic hormones (*insulin and GH*)
  - Acidosis
  - Inflammation
  - Medications (i.e., *steroids*)
  - Chronic diseases (*diabetes, heart, and lung*)
- Acute illness
  - Infections
  - Surgery
  - Hospitalizations

This table describes the major causes of either reduced nutrient intakes or enhanced nutrient requirements which produce the metabolic and nutritional derangements observed in CKD patients not yet on dialysis
CKD chronic kidney disease; *PTH* parathyroid hormone; *GH* growth hormone

The impairment of both body composition and nutritional status actually starts early during the course of CKD, and renal failure by itself is a strong and independent risk factor for protein–energy wasting (Garg et al. 2001). As a matter of fact, there is a spontaneous, progressive reduction of both protein and energy intakes and almost half of the patients are not compliant with prescribed diets and do not consume the needed minimum amount of nutrients, mainly of energy; on the other hand, during CKD, an increase in nutrient requirements occurs due to specific catabolic factors related to uremia, such as metabolic acidosis and inflammation (Table 149.3). This negative nutrient balance may cause nutritional changes during the entire course of CKD with an apparent protein–energy wasting, especially in CKD-5 and CKD-5D, whereas blunted nutritional abnormalities already occur in the early stages of the disease. As protein–energy wasting by itself affects renal function, impairing renal plasma flow, GFR, and tubular excretion capabilities (for sodium, acids, water, etc.), the identification of initial abnormalities in nutritional status is one of the major objectives of a nutritional approach to CKD patients.

149.2 Changes of Anthropometry and Body Composition in Chronic Kidney Disease

149.2.1 Body Weight Changes in Chronic Kidney Disease

A decrease in body weight is expected in CKD patients due to the fact that the complex metabolic abnormalities in such disease lead to reduced lean body mass (see earlier). On the other hand, the mean body weight of the general population has been rapidly growing in the last decades, likely affecting both the onset and progression of CKD (see below). The question is how and to what extent the behavior of body weight in the 'real life' of CKD patients is influenced by these conflicting factors. In the USA, patients starting dialysis showed a rise of body mass index (BMI) from 25.7 to

Table 149.4 Clinical characteristics of prevalent CKD patients

stage 3	27.3 ± 4.8	
stage 4	27.3 ± 4.3	
stage 5	26.6 ± 5.2	

27.5 kg/m^2, observed over an 8-year period (from 1994 to 2002) and a further increase is expected in the future. In Europe, the average BMI was 25.3 kg/m^2 in a cohort of incident dialysis patients, and more than half of patient starting dialysis are expected to be overweight or obese (Zoccali 2009). Observations on BMI and BMI changes in early to advanced CKD prior to dialysis are scarce. In a single-center cohort of 521 mild/moderate CKD US Veterans (males: 68 years; black 21%; eGFR 37 mL/min/1.73 m^2), 50% of the subjects were overweight/obese (BMI >28 kg/m^2) (Kovesdy et al. 2007). A subgroup of participants to the 'AIRC' and 'CHS' studies (carried out in the USA), affected by mild CKD (*n*, 1,669; 70 years; eGFR, 51 mL/min/1.73m^2), had a mean BMI of 27.2 kg/m^2 (for both males and females) and 65% of patients were overweight/obese (Elsayed et al. 2008b). In Asiatic CKD patients, the BMI was lower in a younger (59 years) cohort of mild CKD (eGFR, 54 mL/min/1.73m^2) patients from Japan, the mean BMI being 24.1 kg/m^2, with slight lower values in females (Sawara et al. 2009). In addition, a group of patients in Taiwan, similar for age and CKD stage, had a BMI of 24.7 kg/m^2, both for males and females (Lin et al. 2007). Indeed, it is well known that, in Asian populations, the cutoff points for overweight and obesity correspond to BMI values lower than in Caucasians. To give additional information, we analyzed BMI data from a cohort of Italian patients with moderate to advanced CKD followed up in tertiary care facilities (Table 149.4) (De Nicola et al. 2006). Similarly to a US CKD population, we found a mean BMI of 27.2 kg/m^2, with higher values in females and diabetic patients (Table 149.5). Interestingly, no differences were detected in the course of the disease, the BMI being similar from stages 2 to stage 5. According to the World Health Organization (WHO) classification, two out of three patients (65%) were overweight/obese (Fig. 149.1). Overall, it seems that the burden of overweight/obesity in CKD population is increasing similarly worldwide.

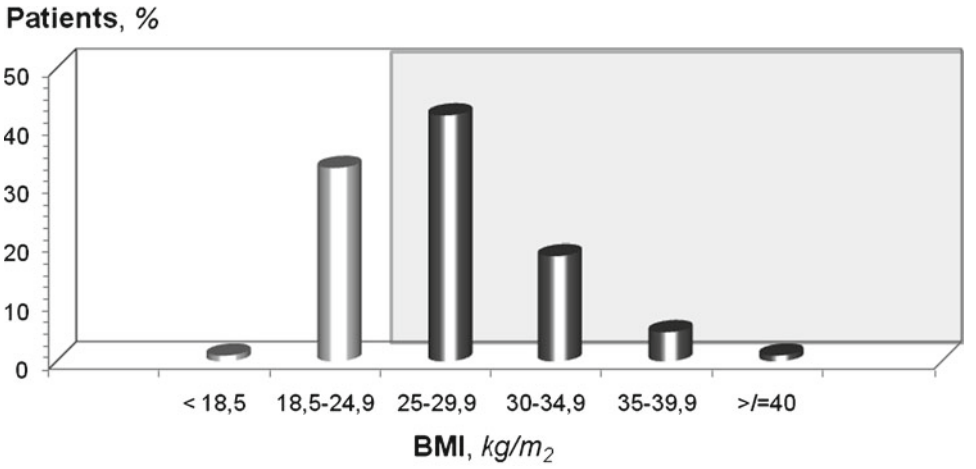

Fig. 149.1 Prevalence of BMI in CKD patients. This figure describes the distribution of groups of BMI in a cohort of 1,396 prevalent CKD patients not yet on dialysis followed in a tertiary care nephrology system (TABLE study database). The *gray* background indicates the area of overweight/obesity according to the WHO classification and the black columns represent the percentage of overweight/obese CKD patients. *BMI* body mass index; *CKD* chronic kidney disease

149.2.2 Body Water Changes in Chronic Kidney Disease

Since the management of water and inorganic ions is mainly accomplished by the kidney, an inadequate homeostasis of body water and electrolytes appears as soon as renal function declines. Because water and electrolyte abnormalities may lead to significant changes of body composition and fatal outcomes, underlying mechanisms should be evaluated and such disturbances have to be ascertained and early corrected. For instance, in CKD, the capability of the kidney to appropriately excrete dietary sodium is impaired due to decreased glomerular filtration. Although, in surviving nephrons, the fractional sodium reabsorption decreases in order to maintain sodium balance, the overall sodium excretion drops and net sodium retention occurs. Such a condition raises serum osmotic pressure, stimulates thirst, increases fluid intake, and rapidly causes water overload. As a consequence, a mild-to-moderate expansion of extracellular volume is expected to occur in the early phases of CKD as well. Of note, even in advanced CKD patients (stages 4–5), edema is not always apparent, except when nephrotic syndrome or heart failure is present. Such water overload in CKD is isotonic and, differently from edema, can lead to hypertension and heart failure.

149.3 Clinical and Prognostic Significance of Anthropometry in Chronic Kidney Disease

149.3.1 Anthropometry and the Onset of Chronic Kidney Disease

In the past decade, several studies have investigated the relationships between obesity and the onset of CKD using simple anthropometric measures as proxy variables of excess body fat or abdominal fat. BMI, waist circumference (WC), and waist-to-hip ratio (WHR) have all been reported to be

proper markers of obesity for assessing the risk for CKD. In 2004, two papers indicated that the onset of ESRD is related to initial body mass index. Data from the Framingham Offspring Study showed that, taking into account a mean follow-up period of 18.5 years, each increase of one standard deviation in BMI augmented the risk for the onset of kidney disease by 23%, whereas in the study carried out in Okinawa the odds ratio for men and women combined was 1.29 before and 1.11 after adjustment for systolic blood pressure and proteinuria (Fox et al. 2004); the risk increased for a BMI >21 kg/m^2 in men (but not in women) (Iseki et al. 2004). Similarly, in a large cohort of individuals living in northern California, BMI remained a strong independent predictor of CKD even after adjustment for a number of factors, including age, gender, race, proteinuria, etc., with the adjusted risk clearly increasing in both overweight and obese individuals (Hsu et al. 2006). The relationship between BMI and the onset of CKD was partially confirmed later by Yamagata and co-workers, who observed a 6% greater risk only in overweight/obese females (not in men) (Yamagata et al. 2007). Similarly, a weak effect was observed in a study on Austrian adults showing that an increase in one unit of BMI was associated with a 4% higher risk (Obermayr et al. 2008). Finally, the combined effects of blood pressure and excess body weight were recently evaluated in a large cohort of individuals in Norway, with ESRD or CKD-related death as principal composite outcome: BMI was not associated with the risk of kidney disease in participants with baseline blood pressure less than 120/80 mmHg and increases substantially if prehypertension is present only in obese individuals (Munkhaugen et al. 2009). The steepest increase in risk was observed in the individuals with a BMI >30 kg/m^2. Altogether, available data have indicated that the onset of CKD is associated with a number of risk factors. A relationship with BMI exists in univariate analyses and, in most cases, also in multivariate analyses. An exception is the paper by Foster and co-workers (Foster et al. 2008), discussing that the increased odds of developing CKD due to BMI does not persist after adjustments for cardiovascular risk factors. Indeed, it should be noted that hypertension, and possibly diabetes, may be considered as covariates and also as obesity-linked pathogenetic factors leading to a decrease in renal function. None of the aforementioned studies reported data on fat distribution. On this topic, interesting results have been obtained by some recent papers investigating the association of anthropometric markers of visceral fat, such as WC or WHR, with the onset of CKD. Elsayed and co-workers examined pooled data from the 'ARIC' study and the 'CHS' study (Elsayed et al. 2008a). Whereas in univariate analysis WHR and BMI were associated with the risk of developing CKD, in multivariable analyses the risk of CKD rose by 22% for each increase in one standard deviation of WHR but no relationship with BMI (or WC) emerged. On the contrary, in a cohort of Iranian adults after a follow-up of 7 years, both BMI and WC, but not WHR, predicted the onset of CKD (Noori et al. 2009), but baseline WC was a better predictor of CKD than BMI. Indeed, the role that abdominal fat may play in the decrease of renal function is also indirectly confirmed by the fact that several epidemiological studies have observed a significant association between metabolic syndrome (often characterized by abdominal obesity) and CKD, which could be even more significant in obese individuals (Sawara 2009).

149.3.2 Anthropometry and Outcomes in Chronic Kidney Disease

It is well known that there is an apparently paradoxical inverse association between mortality and higher BMI in dialysis patients, which indeed is observed in other chronic diseases and in the coeval general population too. In such patients, underweight is also associated with worse prognosis (Mafra 2008). Less information is available on the effects of excess body fat on mortality or morbidity in CKD patients not yet on dialysis. In a review published in 2009 eight studies were listed that had

examined the association between BMI and different outcomes (Kovesdy and Kalantar-Zadeh 2009). Four studies found an inverse relationship with poor outcomes (first of all mortality), but the other four studies did not. Papers differed with respect to experimental protocol, patients' characteristics, and statistical analysis. For instance, in the paper by Weiner and co-workers, around half of the 1,678 individuals with reduced GFR reached the composite endpoint (myocardial infarction, stroke, and all-cause mortality) during a median follow-up of 108 months and no association with BMI emerged (Weiner 2008); no information was given about the number of subjects who started dialysis. On the contrary, Obermayr and co-workers observed that BMI seems to reduce the risk of cardiovascular death in CKD patients with proteinuria, whereas the opposite was true in those without proteinuria (Obermayr et al. 2009). With respect to measures of body-fat distribution, data from two community surveys were pooled by Elsayed and co-workers and examined to assess the relationship between adiposity measures and cardiac events in CKD patients not yet on dialysis (Elsayed et al. 2008b). In multivariable statistical analyses, after a mean follow-up period of 9.3 years, WHR (but not WC or BMI) was observed to be associated with a higher incidence of cardiac events (myocardial infarction and fatal coronary heart disease).

149.3.3 Anthropometry in CKD and application to other areas of health and disease

An increase in the prevalence of overweight and obesity has been observed in most countries, with negative effects on the risk for non-communicable chronic diseases. It is time now to consider that excess body fat also increases the risk for developing CKD, with resulting complex relationships between body fat, inflammation, cardiovascular risk factors, and proteinuria. Programs for the prevention/therapy of overweight and obesity on a community or individual level should take into consideration and evaluate their possible, positive impact on renal disease. This is even more imperative since CKD has been recognized as an independent risk factor for the development of cardiovascular diseases in the general population; indeed, according to the Task Force on Cardiovascular Disease in CKD of the American Heart Association, patients with CKD have to be considered in the 'highest risk group' for subsequent development of cardiovascular events (Sarnak et al. 2003).

149.4 Anthropometry and Nutritional Guidelines for Chronic Kidney Disease

A number of guidelines have been formulated concerning nutritional approaches to CKD patients. Although they mostly focus on dialysis patients, it is of interest to summarize essential indications given on the assessment of body composition and especially on anthropometry and bioimpedance analysis (BIA) (Table 149.6). In general, techniques should be chosen to detect initial changes in muscle mass and body water in the clinical setting, and to acquire information that can be included in a panel of data related to nutritional status.

1. *European Best Practice Guidelines* (EURO-BPGL)
   The European Guideline Steering Committee stated that either anthropometry or other techniques for assessing body composition (such as BIA or dual X-ray absorptiometry) can be used for the diagnosis of malnutrition in dialysis patients (opinion evidence) (Fouque et al. 2007), but no

Table 149.6 Guidelines for nutritional status in CKD

Parameter	Guideline	CKD patients	Dialysis patients
Anthropometry	EBPG 2007	No recommendations	It should be assessed immediately after dialysis (opinion).
Body mass index	EBPG 2007	No recommendations	It should be maintained at a value >23 (evidence level).
MAC, MAMC, and SFT	EBPG 2007	No recommendations	They should be performed by the same operator on the non-fistula arm (evidence level).
Technical investigation	EBPG 2007	No recommendations	Can be recommended for routine follow-up: BIA every 3 months; DXA at dialysis start and every 1 year (opinion)
	K/DOQI 2000	No recommendations	Precision and accuracy of fat mass estimates by DXA are approximately 2–3% in hemodialysis and 3% in peritoneal dialysis patients.
			It is recommended that focus be placed on the direct BIA impedance parameters (R, Xc, and PhA) rather than on regression estimates of edema-free lean body mass or other body compartments (opinion).

This table summarizes the suggestions from international guidelines for the evaluation of the major nutritional parameters in either CKD patients not yet on dialysis or dialysis patients
CKD chronic kidney disease; *EBPG* European Best Practice Guidelines; *MAC* mid-arm circumference; *MAMC* mid-arm muscle circumference; *SFT* skinfold thickness; *BIA* bioimpedance analysis; *DXA* dual X-ray absorptiometry; *K/DOQI* Kidney/Disease Outcome Quality Initiative; *R* resistance; *Xc* reactance; *PhA* phase angle

suggestion was given for CKD patients not yet on dialysis. Dialysis patients should maintain a BMI > 23.0 kg/m^2. Mid-arm anthropometry and four sites' skinfold thickness should be considered as measurements relevant for overall nutritional assessment (Fouque et al. 2007). In particular, mid-arm circumference (MAC) and mid-arm muscle circumference (MAMC) can be used to assess muscle mass. BIA allows estimation of body fluid compartments, which may then be used to make inferences about body composition.

2. *K/DOQI* (Kidney/Disease Outcome Quality Initiative)
According to K/DOQI guidelines, nutritional status in dialysis patients should be assessed by a combination of valid, complementary measures rather than a single measure (K/DOQI 2000). As a matter of fact, there is no single measure which provides a comprehensive indication of metabolic-nutritional status and under-/overnutrition may be identified with greater sensitivity and specificity using a combination of tools. BMI values may be misinterpreted in the CKD population because of fluid overload. MAC and skinfold thickness are recommended as part of the nutritional assessment in CKD. In addition, K/DOQI guidelines describe BIA as an attractive tool for nutritional assessment of individuals undergoing chronic dialysis because it is relatively inexpensive to perform, noninvasive, and painless, requires minimal operator training, and provides data that can be correlated with several aspects of body composition.

3. *United Kingdom Guidelines*
The United Kingdom guidelines give a few indications with respect to the determination of body composition. Only in guideline 4.1 C-NUTR: Nutritional Screening, is it stated that all patients in CKD stages 4–5 should undergo regular nutritional screening (good practice) (No author 2007). A number of potential measures of nutritional state, including serum creatinine, serum cholesterol, serum albumin, subjective global assessment, BMI, lean body mass, and handgrip strength, predict a worse patient survival. Therefore, because there is not a single 'gold standard' measure

for nutritional state in CKD patients, a panel of measurements should be used for assessing different metabolic and nutritional aspects of the disease (No author 2007).

4. *Pediatric guidelines*
   The CARI guidelines (Caring for Australian with Renal Impairment) provide indications only for pediatric CKD patients. Height, weight, head circumference, skinfold thickness, and serum albumin are markers of nutritional status commonly used in children with renal diseases. Nutritional assessment and counseling is mandatory in the management of children with CKD and ESRD, although it is hard to find consistent data to support such statement.

   K/DOQI states that valid measures of protein and energy nutritional status in children treated with maintenance dialysis include dietary interview/diary, nutritional counseling, serum albumin, height and weight, estimated dry weight, weight/height index, mid-arm circumference and muscle circumference or area, skinfold thickness, head circumference in children aged 3 years or less, and standard deviation score for height (K/DOQI 2009).

   According to the British Renal Association, supine length or standing height and weight should be monitored at each clinic visit. Head circumference should be measured at each visit before 2 years of age and 6 monthly up to 5 years of age. All children should undergo dietary assessment by a pediatric renal dietitian at least every 3 months. The best parameter for assessing treatment adequacy in children is the growth rate.

5. *Other guidelines*
   No information is presented on anthropometric measures in CKD patients by KDIGO (Kidney Disease: Improving Global Outcomes), Canadian Organ Replacement Registry (CORR), and Australian guidelines (CARI).

149.5 Anthropometry and Body Composition Measurements in Chronic Kidney Disease

149.5.1 Anthropometry and Assessment of Body Composition in Chronic Kidney Disease

Assessing and monitoring body composition, as well as protein and energy balance, is fundamental to effectively tackle undernutrition and overnutrition in CKD, both of which are common in such patients. In this perspective, anthropometric methods may be an important clinical tool in individuals with CKD since they help evaluate nutritional status, a modifiable factor that can influence morbidity and mortality. The most common anthropometric variables considered are body weight, height, skinfold thickness, mid-arm anthropometry, and WC. They have several advantages (measurement is simple, safe, noninvasive, and not expensive) but also some limitations in CKD patients, mainly because of the possible occurrence of abnormalities in body hydration. From a practical point of view, the interpretation of body weight/BMI values is sometimes difficult since sudden variations in weight can be determined just by changes in body water. Derived estimates of lean body mass should also be considered with attention and prudence because, for instance, a decrease in body cell mass could be masked by an increase in extracellular body water.

Few studies in CKD patients have compared anthropometry with other techniques for assessing body composition, in some cases including together patients before and after entering dialysis. In a study on individuals not yet on dialysis, body fat assessed by skinfold thickness was significantly higher compared to body fat as measured by DXA (Avesani et al. 2004), whereas a good agreement

between skinfold thickness and bioimpedance analysis was observed in non-obese, but not in obese patients (Barreto Silva et al. 2008). With respect to body fat distribution, in a cross-sectional study on 122 CKD patients not yet on dialysis, WC strongly correlated with visceral fat (but also with subcutaneous fat, actually) measured using computed tomography (CT), the linear regression being quite similar in the two genders, with a correlation coefficient of 0.75 in men and 0.81 in women (Sanches et al. 2008); indeed, it was not possible to assess whether this relationship differed in CKD patients compared to healthy individuals because there was no control group. Interestingly, the strength of the correlation between WC and blood lipids or insulin resistance was similar to that observed for CT-derived measures of visceral fat. A similar association between WC and visceral fat was also observed by Sawara et al. (2009). Recently, changes in visceral fat (assessed by CT) were compared to those of WC in patients not yet on dialysis after a follow-up of 12 months (Velludo et al. 2009); the authors concluded that the variations in WC did not accurately reflect variations in visceral fat, but, actually, some very extreme outliers were included in the statistical analysis. Finally, to establish specific criteria for the risk of metabolic syndrome, 217 CKD outpatients were studied in a cross-sectional study using anthropometric measures, CT (for measuring visceral fat), and a number of biochemical variables (Sawara et al. 2009); with respect to WC, the authors proposed cutoff values of 84 cm in males and 83 cm in females that defined high risk of metabolic syndrome.

149.5.2 Anthropometric Measurements and New Techniques in Chronic Kidney Disease

Keeping in mind that the nutritional management of CKD patients is a difficult and complex task, anthropometric measurement may be utilized in such population for either assessing protein–energy wasting or cachexia or defining some relationships between body composition and metabolic abnormalities and/or cardiovascular risk factors. With respect to undernutrition, the usefulness of anthropometry is also demonstrated by the fact that subjective global assessment (SGA), which is a clinical technique widely used in CKD patients, assesses nutritional status considering not only features of the history but also muscle wasting and subcutaneous fat loss (evaluated by physical examination). Actually, the assessment of nutritional status in CKD patients involves the evaluation of visceral proteins and/or somatic stores and requires that a number of different tools are used concurrently. Data on anthropometric measures, for instance, BMI, but also skinfold thickness and mid-arm anthropometry, are reported in many papers and are usually in agreement with those obtained with other techniques. Basic nutritional assessment includes anthropometry, subjective global assessment (SGA), biochemical variables (albumin), and assessment of nutrient intakes. Anthropometry (body weight, body mass index, mid-arm circumference, and mid-arm muscle circumference) represents the first-level assessment tool for somatic protein stores (essentially muscle mass) and body fat (Pupin et al. 2004), but, to the best of our knowledge, no specific reference values for anthropometric variables exist for CKD patients. The estimation of body fat using skinfold thickness could be, at least in theory, of particular interest in patients with edema, who exhibit an increased weight and BMI due to a pathological increase in extracellular body water. From a very different perspective, the association between indices of fatness and cardiovascular risk factors has been evaluated by a number of cross-sectional studies, but often as a secondary endpoint of the protocol. For instance, Madero et al. (2007) in 1,772 subjects in the advanced stages of CKD, but not yet on dialysis, observed that greater BMI quartiles were associated with a greater prevalence of diabetes, higher blood pressure, and LDL-cholesterol, and lower HDL-cholesterol. In another study on CKD patients not yet on dialysis, the correlation between WC and blood lipids or insulin resistance appears to be similar to that observed for CT visceral fat (Sanches et al. 2008). In addition, BMI, truncal fat, or visceral fat

have been found to be associated with inflammatory markers, while a complex relationship between obesity, metabolic syndrome, and CKD has also been described (Kwan et al. 2007). Last but not least, overweight and obesity are a known risk factor for proteinuria (Iseki et al. 2004; Madero et al. 2007; Foster et al. 2008).

149.5.3 Bioimpedance Analysis in Chronic Kidney Disease

Anthropometry represents a relevant part of the assessment of body composition but does not distinguish between body protein, minerals, and water. Therefore, it is reasonable to use anthropometry concurrently with tools that allow easy and reliable measures and/or estimates of body water and possibly body cell mass. Bioimpedance analysis (BIA) is a simple, safe, noninvasive technique measuring the electrical properties of the body (resistance = R; reactance = Xc), which are used to derive measures of body compartments with respect to fluids (total body water = TBW; extracellular water = ECW) and soft tissues (fat mass = FM; fat-free mass = FFM). Phase angle (PhA) is another BIA parameter, corresponding to the Xc/R ratio, which has been found to be related to body cell mass, total body proteins and muscle mass, and the ICW/TBW ratio (Chertow 1999). Also, reference values for BIA in healthy populations have been provided for both adults (percentiles) and children (vectors) (De Palo et al. 2000; Di Iorio et al. 2000). BIA has attracted the interest of nephrologists as a simple tool to assess the body composition in CKD patients since it is a bedside method that provides information on both hydration status and body composition. As a matter of fact, it has been utilized in CKD patients to identify a threshold for apparent edema and compared with deuterium oxide dilution and dual-energy X-ray absorptiometry to obtain estimates of TBW and FFM, respectively (Piccoli et al. 1994). Derived values for FFM, FM, and TBW can be obtained in CKD patients using predictive formulas that include BIA values. Alternatively, R and Xc as raw measures have been used to obtain a qualitative information on a patient's hydration status (BIA vector analysis) (Piccoli et al. 1994). Interestingly, the reduction of phase angle has been considered to reflect an increase in the ratio between extracellular water and intracellular water or a decrease in body cell mass (BCM); in addition, phase angle has been discovered to be an independent predictor of survival in various pathologic conditions and also in dialysis patients (Maggiore et al. 1996). On the other hand, a limitation of BIA accuracy for the evaluation of body composition in CKD is represented by the hydration status; since estimation of lean and fat mass can be inaccurate due to overhydration, BIA should be performed in patients at near-free edema status.

149.5.4 Early Changes in Bioelectrical Estimates of Body Composition in Chronic Kidney Disease

Although several observation on BIA have been reported in dialysis patients, few and conflicting results on BIA are available in early stages of CKD. Bellizzi et al. (2006) studied consecutive, incident, CKD patients who had a CKD stage ranging from 3 to 5 without clinically detectable edema; other major clinical conditions that should affect body composition were also considered as exclusion criteria. A further strength of that paper was the presence of a consistent healthy control group (Bellizzi et al. 2006).

Table 149.7 BIA in CKD patients

	Males			Females		
	Patients	*Controls*	*p*	*Patients*	*Controls*	*p*
Resistance, ohm	465 ± 81	492 ± 64	<0.01	550 ± 80	574 ± 63	<0.05
Reactance, ohm	39 ± 9	53 ± 9	<0.01	43 ± 11	59 ± 9	<0.01
Phase angle, degrees	4.8 ± 1.0	6.2 ± 0.9	<0.01	4.5 ± 1.0	5.8 ± 0.8	<0.05
TBW, L	41.8 ± 7.3	40.1 ± 5.1	<0.05	30.0 ± 4.7	29.0 ± 3.4	=0.06
BCM, kg	26.0 ± 4.3	27.9 ± 3.4	<0.01	15.3 ± 2.5	16.4 ± 2.1	<0.01

This table lists the gender-related BIA characteristics (raw measures and derived estimates) in a cohort of incident CKD patients not yet on dialysis as compared with a cohort of healthy control subjects. Data are reported as mean ± SD. The *p* value represents the significance for the *t*-test

BIA bioimpedance analysis; *CKD* chronic kidney disease; *TBW* total body water; *BCM* body cell mass

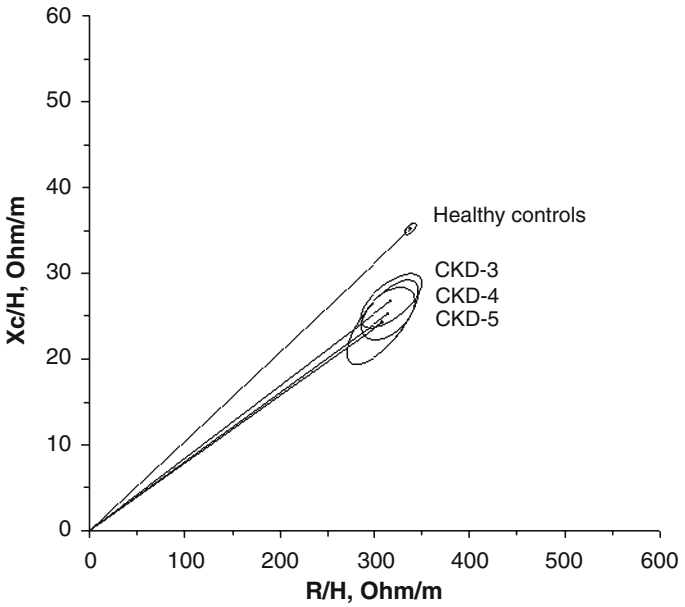

Fig. 149.2 R/Xc graph in CKD patients according to disease stage. This figure shows the R/Xc graph, representing both vectors and confidence ellipses for groups of CKD patients on stages 3–5 (not yet on dialysis) as compared with healthy controls. Compared to controls, vectors for CKD groups were shorter and more downsloping, indicating overhydration in CKD; no difference emerged in the mean impedance vector between the CKD groups (Hotelling's *t*-test). *CKD* chronic kidney disease; *R/Xc* resistance/reactance; *Xc/H* reactance/height; *R/H* resistance height

CKD patients showed overt abnormalities of measured BIA variables, that is, lower R, Xc, and phase angle, and derived measures of body composition (Table 149.7). Definite differences emerged in mean impedance vector analysis in both male and female CKD patients as compared to control subjects: vectors were similarly shorter and downsloping in all CKD stages, suggesting the presence of overhydration since the early stages of CKD, even in absence of edema (Fig. 149.2). Additionally, bioimpedance index (height^2/R), which is considered a variable directly related to TBW, was higher in CKD, with 27% of men and 20% of women being above the 90th percentile derived in healthy subjects. Also, the differences in BIA-derived TBW were similar to those observed for R index: TBW increased in CKD patients (+4%) to an extent which was similar in the different stages of disease. On the contrary, BIA-derived BCM was reduced in CKD (around 7%). Interestingly, phase

angle, which reflects the distribution between ICW and TBW, was markedly lower (-22%) in each of the CKD stages than in controls; the occurrence of short mean impedance vectors associated with a lower phase angle further confirms the presence of fluid overload (Maggiore et al. 1996). Overall, the study indicated that CKD patients suffer of complex changes of body composition starting in the early stages of the disease; in particular, overhydration occurs in patients with mild-to-moderate CKD, even in the absence of clinically detectable edema, whereas body cell mass tends to decrease. Thus, bearing in mind that guidelines pointed out the need for sensitive measures of nutritional status in early CKD stages to prevent the onset of protein–energy wasting, BIA could represent an attractive tool to discover initial abnormalities of body composition in such patients.

149.5.5 Anthropometry in Chronic Kidney Disease: Overall Considerations

The use of anthropometric variables in dialyzed patients as also in CKD patients not yet on dialysis has already yielded interesting information on the changes in nutritional status due to undernutrition or overnutrition. From a practical point of view, fewer indications are available on the use of anthropometric variables in the single patients, and this is even truer for CKD patients not yet on dialysis. Anthropometry should be used in basic nutritional assessment in combination with a panel of other variables exploring biochemical and functional areas. Data obtained in patients with large shifts of body water or edema should be interpreted with caution. Bedside techniques, such as BIA, that assess body fluid compartments, should be utilized concurrently with anthropometry to allow an appropriate evaluation of changes in nutritional status and body hydration. Finally, the use of anthropometry and BIA in monitoring nutritional status during the entire course of CKD should be better evaluated in the future.

Summary Points

- Most CKD patients are overweight or obese.
- Emerging studies show an association between protein–energy malnutrition and mortality in CKD patients not yet on dialysis.
- In CKD patients some, but not all, studies indicate that there is an inverse relationship between body mass index and some outcomes, such as mortality and cardiovascular events.
- Body mass index seems to be a predictor of the onset of CKD; a possible association with waist circumference or waist-to-hip ratio has been described as well.
- International guidelines do not produce very clear indications about the evaluation of nutritional status in CKD patients not yet on dialysis.
- Some anthropometric measures such as body mass index, arm circumference, mid-arm muscle circumference, and some skinfolds may be useful in the evaluation of early abnormalities of nutritional status in CKD patients not yet on dialysis.
- Anthropometric variables should be used together with other tools for a multidimensional evaluation of nutritional status in CKD patients not yet on dialysis.
- In most cases, bioelectrical impedance analysis could be a valuable technique for evaluating body fluids in CKD patients.
- The use of anthropometry or bioelectrical impedance analysis for monitoring changes in nutritional status of CKD patients with time is still not well defined.

Acknowledgment We are in debt to the TABLE study group (Prof. G. Conte, Prof. L. De Nicola, and Prof. R. Minutolo; Nephrology Division, Department of Gerontology, Geriatrics and Metabolic Diseases, Second University of Naples, Naples, Italy) for providing us the database of CKD outpatients in the Italian tertiary nephrology care system which we used to obtain information on prevalence of overweight/obesity in chronic kidney disease.

Chapter 150
Obesity, Leptins, Hypogonadism and Waist–Hip Ratio in men: An Interplay

J. Elizabeth, C. Rakshita, and S. Ramkumar

Abstract Adipose tissue and androgens have a reciprocal link in obese men. Hypogonadism is a nonspecific term for decreased testicular function. It is diagnosed by the low serum testosterone levels and low serum gonadotropin levels due to various etiologies. A deficiency of Testosterone is associated with decreased libido, male erectile dysfunction, excessive sweating and symptoms associated with aging like lack of energy, fatigue, central adiposity, reduced strength, cognitive decline and depression (Davidson et al. 1983; Yesavage et al. 1985). Many of the symptoms are seen in men with increasing age and are not specific in all cases of hypogonadism. Obesity predicts increased mortality due to the link with co morbidities such as diabetes mellitus, cardiovascular disease, the Metabolic Syndrome and Obstructive sleep apnoea (Poirier et al. 2006). Anthropometric measurements like Body Mass Index (BMI), Waist Hip Ratio (WHR) and Waist Circumference (WC) and Waist to Height Ratio (WHtR) have been used as tools to assess obesity and hence the cardiovascular risk status in individuals with hypogonadism.

The Waist Hip Ratio (WHR) measurement is considered a good indicator of abdominal obesity which predisposes to serious health risks. The WHO recommends these measurements as a universal criterion for the detection of obesity. WHR which is a better measure of abdominal fat accumulation has been implicated as a more sensitive predictor of cardiovascular risk than BMI (Cambien et al. 1980; Yusuf et al. 2005). There is a fundamental relationship between energy balance and reproductive function in the mammalian species wherein population growth is controlled during times of scarcity. Recent epidemiological studies have shown that Androgens play an important role in the pathogenesis of Metabolic Syndrome in men. Conversely hypogonadism can develop in established metabolic syndrome (Laaksonen et al. 2005). Studies have shown that Androgen therapy has been found to reduce visceral abdominal obesity which is the main target in the treatment of obesity in hypogonadal men (Schroeder et al. 2004).

The WHR is not recommended to be used as a lone indicator of cardiovascular disease in an obese individual as it was thought earlier. Recent studies have shown Waist Circumference to be a better tool to assess the cardiovascular risk than WHR.

Abbreviations

BMI	Body mass index
BMR	Basal metabolic rate
CAD	Coronary artery disease
CRF	Corticotropin releasing factor
FFM	Fat free mass
FM	Fat mass
FSH	Follicle stimulating hormone
GLP 1	Glucagon like peptide-1
GnRH	Gonadotropin releasing hormone
hCG	Human chorionic gonadotropin
IHH	Idiopathic hypogonadotropic hypogonadism
kDa	Kilo Dalton
LEP	Leptin gene
LEPR	Leptin receptor
LH	Luteinising hormone
MRI	Magnetic resonance imaging
MSH	Melanocyte stimulating hormone
NPY	Neuropeptide Y
PCSK 1	Protein convertase subilisin/kexin type 1
SHBG	Serum hormone binding globulin
WC	Waist circumference
WHR	Waist hip ratio
WHtR	Waist to height ratio

150.1 Introduction

The obesity epidemic is spreading worldwide in genetically predisposed populations who have a high caloric diet and a sedentary lifestyle (Cambien et al. 1980). There is a known evolutionary relationship between energy balance and reproduction in humans, which ensures population control.

Numerous advances in the study of obesity have given us a better understanding but definitive answers remain elusive. Identification of the *ob* gene and transcription factors that regulate adipocyte differentiation, proliferation, and metabolism has produced significant advances in the understanding of the pathophysiology of adipose tissues. The most important concerns in relation to obesity are the associated comorbidities, such as cardiovascular disease, diabetes mellitus, and metabolic syndrome.

Leptin, the adipocyte hormone, has a direct relationship to BMI and WHR, which are considered to be good indicators of the degree of obesity. Leptin has been shown to play a pivotal role in regulation of fertility, and various researchers have studied its relationship with testosterone levels. The most proven relationship between testosterone and leptin is that a deficiency of androgen was associated with obesity and raised serum leptin levels in hypogonadal men. Altered secretory rhythm resulting in very high levels of leptin as a result of obesity will have deleterious effects on the steroidogenic cell and, hence, the synthesis of testosterone. The regulation of testosterone is primarily by pituitary LH. On the contrary, FSH facilitates Leydig cell maturation. Testosterone also maintains the sensitivity of the pituitary to the hypothalamic-releasing factor GnRH. In addition, it acts on the

hypothalamus to slow down the GnRH formation, thus decreasing pulsatile LH release. Under physiologic conditions, the LH response to feedback from testosterone is unique; however, a prolonged elevated plasma LH level as seen in hypogonadism reduces the pituitary's sensitivity to the negative feedback control by the androgen.

Usually, hypogonadism indicates gonadal failure associated with androgen deficiency. There are two types of hypogonadism, hypergonadotropic and the hypogonadotropic. Hyper-gonadotropic hypogonadism or primary gonadal failure results when the gonads do not produce sufficient androgen to suppress LH and FSH by a negative feedback mechanism. Reduced androgen levels and increased levels of LH and FSH characterize this condition.

Hypogonadotropic hypogonadism is a deficiency or absence of gonadal function secondary to lack of gonadal stimulating hormones, LH and FSH. It is characterized by low levels of androgens and low to normal levels of LH and FSH.

Leptin is a 16 kDa cytokine produced by the adipocytes that circulate in plasma at concentrations that parallel the amount of fat reserves. Generally, obese humans show high levels of leptin.

Obesity is known to have a reciprocal link with testosterone levels and total and free testosterone decrease in proportion to its severity. Major pathogenic factors leading to this reduction of testosterone levels in obesity are:

(a) Reduced binding capacity of SHBG (in spite of which the low androgens clearly indicate a failure in production);
(b) Decreased LH pulse amplitude; and
(c) Excessive increase of estrogen or hyperestrogenemia.

Obesity itself is one of the several conditions which can lead to a reduced SHBG level. This results in a low normal or below normal range of total testosterone, wherein the free or bioavailable testosterone is however within normal limits. These changes are reversible with weight loss, suggesting that they are consequences of obesity. Body weight, as is generally known, is regulated by numerous complex afferent metabolic and hormonal signals to the brain. Abnormal production or action of the afferent messengers may lead to a gain in weight. Subsequent increase in leptin levels reflects the body's attempt to counterbalance the increased body fat stores.

150.2 WHR in Hypogonadism

Studies have shown inverse correlations between testosterone levels and BMI, WC, WHR, amount of visceral fat, and serum leptin levels. In 16 different studies, inconsistent and conflicting results were provided on the relation of testosterone and CAD. WHR is measured by the circumference of the waist at its smallest point, divided by the circumference of their hips at the widest point. A waist-to-hip ratio of greater than 0.9 for men and 0.85 for women indicates increased health risks.

Although WHR has been strongly recommended as a cardiovascular risk predictor, it has also been critically commented upon for not representing the accretion of abdominal fat, if the WC is also increased. In the Asian population, the WHtR has already been suggested as a common measure of central obesity with the cutoff level being 0.5 for both sexes. Among the ways to understand the effect of testosterone is to observe the effects of induced hypogonadism. This condition is induced medically or surgically in patients with metastatic prostate cancer. In such cases, induction of hypogonadism results in increased insulin resistance and increased body fat mass.

Besides energy storage, adipose tissue can also synthesize and release substances that can act on distant targets in an endocrine fashion or act locally in a paracrine or autocrine fashion (Griffin et al.). Excess adipose tissue can compound the hypogonadal state as the enzyme aromatase is found in abundance. This enzyme converts testosterone to estradiol (Cohen 2001). Evidence suggests that testicular interstitial function can be impaired due to either an altered fat metabolism or an excess of fat-derived hormonal products (Markku et al. 2006).

There have been interventional studies to establish the relationship between energy balance and androgens in obese men, but they have been inconclusive. It is seen that metabolic syndrome, which is a combination of obesity, hypertension, dyslipidemia, impaired glucose regulation, and insulin resistance, is seen in hypogonadal men. The altered lipid metabolism may be attributed to these integrating signals, primarily leptin, one of the messengers released by the adipocyte.

150.3 Role of Leptin in Abdominal Obesity

The relationship of adipose tissue mass, fat metabolism, and energy balance to reproduction was illuminated by the discovery of the genes encoding leptin, an adipocyte satiety factor, and its receptor. Leptin is a highly conserved 167-amino-acid cytokine-like protein produced mainly, but not exclusively, by adipose tissue; a mutant gene was first isolated from the very obese ob/ob mouse by positional cloning. Soon thereafter, the leptin receptor was cloned, which is a member of the gp family of cytokine receptors and the mutation identified in the obese db/db mouse.

Animal models that exhibit hypogonadotropic hypogonadism have also demonstrated the important role of leptin in reproduction. This was further substantiated by the correction of infertility on administration of recombinant leptin. This protein may play a triggering role as a hormonal determinant of energy balance in addition to the role played by catecholamines, insulin, glucagon, and thyroid hormones. Leptin was found to be the satiety factor, inhibiting food intake and increasing energy expenditure. It acts as a communication between the adipocyte and the hypothalamus (Styne et al. 2008).

Leptin has been implicated to play a crucial role in regulation of body weight, more specifically the body fat stores. Almost all studies have reported a strong relationship between leptin and body weight, expressed as BMI.

BMI and WHR were the only easily measurable indices and are considered as the most precise measure of short-term longitudinal changes in the body fat, although BMI does not discriminate between fat and fat-free mass.

Leptin and its receptor are the important components of the homeostatic system regulating body fat. The signaling by leptin of the hypothalamus involves the modulation of many other molecules, such as NPY, MSH, GLP-1, and CRF. Autoradiography and in situ hybridization techniques have helped in identifying leptin receptor sites in the ventromedial and arcuate nuclei of the hypothalamus and the choroid plexus (Widjaja et al. 1997).

Studies on leptin receptors and genes have demonstrated the role of mutations of these components in obesity (Wilding et al. 1997). Such receptor polymorphisms are seen in humans as well (Chen et al. 1996). The expression of leptin mRNA in the adipocyte also correlates significantly with BMI (Oksanen et al. 1998). Studies have shown correlations between leptin and BMI, and waist and hip circumferences, thus indicating that leptin levels may be associated with the fat depots. These suggest that human obesity is associated with insensitivity to leptin. This could be due to a problem with the transport at the blood–brain barrier, as described by the saturable binding model (Considine et al. 1996).

Generally, obese humans show high levels of leptin. It may be the 'lipostat' factor, which governs the energy balance through a negative feedback originating in the adipocyte and acting on the

hypothalamus. There are evidences of leptin levels being very low in some obese people, indicating an abnormal secretion from the adipocyte stores themselves (Caro et al. 1996).

Higher leptin mRNA levels may be found in subcutaneous than in omental adipocytes (Montague et al. 1997). This indicates that leptin plays a role in the adipose tissue distribution in the human body (Friedman 1997).

In obese males, androgen levels decline in proportion to the degree of obesity. In vitro studies have shown that leptin inhibits hCG-stimulated testosterone secretion at the concentrations found in obese men (Montague et al. 1997). Increased leptin concentrations not leading to weight loss may be because of the defects in other systems regulating body weight. It is thus clear that an increased leptin level is a mere reflection of the attempt made by the human body to reduce the increased fat stores (Caprio et al. 1999). Even if the leptin receptor is functional in obese men, it is apparent that it does not alter their food intake or their BMR in response to a high serum leptin concentration.

Recent studies (Piji et al. 1996; Rolf et al. 2002) have shown that when the expected fall in testosterone levels with aging was prevented by exogenous testosterone replacement in hypogonadal men, the age-related increase in BMI and leptin did not occur.

A significant correlation was found between leptin and most anthropometric parameters, such as BMI, hip circumference, FFM, and FM in kilogram and as a percentage (Rolf et al. 2002).

However, few studies on the effect of testosterone replacement in cases of IHH and Klinefelter's syndrome concluded that mean plasma leptin levels were not influenced by testosterone (Vaan Gaal et al. 1999). Another study reported that there was no correlation between leptin and testosterone in middle-aged normoglycemic men (Kilciler et al. 2002). The reason for these conflicting results is still unclear, but considering the complexity of the factors affecting leptin secretion and the heterogeneity of the population studied, the varied etiology of the hypogonadal cases may be the contributing factor. The primary cause of the inverse correlation between testosterone and leptin could be ascribed to the action of the androgen at the adipocyte level.

A short-term replacement with testosterone may not alter the BMI and WHR, probably because of the anabolic effects of testosterone and conversion of fat into fat-free mass. In support of this, Snyder et al. (2000) have shown that a minimum of 6 months of replacement with testosterone was required to cause a 5.8% increase in fat-free body mass. Evidence suggests that a 6-month testosterone replacement leads to a 16% reduction in fat mass (Pugeat et al. 1991).

In our study of testosterone and leptin levels in 20 hypogondal men, prior to and after exogenous testosterone, the pre-treatment values of testosterone in subjects were found to be significantly lesser than that in the control group. The leptin values too were significantly lower in controls in comparison to the untreated hypogonadal men. The lipid profile showed varied significances. The total cholesterol and low-density lipids showed a significant difference ($p < 0.001$) between pre-treatment subjects and controls. Both total cholesterol and low-density lipids were significantly higher in the hypogonadal men when compared to controls.

High-density lipids showed significant difference between pre-treatment subjects and controls ($p < 0.01$). The study group of untreated hypogonadal men had a significantly reduced level of high-density lipids. Triglycerides and very low-density lipids did not show a significant difference between the subjects pre-treatment and controls ($p > 0.05$). The serum triglyceride levels and very low-density lipid levels did not differ in the hypogonadal men and the controls.

The post-treatment levels of testosterone had improved significantly with reduction in leptin levels in hypogonadal men. These differences were statistically significant ($p < 0.05$).

The total cholesterol and low-density lipids pre- and post-treatment showed significant reduction in levels ($p < 0.001$). (Tables 150.1 and 150.2).

Table 150.1 Mean, standard deviation, *t*-value, and significance levels of testosterone and leptin in Controls and Study Group (pre-treatment) (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

Variable	Group	Mean	SD	*t*-value	DF	*p*-Value
Testosterone	Study Group	0.50	0.61	11.595	38	$p < 0.001$
	Controls	5.95	2.01			
Leptin	Study Group	40.25	37.05	3.658	38	$p < 0.01$
	Controls	8.80	10.30			

The subjects in the study group had lower levels of testosterone and higher levels of leptin in comparison with the controls prior to treatment. The difference was found to be statistically significant.

Table 150.2 Mean, standard deviation, *t*-value, and significance levels of testosterone and leptin in post-treatment Study Group and Controls (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

Variable	Group	Mean	SD	*t*-Value	DF	*p*-Value
Testosterone	Study group	6.00	5.53	0.038	38	NS
	Controls	5.95	2.01			
Leptin	Study group	19.95	19.20	2.288	38	$p < 0.05$
	Controls	8.80	10.30			

The testosterone levels increased while the leptin levels decreased after treatment in the study population. The difference in leptin levels following treatment was found to be statistically significant.

On the other hand, high-density lipids showed a highly significant increase in levels following treatment with testosterone ($p < 0.001$). Triglycerides and very low density lipids showed no significant differences in the study group following exogenous replacement with testosterone.

The testosterone levels in the post-treatment state and controls showed no significant differences. This was because of the normal levels of testosterone, which matched the controls that were achieved post-treatment.

The leptin levels showed a significant difference post-treatment and ($p < 0.05$). This indicates that leptin levels did not match that of the controls in the post treatment of subjects (Figs. 150.1–150.3).

150.4 Waist Circumference, the Newer Measurement

Numerous epidemiological studies have established a close relationship between obesity and low serum testosterone levels in healthy men. In men with hypogonadal values of testosterone, testosterone administration has been shown to improve body composition, decrease fat mass, and increase the lean body mass. (Rita et al. 2007).

Body mass index has been recommended by the WHO as a universal criterion to determine obesity. Waist circumference and waist/hip ratio have been used as markers of abdominal obesity. However, few studies consider that WHR predicts cardiovascular risk better than BMI (Figs. 150.4–150.6).

Waist circumference, on the other hand, has been promoted by some studies and two different criteria have been proposed based on population studies (92–102 cm for men and 80–88 cm for women). The WC has also correlated well with MRI of visceral fat assessed. This measure has not escaped controversy due to the fact that it does not take into account the height and, hence, the waist-to-height ratio (WHtR) was proposed by some others as a better predictor of cardiovascular risk.

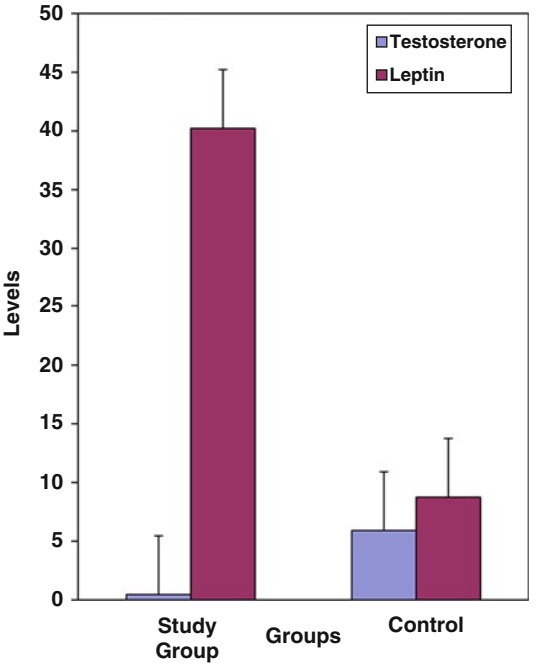

Fig. 150.1 Mean and Standard deviation of testosterone and leptin levels in control group and study group prior to treatment. In comparison to the controls, the study group had lower testosterone and higher leptin levels. (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

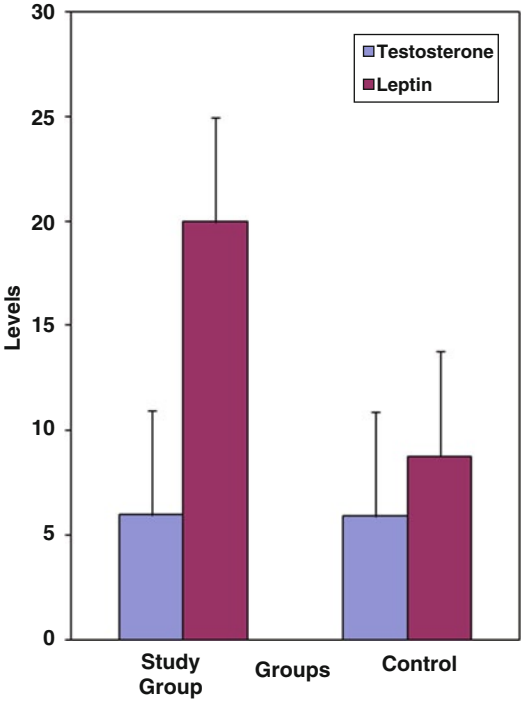

Fig. 150.2 Mean and Standard Deviation of testosterone and leptin levels in the study and control groups following treatment. The levels of testosterone had improved while leptin levels also showed a reduction post-treatment in the study group. (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

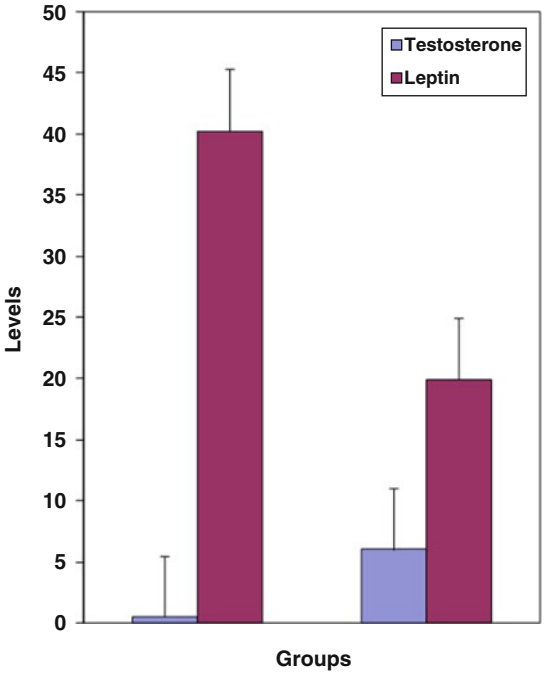

Fig. 150.3 Mean and standard deviation of testosterone and leptin in the study group – Pre- and Post treatment. This figure shows the effect of exogenous testosterone administration on testosterone and leptin levels in the study group (hypogonadal men). The testosterone levels had improved significantly, while the leptin levels showed reduction after exogenous testosterone administration (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

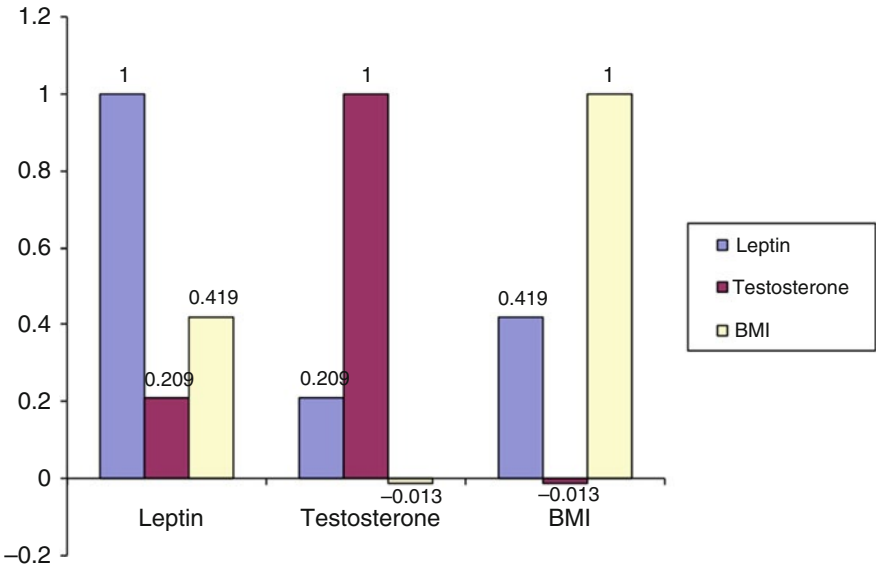

Fig. 150.4 Pearson correlation between leptin, testosterone levels, and BMI prior to treatment in the study group. A direct relationship exists between BMI and leptin levels while BMI and testosterone levels vary inversely. (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

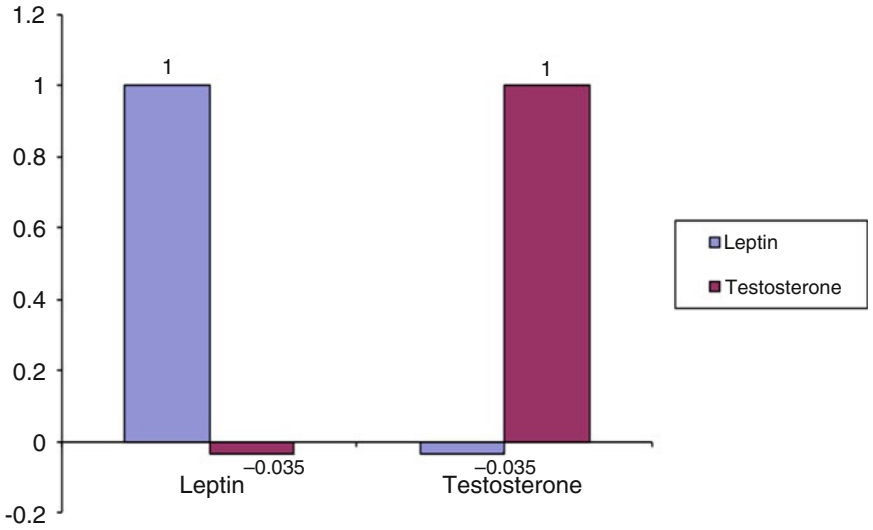

Fig. 150.5 Pearson correlation between leptin and testosterone levels post-treatment in the study group. This figure explains the relationship between serum leptin and testosterone levels on the study group following administration of exogenous testosterone. Leptin and testosterone levels in serum are inversely (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

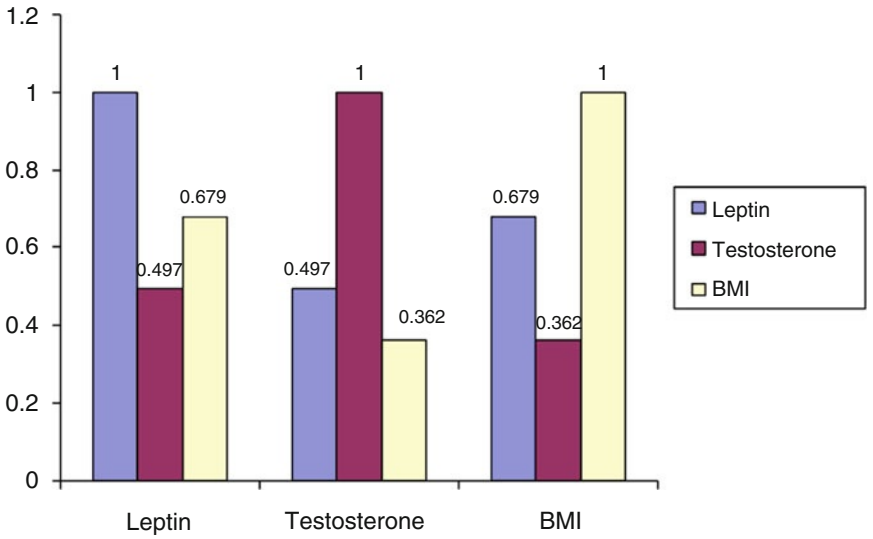

Fig. 150.6 Pearson Correlation between leptin and testosterone levels with BMI in the control group. This figure explains the relationship between serum leptin and testosterone levels and BMI in the control group. BMI and leptin levels show a positive correlation, while leptin and testosterone levels are inversely related. (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

Table 150.3 Mean, standard deviation, *t*-value, and significance levels of testosterone and leptin from pre-treatment and post treatment – Study Group (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

Variable	Mean	SD	*t*-Value	DF	*p*-Value
Testosterone pre-treatment	0.50	0.61	4.373	19	$p < 0.001$
Testosterone post-treatment	6.00	5.53			
Leptin pre-treatment	40.25	37.05	2.576	19	$p < 0.05$
Leptin post-treatment	19.95	19.02			

WHtR has advantages over BMI as it is easier to calculate and understand for the ordinary man as the formula is simpler and the measurement taking is less cumbersome. WC, on the other hand, is more likely to vary with diet and physical activity than the BMI because a replacement of fat by muscle mass might lead to little change in BMI but to clear changes in WC and WHtR. The WHR is not only more complicated to assess, but it also has been shown to be a far weaker predictor of cardiovascular risk factors.

Testosterone treatment may improve body composition, but studies have not sufficiently proven whether it is a significant weight change or change in adipose tissue depots.

A reduction in fat mass was seen with androgen therapy in ancillary data obtained from 32 older men, indicating a reduction in total and abdominal fat (Table 150.3).

150.5 Metabolic Syndrome, Hypogonadism, and WHR – Role of Exogenous Testosterone

Hypogonadism can result in a decreased lean body mass, decreased bone mineral density, and an increased body fat distribution. Baseline androgen levels have been shown to be inversely related with metabolic syndrome, and manifestations, such as higher plasma fasting glucose, increased waist circumference, hypertension, and dyslipidemia, have been seen in such men (Carr et al. 2004). There have been longitudinal and population-based cohorts, which showed that metabolic syndrome can predict the development of hypogonadism (Schroeder et al. 2004).

There is a cause–effect relationship between low serum testosterone levels and visceral obesity, leading to one contributing to the other. This leads us to the fact that obesity is a state of androgen deficiency which is relative.

Waist circumference has been proven to be a more important component of prediction of cardiovascular risk than total fat mass, which is measured by BMI (Yusuf et al. 2005). Visceral abdominal fat has been shown to be an independent predictor of cardiovascular disease.

Therefore, treating visceral abdominal obesity is the main target in the correction of metabolic syndrome. Androgen therapy has been advocated in order to reduce WHR and, hence, visceral abdominal obesity in men. Various studies on testosterone replacement in older men (Katznelson et al. 1996) and hypogonadal men (Rodriguez et al. 2007) have shown a reduction in visceral abdominal obesity.

Therefore, WC appears to be a better indicator of cardiovascular risk than BMI. Moreover, WC is more sensitive to diet and training than BMI because increase of muscle mass might lead to little change in BMI but to clear changes in WC. WHR is not only more complicated to assess, but it also has been shown to be a far weaker predictor of cardiovascular risk factors (Table 150.4).

Table 150.4 Pearson correlations in Study Group pre-treatment (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

	Leptin	Testosterone	BMI
Leptin	1.000	0.209	0.419
Testosterone	0.209	1.000	–0.013
BMI	0.419	–0.013	1.000

This table shows the Pearson correlation coefficients between leptin, testosterone, and BMI of individuals in the study group prior to treatment. Leptin levels are higher in individuals with a higher BMI, that is, obese individuals, while BMI and testosterone seem inversely related.

Table 150.5 Pearson correlations in the Study Group post-treatment (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

	Leptin	Testosterone
Leptin	1.000	–0.035
Testosterone	–0.035	1.000

The table shows the correlation between serum testosterone and leptin levels in the study group following the administration of testosterone. The two parameters are inversely related

Table 150.6 Pearson correlations in the Control Group (The effect of testosterone replacement on waist hip ratio, serum leptin and lipid profile in hypogonadal subjects. Elizabeth et al. 2008)

	Leptin	Testosterone	BMI
Leptin	1.000	0.497 (*)	0.679 (**)
Testosterone	0.497(*)	1.000	0.362
BMI	0.679 (**)	0.362	1.000

This table explains the relationship of serum leptin and testosterone levels with BMI of individuals in the control group
*Correlation is significant at the 0.05 level (two-tailed)
**Correlation is significant at the 0.01 level (two-tailed)

150.6 Application to Other Areas of Disease

As mentioned earlier, short-term testosterone replacement can help in reducing leptin levels in hypogonadal subjects and can further decrease the waist/hip ratio. This has a direct effect on the risk of acute coronary syndromes in the individual (Tables 150.5 and 150.6).

Leptin, on binding to neuropeptide Y (NPY) neurons in the Arcuate nucleus, reduces the activity of these neurons. Satiety is brought about by leptin signals to the brain, indicating that the body has had enough to eat. A homozygous mutation for the leptin gene, which results in severe obesity, leads to a constant desire for food. This condition may be treated by the administration of recombinant human leptin.

Both these concepts require further study before they can be used in clinical practice.

150.7 Conclusion

In hypogonadism, low testosterone levels, raised leptin levels, and anthropometric changes are all associated with each other and are components of the predisposing factors that lead to obesity, which is the cornerstone in the development of metabolic syndrome. WHR was a good predictor of visceral abdominal obesity but it has been recently proven beyond doubt that WC is a better measure of the same.

Summary Points

- The waist–hip ratio (WHR) measurements are considered as a good indicator of visceral abdominal obesity, which predisposes to serious cardiovascular health risks.
- Leptin has a major role in body fat distribution.
- WHR and WC, which are better measures of abdominal fat accumulation, have been implicated as more sensitive predictors of cardiovascular risk than BMI.
- Androgens play an important role in the pathogenesis of metabolic syndrome in men and, conversely, hypogonadism can develop in established metabolic syndrome.
- Androgen therapy has been found to reduce visceral abdominal obesity, which is the main target in the treatment of obesity in hypogonadal men.

Key Points

Table 150.7 Significance of various anthropometric indicators

Anthropometric measurement	Significance
Body Mass Index(BMI)	Commonly used measure of obesity but does not differentiate fat from fat-free mass
Waist–Hip Ratio (WHR)	Commonly used to measure visceral abdominal obesity but is considered as a poor predictor of cardiovascular risk
Waist-to-Height Ratio (WHtR)	Used as a measure of obesity, considered a better measure of cardiovascular risk than BMI
Waist Circumference (WC)	Considered as the most reliable predictor of visceral abdominal obesity and thus of cardiovascular disease

This table lists the various anthropometric indicators and their significance in estimating the risks of obesity

Table 150.8 Key points: leptin – a brief summary

1. *Leptin, a cytokine-like protein* is one of the key factors influencing adipose tissue accumulation and distribution in the body.
2. *Leptin receptor sites* are present in the *Ventromedial and Arcuate nuclei* of the hypothalamus and the *choroid plexus* in the brain.
3. Leptin plays a triggering role as a hormonal determinant of energy balance, in addition to other hormones.
4. Leptin functions as the *satiety factor* – it acts as a communication between the adipocyte and the hypothalamus.
5. Leptin *levels in blood parallel the fat reserves* in the body.

This table outlines role of leptin in the body

Chapter 151
Usage of Anthropometry to Determine Etiological and Risk Factors in Deep-Tissue Injury

Amit Gefen

Abstract Pressure ulcers, also termed pressure sores, bedsores or decubitus, are a serious complication which is typical of patients with impaired motosensory capacities, and of those confined to a wheelchair or bed for long periods. There is medical evidence associating severe pressure ulcers with life-threatening conditions including sepsis, osteomyelitis, myocardial infarcts, renal failure and multiple organ system failure. The American National Pressure Ulcer Advisory Panel recently defined a *deep tissue injury* (DTI) as a particularly severe type of pressure ulcer which onsets internally, in skeletal muscle tissue overlying weight-bearing bony prominences. A DTI spreads subdermally and often develops to a full-thickness pressure ulcer, i.e. it evolves into an open wound that extends from skin to bone. This chapter is focused on anthropometric features that increase internal mechanical loading in skeletal muscle tissue adjacent to weight-bearing bony prominences, and therefore, increase the risk for DTI. The ischial tuberosities in the pelvis are being considered herein as the main example for this interaction. Specifically, this chapter reviews the effects of whole-body anthropometric measures, such as the bodyweight and body mass index, as well as effects of internal anthropometric characteristics, e.g. the thickness of the gluteus muscles that envelop the ischial tuberosities, or the curvature of the ischial tuberosities, on the internal mechanical conditions in adjacent skeletal muscle tissue, and on the consequent risk for DTI.

151.1 Introduction

Pressure ulcers (PUs), also termed pressure sores, bedsores, or decubitus, are a serious complication which is typical of patients with impaired motosensory capacities and of those confined to a wheelchair or bed for long periods. There is medical evidence associating severe PU with life-threatening conditions, including sepsis, osteomyelitis, myocardial infarcts, renal failure, and multiple organ system failure (Agam and Gefen 2007). The American National Pressure Ulcer Advisory Panel (NPUAP) recently defined a *deep-tissue injury* (DTI) as a particularly severe type of PU which onsets and spreads subdermally (Black 2009). A DTI often develops to a full-thickness PU, that is, it evolves into an open PU that extends from skin to bone. Treatment is typically surgical and combined with aggressive medications to prevent or treat infections. A DTI is currently described by the NPUAP as a "purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared to adjacent tissue." This clinical manifestation of DTI is the outcome of sustained mechanical deformations in soft tissues, which are warped between loaded bony prominences of the body, for example, the ischial tuberosities (IT) or sacrum, and a supporting surface, such as a mattress or a wheelchair cushion (Fig. 151.1).

Elevated tissue deformations that occur over critical time periods lead to cell death and tissue necrosis via the following mechanisms: (1) collapse or crush of cell membranes or intracellular structures, for example, cytoskeletons (Slomka et al. 2009), (2) hindered diffusion of metabolites in the deformed, denser extracellular space (Gefen et al. 2008), (3) obstruction to blood flow at the geometrically distorted capillaries and possible capillary occlusion by clots, which leads to ischemia (Linder-Ganz and Gefen 2007), (4) oxidative damage from free radicals that are flushed into the tissue when capillaries reopen, for example, if the body posture has been changed after a period of ischemia (Tsuji et al. 2005); such reperfusion events cause both direct cell death by free radicals reacting with intracellular chemical compounds and increased permeability of capillaries that leads to edema, which in turn increases localized tissue and cellular deformations, and (5) impaired lymphatic flow, which, similarly to the dysfunction of the capillary bed, allows for more edema to build up and exacerbates mechanical loading conditions at the tissue and cellular levels (Pieper 2007) (Table 151.1).

Clearly, all the damage pathways listed above are either directly or indirectly caused by mechanical deformations in soft tissues. Skeletal muscle tissue is especially susceptible to these deformation damage pathways since for many anatomical locations, and for the clinically relevant supported body postures (e.g., recumbency and sitting), muscles directly overlie bony prominences, for example, the gluteus muscles which pad the IT during sitting. Indeed, soft tissues around the IT are one of the most frequent anatomical locations for PU and DTI, particularly in patients who use a wheelchair (Gefen 2007a). Not only that muscle tissue at these locations is subjected to high deformations as the weight-bearing IT bones sag into the viscoelastic muscle tissue while sitting or lying (Fig. 151.1), muscle is also rich with capillaries and is a metabolically more demanding tissue compared with adipose tissue, fascia, or skin. These factors, altogether, make skeletal muscle tissue highly susceptible to deformation damage. Accordingly, this chapter is focused on anthropometric features that increase internal mechanical loading in skeletal-muscle tissue adjacent to weight-bearing bony prominences, and, therefore, increase the risk for DTI. The IT is being considered herein as the main example for this interaction. Specifically, this chapter reviews the effects of whole-body anthropometric measures, such as the bodyweight and body mass index (BMI), as well as effects of internal anthropometric characteristics, for example, the thickness of the gluteus muscles that envelop the ITs, or the curvature of the ITs, on the internal mechanical conditions in adjacent skeletal muscle tissue and on the consequent risk for DTI.

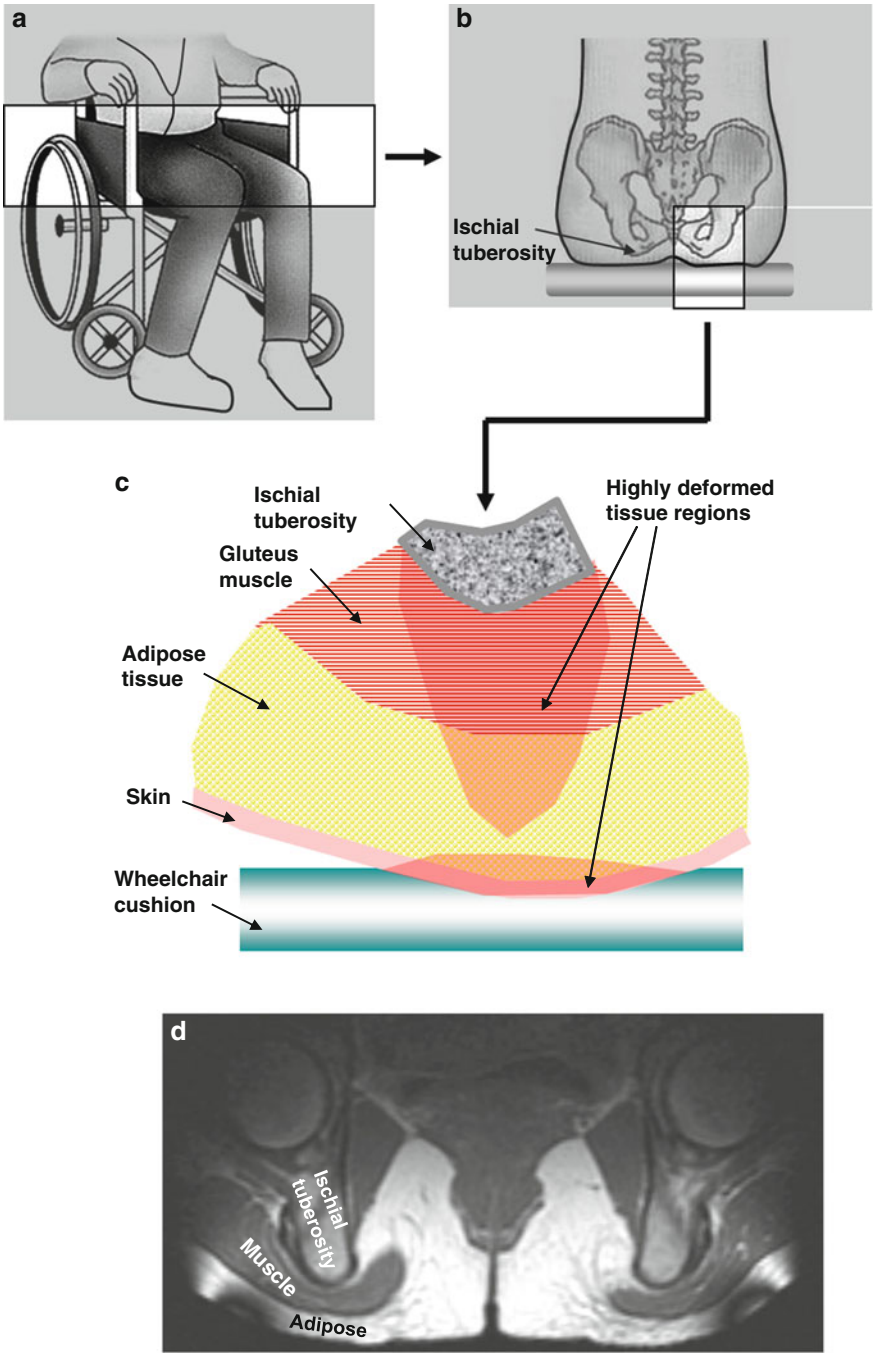

Fig. 151.1 A deep-tissue injury is formed in skeletal muscle due to sustained tissue deformations. For example, in individuals confined to a wheelchair (**a**), the soft tissues of the buttocks are being deformed between the ischial tuberosities and the wheelchair cushion (**b**), which induces elevated tissue deformations, particularly in gluteus muscle tissue adjacent to the ischial tuberosities, as shown schematically in (**c**) and in a magnetic resonance image of the buttocks of a sitting female in (**d**). Internal deformations that occur in weight-bearing soft tissues under bony prominences can be clearly demonstrated by means of weight-bearing magnetic resonance imaging (MRI), as shown in the bottom frame for the muscle and adipose tissues that are deformed under the ischial tuberosities of the buttocks during sitting in an Open-MRI system

Table 151.1 Key facts of anthropometry usage in deep-tissue injury

1. Obesity and reduced gluteal muscle thickness associated with disuse atrophy are anthropometric features that biomechanically increase the risk for DTI.
2. Flattened ischial tuberosities are associated with a faster occurring, more severe DTI.
3. New clinical risk-assessment tools designed to identify patients at risk for a DTI should screen for these anthropometric changes, for example, by employing imaging modalities to measure these internal bone and muscle changes, which are particularly characteristic of the population of patients with spinal cord injuries.

This table summarizes the key facts of anthropometric usage in deep-tissue injury (DTI). It specifically lists obesity, reduced thickness of the glutei muscles, and flattened ischial tuberosities as anthropometric characteristics that make patients more prone to DTI, and who should be screened for in DTI risk assessments

151.2 Bodyweight and Body Mass Index

Using the weight categories of the World Health Organization (underweight denoting BMI < 18.5, obese as BMI > 30), epidemiological studies report higher prevalence of PU and DTI in patients with both abnormally low and abnormally high bodyweights (VanGilder et al. 2009). Surgical patients who are morbidly obese (BMI > 40) were identified in up-to-date nursing literature to be especially vulnerable to DTI (Baugh et al. 2007), which apparently puts an end to the myth that obese patients are more protected from PU, because they have 'more padding'. The understanding that obesity is actually a serious risk factor for DTI is already implemented in practice, in the Waterloo risk assessment tool, which is commonly used in the UK for evaluating the individual's risk for developing a PU. Based on expert views and clinical experience (but still lacking sufficient basic-science foundations), the Waterloo risk assessment tool assigns more risk scores to patients having BMI > 30 and to those with BMI < 20 kg/m^2 (http://www.judy-waterlow.co.uk/). Biomechanical theory can provide the missing theoretical foundations for this clinical practice, as follows.

An analytical biomechanical approach, employing the contact mechanics theory, was used by Gefen (2008). Based on calculations of muscle-tissue distortion in a simplified model of a spherical-shaped bony prominence that sags into an elastic muscle layer (Fig. 151.2a), a compression intensity index (CII) was defined as

$$\mathrm{CII} = \frac{\mathrm{BW}}{\sqrt{R \cdot t}} \tag{151.1}$$

where BW is the bodyweight in kilogram, R is the radius of curvature of the weight-bearing bony prominence in millimeter, and t is the thickness of skeletal muscle tissue overlying that bony prominence, also in millimeter. The higher the CII is, the more intense the localized loading in the soft tissues will be. The CII is particularly useful for understanding the long-term effects of obesity on internal loading in muscle tissue. Obesity involves loss of lean muscle mass and thickness due to a sedentary lifestyle, by a process called muscle-disuse atrophy. As obesity worsens, the BW increases, whereas the muscle thickness t decreases. The decrease in t over time is accelerated if there are neuromuscular impairments, such as after a spinal cord injury (SCI) (Berry et al. 2008). The increase in BW and the decrease in t both act to increase the CII, but, for lower muscle thicknesses t, a rise in BW will have a more substantial adverse effect, as depicted in the plot in Fig. 151.2b for anthropometric dimensions representative of the IT bone and the biological variability in thicknesses of the gluteus muscles of the buttocks. It is shown in these plotted biomechanical model predictions that morbidly obese subjects, with BMI of 60, develop at least 1.5-times higher loads in skeletal muscle under the IT compared to subjects with a normal BMI of 25. It is further shown in Fig. 151.2b that

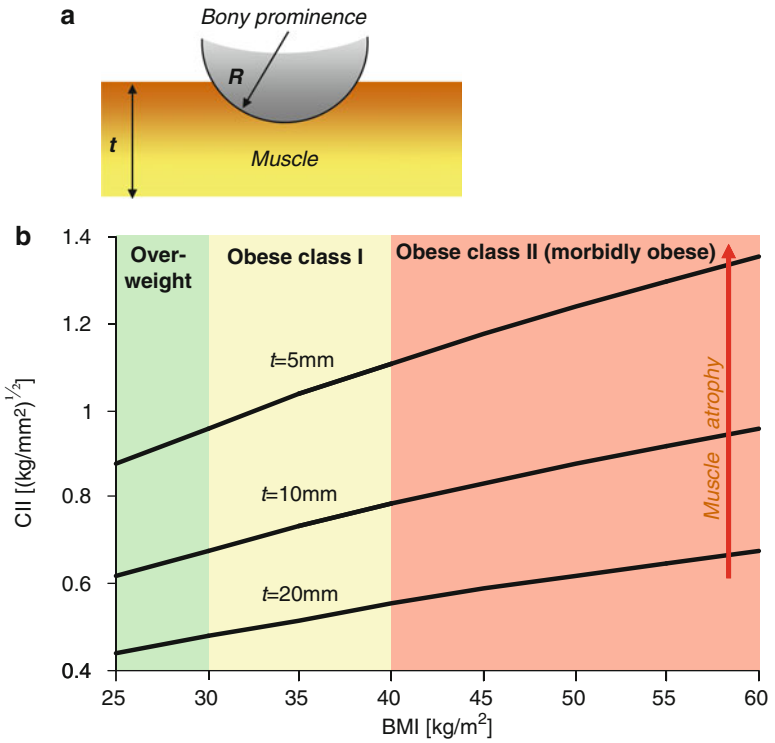

Fig. 151.2 The compression intensity index (CII) for evaluating the effect of the body mass index (BMI) on internal loading in skeletal muscle tissue deformed under a weight-bearing bony prominence. (**a**) The biomechanical model used to formulate the CII. (**b**) Curves of rise in CII with an increase in BMI for muscle tissue thicknesses *t* of 20, 10, and 5 mm, the last two values being representative of gluteal muscle atrophy (Gefen 2008). The body height was taken as 1.75 m for all calculations shown in this figure, and the bony prominence was assumed to be the ischial tuberosity, with radius of curvature of 20 mm (Gefen 2008). The categories of obesity (used in the horizontal axis) are those of the World Health Organization

these internal muscle loads can rise by as much as threefold from non-obese to morbidly obese conditions if a disuse muscle atrophy, reducing muscle thickness to 25% of its original thickness, also occurs. This extent of decrease in muscle thickness is expected in patients with neuromuscular impairments. For example, magnetic resonance imaging (MRI) studies of thickness of the gluteus muscles under the IT in patients one year post-SCI showed that their muscle thickness was 6 ± 1 mm, whereas the thickness of controls was 21 ± 2 mm (Linder-Ganz et al. 2008).

More complex modeling to study the effects of obesity on internal tissue loading in the buttocks, which considered a more anatomically realistic buttock structure, was conducted by Elsner and Gefen (2008). In their work, mechanical strain (relative tissue deformation) and stress (force per unit area of tissue) magnitudes and distributions were determined in the gluteus muscles and enveloping fat of the seated buttocks, using finite element (FE) modeling. Elsner and Gefen (2008) specifically studied the internal loading in coronal slices through the seated buttocks in five cases: a 'reference model' representing BMI = 25.5 kg/m^2 (non-obese), BMI = 30 kg/m^2 (grade-I obesity), BMI = 35 kg/m^2 (grade-II obesity), BMI = 40 kg/m^2 (grade-III morbid obesity), and BMI = 40 kg/m^2 also involving 30%-atrophied glutei (Fig. 151.3). Their reference model was developed from a non-weight-bearing MRI scan of the

buttocks of a non-obese male, who was sitting on a rubber tire so that his soft tissues of the buttocks were mostly unloaded (Fig. 151.3a). Contours of bones and soft tissues were detected and segmented from the MRI to form the geometry of the reference model, using solid modeling software (Fig. 151.3a). The reference model was then modified, using the solid modeling software, to virtually form the anthropometric changes in the buttocks that are associated with increasing levels of obesity (Fig. 151.3b). The increase in volume of adipose tissue in the buttocks was estimated by employing an empirical relation between BMI and percentage body fat (Jackson et al. 2002):

$$\text{Body fat}(\%) = 3.76\text{BMI} - 0.04\text{BMI}^2 - 47.80 \tag{151.2}$$

In order to construct the variant BMI models shown in Fig. 151.3b, so that they together represent the biomechanical outcomes of a process of gradually gaining weight, the superficial border of fat tissue in the reference model was stretched out uniformly, until the percent increase in body fat predicted by eq. 2 was accomplished for each BMI level. The additional model, built to represent a combination of obesity and disuse muscle atrophy (Fig. 151.3b, bottom), was identical to the BMI = 40 kg/m^2 model in all aspects but the volume of skeletal muscle tissue, which was reduced by 30%, which is a reasonable muscle loss expected in the chronic phase of SCI (Weaver et al. 2007; Linder-Ganz et al. 2008). The reference model and all the model variants in Elsner and Gefen (2008) were solved by simulating the vertical sagging of the IT toward the sitting surface during weight-bearing sitting.

Consistent with the mathematical modeling used to develop the CII ((151.1), Fig. 151.2), the study of Elsner and Gefen found that mechanical strains and stresses in skeletal-muscle tissue of the buttocks increase with the extent of obesity (Fig. 151.3c). The trends for peak strain and stress measures in skeletal muscle of the seated buttocks are shown in Fig. 151.4, as a function of the BMI. It is evident from these data that peak compression and shear strains in muscle tissue increase by approximately 7% for each five BMI units added above a BMI of 25 kg/m^2. The peak tensile strains in muscle tissue increase even more rapidly, by about 16% for each five BMI units added. Peak compression stresses in muscle tissue increase by approximately 4 kPa for each five BMI units added, whereas tensile and shear stresses increase more moderately, by about 2 kPa for this extent of rise in BMI. The increase in BMI at the obese levels results in not only an increase in peak muscle strains and stresses but also a dispersion of the concentrated peak strain region in muscle tissue under the IT into several such regions (Fig. 151.3c). Disuse atrophy in the gluteus muscles, on top of obesity, escalated the intensity of mechanical loads in muscle tissue under the IT, particularly for tensile stresses (which were 1.3-times higher for atrophied muscles) and shear stresses (1.2-times higher), and also increased the region in muscle tissue that is subjected to concentrated loads (Elsner and Gefen 2008).

Fig. 151.3 The biomechanical model of Elsner and Gefen (2008) for studying the effects of obesity on internal tissue loading in the buttocks. (**a**) The 'reference model' geometry, representing a coronal slice through the seated buttocks of a person with a normal body mass index (*BMI*); the model geometry was built from an MRI scan of a sitting male (*left frame*). (**b**) Variant model geometries, representing increasing degrees of obesity (*top row*) and obesity combined with a disuse muscle atrophy (*bottom*). (**c**) Magnitudes and distributions of internal mechanical compressive strains in skeletal muscle and fat tissues of each of the BMI models, obtained from computer analyses of tissue deformations, which are compared to tissue deformations seen in the weight-bearing MRI scan for validation (*top left frame*). Sites of elevated localized mechanical strains in muscle tissue, identified as such by the computer models of Elsner and Gefen (2008), are marked in yellow and red colors in the color-coded maps in (**c**). Internal strains in muscle tissue maximize directly under the ischial tuberosities and fade away medially and laterally to these bones. The intensity of muscle-tissue strains and the number of sites of elevated strains in muscle increase with the level of the body mass index (BMI)

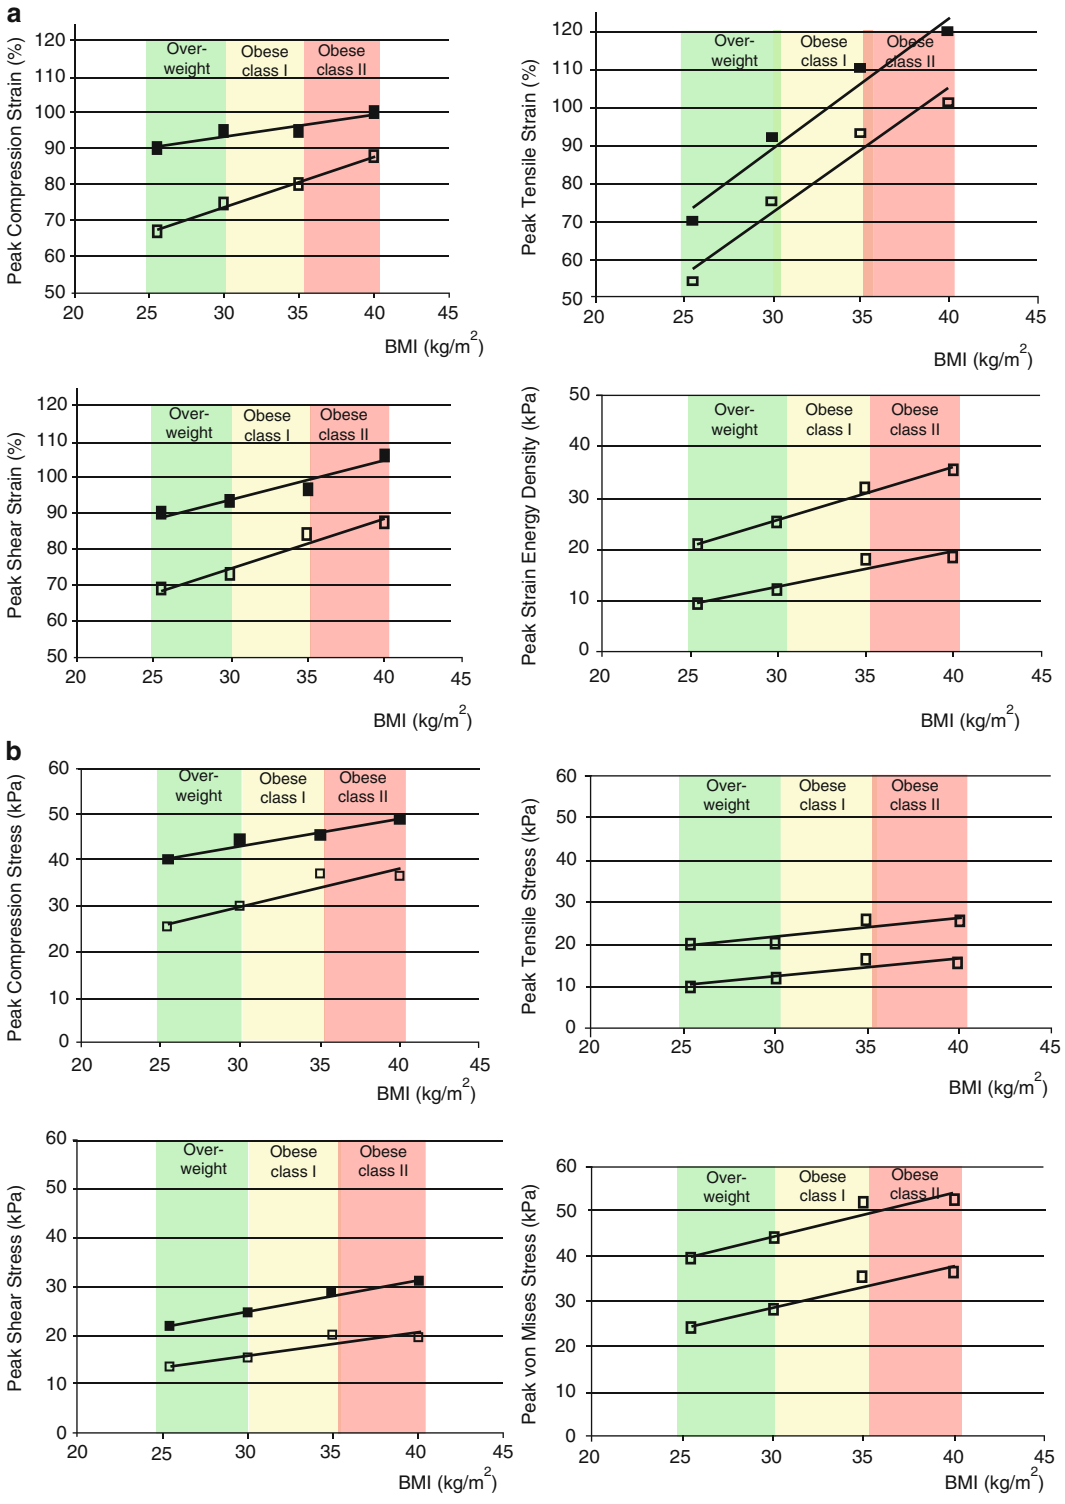

Fig. 151.4 The rise predicted in (**a**) mechanical strain measures in gluteal muscle tissue and (**b**) mechanical stress measures in muscle for increasing levels of body mass index (*BMI*) in the obesity categories, based on the biomechanical modeling study of Elsner and Gefen (2008), for sitting on a hard surface (■) and on an elastic cushion (□). Internal tissue strains and stresses in the gluteus are consistently higher for sitting on a hard surface compared to sitting on an elastic cushion, regardless of the level of the body mass index (*BMI*). The categories of obesity are those of the World Health Organization

The FE analyses of Elsner and Gefen (2008), representing growing extents of obesity (Fig. 151.3), clearly show a trend of increase in all the geometrical distortion and loading measures for the internal soft tissues, with the BMI level (Fig. 151.4). Measurements of seat-interface pressures generally report that the highest pressures occur in thin individuals, not in overweight ones (Kernozek et al. 2002), but epidemiological studies indicate that, among individuals with SCI, obesity is common (Weaver et al. 2007). Moreover, recent case-series reports state that obesity could be a risk factor for DTI (Baugh et al. 2007; Gallagher 2005). These seemingly contradicting indications can be settled if it is recalled that interface pressures of the seated buttocks are not a reliable predictor of subdermal tissue loads (Gefen and Levine 2007). The study of Elsner and Gefen (2008) supports this, because it demonstrated that seat-interface pressures at the different BMI levels changed only slightly, by no more than 10%, despite a 1.5-times increase (on average) in strains and stresses at skeletal muscle tissue when the BMI was increased from 25 to 40 kg/m^2 (Fig. 151.4).

In subjects with SCI, the progressive increase in bodyweight and BMI post-injury (Weaver et al. 2007) is physiologically coupled with a process of loss of muscle mass (Linder-Ganz et al. 2008). A recent study comparing BMI-matched groups of subjects with SCI and controls (BMI was approximately 24 kg/m^2 in the two groups) concluded that the total lean tissue mass in SCI was 8.9 kg lower (Jones et al. 2003), which clearly demonstrates that muscle–fat ratios can be substantially different between SCI and controls, despite similar BMI values. In this regard, Elsner and Gefen (2008) showed that inducing some muscle atrophy (30%) on their BMI = 40 kg/m^2 FE model resulted in a substantial increase in all measures reflecting geometrical distortion and internal loading of muscle tissue with respect to the no-atrophy condition. This increase was not only in peak strain and stress values, but also in the size of the affected tissue regions, which is unsurprising considering the reduced muscle thickness subjected to elevated loading by the IT in disuse atrophy coupled with obesity. This result of Elsner and Gefen (2008) highlights that obesity and muscle atrophy, which are both typical of the chronic phase of SCI, contribute together to the state of elevated tissue loads, which consequently increases the likelihood of DTI. Since physical exercise is well known to counteract both obesity and muscle atrophy in individuals with SCI, a practical interpretation of this could be that exercise is highly recommended for the SCI population, wherever possible.

Although there is an association between BMI and adiposity, BMI is a poor evaluator of adiposity or of the lean tissue mass on an individual basis (Kuk and Ross 2007). This is particularly true for subjects with SCI, for whom there are no specific measures of obesity. Hence, one topic that requires further research is the development of specific anthropometric measures for the SCI population, particularly for characterizing obesity and loss of muscle mass and thickness. For example, surface anthropometry, such as skinfold measurements, has been suggested to evaluate adiposity better than BMI (Nevill et al. 2006), and this has to be tested specifically for the SCI population. Another topic that warrants future research is the effect of the other side of the extreme in the BMI range, namely, underweight conditions, on the risk for DTI. This question has not yet been investigated at all, from an anthropometrical or biomechanical point of view. However, there are medical reports that malnourished patients face higher risk for PU (Russell 2000), and indeed, the Waterloo risk assessment tool, which is in practical clinical use, already assigns greater risk scores to patients with BMI < 20 kg/m^2 (http://www.judy-waterlow.co.uk/). From anthropometrical and biomechanical aspects, underweight conditions impose a problem of counteracting the effects of bodyweight and tissue cushioning in the seated buttocks, which is analogous to the questions related to obesity discussed in detail earlier. Future research work should therefore look into effects of underweight and thinning of fat and muscle tissues and their potential role in influencing the risk for DTI.

151.3 Thickness of the Musculature Under Loaded Bony Prominences

Linder-Ganz et al. (2008) used Open MRI to compare anthropometric characteristics of internal hard- and soft-tissue structures in the seated buttocks between subjects with SCI, 1–35 years post-injury, and controls (six subjects were included in each group). The authors found significant differences between the groups (Table 151.2); specifically, gluteus muscle thicknesses under the IT were approximately 2.3-times higher in the controls ($p < 0.01$, Table 151.2), indicating the extent of atrophy in the muscles of the subjects with SCI. The loss of muscle mass induced an average of 36% less ($p < 0.01$) overall soft-tissue thickness under the ischial tuberosities in the SCI group (muscle and adipose tissues taken together for this calculation). This is despite the fact that the fat thickness in the SCI group was slightly higher (but not statistically significantly higher), and also that the mean bodyweight in the SCI group was 8% higher than that of the control group (Table 151.2). From the muscle thickness data of the SCI group, it could be generally seen that the decrease in their gluteal thickness (and also, in their overall soft tissue thickness) under the ischial tuberosities became more prominent with the time post SCI (Linder-Ganz et al. 2008, 2009). These measurements were consistent with numerous previous literature that overall reports loss of muscle mass in the chronic phase of SCI (Castro et al. 1999; Giangregorio and McCartney 2006), but Linder-Ganz et al. (2008) were the first to quantify this loss specifically for the gluteus muscles in a sitting posture, which is relevant to sitting-acquired DTI.

In order to study potential effects of these group differences on the risk for DTI in the SCI population, Linder-Ganz and Gefen (2009) later developed an FE-based algorithm for simulating DTI onset and progression in muscle tissue overlying the IT, based on experimental data from their previous animal studies, including a muscle cell-death injury threshold and an injury-stiffening damage law for muscle tissue (Fig. 151.5). Their computational simulations successfully reproduced clinically reported 'crater' shapes of DTI in muscles (Fig. 151.5) that progress to full-thickness muscle injury and then spread to more superficial tissues, until eventually penetrating the skin. The shapes of the simulated DTI obtained in the study of Linder-Ganz and Gefen (2009), as shown in Fig. 151.5,

Radius of curvature of the ischial tuberosities^{+} (mm)	12 ± 2	19 ± 4*
Distance between the ischial tuberosities (horizontal) (cm)	122 ± 15	125 ± 10
Thickness of the gluteus muscle under the ischial tuberosities^{+} (cm)	21 ± 3	9 ± 10*
Thickness of the adipose tissue under the ischial tuberosities^{+} (cm)	12 ± 4	13 ± 8
Overall soft-tissue thickness (muscle + fat) under the ischial tuberosity^{+} (cm)	33 ± 5	21 ± 12*

(+) Left and right body sides averaged per each subject. *$p < 0.01$ in an unpaired, two-tailed t-test.
This table specifies the mean values ± standard deviations of the internal anatomy of the buttocks of subjects with spinal cord injury (SCI), 1–35 years post the injury, and those of controls (each group included six subjects). All data were measured from Open MRI scans of the participating subjects when they were sitting on a rubber tire in the MRI, with their soft tissues being unloaded under the ischial tuberosities (Linder-Ganz et al. 2008, 2009)

Fig. 151.5 (continued) simulations, the DTI first appears after 15 min of continuous sitting and is increasing monotonically in size to about 10% of the total gluteus muscle volume, until approximately 75 min, where it quickly escalates to occupy 53% and 74% of the muscle volume at 90 and 110 min, respectively. It was assumed in these simulations that the glutei muscles are 70% atrophied (that is, 70% of the normal muscle mass was lost), that the radius of curvature of the ischial tuberosities is 11 mm, and that the buttock is seated on a cushion with stiffness of 100 kPa

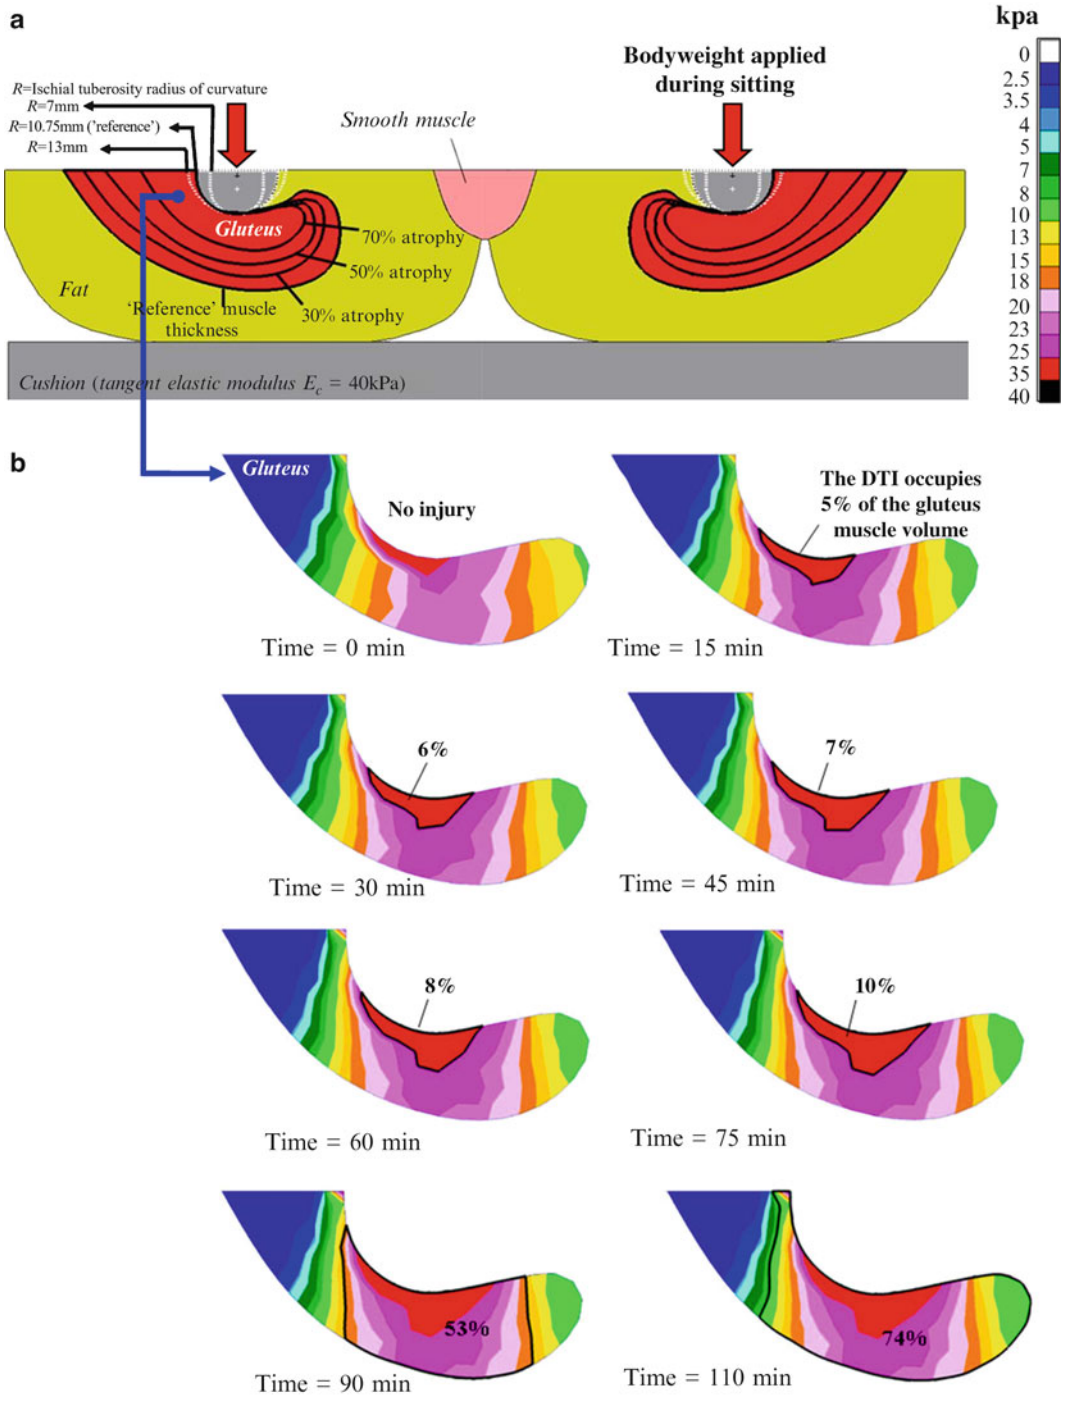

Fig. 151.5 Computer simulations of a deep-tissue injury (*DTI*) occurring in a severely atrophied gluteus muscle as a result of prolonged sitting with no relief of the bodyweight loads. (**a**) The biomechanical model, which included a time-dependent cell-death injury threshold for skeletal muscle and was able to represent different degrees of muscle atrophy (Linder-Ganz and Gefen 2009). (**b**) The resulted distributions of internal mechanical stresses in the gluteus at different time points over a total simulated time of 110 min are depicted using a color scale, and the computer-predicted boundaries of the DTI are marked at each time point (equal to or over 15 min) using *solid lines*. In this set of

markedly resemble DTI shapes in humans, which were recently characterized by means of computed tomography and ultrasound imaging (Ohura et al. 2007). The biomechanical FE modeling analyses of Linder-Ganz and Gefen (2009) have identified the level of muscular atrophy as being the most important predictor of the rate and final extent of the DTI (Fig. 151.5), with a thinner muscle predicting a faster injury, which results in a larger percentage of non-viable muscle tissue. Moreover, some simulations of severe muscle atrophy levels, particularly those representing loss of over 50% of the gluteal muscle mass, showed concurrent DTI-onset events at multiple sites that fused with time to form a larger wound. The final extent of tissue damage over a long time, over 90 min, grew exponentially with the degree of loss of muscle thickness.

151.4 Sharpness of Loaded Bony Prominences

In their Open MRI study, Linder-Ganz et al. (2008) compared the radius of curvature of the IT bones, which were scanned during sitting, between their groups of subjects with SCI and controls ($n = 6$ in each group). Interestingly, the IT radii of curvature were approximately 1.6-times higher in the paraplegics compared with controls ($p < 0.01$, Table 151.2), indicating significant changes in bone structure in addition to the soft-tissue changes discussed earlier, due to the chronic sitting in the SCI group. Similarly to the muscle-thickness data, the IT curvature data from the SCI group also generally indicated that changes in IT shape became more pronounced with the time post-SCI.

Linder-Ganz and Gefen (2009) further studied the effect of the surface curvature of the IT, the 'IT sharpness', on the predicted prognosis of DTI, using FE computer simulations employing the model in Fig. 151.5. They reported that the resulting data were more difficult to interpret than those pertaining to the effect of the muscle thickness under the IT. Specifically, an IT bone with a larger radius, namely, a 'flattened' IT, eventually resulted in a wider damage region in the muscle post 90 minutes, despite the fact that more 'sharp' IT bones induce higher peak mechanical stress values during sitting (Linder-Ganz and Gefen 2009). Injury rate analyses of Linder-Ganz and Gefen (2009) further showed that a flattened IT produced the damage faster than a sharp IT. This is consistent with the previously reported results of Gefen (2007b), who employed a simpler, analytical modeling approach that indicated an increase in the extent of injury for larger IT radii at long times, over 2 h. To summarize this point, although a sharper weight-bearing IT appears to induce higher localized mechanical stresses in muscle tissue overlying the IT during sitting, these stress concentrations are confined to a relatively small area adjacent to the bones (Linder-Ganz and Gefen 2009). Accordingly, if a DTI develops under sharp IT, it will occupy a relatively small volume of muscle tissue (less than 10% of the total volume), at least during the first hour after the DTI onsets (Fig. 151.5). However, flattened IT bones load a larger part of the glutei muscles when they bear the bodyweight, and if muscle stresses exceed critical levels (specified in Linder-Ganz and Gefen 2009), for example, if the muscle is atrophied and thin, and/or if a rigid support is used, the size of the resulting DTI is eventually greater (Linder-Ganz and Gefen 2009). The fact that larger muscle-tissue volumes are affected by a flattened IT and become necrotic activates a positive feedback that spreads the injury faster, as the large necrotic-tissue volumes become stiffer, and, therefore, produce significant inhomogeneities in the tissue material, which accelerate the injury spiral (Linder-Ganz and Gefen 2004; Gefen et al. 2005). The more detrimental effect of a flattened IT with respect to a sharp IT, as found in the Linder-Ganz and Gefen (2009) study, is highly relevant to the clinical setting, considering that individuals with SCI tend to have flattened IT shapes compared with controls (Table 151.2), likely owing to bone loss and shape adaptation. Individuals with SCI whose ITs are flattened might therefore become more prone to massive DTI, in the sense that if the DTI onsets, it will spread faster and will eventually

occupy a larger percentage of volume of their muscle tissues. Taken together, the findings of Linder-Ganz and Gefen (2009) indicate that loss of muscle mass per se is a major risk factor for DTI in patients who are chairfast (and likely, also in those who are bedfast), but IT bone loss and shape adaptation of the IT, which were both previously observed experimentally in subjects with SCI (Linder-Ganz et al. 2008), are associated with faster occurring, more severe DTI. Accordingly, both muscle atrophy and hard-tissue changes appear to contribute to the higher susceptibility of SCI patients to DTI.

151.5 Applications to Other Areas of Health and Disease

Many believe that PU and DTI are a problem restricted to the elderly population and particularly to patients at the end of their life. While elderly, especially bedfast or chairfast elderly, are indeed at high risk, there are many other populations of young individuals, who are at high risk. These include individuals with SCI, those with a serious neurological or neuromuscular disease (such as multiple sclerosis or amyotrophic lateral sclerosis), patients who are admitted for orthopedic or cardiovascular surgeries, and even pediatric patients who cannot move freely or who are connected to tubing for long periods (e.g., for ventilation or intravenous drug administration). With an ever-growing elderly population, the impact of PU and DTI on human society is expected to escalate quickly over the next few years, and this necessitates development of screening measures to identify patients who are at the greatest risk, so that attention of the medical staff can be prioritized to giving them preventive care. The quickest, most economical means for such screening, which could become available through nearly all nurses in clinical settings, are classic anthropometric measures, such as BMI and adiposity. More complex anthropometric measures, requiring some imaging technology, for example, ultrasound, could also be employed in the screening process where possible, to identify, for instance, patients with either thin musculature or irregularly sharp/flat IT. New risk-assessment procedures that are specific to DTI should therefore include such anthropometric measures and weigh them in the calculation of risk scores in order to lower the prevalence of DTI in the large number of susceptible populations. Finally, much of the contents of this chapter were focused on overweight and obesity as anthropometric measures which indicate a greater risk for DTI. Bariatric medicine, the branch in medicine that deals with obesity and its complications, is a relatively young field of medical expertise, which is growing day by the day, corresponding to the rise in sizes of populations of obese individuals in Western countries. In this chapter, it has been well demonstrated that bariatric patients are especially susceptible to DTI because of the high mechanical loads that are developed internally in their soft tissues at weight-bearing postures, such as sitting. Hence, the data presented in this chapter are important to several branches in medicine where PU and DTI are relevant, including rehabilitation, gerontology, neurology, and bariatrics.

151.6 Practical Methods and Techniques

Though BMI is a relatively simple anthropometric measure to record in large population studies of DTI, internal anthropometric data, for example, thicknesses of the glutei muscles and radii of curvature of the IT, are more complicated to obtain. In the present chapter, these internal anthropometric data were derived from MRI scans, which provide high accuracy but might not be economical in large population studies or as a clinical routine to conduct risk assessments for DTI. However, if measurements of

thickness of the glutei muscles and radius of curvature of the IT are obtained by means of ultrasound, they can be integrated into large population studies at reasonable costs. Ultrasound measurements of muscle thickness and bone curvature can also be included in new cost-effective risk-assessment scales for DTI, in facilities such as nursing homes, community clinics, small hospitals, and rehabilitation centers where, even in the future, it may appear either impractical or too expensive to conduct MRI scans. The potential for employing ultrasound scans in DTI risk assessments is discussed in detail in Gefen (2008).

Summary Points

- Deep-tissue injury is a serious category of pressure ulcers. A DTI onsets in skeletal muscle tissue overlying load-bearing bony prominences and then progresses subdermally until skin breakdown occurs.
- This chapter reviewed some key anthropometric characteristics that raise the risk for development of DTI by increasing the internal mechanical loads transferred to gluteal skeletal-muscle tissue of the seated buttocks via the IT, which were used herein as an example to study the bone–muscle interactions.
- The specific anthropometric characteristics referred to in this chapter were the bodyweight and BMI, and, internally, the thickness of the glutei muscles and the curvature of the IT.
- It was shown that obesity (defined as BMI ≥ 30 kg/m^2) and disuse atrophy (loss of over 30% of the gluteal muscle volume or reduction exceeding 50% in thickness under the IT), which are typical of the chronic phase of spinal cord injuries, each contributes to the state of elevated muscle loads.
- When obesity and muscle atrophy coexist, internal loads in muscle tissue under the IT escalate substantially. Hence, obesity and reduced gluteal muscle-tissue thickness are anthropometric features that biomechanically increase the risk for a DTI.
- Loss of bone tissue mass, which is also known to occur during the years after an SCI, affects the shape and curvature of the IT, and gradually flattens them. Flattened ITs were associated herein with a faster occurring, more severe DTI.
- The anthropometric information presented in this chapter is important to several branches in medicine where PU and DTI are relevant, including rehabilitation, gerontology, neurology, and bariatrics.
- In particular, the present anthropometric information is useful for formulating risk-assessment scales, in order to screen patients admitted to hospitals, rehabilitation centers, or nursing homes and identifying the ones most susceptible to DTI, so that the occurrence of these dreadful wounds can be minimized.

Chapter 152
Anthropometry in the Assessment of HIV-Related Lipodystrophy

Giovanni Guaraldi, Stentarelli Chiara, Stefano Zona, and Bruno Bagni

Abstract Infection with HIV causes a spectrum of clinical problems. Abnormalities in body composition have been reported in 40–50% of ambulatory HIV-infected patients.

Progressive, involuntary weight loss is an AIDS-related metabolic disorder called "wasting syndrome". Its etiology in untreated HIV infection, is multifactorial. This condition is still common in developing countries while is much more rarely seen in industrialized countries.

Indeed, in the late 1990s, reports of unusual changes in body fat distribution named "Lipodystrophy" began to appear in HIV patients. This syndrome includes peripheral fat loss (lipoatrophy; LA), central fat accumulation (lipohypertrophy; LH) separately present or in combination in the same individual (mixed forms). In this clinical condition, abnormal fat accumulation is observed in intra-abdominal region, as well as in subcutaneous area of the cervical, retroauricolar, dorsal and pubic region. Abnormal fat loss is observed from the arms and legs, face, and buttocks. The driving force behind lipoatrophy is undoubtedly the cumulative exposure to thymidine analogue (TA) drugs. Risk factors for fat accumulation, on the contrary, are still obscure.

The absence of a clear-cut definition unavoidably has led to uncertainty about changes in prevalence and incidence of lipodystrophy over time. The absence of a precise definition of lipodystrophy suggested the need for regulatory consideration for its anthropometric measurement and the choice of objective treatment goals.

Objective lipodystrophy (LD) measurement tools analysed refer to general anthropometry evaluation (BMI, Waist girth and waist to hip ratio), as well as to radiological evaluation for lipoatrophy or fat accumulation (Ultrasound, Dual Energy X-ray absorptiometry, abdomen and limb Computed Tomography or Magnetic Resonance). Given that lipoatrophy and fat accumulation may coexist in the same individual, radiological tools for measuring both these changes are needed for the assessment of the same individual analysing at the same time the degree of lipoatrophy in the limbs and fat accumulation in the visceral area: lipoatrophy is measured with Dual Energy X-ray absorptiometry (DXA); fat accumulation is usually measured with lumbar computed tomography (CT) or with Magnetic resonance Imaging (MRI). Several studies have investigated changes in body composition that occur in HIV-infected individuals.

There are also some relevant clinical implications of body fat changes in HIV: morphological changes induced by HIV-related lipodystrophy profoundly affect body image and influence health-related quality of life. Additionally, HIV infection and elevated VAT are significantly associated, linking HIV and VAT to inflammatory events and to an increased cardiovascular risk.

Abbreviations

AIDS	Acquired immunedeficiency syndrome
ART	Active antiretroviral therapy
BIA	Bio-impedentiometry
BMI	Body mass index
CRP	C-reactive protein
CAC	Coronary calcium score
CI	Confidence Interval
CT	Computed tomography
CV	Cardiovascular
CVD	Cardiovascular disease
DM	Diabetes mellitus
DXA	Dual Energy X-ray absorptiometry
FRAM	Fat Redistribution and Metabolic Change in HIV Infection
LA	Lipoatrophy
LD	Lipodystrophy
LH	Lipohypertrophy
MRI	Magnetic resonance imaging
OR	Odds ratio
PI	Protease inhibitor
SAT	Subcutaneous fat mass
SKF	Skin fold assessment
TA	Thymidine analogue
VAT	Visceral adipose tissue
WC	Waist circumference
W/H	Waist to hip ratio

Infection with HIV causes a spectrum of clinical problems beginning at the time of seroconversion and terminating with AIDS and death. It is now recognized that it may take 10 years or more for AIDS to develop after seroconversion.

The progression of HIV infection is a result of a decline in immune competence that occurs due to increased replication of HIV, clinically evident with constitutional symptoms including malaise, fevers, night sweats, weight loss, and diarrhea.

Progressive, involuntary weight loss reflects the adverse effect of HIV on nutritional status.

The etiology of weight loss and wasting in untreated HIV infection is multifactorial and may include decreased dietary intake, malabsorption, opportunistic infection or malignancy, or an increased expenditure of energy (Coodley et al. 1994).

This AIDS-related metabolic disorder is called ‘wasting syndrome’ and is characterized by a decrease in lean body mass, fat body mass, and intracellular water volume, as assessed with bioimpedentiometry.

HIV-associated wasting is clinically defined as a patient meeting one of the following (Wanke et al. 2002): loss of 10% of body weight in 1 year, loss of 5% of body weight in 6 months (between two study visits), and a decrease in BMI to <20 kg/m^2.

This condition is still common in developing countries where antiretroviral treatment is limited, though it is much more rarely seen in industrialized countries, where a decrease in viral load in response to the introduction of antiretroviral therapy often corresponds to a complete or partial resolution of constitutional symptoms and weight recovery.

In the late 1990s, reports of unusual changes in body fat distribution named 'lipodystrophy' began to appear in HIV patients, mitigating the enormous enthusiasm about improvement of survival and quality of life provided by highly active antiretroviral therapy (ART), which had just become available at that time. This syndrome includes peripheral fat loss (lipoatrophy; LA), central fat accumulation (lipohypertrophy; LH) separately present or in combination in the same individual (mixed forms), usually, but not invariably, associated with alterations of lipid metabolism, and derangement of insulin sensitivity and diabetes mellitus (Carr et al. 1998).

In this clinical condition, abnormal fat accumulation is observed in the intra-abdominal region, (Engelson et al. 1999; Miller et al. 1998) (Fig. 152.2–152.3), as well as in the subcutaneous area of the cervical, retroauricolar, dorsal, and pubic regions (Lo et al. 1998). Abnormal fat loss is observed from the arms and legs, face, and buttocks (Carr et al. 1998; Bacchetti et al. 2005; Lichtenstein et al. 2003) (Fig. 152.4–152.6).

Abnormalities in body composition have been reported in 40–50% of ambulatory HIV-infected patients (Lichtenstein et al. 2001); the proportion is greater in those receiving combination antiretroviral therapy. Prevalence rates vary widely, from 11% to 83%, in cross-sectional studies (Carr et al. 1999). Lipoatrophy rates may be even higher, depending on the characteristics of the cohort (sex, age, and possibly race), the type and duration of antiretroviral therapies, the criteria for changes in body composition, and the comparison population.

The absence of a clear-cut definition has led unavoidably to uncertainty about changes in prevalence and incidence of lipodystrophy over time (Carter et al. 2001).

The contributing factors are CD4+ lymphocyte cell count, HIV clinical stage, race, sex, exercise level, and age at the start of antiretroviral therapy (Lichtenstein et al. 2001), but the driving force is undoubtedly the cumulative exposure to thymidine analog (TA) drugs. These drugs, in particular, stavudine and to a lesser extent zidovudine, antagonize mitochondrial DNA polymerase function resulting in apoptosis of fat cells. Risk factors for fat accumulation, on the contrary, are still obscure and are not directly related to the use of any antiretroviral drugs.

Earlier detection and treatment of HIV infection (Kitahata et al. 2009), as well as the use of antiretroviral drugs with less deleterious effects on body fat, make it reasonable to hypothesize a decrease in prevalence of lipodystrophy in the coming years.

Decreasing thymidine analog (TA) use, the leading risk factor for LA development and, moreover, the availability of new drugs and drug classes that allow treatment scenarios where a TA-based backboneparadigms is over, as well as the effort for earlier detection and treatment of HIV infection (Kitahata et al. 2009), reasonably lead to the same hypothesis.

Few epidemiological data exist to verify this so far. A Swiss HIV Cohort Study recently reported a reduced likelihood, by life-table Kaplan–Meier analysis, of lipodystrophy development in patients who started ART between 2003 and 2006 compared with those who started ART between 2000 and 2002, coinciding with decreased rates of TA use, mainly stavudine. Unluckily, the study did not provide any objective assessment of body fat changes (Nguyen et al. 2008).

In the same time period, epidemiological data from the southern hemisphere demonstrated an opposite trend toward an emerging epidemic of lipodystrophy in those countries. In a study from Rwanda, lipodystrophy was observed in 34% of subjects, with prevalence increasing to 69.6% in those receiving ART for 72 weeks. Peripheral LA combined with abdominal LH was observed in

72% of lipodystrophy subjects (Mutimura et al. 2007). In a more recent case-control study from Senegal, the prevalence of moderate–severe lipodystrophy was 31.1%, with 13.3%, 14.5%, and 3.3% for LA, LH, and mixed forms, respectively. The overall prevalence of lipodystrophy was 65.0% and stavudine was the only independent risk factor (Mercier et al. 2009). In both these studies, lipodystrophy was only clinically assessed, and body fat changes not unexpectedly coexisted with abnormalities of glucose and lipid metabolism.

The absence of a precise definition of lipodystrophy suggested the need for regulatory consideration for its anthropometric measurement and the choice of objective treatment goals.

Objective LD measurement tools analyzed refer to general anthropometry evaluation (BMI, waist girth, and waist-to-hip ratio), as well as to radiological evaluation for lipoatrophy or fat accumulation (ultrasound, DEXA, and abdomen and limb CT or MRI).

The body mass index (BMI) is a crude index (kg/m^2) of overall body fatness, and it is commonly used in large-scale epidemiological surveys and clinical settings to classify individuals as obese, overweight, or underweight (respectively, BMI >30; >25; <18.5) (Joy et al. 2008).

This index has limited value in evaluating LD, given that most HIV-infected patients have BMI within the normal range but may have a significant alteration of body fat component, with a characteristic body fat redistribution pattern from periphery to central accumulation.

Waist-to-hip ratio (W/H) is commonly used as an indirect measure of lower- and upper-body fat distribution. Given that most HIV patients with LD may have severe fat loss in the buttock region, this index appears to be less reliable than waist circumference (WC) to assess intra-abdominal (visceral) fat deposition and appears to be less influenced by age, gender, height, and degree of overall adiposity. WC is highly related to MRI and CT measures of visceral fat in men and women and to cardiovascular risk factors.

The skinfold assessment (SKF) is a measure of the thickness of the two layers of skin and the underlying subcutaneous fat. This measurement is considered not useful in the assessment of patients with LD, because, in this clinical condition, it does not appear to have any reliable relationship between subcutaneous fat and total body fat; for this reason, the sum of several SKFs cannot be used to estimate total body fat. For the same reason, bioimpedentiometry (BIA) (a function of resistance and reactance to current flow through the body) is of limited use in LD evaluation.

152.1 Radiological Tools for Assessing Lipodystrophy

Given that lipoatrophy and fat accumulation may coexist in the same individual, radiological tools for measuring both these changes are needed for the assessment of the same individual, analyzing at the same time the degree of lipoatrophy in the limbs and fat accumulation in the visceral area. For both these measurements, there are no defined cutoff values and results are best considered in longitudinal evaluation using each patient as control for themselves (Mallon et al. 2003; Dube et al. 2007; Martin et al. 2004).

1. Lipoatrophy is measured with dual energy X-ray absorptiometry (DXA), which is based on the attenuation of two different X-ray energies as they pass through tissues having different densities and chemical compositions. DXA estimates of whole-body composition are based on a three-component tissue model (fat mass/bone mineral density/bone-free lean mass) (Smith et al, 2003; Podzamczer et al, 2007; Mallal et al, 2000; Delpierre et al, 2007).
   DXA of the limbs measures the total fat mass of the limbs or the ratio of the limbs' fat mass over the total limb mass as surrogate markers for lipoatrophy.
2. Fat accumulation is usually measured with lumbar computed tomography (CT) or with magnetic resonance imaging (MRI). CT is a radiographic method that measures the differences in the

attenuation (or the weakening) of X-ray beams as they pass through the participant. It allows for separate recognition of bone, adipose tissue, and lean tissue. It is usually limited to regional assessment. MRI creates a computer-generated image from radiofrequency signals emitted by hydrogen nuclei. CT and MRI measure body composition at the tissue level and are the preferred methods for separating total adipose tissue into its subcutaneous and visceral components.

Fat accumulation is measured in the abdominal area using the fourth lumbar vertebra as the anatomic reference. The absolute value of visceral adipose tissue or the ratio of VAT over the sum of subcutaneous fat mass (SAT) and the VAT (total fat mass – TAT) is used as a surrogate for fat accumulation (Andrade et al. 2002; Bacchetti et al. 2005; Saint-Marc et al. 2000).

Several studies have investigated changes in body composition that occur in HIV-infected individuals. The Fat Redistribution and Metabolic Change in HIV Infection (FRAM 2006) study compared fat distribution between HIV-infected individuals and HIV-negative controls and revealed a greater degree of fat loss in peripheral and most central depots among HIV-infected men and women when compared with controls (Bacchetti et al. 2005).

Peripheral lipoatrophy can be considered a consistent finding among HIV-infected men and women with metabolic abnormalities.

Importantly, the FRAM study and several recent studies have shown that peripheral lipoatrophy is not linked to central lipohypertrophy in most HIV-infected individuals (Bacchetti et al. 2005, 2006; Mulligan et al. 2006). Weight itself may influence the amount of adipose tissue present, however, and there may be differences in VAT, SAT, and regional body adipose measurements within specific anthropometric categories.

Relative increases in VAT are most pronounced among male and female HIV-infected subjects in the normal weight and overweight categories.

Gender differences in abdominal SAT accumulation are observed, with preservation of SAT among HIV-infected women relative to control subjects (Joy et al. 2008).

With HAART initiation, HIV-infected patients often demonstrate increases in weight and trunk and limb fat over the first 16–24 weeks of therapy (Mallon et al. 2003; Gallant et al. 2004). Subsequently, whereas amounts of trunk fat generally stabilize, limb fat frequently decreases progressively over time, which is most closely correlated with stavudine exposure (Mallon et al. 2003; Gallant et al. 2004). Mallon, for example, reported a 13.6% decrease per year in limb fat after the initial 24 weeks of stavudine containing HAART over 96 weeks among 40 HIV-infected men initiating therapy (Mallon et al. 2003). The stability of these body composition changes after prolonged HAART is unknown. In addition, the extent to which body composition changes occur as a result of aging or HIV infection per se is unknown.

A forum for collaborative HIV-related lipodystrophy research [http://www.hivforum.org/storage/hivforum/documents/Liporegfinal.pdf] was held at the 6th International Workshop on Adverse Drug Reactions and Lipodystrophy in HIV on October 27, 2004, in Washington, DC. The main goals of this document were to review the types of lipodystrophy and recommend methods of objective and subjective measurement so as to be able to advocate entry criteria for clinical trials, based on the type of lipodystrophy. These recommendations identify surrogate markers for different LD phenotypes:

152.2 Facial Lipoatrophy

Up to now, there is neither a standardized available tool to measure facial-pad thickness nor clear facial reference points that could be of use in the clinical setting. The severity of facial lipoatrophy has been established using a photo-comparison grading scale. It should be stressed that the buccal

fat pad has a minor role in facial appearance and does not have a concrete area in superficial anatomy. For this reason, ultrasound evaluation of the cheek is a controversial endpoint in plastic facial-reconstruction surgery.

Entry into a clinical trial should be decided by the patient and the physician, based on subjective determination of the presence of facial lipoatrophy not caused by HIV wasting.

Effectiveness of treatment should be based on (1) objective measurements of fat restoration, for example, by ultrasound and photograph and (2) subjective determination of satisfactory improvement on the part of the patient and the physician.

152.3 Peripheral Lipoatrophy

Entry into a clinical trial should be decided by both the patient and the physician, most likely based on a subjective determination of peripheral fat loss and, if possible, an objective DEXA measurement indicating less than 8 kg of peripheral limb fat or a 25% loss of limb fat compared to population normal values (although normal values are not available for all population types).

Effectiveness of treatment should be based on objective DEXA measurements. The percentage of increased fat that will indicate effectiveness of a treatment will depend on the baseline value.

152.4 Visceral Adiposity

Entry into a clinical trial should be based on objective waist circumference and waist-to-hip ratio measurements and, to a lesser extent, on patient and physician selection depending on a subjective determination of increased truncal fat.

Early trials should recruit subjects with body mass indices in the overweight or obesity range.

Effectiveness of treatment should be based on CT scans at the L4–L5 level (a direct measure of visceral adipose tissue [VAT] and the preferred measurement), DEXA scans (a measure of truncal fat, i.e., VAT plus subcutaneous abdominal fat), and objective anthropometry, such as waist-to-hip ratio. Induction of satisfactory efficacy after at least 3 months of treatment and durability of efficacy after at least six additional months of treatment should be demonstrated. Inclusion of quality-of-life outcomes assessed by validated instruments is strongly recommended. All studies should be placebo controlled.

152.5 Clinical Implications of Body Fat Changes in HIV

Morphological changes induced by HIV-related lipodystrophy profoundly affect body image and influence health-related quality of life. Additionally, HIV infection, elevated VAT, and elevated C-reactive protein (CRP) are significantly associated, linking HIV and VAT to inflammatory events.

The adipocyte has shifted from being a passive storage cell for triglycerides to a secretory organ of adipokines, such as leptin, adiponectin, and inflammatory factors, such as tumor necrosis factor alpha. The role of lipodystrophy and central adiposity and visceral adipose tissue, in particular, VAT, in cardiovascular (CV) and diabetes mellitus (DM) risk, has been recognized independently and through the metabolic syndrome (Balkau et al. 2007).

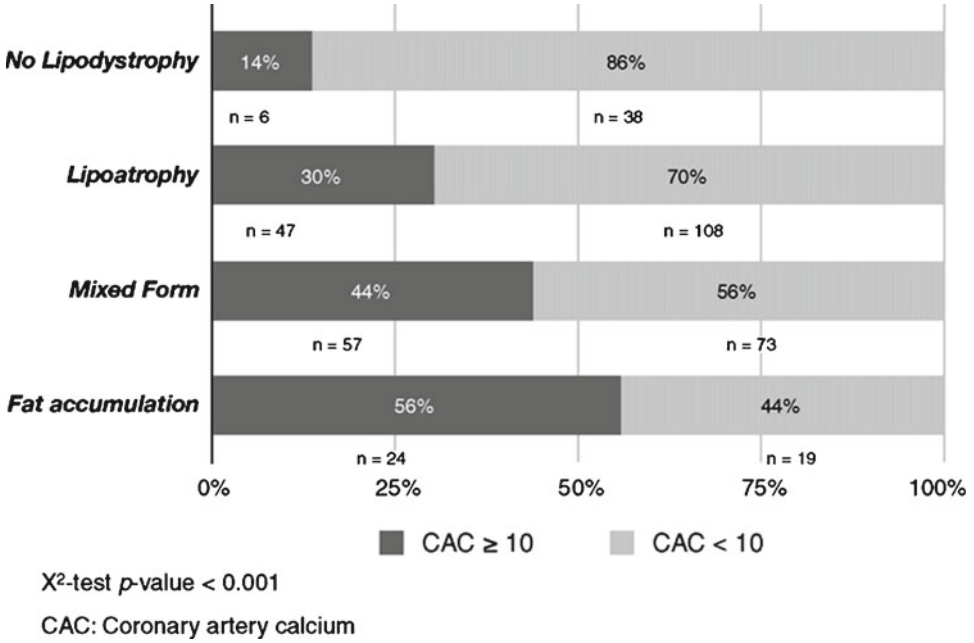

Fig. 152.1 Prevalence of coronary artery calcium score >10 in different phenotypes of lipodystrophy and in its absence

There is widespread concern that the metabolic and morphological abnormalities in HIV-infected patients lead to an increased risk of cardiovascular disease. Some observational studies suggest an increased risk of cardiovascular disease among HIV-infected patients compared with the general population.

The extent of the increased risk of cardiovascular disease in this population and its association with factors related to HIV infection, antiretroviral therapy, and its metabolic consequences are topics of intense investigation. In the recent years, cardiology taught us that a combination of blood serum biomarkers of atherosclerosis and inflammations and vascular markers may constitute a better way to identify people vulnerable to cardiovascular disease. Silent plaque imaging assessed with coronary calcium score (CAC) may be able to globally define a patient's CVD event risk by virtue of its strong association with total coronary atherosclerotic disease burden. CAC score is the strongest predictor of subsequent CVD and, recently, it has been shown that slowing the coronary artery calcification process will translate into a reduced risk of events (as previously demonstrated with regression of luminal stenosis in angiographic trials).

The contribution of chronic HIV infection, ART use, and LD to the presence of subclinical atherosclerosis as evaluated by coronary artery calcium (CAC) imaging was assessed in an observational cross-sectional study of 372 HIV-infected patients receiving ART attending Modena's University cardiometabolic clinic. Presence of CAC defined as a score >10 was found in 134 patients (36%) with a median CAC score of 50 (range 10; 1,243). Lipoatrophy alone (OR 3.82, 95% CI: 1.11; 13.1), fat accumulation alone (OR 7.65, 95% CI: 1.71; 37.17), and mixed lipodystrophy phenotypes (OR 4.36, 95% CI: 1.26; 15.01) were strongly associated with presence of CAC after adjusting for age, sex, hypertension, and cumulative exposure to ART (Fig. 152.1) (Guaraldi et al. 2009).

The prospective extension of this study analyzing predictors of progression of CAC in 132 patients who underwent two sequential CT scans (median follow-up time 333 days) showed that probability of CAC progression in the follow-up period was independently related with any single year of age

increase, any 10 mg of increase of LDL cholesterol, any 50 cells increase of CD4 lymphocytes, and any 10 cm^3 of VAT (Fig. 152.1).

These findings may have important implications for the management of HIV-infected patients receiving long-term ART therapy and demonstrating features of LD. Such patients may be at increased risk for the development of atherosclerotic coronary artery disease and consideration should be given to switch choice of ART; furthermore, these patients may be targeted to undergo early and aggressive cardiovascular disease risk-modification strategies.

Summary Points

- Manifestations of HIV-related body fat distribution are 'wasting syndrome' and lipodystrophy. Progressive weight loss is an AIDS-related metabolic disorder called 'wasting syndrome:' this condition is actually more rarely observed in industrialized countries. The lipodystrophy syndrome includes peripheral fat loss (lipoatrophy; LA) and central fat accumulation (lipohypertrophy; LH) present separately or in combination in the same individual (mixed forms), and this is considered to be a side effect of antiretroviral therapy.
- *Objective lipodystrophy (LD) measurement tools*: They refer to general anthropometry evaluation (BMI, waist girth, and waist-to-hip ratio), as well as to radiological evaluation for lipoatrophy or fat accumulation (ultrasound, dual energy X-ray absorptiometry, and abdomen and limb computed tomography or magnetic resonance).

  WC is highly related to magnetic resonance imaging and computed tomography measures of visceral fat in men and women and to cardiovascular risk factors.
- *Lipoatrophy*: Lipoatrophy is measured with dual energy X-ray absorptiometry (DXA); DXA of the limbs measures the total fat mass of the limbs or the ratio of the limbs fat mass over the total limb mass as surrogate markers for lipoatrophy.
- *Fat accumulation*: Fat accumulation is usually measured with lumbar computed tomography (CT) or with magnetic resonance imaging (MRI). CT is a radiographic method that measures the differences in the attenuation (or the weakening) of X-ray beams as they pass through the participant. It allows for separate recognition of bone, adipose tissue, and lean tissue.
- Several studies have investigated changes in body composition that occur in HIV-infected individuals.

  The Fat Redistribution and Metabolic Change in HIV Infection (FRAM 2006) study compared fat distribution between HIV-infected individuals and HIV-negative controls and revealed a greater degree of fat loss in peripheral and most central depots among HIV-infected men and women when compared with controls.

  Importantly, the FRAM study and several recent studies have shown that peripheral lipoatrophy is not linked to central lipohypertrophy in most HIV-infected individuals.

  Relative increases in VAT are most pronounced among male and female HIV-infected subjects in the normal weight and overweight categories.

- Recommended entry criteria for clinical trials are based on the type of lipodystrophy. These recommendations identify surrogate markers for different LD phenotypes: for example, an objective DEXA measurement for peripheral lipoatrophy indicates less than 8 kg of peripheral limb fat or a 25% loss of limb fat compared to population normal values.

Key Points

- HIV is an infection that results in an impaired immune system. AIDS is the end stage of HIV and wasting is a major prognostic marker from mortality in this disease.
- Lipodystrophy is a fat-redistribution syndrome characterized by thinning in extremities but increased fat in the trunk. This is a side effect of antiretroviral therapy against HIV infection.
- Why is the use of anthropometric technique so relevant in HIV infection?
- Because body changes are strongly linked to mortality;
- Because studying anthropometric alterations can give insight into the knowledge of drug toxicities; and
- Because body fat changes profoundly affect body image and consequently health-related quality of life.

Chapter 153
Use of Anthropometry in Monitoring the Nutritional and Health Status of Persons Living with HIV/AIDS

Selby Nichols, Nequesha Dalrymple, and Marlon Francis

Abstract Approximately 33 million persons are living with HIV/AIDS globally. Majority of these persons living with HIV/AIDS (PLWHA) reside in low and middle income countries where there is a scarcity of resources to deal with the magnitude of the problems associated with this HIV/AIDS pandemic. Weight loss is common feature of HIV/AIDS. In fact, the extent of this weight loss is a reasonable predictor of the morbidity and mortality among PLWHA. Malnutrition in PLWHA results from several factors. Among these are changes in metabolism resulting in increased utilization of nutrients, mal-absorption of nutrients associated with the frequent diarrheas and reduced dietary intakes due to nausea and vomiting, inability to swallow, and reduced access to nutritious foods. Malnutrition and HIV/AIDS act in a synergistic manner to accelerate and perpetuate the deleterious effect of the latter. HIV/AIDS is associated with deficiencies of zinc, vitamins B, C, E, proteins and calories. Consequently, PLWHA tend to exhibit clinical symptoms that are relatively similar to those associated with macro and micronutrient deficiencies. More recently, HIV/AIDS has been associated with unhealthy lipid profiles, especially among those on Highly Active Anti-Retroviral Therapy (HAART). While nutritional status cannot be measured directly, there are several anthropometric measures that can provide useful information on aspects of the nutritional status of PLWHA. To ensure accuracy of the data generated, anthropometric measures of nutritional status in PLWHA should be highly sensitive, specific and have good predictive values. They should also be simple to use, relatively inexpensive, acceptable to PLWHA, non-invasive, easy to interpret by all categories of workers in the health care system and applicable to all stages of the life cycle from infancy to adulthood. Among the anthropometric measures fulfilling these criteria are weight, height, weight-for-age (WA), weight-for-height (WH), body mass index (BMI), mid upper arm circumference (MUAC), skinfold thickness (SF), waist circumference (WC) and waist-hip ratio (WHR). Studies suggest that several of these anthropometric measures are associated levels of immune function (e.g., CD4+, CD8+ cells counts), blood proteins levels, and anaemia. Moreover, excess weight loss is predictive of both the morbidity and mortality among PLWHA. Anthropometric indices therefore provide useful tools for monitoring and evaluating the patho-physiological changes among PLWHA. While anthropometry allow us to monitor and evaluate changes in the nutritional status of PLWHA, its greatest benefit can only be realized as part of a comprehensive monitoring strategy that includes clinical assessment and biochemical tests.

153.1 Introduction

Globally, it is estimated that there are 32.8 million persons living with HIV/AIDS (PLWHA). Additionally, nearly 15 million children have lost one or both parents to the epidemic (Worldwide HIV & AIDS Statistics Commentary 2009). Moreover, majority of PLWHA reside in developing and emerging economies where there is a paucity of resources for effective management of the epidemic. While sub-Saharan Africa accounts for approximately two-thirds of PLWHA and Asia a further 20%, Latin America and the Caribbean represent regions that have experienced high rates of new infections. The impact of HIV/AIDS is felt at all levels of the society from individuals to communities and, by extension, the nation. In fact, the increasing prevalence of the epidemic among women of reproductive age and the working class has serious implications for the economies of the countries concerned. Thus, the potential socioeconomic impact of HIV/AIDS has tremendous consequences for national development, especially among developing countries (Dixon et al. 2002).

Studies in Africa have shown that HIV/AIDS can have devastating effects on a country's pool of skilled workers (Ilinigumugabo 1996; Gentilini and Chieze 1990). In the case of countries such as Mozambique and Kenya, HIV/AIDS has depleted the pool of skilled workers, such as teachers, engineers, and nurses (Gentilini and Chieze 1990). These workers usually represent key sectors of the economy that are crucial to infrastructural and human development. In turn, this can lead to a scarcity of resources needed to comprehensively manage existing cases and reduce the numbers of new infections in the population (Fig. 153.1). It is estimated that it will cost some 2.69 US$ each day to effectively treat this disease (Koenig et al. 2008; Keiser et al. 2001). This will pose a serious problem for many of the countries with the highest burden of infections, as majority of their citizens exist on less than US$ 1 per day (Bachmann and Booysen 2003). Improved nutrition remains the last bastion of hope for prolonging the quality of life and minimizing the symptoms among PLWHA even when they are on HAART (Mangili et al. 2006).

One of the hallmarks of HIV/AIDS is the weight loss that accompanies disease progression (Siddiqui et al. 2009). This is usually an indication of nutritional inadequacies and requires proper clinical management to prevent progression to severe malnutrition. Malnutrition in turn can lead to

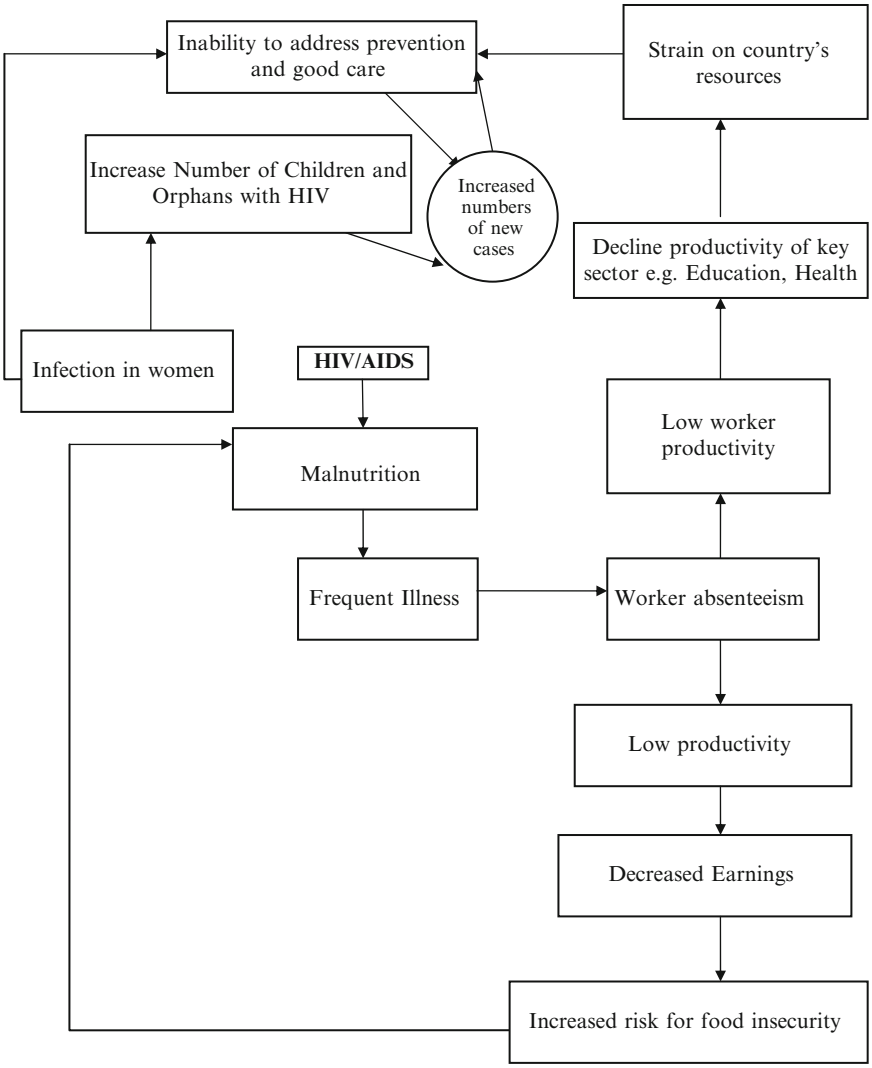

Fig. 153.1 Impact of HIV/AIDS on Society. It presents a scenario for the socio-demographic impact of HIV/AIDS leading to malnutrition and food insecurity

impaired immune function. The synergistic effects between nutrition and immune function are well known (Oguntibeju et al. 2007). HIV/AIDS also has major physiological effects on the immune system that are independent of the effects produced by the malnutrition associated with the disease. The links between malnutrition, infection, health, and development place HIV/AIDS at the center of a chain of events that have tremendous socioeconomic consequences. In this chapter, we review the pathophysiological issues in HIV/AIDS that have implications for the nutritional status of individuals. We also review the role of anthropometry in monitoring and evaluating changes in the nutritional status of PLWHA. Additionally, we will propose a framework for the use of anthropometry in the regular monitoring and evaluation of PLWHA. Finally, we present suggestions for increasing the use of anthropometry at all levels of the healthcare system.

153.2 Nutrition and HIV/AIDS

The nutritional issues in HIV/AIDS are primarily due to changes in metabolism that influence nutrient utilization, malabsorption-associated opportunistic infections, and reduction in dietary intakes resulting from a combination of factors that reduce the ability to acquire foods (Oguntibeju et al. 2007). HIV infection is accompanied by a myriad of metabolic changes. It is also associated with the production of several cytokines, such as gamma interferon, macrophage inflammatory factors, and tumor necrosis factor alpha, by $CD8^+$ cells in an attempt to rid the body of the invading virus (Migueles and Connors 2002). These cytokines modify metabolic function resulting in a hyper-catabolic state, thereby increasing the demand for nutrients (Crocker 1989). In particular, evidence suggests that there is a greater demand for energy and protein (Charlin et al. 2002; Sattler et al. 2008). This increases the risk of developing protein energy malnutrition (PEM) among PLWHA. Micronutrient deficiencies, especially deficiencies in zinc, selenium, and vitamins A, C, and E, are common in HIV/AIDS (Lanzillotti and Tang 2005). Moreover, increasing the serum level of these nutrients improves control of viral replication (Jones et al. 2006). Figure 153.2 shows the impact of HIV/AIDS with implications for nutrition.

More recently, HIV/AIDS has been shown to result in unfavorable lipid profiles (Ogunro et al. 2008). This increases the risk of cardiovascular ailments among PLWHA (Farrugia et al. 2009). HIV/AIDS also affects several organs and systems in a manner that impacts directly on nutrition (i.e., the ability to feed and effectively utilize nutrients). Systems affected include the nervous, gastrointestinal, immune, skeletal, and pulmonary systems (Timbo and Tollefson 1994). Figure 153.3 shows the impact of HIV/AIDS on body organs and systems, with implications for nutrient availability and utilization.

153.3 Wasting Syndrome and HIV/AIDS

Weight loss is characteristics of HIV/AIDS. In this respect, HIV/AIDS shares a common characteristic with PEM, cancers, and anorexia nervosa through the pathophysiological and etiological process leading to rapid weight loss (Colecraft 2008; Hoyt and Staats 1991; Kotler 1995). This similarity in weight loss suggests that anthropometric techniques for monitoring changes in nutritional status in these diseases may be applicable for monitoring nutritional status among PLWHA. Weight loss in HIV/AIDS >10% (indicative of the wasting syndrome) is associated with an increase in the risk of death. On the other hand, the increased use of antiretroviral therapy and aggressive treatments to increase weight and prolong survival has made overweight and obesity an issue that must be addressed in PLWHA. Furthermore, HAART can independently increase the risk of cardiovascular disease by its ability to increase serum lipid levels (Adeyemi 2007; Martínez et al. 2009). The clinical effects of HIV/AIDS on PLWHA go beyond issues of weight loss and nutritional status. In fact, HIV/AIDS is associated with conditions, such as diarrhea, anemia, and impaired immune status, to name a few. Table 153.1 shows the effect of HIV/AIDS on organs/systems that have important consequences for nutrition.

153.4 Use of Anthropometry in HIV/AIDS

Anthropometric measures can be used to indicate changes in the progression of HIV/AIDS (Justman et al. 2008). For anthropometric measures to be efficacious in monitoring changes in nutritional status among PLWHA, they should be sensitive, specific, easy to use, relatively cheap, and provide data that are easy to interpret by all levels of the healthcare team. They should also correlate with

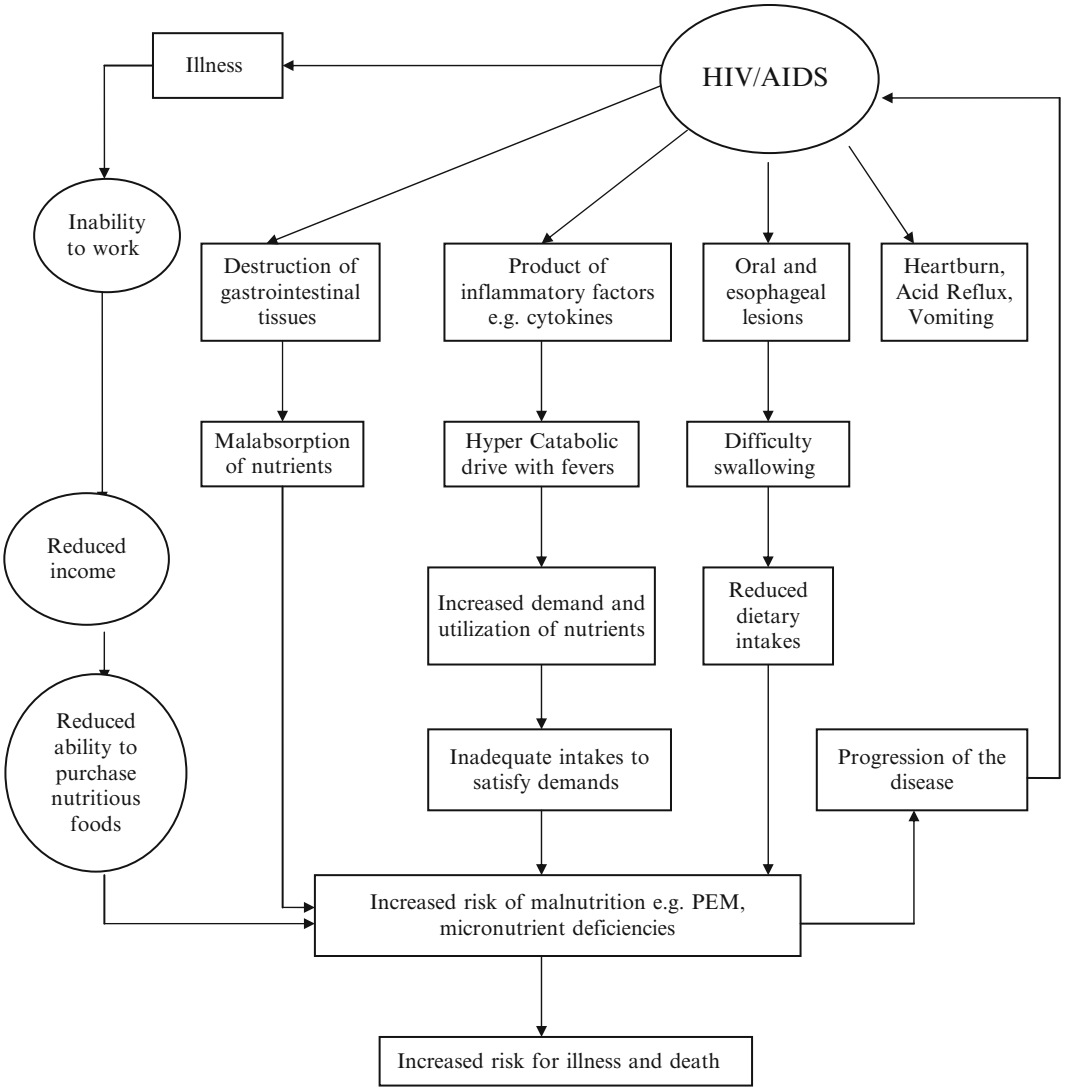

Fig. 153.2 Pathophysiology of HIV/AIDS with Implications for Nutritional Status. It shows the impact of HIV/AIDS on organs and body systems that increases the risk for illness and death

pathological changes in HIV/AIDS, should be easily accepted by PLWHA, capable of providing consistent results in field and clinical situations, and should be applicable to all stages of the life cycle (i.e. infancy to adulthood). Anthropometry provides us with a wide range of indicators of body composition and nutritional status. In this section, we review the main indicators which are of importance in monitoring and evaluating changes in body habitus associated with HIV/AIDS. Nutritional status cannot be measured directly and anthropometry is simply a proxy for this state. Other proxies include clinical assessment and biochemical markers. Consequently, it is important to interpret the information that anthropometry offers in a manner that reflects the context of the measurement. In addition, more than one indicator should be used to provide evidence of changes in the nutritional status of individuals. In fact, anthropometry should be grounded in a comprehensive plan for the monitoring and evaluation of individuals. Figure 153.4 shows a framework for incorporating anthropometry in the monitoring and evaluation of PLWHA.

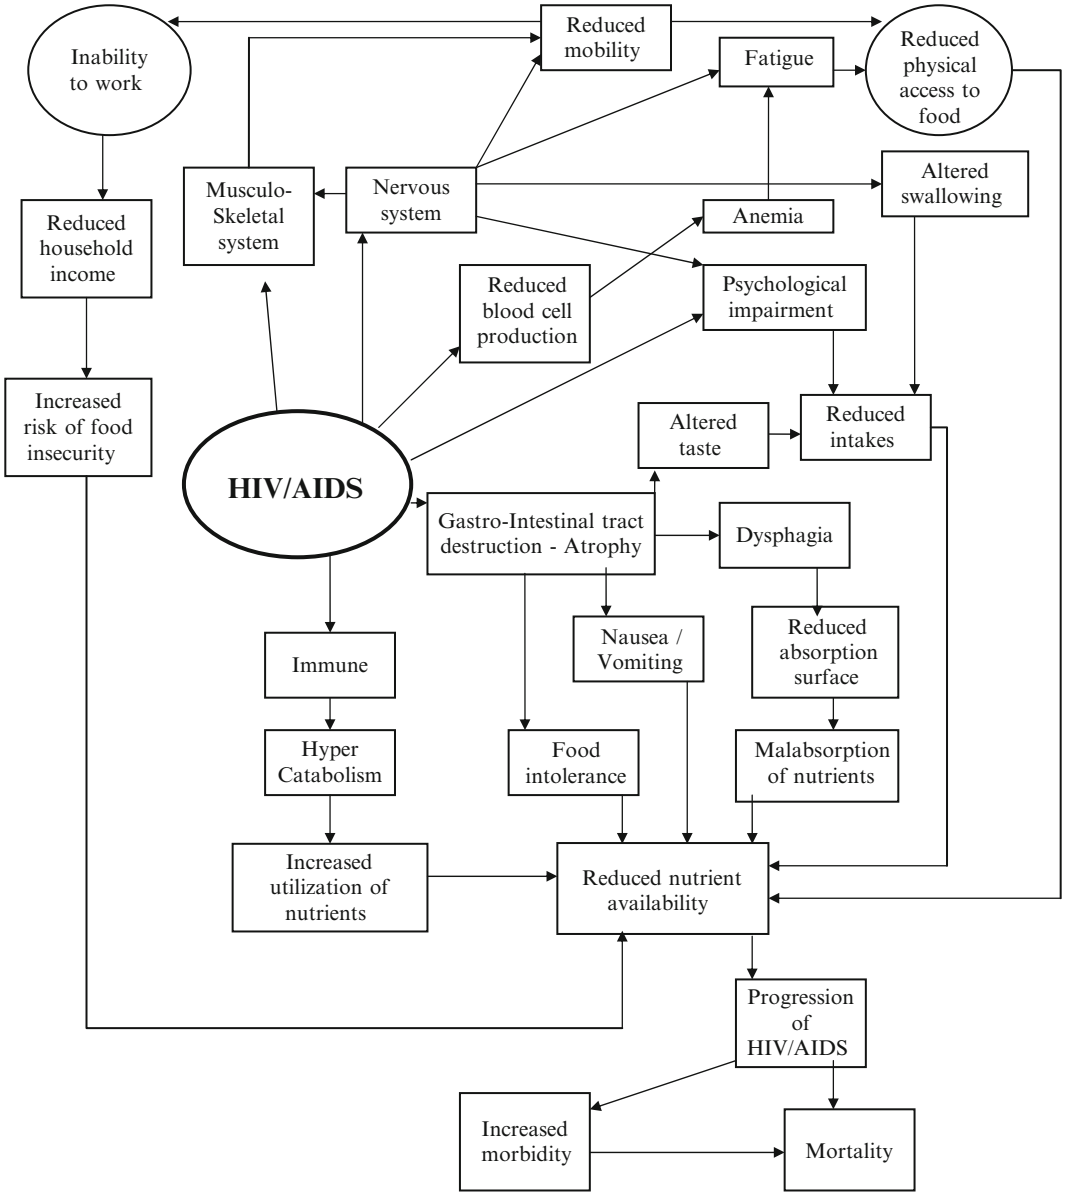

Fig. 153.3 Impact of HIV/AIDS on Body Organ Systems and Nutrient Availability. It shows the manner in which HIV/AIDS impacts on the availability of nutrients in the body

153.5 Height/Length

Height is a good index of the nutritional status of individuals and populations. Severe height deficit (stunting) is a useful indicator of chronic malnutrition.

Requirements: Recumbent length board, knee-height calipers, and stadiometer.

Applicability: Children and adults.

Table 153.1 Impact of HIV/AID on key organ systems in the body

Reference	Study design, objective and method	Organ/system affected with implications for nutrition	Findings
Stebbing et al. (2010)	The purpose of this study was to document patient, virologic, and tumor characteristics and clinical outcomes among HIV-positive patients. A total of 19 patients of ages 35–69 years with primary adenocarcinoma and/or squamous cell carcinoma of the esophagus was identified	Upper gastrointestinal	Prior esophageal disease (reflux, peptic ulcers, and achalasia) was reported in almost half of all patients. Primary esophageal carcinoma was associated with moderate immunosuppression and lifestyle habits including tobacco and alcohol use
Roc et al. (2007)	This study sought to examine whether lactate, a marker of inflammation and anaerobic glycolysis, and lipid, an indicator of cell membrane turnover resulting from oxidative stress, could serve as surrogate biomarkers within the lenticular nuclei of HIV-positive patients with different degrees of neurocognitive impairment. Ten seronegative controls and 45 HIV-positive patients with different degrees of neurocognitive impairment participated in this study. In vivo two-dimensional chemical-shift-imaging magnetic resonance spectroscopy analysis of *N*-acetyl aspartate:creatine, choline:creatine, lactate:creatine, and (lipid + lactate): creatine ratios were determined.	Brain	The lactate-to-creatine ratio was significantly greater in HIV-positive patients with moderate-to-severe impairment compared with seronegative controls. The (lipid + lactate):creatine ratio was significantly elevated within each HIV-positive subgroup compared with seronegative controls (0.01± 0.01 vs. 0.13 ± 0.03 and greater).
Chhagan and Kauchali (2006)	The purpose of this study was to describe the profile of comorbidities in children admitted with diarrhea to an urban hospital with high human immunodeficiency virus (HIV) prevalence in South Africa and to examine the contribution of comorbidities to inpatient mortality. Data from a retrospective random sample of 319 children were extracted and analyzed from a total of 1,145 children hospitalized for diarrhea in 2001	Lower gastrointestinal	Overall, 68% of the diarrheal admissions were classified as HIV infected and 61% were classified as malnourished. Mortality was higher among HIV-infected than among uninfected children [crude odds ratio (OR), 6.0; 95% CI 2.1–17.0].
Dolan et al (2006)	The objective of the study was to investigate change in bone mineral density (BMD) over time in HIV-infected women in comparison with healthy control subjects similar in age, race, and body mass index (BMI). BMD was measured by dual-energy X-ray absorptiometry in 100 HIV-infected females and 100 healthy controls similar in age (41 ± 1 vs. 41 ± 1 year, $p = 0.57$)	Bone	HIV-infected subjects had lower BMD at the lumbar spine (1.01 ± 0.01 vs. 1.07 ± 0.01 g/cm(2), $p = 0.001$), hip (0.94 ± 0.01 vs 0.98 ± 0.01 g/cm(2), $p = 0.02$), and femoral neck (0.83 ± 0.01 vs. 0.87 ± 0.01 g/cm(2), $p = 0.02$). Forty-one percent of the HIV-infected women demonstrated osteopenia at the hip, femoral neck, or spine, and 7% demonstrated osteoporosis. BMD in the HIV-infected subjects remained lower than that in control subjects over 24 months of follow-up ($p = 0.001$ for the spine, $p = 0.04$ for the hip, and $p = 0.02$ for the femoral neck)

(continued)

Table 153.1 (continued)

Reference	Study design, objective and method	Organ/system affected with implications for nutrition	Findings
Adediran and Durosinmi (2006)	The aim of this study was to evaluate the importance of peripheral blood and bone marrow changes in a population of adult Nigerians managed for symptomatic HIV infection. Peripheral blood cell counts and bone-marrow cytology of serologically confirmed HIV/AIDS patients 21–51 years were studied	Blood	Nearly two-thirds (68%) of the data were evaluable. None of the patients had conventional antiretroviral therapy. Lymphopenia (lymphocytes < 2× 10(9)/l) was seen in 64.4% of the patients; 50% and over 40% of the patients had moderate–severe anemia and neutropenia, respectively
Masiá et al. (2010)	Endothelial dysfunction was evaluated in HIV-infected patients with and without lipodystrophy in a prospective study. Endothelial function was measured through flow-mediated dilatation (FMD) of the brachial artery. Inflammation, endothelial activation, and coagulation associated with adipose tissue and endothelial dysfunction were evaluated by measuring interleukin 6 (IL-6), plasminogen activator inhibitor 1 (PAI-1), adiponectin, and vascular cell adhesion molecule 1	Cardiovascular	FMD was significantly lower in patients with lipodystrophy than in those without lipodystrophy (median [IQR] 3.1% [0.4–8.9] versus 6.3% [3.3–10.7]; $p = 0.004$). Lipodystrophy was associated with significantly higher plasma levels of IL-6 and PAI-1 and lower levels of adiponectin; severe lipodystrophy was associated with higher concentrations of vascular cell adhesion molecule 1. Lipodystrophy was an independent predictor of endothelial dysfunction (odds ratio 5.22, 95% confidence interval 1.76–15.46; $p = 0.003$)
George et al. (2010)	The objective of this study was to determine the correlation between kidney function and the risk of cardiovascular events (CVEs) among the HIV-infected persons. A nested, matched, case-control study design was employed in this investigation of 315 HIV-infected patients (63 patients who had CVEs and 252 controls). Estimated glomerular filtration rate (eGFR) and proteinuria were the primary exposures of interest	Kidney	Mean eGFR was significantly lower in the patients compared with controls by both estimation methods (68.4 vs. 103.2 ml/min per 1.73 m, $p < 0.001$ and 69.0 vs. 103.1 ml/min per 1.73 m, $p < 0.001$). The prevalence of proteinuria in HIV-positive participants was approximately twice that of controls (51 vs. 25%, $p < 0.001$, respectively)
Pierre et al. (2004)	This study sought to document the frequency of clinical conditions, opportunistic and co-infections among children with HIV/AIDS. A total of 110 HIV-infected children 0.9–17.5 years from several clinics in Jamaica was monitored over a one-year period and clinico-pathologic characteristics were recorded	Multi-systemic	The most common symptoms were lymphadenopathy (29.7–42.8%), dermatitis (19.8% of children mildly symptomatic), persistent or recurrent upper-respiratory-tract infections (19.8% of children mildly symptomatic), bacterial sepsis (34.6% of children moderately symptomatic), recurrent diarrhea (21.2%) of children mildly symptomatic and wasting (30.0% of children severely symptomatic), and encephalopathy (26, 27.9%). Pulmonary tuberculosis (7.5%) and *Pneumocystis* (*jiroveci*) *carinii* pneumonia (5.4%) were the most frequent opportunistic infections

Table shows the effect of HIV/AIDS on organs/systems which have important consequences for nutrition and food security. Values shown are a combination of absolute change, mean ± standard deviation, percent change, and odds ratio

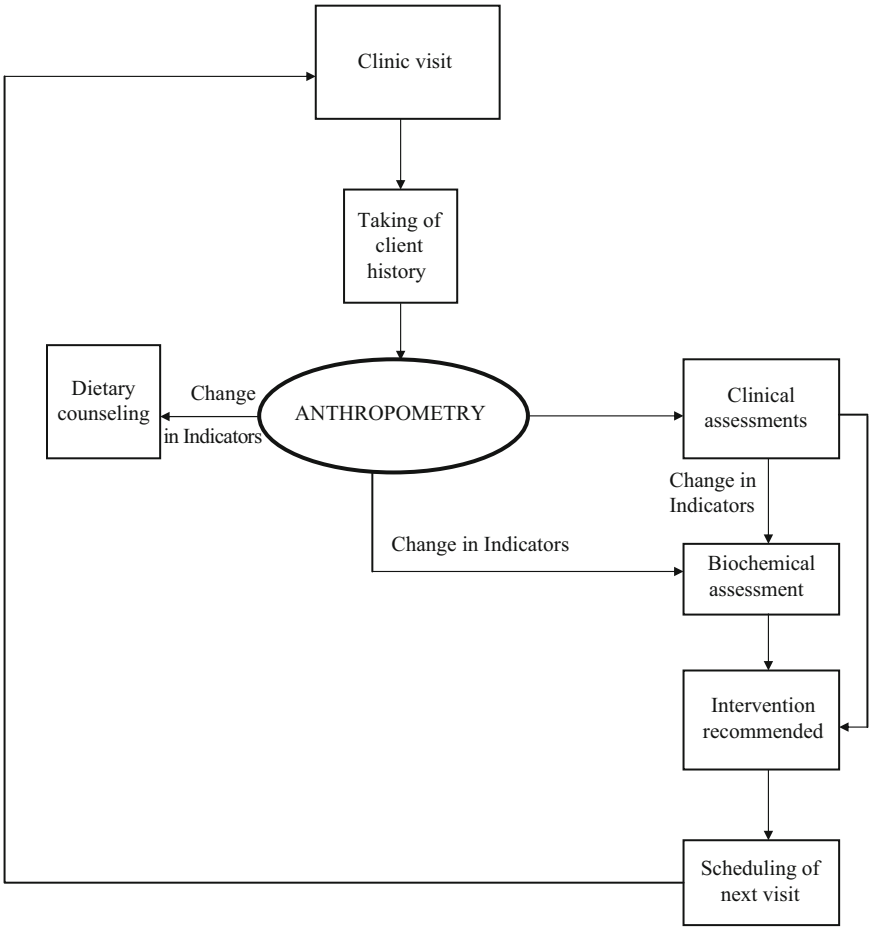

Fig. 153.4 Framework for Anthropometry in the Monitoring and Evaluation of PLWHA. It presents a contextual framework for the role of anthropometry in the monitoring and evaluation of the health status of PLWHA

153.5.1 Clinical Correlations in PLWHA

Studies have suggested that while there may be little differences between HIV-infected and HIV-uninfected children at birth, the former are significantly shorter at ages 8–10 years. Height is also predictive of the risk of developing anemia among HIV-infected children. Severe height deficits are associated with chronic diarrhea and final percentage CD_4^+ cells (Arpadi et al. 2009; Shet et al. 2009).

153.5.2 Practical Methods

The methods used to assess height in PLWHA depend primarily on their age and overall health status. For children who are unable to stand, height should be measured using a recumbent length board. Several brands are available commercially. They can also be manufactured on demand to

meet the needs of users. The effective use of this device requires two trained individuals to take accurate measurements. One person is required to hold the child's head against the board with the head in the Frankfort plane while the other individual presses the bottom of the heel against the sliding board and adjusts the latter until there is no change in height. Height should be measured to the nearest 0.1 cm (Gibson 1990). The averages of three such measurements should be recorded as the final height. Interpretation of height requires persons to be familiar with a relevant reference population. The CDC height chart represents one of the most popular reference growth charts and may be used in situations where there are no population-specific reference standards (Mei et al. 2008). The use of these charts requires that the age of the child be accurately known. This can be problematic in countries where majority of children are delivered outside of a clinic setting. In such circumstances, it might be appropriate to use other chemical markers of age as well as information from family or relatives. Using this age, we plot a vertical line on the reference height chart and note the values for the 97th, 95th, 50th, 5th, and 3rd percentiles. Children whose height falls below the 5th percentile may be experiencing severe height defects. Similarity of growth in the reference standard to the true growth projections of the population being measured is crucial to the eventual interpretation of the data. For HIV-infected adults and children who can stand unassisted, a stadiometer should be used to measure height. Measurement should be taken to the nearest 0.1 cm. Individuals should be positioned with their heads in the Frankfort plane with both heels pressed against the vertical part of the stadiometer. Height should be measured using the headboard or similar device at the top of the head. An average of three such measurements should be used as the mean height. Data can then be interpreted using the CDC or appropriate standard, as outlined earlier. For persons who are bedridden or have spinal deformations, height may be estimated from limb measurements. Knee height may be measured using a knee-height caliper. For knee-height measurements, the knee is bent at a 90° angle with the subject supine left. The immovable blade of the caliper is placed under the heel and its sliding end is placed against the elevated thigh 5-cm proximal to the patella and above the condyles of the femur (Gibson 1990). The caliper can also be positioned with the person in a sitting position. This measure can be done using the right or left leg. We recommend the average of at least two measurements for knee-height measurements. Stature may then be calculated using established equations. Again, the utility of the calculated height depends on the similarity of the reference population to the population being measured (e.g., age, health status, ethnicity, and gender). Many of the algorithms used to estimate stature from these equations require that the age of the person being measured be known. Given the neurological impairment that may be associated with HIV/AIDS, it is important to record age from a verifiable and accurate source. When the proper technique is used, height can be measured with great accuracy.

153.6 Weight

Weight loss is an important feature of HIV/AIDS. The loss of weight and its concomitant effect on lean body mass is a good predictor of the progression of HIV/AIDS. More recently, with the introduction of HAART, there have been concerns about excess weight gain in persons with HIV/AIDS and its impact on health. The measurement of weight is therefore an important variable in the monitoring and evaluation of the health of PLWHA.

Requirement: Infant balance beams and electronic foot scale (preferably one that operates on strain-gauge technology).

Applicability: Children and adults.

153.6.1 Clinical Correlations in PLWHA

HIV-infected children are known to have weight-for-age and weight-for-height values that are significantly lower than their non-infected counterparts (Guillén et al. 2007). Among infected children, lower weight is associated with increased risk for diarrhea, respiratory illness, poorer nutritional status, lower CD4+ cell count, and increased risk for anemia. In fact, weight loss in excess of 10% of body weight is a strong predictor of mortality resulting from HIV/AIDS, while losses of 2–5% are associated with increased risk for morbidities. This includes the risk of anemia, opportunistic infections, and increased use of antiretroviral medications. HIV-infected persons on HAART are at an increased risk for being overweight as well as having an altered fat distribution. Overweight in PLWHA has been linked to the development of serum lipid profiles highlighted by high levels of cholesterol and triglycerides, thereby increasing the risk of cardiovascular diseases (Sodjinou et al. 2008).

153.6.2 Practical Methods

Weight can be measured accurately under standardized conditions. We recommend the use of beam balances and electronic scales. As a general principle, persons should be weighed with minimal clothing and without shoes. Persons should also void their bladders prior to taking their weights. As far as possible, weight should be taken at the same time of day at the different visits. This can be difficult in a typical clinical setting. For adult persons who cannot stand, a bed scale or similar device may be used in the clinical setting. When weighing infants and children, the beam balance or suitable electronic scale should be used. For interpretation of weight among children, suitable weight-for-age and weight-for-height reference standards should be used to establish suitable cutoff points. Again, a relevant standard may be used when there are no population-specific reference data. The important cutoff points are the 97th, 95th, 50th, 5th, and 3rd percentiles of the relevant growth chart. HIV infants and children below the 5th percentile weight-for-age and weight-for-height reference standard are at increased risk for wasting and accelerated progression of HIV/AIDS. Children above the 97th percentile of the weight-for-age and weight-for-height reference standard are at increased risk for being overweight. The reading and interpretation of these charts require trained personnel. Where children are approaching the 3rd percentile, we recommend weekly visits or, if possible, clinic-based interventions. Again, the interpretation of these charts is dependent on the similarities in growth between the population being measured and the reference population. We also recommend continuous charting of the growth record of HIV-positive children. Where the continuous growth curve appears to be flattening or has a negative slope, suitable interventions should be instituted immediately. This may range from nutrition counseling to hospitalization. Among adult PLWHA, unexplained weight loss of >5% in 1 month or >10% in 6 months is indicative of severe risk of undernutrition, which may facilitate the progression of the disease. This change can be calculated as

$$\text{Percentage change in weight } (\%) = \frac{\text{New weight} - \text{weight last visit} \times 100}{\text{Weight at last visit 1}}$$

If the visits were months apart, divide the percentage calculated above by the number of months to calculate an average monthly weight loss. If possible, information on the period of most rapid weight loss should be collected. PLWHA who are >120% of their ideal body weight are considered overweight and should have their serum lipids monitored regularly, especially when they are receiving HAART.

Table 153.2 Anthropometry of persons with (PLWHA) and without (CONTROL) (Burgin et al. 2008)

Variable	PLWHA $n = 36$	CONTROLS $n = 37$	p value
Weight (kg)	63.7 ± 14.0	72.9 ± 12.5	0.004
Height (cm)	167.9 ± 9.3	168.0 ± 8.9	0.93
Waist circumference (cm)	80.3 ± 9.9	83.5 ± 11.3	0.20
Hip circumference (cm)	95.9 ± 12.6	101.4 ± 14.6	0.10
Waist/hip	84.2 ± 8.1	82.7 ± 6.1	0.38
Upper mid-arm circumference (cm)	27.2 ± 4.3	36.7 ± 6.4	0.001
Triceps skinfold (mm)	26.2 ± 8.6	28.9 ± 7.6	0.16
Arm muscle area (cm^2)	22.0 ± 10.08	34.5 ± 17.0	< 0.001
Arm fat area (cm^2)	30.8 ± 13.7	40.1± 16.0	0.01
Perception of weight			
Underweight	15 (41.7)	0	$p < 0.001$
Normal weight	19 (52.8)	28 (75.0)	
Overweight	2 (5.6)	9 (25.0)	
Changes in weight in the past 3 months (%)	22 (60.0)	18 (49.0)	0.34
BMI (kg/m^2)	22.6 ± 4.9	25.8 ± 4.0	0.003
<18 Underweight	2 (5.6)	1 (2.7)	
18–24.9 Normal weight	28 (77.8)	15 (40.5)	
25.0–29.9 Overweight	3 (8.3)	14 (37.8)	
30^+ Obese	3 (8.3)	7 (18.9)	0.004

153.6.2.1 Body Mass Index (BMI)

Body mass index (BMI) is a measure of body habitus, which takes weight and height into consideration. It is calculated as Weight (kg)/height $(m)^2$ or Weight (lb) * 704.5/height $(in.)^2$. BMI has become popular as an index of overweight and obesity. Persons with BMI 25–29.9 are considered overweight and those with BMI 30 and above as obese. Adults with BMI <18 are considered at increased risk for undernutrition. Studies suggest that low BMI in PLWHA is associated with increased risk of anemia, low $CD4^+$ count, and increased risk for diarrhea and opportunistic infections (Villamor et al. 2005). The CDC has several reference charts for BMI of persons 2–20 years, which may be used in assessing the BMI of HIV-positive children and adolescents. The use of BMI in assessing nutritional status must be interpreted with caution as BMI may not accurately reflect body composition (Nichols and Cadogan 2009). As with the weight and height charts, persons below the 5th percentile of the reference chart may be at increased risk for becoming underweight, while those above the 95th percentile are at increased risk for overweight and obesity. Table 153.2 shows a comparison of anthropometry between persons with and without HIV/AIDS. These results suggest that PLWHA are at increased risk for wasting, as suggested by their lower weights and BMI.

153.7 Body Circumferences

Common circumferences that are measured in PLWHA include head circumference (HC), mid-upper-arm circumference (MUAC), waist circumference (WC), and hip circumference (H).

153.7.1 Head Circumference

Requirements: Non-stretchable measuring tape
Applicability: Infants and children <5 years

153.7.1.1 Clinical Correlations in PLWHA

Head circumference (HC) in infants is closely associated with brain and neurological development. Humans have a significant brain growth and development spurt during the first 2 years of life. During this phase, the brain is particularly sensitive to factors that impact on its development. Research conducted over the past few decades have suggested that early malnutrition can result in reduced cognitive development (Kar et al. 2008). Infants who are HIV positive have lower HC than their non-infected counterparts (Mac Millan et al. 2001; Llorente et al. 2003). Given the high risk of undernutrition in infants living with HIV/AIDS, HC measurements represent a good opportunity to assist in timely interventions that may be protective against subsequent poor cognitive development.

153.7.1.2 Practical Methods

Head circumference is measured at the widest circumference of the head. Measurements should be taken to the nearest 0.1 cm. The interpretation of the resulting data requires a reference standard against which it can be compared. The CDC head circumference reference charts for males and female are the most popular in use. The risk for impaired neurological and cognitive development increases with measurements that are below the 5th percentile for the particular age. These charts encompass ages 0–36 months.

153.7.2 Waist and Hip Circumference

Requirements: Non-stretchable measuring tape
Applicability: Children and adults

153.7.2.1 Clinical Correlations in PLWHA

Abdominal fat is an independent predictor of morbidity and mortality among adults (Kuk et al. 2006). Research has shown that waist and hip circumferences are strongly associated with abdominal visceral adiposity among adults (Onat et al. 2004). Waist circumference above 102 cm in males and 88 cm in females is associated with an increased risk for developing diabetes mellitus, high blood pressure, and elevated serum lipids (Grundy et al. 2005; Carroll et al. 2000). This is especially important for persons on HAART which has been shown to increase the risk of overweight and obesity and alter fat patterning of the body in a manner that increases their risk for developing cardiovascular disease (Mutimura et al. 2007; Shevitz and Knox 2001). It has been recommended that the waist-to-hip ratio among adults should be less than 0.9 in males and 0.8 in females (Gibson 1990). Low waist and hip circumference are also indicative of weight changes in PLWHA. In fact, low waist

and hip circumferences among adult PLWHA are associated with an increased risk of diarrhea, opportunistic infections, and reduced immune function (Burgin et al. 2008).

Shevitz AH, Knox TA Nutrition in the Era of HAART

153.7.2.2 Practical Methods

Waist circumference is taken midway between the last rib and the iliac crest (top of the hip bone). Clients should be measured with this area exposed. Where it is culturally inappropriate or the PLWHA may be self-conscious of their physical appearance in this area, measurements should be taken with minimal clothing over this area. The midpoint should be marked using a marker whose writing can be easily erased after measurement. The non-stretchable measuring tape should be placed over this point and the measurement taken. It is important that the tape be placed horizontally over the area to be measured (Lohmann et al. 1988). Also, subjects should breathe normally. The average of three measurements over the area while the subject is exhaling should be used as the measure of waist circumference. Hip circumference should be measured with the person standing with their feet together. Measurement should be taken at the maximum circumference of the buttocks. Again, the average of three measurements should be taken in a manner similar to the measurement of hip circumference. All measurements should be taken to the nearest 0.1 cm or 1/8 in.

153.7.3 Mid-Upper-Arm Circumference (MUAC)

Requirements: Non-stretchable measuring tape
Applicability: Children and adults.

153.7.3.1 Clinical Correlations in PLWHA

In both children and adults, mid-upper-arm circumference is a useful indicator of adipose tissue and muscle reserves. MUAC can be used in conjunction with triceps skinfold to estimate arm muscle area (AMA). AMA is also a useful indicator of lean body mass. Using the following equations, corrected AMA can be calculated for males and females:

$$\text{Corrected AMA} = \left[\text{MUAC} - (\pi \times \text{TSF})\right]^2 \div (4 \times \pi)$$

where TSF=triceps skinfold (cm), π = 3.14 and MUAC = mid-upper-arm circumference (cm). From this value, we must subtract 6.5 for females and 10 for males (Heymsfield 1982). Values below 32 cm^2 in males and 18 cm^2 in females are indicative of depleted reserves (Merck Manual Professional 2009). Lower corrected AMA is associated with reduced CD4+ cell count among PLWHA. Other studies have shown increases in infections and anemia with reduced MUAC (Burgin et al. 2008). Furthermore, MUAC is highly correlated with weight, BMI, WC, hip circumference, and peripheral energy stores as indexed by arm fat area among PLWHA (Table 153.3).

CAMA Corrected arm muscle area (cm^2); *MUAC* Mid-upper-arm circumference (cm)

153.7.3.2 Practical Methods

To determine the position of the midpoint of the upper arm, the upper arm is positioned parallel to the body. The forearm is then placed palm down over the mid body with the elbow bent at a 90° angle. Either the left or right arm could be used. The upper mid-arm is located midway between the acromion and olecranon processes. This point should be marked. The MUAC should be measured at the level of the established midpoint using a non-stretchable tape. This tape should be perpendicular to the humerus and should not compress the skin and underlying tissue during measurements. An average of three measurements should be used as the MUAC. Overall, circumferential measurements, when not conducted properly, result in tremendous errors. It is therefore necessary to conduct regular training sessions to ensure that measurements are taken accurately.

153.8 Skinfold Measurement

Requirements: Skinfold caliper and non-stretchable measuring tape.
Applicability: All age groups.

153.8.1 Clinical Correlation in PLWHA

Skinfold measurement provides an indirect way of estimating adiposity. When used in conjunction with certain body circumference measures, as outlined earlier, it is possible to estimate body adiposity and lean body mass. Both these measures are important for PLWHA as they index body compartments which are important sources of energy and protein. Triceps and subscapular skinfold are two of the more common skinfold measurements taken. Studies have shown that skinfold thickness is lower in PLWHA compared to non-infected persons. Furthermore, infected persons experiencing the wasting syndrome associated with HIV/AIDS show significant reduction in their triceps skinfold thicknesses (Burgin et al. 2008).

153.8.2 Practical Methods

153.8.2.1 Triceps Skinfold

The triceps skinfold is taken on the posterior midline at the site established for MUAC, as described earlier. After establishing the midpoint of the upper arm, the arm should hang loosely with the palm facing forward. The person taking the measurement should stand behind the client. The skinfold should be grasped about 1 cm posterior to the midpoint with the thumb and index finger of the left hand. The caliper should be placed over the midpoint perpendicular to the humerus. The average of three such measurements should be taken as the triceps skinfold (Gibson 1990).

153.8.2.2 Subscapular Skinfold

The individual to be measured must stand erect with shoulders and arms relaxed at their side. The inferior angle (or triangle portion) of the right scapula should then be located and marked. A fold of the skin and subcutaneous adipose tissue directly below (1.0 cm) and medial to the inferior angle should then be grasped. The skinfold would then form a line about 45° below the horizontal, extending diagonally toward the right elbow. The jaws of the caliper should then be placed perpendicular to the length of the fold about 2.0 cm lateral to the fingers, with the top jaw of the caliper on the mark over the inferior angle of the scapula. The skinfold thickness is measured to the nearest 0.1 mm, while the fingers continue to hold the skinfold (Lohmann et al. 1988).

153.8.2.3 Suprailiac Skinfold

The right hip area should be exposed for this measurement. The iliac crest should be marked. The left thumb should be placed on the intersecting marks and the skinfold should be picked up with the thumb and fingers. The skinfold should slope downward and forward at a 45° angle extending toward the pubic symphysis. The caliper should be placed perpendicular to the skinfold about 2.0 cm medial to the fingers and the skinfold is measured to the nearest 0.1 mm (Lohmann et al. 1988).

153.8.2.4 Abdominal Skinfold

The abdominal skinfold is measured at a site 3 cm to the side of the midpoint of the umbilicus and 1 cm below it. The skinfold is horizontal and should be measured on the right side of the body while the subject relaxes the abdominal wall as much as possible. In order for skinfold measurements to generate information that can be of use in monitoring aspects of the nutritional status of PLWHA, it is necessary to associate them with well-established indices of nutritional status. For example, skinfold measurements can be used to generate information on body composition. This can be done by converting skinfold thickness into body density by using well-established equations, such as those developed by Durnim and Womersley. Body density can be converted to percentage body fat by using Siri's equation (i.e. 490/d – 450, where d is the calculated body density). Other equations that use skinfold measurements allow the direct estimation of percentage body fat (Lee et al. 2003). Overall, anthropometry can be used to monitor and evaluate several adverse clinical outcomes among PLWHA. Table 153.4 shows a summary of clinical outcome in PLWHA for which anthropometry can provide useful monitoring and evaluation data.

Table 153.4 HIV and change in anthropometry

Reference	Study design, objective, and method	Age	Results
Miller et al. (1993)	Prospective study of 89 children born to HIV-infected mothers following from 1986 to 1991. Children were compared using length, weight, and weight for height percentiles and *Z*-scores. Triceps skinfold and arm muscle circumference percentiles were also determined	0–4 years	HIV-infected children had significantly higher rates of decrease in triceps skinfold (–1.09 +0.30 vs. –0.20 +1.06) and smaller rates of increase in arm muscle mass (0.26 + 0.30 vs. 2.30 + 0.71) than seroreveters
Bailey et al. (1996)	Prospective cohort of 258 children born to HIV-positive mothers. These children were followed from birth to 20 months, and anthropometric measures such as length, height, and weight were measured	0–20 months	Height-for-age *Z*-scores were lower in HIV-infected children compared to seroreverters at 6 months
Brown et al. (2006)	Prospective 4-year follow-up of HIV-infected and HIV-uninfected men to determine the pattern of BMI, waist circumference, hip circumference, and waist-to-hip ratio		Increased BMI in HIV seronegative compared to HIV infected (0.12 ± 0.04 kg/m^2 vs. 0 kg/m^2; $p < 0.01$); increased waist circumference in HIV seronegative compared to HIV infected (0.49 ± 0.07 cm/year vs. 0.18 ± 0.06 cm/year; $p < 0.01$); increased hip circumference in HIV on HAART compared to HIV seronegative (0.51 ± 0.14 cm/year vs. 0.63 ± 0.18 cm/year; $p = 0.03$); increased waist-to-hip ratio in HIV on HAART compared to HIV seronegative (0.005 ± 0.001 vs. 0.0003 ± 0.001; $p < 0.01$)

Reference	Study design, objective, and method	Age	Results
Webb et al. (2009)	Prospective cohort. This study investigated the predictors of growth among 1,078 HIV infected women. Length for age and weight for length Z-scores were monitored among their newborns or the first 2 years of life	0–2 years	After controlling for mother's age, education and CD4+ count, and infant's sex and weight at birth, HIV-positive children had significantly lower mean, length for age *Z*-scores at 6 months (–0.23), 12 months (–0.38), and 24 months (–0.63) than their uninfected counterparts. Similarly, they had lower weight for length *Z*-scores at 6 months (–0.38), 12 months (–0.35), and 24 months (–0.69)
Justman et al. (2008)	Prospective cohort. This study described the longitudinal pattern of body mass index (BMI), waist–hip ratio, and waist and hip circumference among 942 HIV-infected women and 266 uninfected women over a four-year period	41 years	Mean BMI at each visit was significantly lower in HIV-infected men compared to HIV-uninfected men (range = –1.29 kg/m^2 to –4.33 kg/m^2). Over the duration of the study, mean BMI in HIV-uninfected men increased by 2.49 kg/m^2 or 8.2%. Waist-to-hip ratio for HIV-infected women increased from 0.016 to 0.032 ($p = 0.024$)
			HIV-uninfected women had significant increase in waist circumference (+4.1 cm or 4.4%) and hip circumference (3.76 or 3.5%)

Table shows the impact of HIV/AIDS on commonly used anthropometric measures. Values shown are a combination of absolute change, mean ± standard deviation, percent change, and changes in *Z*-scores. These findings suggest that anthropometric measures may be useful for monitoring and evaluating disease progression among PLWHA

153.9 Applications to Other Areas of Health and Disease

The similarity of the pattern of weight loss seen in HIV/AIDS to that seen in other diseases, such as cancer, anorexia nervosa, and severe protein–energy malnutrition, suggests that anthropometric measurements for monitoring and evaluating nutritional status among PLWHA may be useful for monitoring and evaluating persons with these conditions and vice versa.

Summary Points

- Approximately 33 million persons globally are living with HIV and AIDS.
- Majority of persons living with HIV/AIDS reside in developing countries.
- Persons living with HIV/AIDS are at increased risk of malnutrition and food insecurity, as a result of increased nutrition utilization, malabsorption of nutrients, and inability to acquire food, as the disease progresses.
- Anthropometric measurements, such as weight, height, body circumferences, and skinfold thickness, are good proxies for gauging the nutritional status of individuals.
- Anthropometric measurements are associated with the morbidity and mortality among PLWHA.

- Anthropometric measurements are easy to take; they are also relatively cheap, reliable, and noninvasive.
- Anthropometry should be a component part of any comprehensive strategy for monitoring and evaluating PLWHA.

Key Facts on the Role of Nutrition and Anthropometry in Monitoring the Nutritional Status of Plwha

- HIV/AIDS is associated with changes in metabolic physiology that influence the metabolism, absorption, and ability of infected persons to acquire foods.
- PLWHA are at increased risk for food insecurity and malnutrition.
- HIV/AIDS increases the risk for illness and death.
- HIV/AIDS is most prevalent in the 15–44-year age group – a group that forms a large portion of the productive workforce in many developing countries.
- The link between nutrition, health, and development is well established.
- Indices of nutritional status of individuals and populations can provide a useful proxy for future development of nations.
- Anthropometric measures provide us with useful proxies to the nutritional status of individuals.
- Anthropometric measures, such as weight, height, waist circumference, and mid-upper-arm circumference, are associated with morbidity, mortality, and clinical and biochemical parameters among PLWHA.
- Anthropometric measures can provide valuable information that would allow timely intervention to prevent and mitigate poor health outcome among PLWHA.

Chapter 154
Antropometry in HIV Patients: Effects of Recombinant Human Growth Hormone

Livio Luzi, Ileana Terruzzi, and Stefano Benedini

Abstract Patients with HIV infection treated with protease inhibitors (PIs) drugs for a long period have a prolonged life expectancy and an improvement of quality of life. Often, HIV-patients on PIs develop a syndrome characterized by peripheral lipoatrophy, truncal fat accumulation, hyperlipemia and insulin resistance.

In HIV-1 patients undergoing antiretroviral treatment, lipodystrophy is associated with peripheral fat wasting and central adiposity, dyslipidemia, insulin resistance, and increased intramuscular fat accumulation.

In HIV lipodystrophy fat distribution changes are heterogeneous and can include reduced subcutaneous fat and increased visceral fat. In literature there are evidences showing overnight growth hormone (GH) secretion and pulse amplitude reduction in patients with HIV lipodystrophy, in response to standard GH stimulation test.

Excess accumulation of visceral fat with increasing of intra-abdominal adiposity (central obesity) is also a typical feature of patients with GH deficiency. Recombinant human growth hormone (rhGH) can be a useful treatment to diminish excess visceral fat. Up to day there are evidences that GH therapy in HIV-infected patients with syndromes of central fat accumulation show a significant decrease of body fat.

In this chapter, we discuss the anthropometry of lipodystrophy in HIV patients and the indication of rhGH treatment in HIV-related lipodystrophy.

GLUT4	Glucose transporter 4
GR	Glucocorticoid receptor
Grb2	Growth receptor binding protein 2
HAART	Highly active antiretroviral therapy
HDL-C	High Density Lipoprotein-Cholesterol
HIV	Immunodeficiency virus
HMG CoA	3-Hydroxy-3-methylglutaryl coenzyme A
IDL	Intermediate density Lipoprotein
IGF-I	Insulin-like growth factor I
IGFBP-3	Insulin-like growth factor -binding protein 3
JAK	Janus Activated Kinase
Lp (a)	Lipoprotein (a)
LPL	Lipoprotein lipase
MAPK	Mitogen-activated protein kinase
MCP-1	Monocyte chemotactic protein-1
MRI	Magnetic resonance imaging
NRTIs	Nucleoside Reverse Transcriptase Inhibitors
PIs	Protease inhibitors (drugs)
Pl3K	Phosphatidylinositol 3-kinase
rhGH	Recombinant human growth hormone
Shc	Src (it is short form for sarcoma) homology domain containing
SOCS	Suppressor of cytokine signaling
SOS	Son of sevenless
STATs	Signal transducer and activator of transcription factors
TC	Total cholesterol
TG	Triglycerides
TNFα	Tumor necrosis factor-α
VLDL	Very Low Density Lipoprotein

154.1 Introduction

In adulthood, a reduction in GH production causes a particular syndrome, characterized by an alteration of body composition which includes increased total visceral fat, decreased muscle mass, and bone density (Ho et al. 1996). All symptoms are improved by GH replacement (Carroll et al. 1998). The dose of GH recommended in the adult is much lower than that used in pediatric practice; consequently, hormone side effects are proportionally lesser.

In the last years, protease inhibitor (PI) therapy improved survival and quality of life of HIV-infected patients. These patients often develop a syndrome characterized by peripheral lipoatrophy, trunk fat accumulation, and metabolic alterations. The causes of this syndrome are still not completely defined. Both the infection with human immunodeficiency virus-1 (HIV-1) per se and the combination of HIV with different anti-retroviral drugs seem to play a role in the pathogenesis of the

lipodystrophic syndrome. Insulin resistance leads to an alteration of lipid metabolism resulting in a metabolic picture similar to the one of patients affected by the metabolic syndrome (Carr et al. 1998). In fact, in HIV-lipodystrophy, the intramuscular fat accumulation contributes to development of insulin resistance. Additional metabolic alterations are hypertriglyceridemia, reduction of high-density lipoprotein (HDL) cholesterol, glucose intolerance, and hyperuricemia. The most relevant hormone alterations in these patients are: increased levels of insulin, C-peptide, prolactin, erythropoietin, and tumor necrosis factor-α (TNFα) (Haugaaer et al. 2006b). An abnormal circadian cortisol pattern was also described.

A defect of growth hormone (GH) secretion following a combined arginine/GH-releasing hormone (GHRH) stimulation (Koutkia et al. 2005) was demonstrated. In adulthood, a defective GH secretion is associated with abnormal fat distribution, and GH administration normalizes the pattern of fat deposition. A beneficial effect of growth hormone (GH) administration (clinically justified when an absolute or a relative GH secretory defect is assessed by GHRH/arginine test) was recently suggested by our group (Luzi et al. 2003).

A low-dose GH treatment improves body fat distribution and is devoid of major metabolic side effects once drug administration is discontinued. The question, which is still open, is the duration of the effect of the GH treatment. Previous work suggested a reversal of the effect on fat distribution after cessation of GH treatment. For this reason, even in the light of the results of previous studies (Esposito et al. 2006), a temporary low-dose GH treatment (for example, 6 months, Luzi et al. 2005) combined with a program of physical activity (to be performed continuously both during the treatment and the wash-out periods) could be recommended in HIV patients with lipodystrophy. Physical exercise is known to be a powerful physiological stimulus for GH release in humans per se (Thomas et al. 2003) and can be a lifestyle intervention to maintain the effects of recombinant GH in patients with HIV lipodystrophy for a longer time after discontinuation of the GH treatment.

In this chapter, we suggest the possible use of recombinant human growth hormone for the treatment of HIV-associated adipose-tissue redistribution syndrome and the anthropometric changes in body composition before and after GH therapy.

154.2 Growth Hormone Action

Growth hormone (GH) has been known for a long time to have a role in the promotion of postnatal somatic growth in children and adolescents, and to have “important metabolic action” both fat and lean body mass in adult. Nonetheless, the cellular and molecular bases for these effects of GH are not completely understood. A summary of the mechanisms by which GH affects cellular function is provided in this section.

The start of GH signaling pathway is mediated by the GH receptor (GHR), and it is characterized by a first step which is the formation of a trimer complex with one molecule of ligand and two molecules of receptors. Two specific sites (sites 1 and 2) on a single GH molecule are responsible for this interaction.

The mature human GHR is a 620-amino-acids molecule. A soluble form of the GHR, known as the GH-binding protein (GHBP), derives by a simple proteolytic cleavage of the extracellular domain of the GH receptor.

Receptor dimerization appears to be crucial for signal transduction, since bringing the two GHRs in close proximity increases the affinity of each GHR for JAK2 and its consequent GH-dependent activation. JAK2 is a member of the Janus kinase family of cytoplasmic tyrosine kinases characterized by the presence of an N-terminal domain believed to be important for both GHR-induced phosphorylation and other cytoplasmic signal molecules’ activation. The downstream signaling

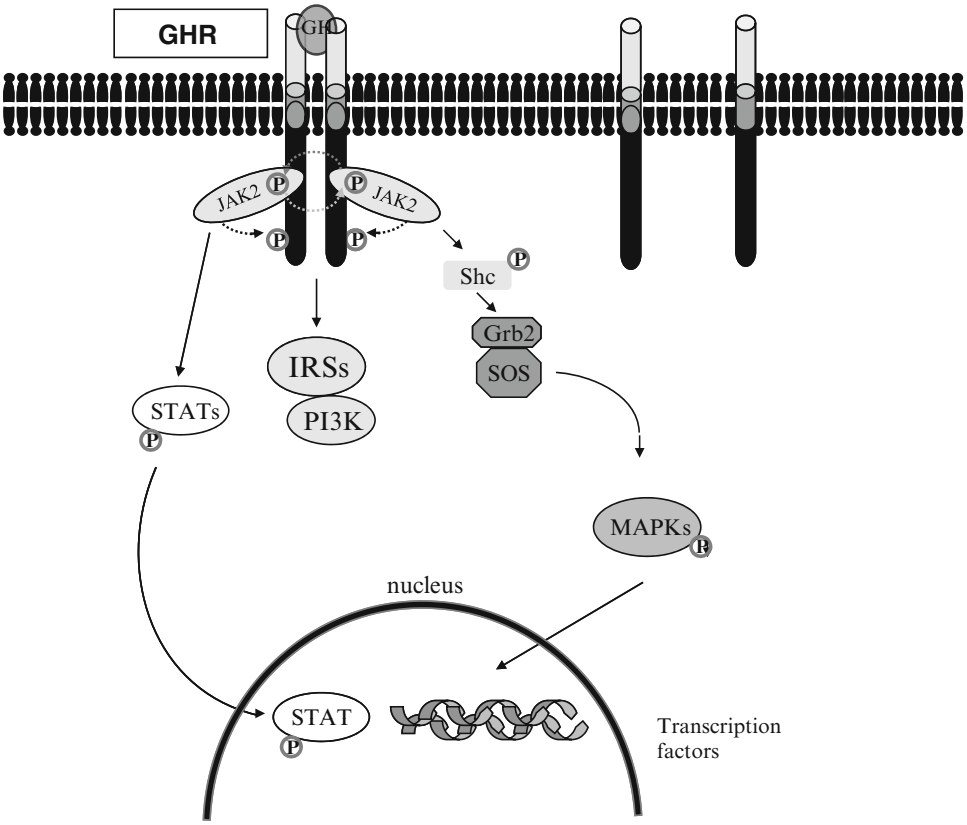

Fig. 154.1 Intracellular Mechanism of Growth Hormone Action. Intracellular mechanism of growth hormone (*GH*) action. *GHR* growth hormone receptor; *Grb2* growth receptor binding protein 2; *IRS* insulin receptor substrate; *JAK2* Janus-activated kinase 2; *MAPK* mitogen-activated protein kinase; *MEK* MAPK kinase; *Pl3K* phosphatidylinositol 3-kinase; *Shc* Src homology domain containing protein; *SOS* son of sevenless; *STATs* signal transducer and activator of transcription factors

pathway recruited and activated by the GHR–JAK2 complex includes signal transducers and activators of transcription (Stat) factors. STATs are a family of cytoplasmic proteins that directly bind the phosphorylated tyrosine residues on the GHR in a GH-dependent manner, allowing them to be phosphorylated and activated by JAKs. GH is able to modulate this pathway by activating the binding of the protein Shc to phosphorylated residues in both JAK2 and GHR. Phosphorylated Shc sequentially activates growth factor receptor bound 2 (Grb2) and son of sevenless (SOS), which can then activate MAPK (see Fig. 154.1).

Growth hormone is not only a regulator of somatic growth, but it also exerts relevant effects on body composition through effects on adipose-tissue kinetics of accumulation and reduction of triglyceride deposition acting on lipoprotein lipase activity. LPL induces the uptake of FFA derived from the complete hydrolysis of the triglyceride. The GH-induced suppression of LPL activity inhibits the hydrolysis of triacylglycerols in chylomicrons and very low density lipoproteins for the provision of free fatty acids for tissue utilization or storage.

The hormone is also necessary for the regulation of the metabolism of mature adipocyte. Growth hormone enhancement of the lipolytic activity of adipose tissue in combination with a reduction of triglycerides' accumulation via inhibition of lipoprotein lipase activity appears to be the major mechanism by which GH administration results in a reduction of total fat mass.

Summarizing growth hormone actions, GH exerts profound effects on whole-body- and district-body composition through a combination of anabolic and lipolytic actions playing a central role in human metabolic homeostasis (Benedini et al. 2008).

154.3 Anthropometric Feature of HIV: Lipodystrophy

Lipodystrophy was originally described as a condition characterized by regional or generalized loss of subcutaneous fat. Lipodystrophies are rare disorders characterized by the selective loss of adipose tissue in certain body regions, coupled with accumulation of fat in other body districts. Adipose tissue is a key player in metabolic homeostasis through its role as an energy depot and an endocrine organ.

In humans, the distribution of fat is regulated by many factors, including genetics, sex, age, environmental factors (such as diet, exercise, and drugs), and illness. Anthropometrical measurements, in particular, waist–hip ratio and the body mass index (squared body weight in kilograms divided by height in meters), correlate well with total body fat in simple obesity and are good measures of central adiposity.

Localized fatty changes may occur in some illnesses, such as the development of dorsocervical fat accumulations and peripheral subcutaneous fat atrophy in hypercortisolism.

Lipoatrophy is primarily subcutaneous fat loss. Fat deposition in patients with HIV occurs in the visceral depot (intra-abdominally), breasts, and dorsocervical area of the neck. Some patients have fat deposits in the form of lipomas. The term 'HIV-associated adipose redistribution syndrome' has been used to define a distinct subset of general lipodystrophy that is primarily characterized by the abnormal accumulation of visceral adipose tissue, with or without comorbid lipoatrophy and metabolic abnormalities, such as dyslipidemia or insulin resistance (Cofrancesco et al. 2009).

In particular, the term 'lipodystrophy syndrome in association with HIV' was introduced to describe a complex medical condition including the apparent abnormal fat redistribution and metabolic disturbances seen in HIV patients receiving protease inhibitor therapy. After the first description, several papers correlated lipodystrophy with HIV (Carr et al. 1998). The mechanisms of HIV lipodystrophy are unknown and may relate either to specific drug effects of protease inhibitors and nucleoside reverse transcriptase inhibitors (Kravcik 2000) or to an interaction between pharmacological and non-pharmacological factors. Furthermore, it is still unknown whether HIV-related lipodystrophy represents a single syndrome or several distinct clinical conditions. Among the NRTIs, stavudine leads to an earlier onset of clinically apparent fat wasting compared with zidovudine. Fat wasting associated with NRTI use may be a manifestation of mitochondrial toxicity, which may be exacerbated by PI use. For all the above reasons, lipodystrophy will be considered to have several features, which can either be isolated or occur in various combinations among them. Features of lipodystrophies may be hypertrophic, atrophic, and metabolic manifestations. Hypertrophic changes consist of excess fat deposition, most commonly around the abdominal region, and also in the neck, in the supraclavicular fossae, or in the subcutaneous tissues of the posterior neck, between the scapulae. Fat deposition may also take the form of bilateral symmetrical lipomatosis or breast enlargement. Atrophic changes consist of subcutaneous fat atrophy in the legs, buttocks, arms, and nasolabial and malar fat pads (Fig. 154.2). Often, veins are prominent in the limbs, but varicosities are absent. The cosmetically disfiguring changes that occur with lipodystrophy may have a significant impact on quality of life and relational/social activities. Dyslipidemia was reported in HIV-infected individuals on and off drug therapy (Carr et al. 1998). PI therapy of HIV-infected individuals was associated with increased total cholesterol, non-HDL-C, triglyceride, IDL, and VLDL cholesterol. The increased VLDL levels were due to increased concentrations of large VLDL particles,

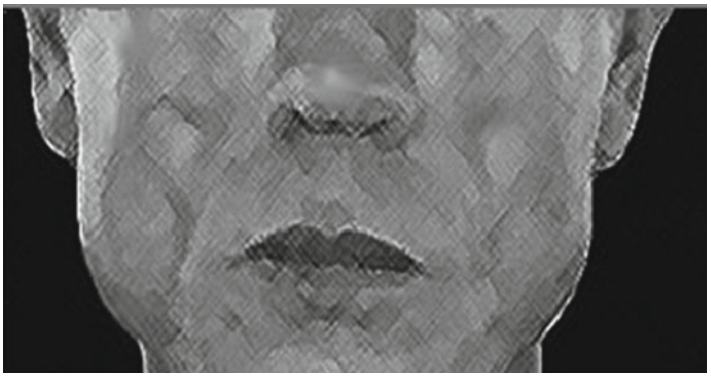

Fig. 154.2 Fat atrophy in nasolabial folds and malar fat pads. This figure represents a clear example of atrophy of the face in an HIV patient

which include chylomicron remnants. Furthermore, the individuals receiving PI therapy were shown to have altered flow-mediated vasodilation of the brachial artery, indicative of endothelial dysfunction (Hoffmann et al. 2005). The fact that the dyslipidemia in these individuals was significantly predictive of the endothelial dysfunction suggests that this dysfunction is mediated by the PI-related dyslipidemia. Of interest, a unique and unexplained aspect of the HIV/PIs-associated dyslipidemia is the significant increase observed in Lp(a). Lp(a) levels are thought to be largely genetically determined and generally not suitable for therapeutic intervention, and administration of PIs was associated with an increase in plasma levels of Lp(a) in case of subjects who had elevated pretreatment plasma Lp(a) levels. Therefore, this category of patients could be at high risk of premature atherosclerosis. Also, as described below, other studies suggest that HIV-associated dyslipidemia is due to increased synthesis, not to decreased breakdown of triglycerides.

The prevalence of HIV lipodystrophy is variable, but, in the patients treated with PIs, the prevalence varied between 5% and 83% and may increase with duration of use of such a drug (Kravcik 2000).

Often, patients receiving PIs who developed LD had higher triglyceride, cholesterol, insulin, and C-peptide levels and greater insulin resistance than patients taking PI but without lipodystrophy (Carr et al. 1998). It is not clear if these altered metabolic factors are secondary to the lipodystrophy, or are somehow involved in its pathogenesis.

Both the lack of a formal definition and uncertainty about the pathogenesis and possible long-term consequences lead to a continuing discussion about appropriate guidelines for the assessment and management of HIV lipodystrophy syndrome and its metabolic abnormalities. The diagnosis relies principally on the occurrence of apparent clinical signs and the patient reporting them. A standardized data collection form may assist in diagnosis. This appears sufficient for the routine clinical assessment, especially when the body habitus changes develop rather rapidly and severely. However, for clinical investigations, especially in epidemiological studies, more reliable measurements are required.

Unfortunately, no diagnostic protocol demonstrated sufficient sensitivity, specificity, or predictive value to definitively diagnose the HIV lipodystrophy syndrome by comparison with results obtained from a ‘normal’ (not lipodystrophic) population (Hoffmann et al. 2005).

In fact, a standardized measure of the localized manifestations of fat accumulation is not available (Kravcik 2000). Several techniques are suitable for measuring regional fat distribution. These include dual-energy X-ray absorptiometry (DEXA), computed tomography (CT), and magnetic resonance imaging (MRI). DEXA is a noninvasive radiological method that allows for direct measurement of

lean mass, fat mass, and bone mineral mass. CT and MRI should only be considered in routine clinical practice for selected patients because limitations of these methods include most notably their cost, availability, and radiation exposure (CT). Interestingly, a refined evaluation of content of tryglicerides in some organs (in this case muscle) can be performed using 1H MR spectroscopy. This method was recently applied in patients affected by HIV lipodystrophy (Luzi et al. 2003), although many authors have used 1H MR spectroscopy during recent years for evaluation of intramyocellular triglycerides' concentration in several clinical conditions. High-resolution, T1-weighted images of the right calf are obtained before spectroscopic acquisition to localize the voxel of interest for the 1H spectroscopy study. Voxel shimming is executed to optimize the homogeneity of the magnetic field within the specific volume of interest. Two 1H spectra are collected from a $15 \times 15 \times 15$ mm^3 volume within the soleus and tibialis anterior muscles. A PRESS pulse sequence (repetition time = 2,000 ms and echo time = 60 ms) is used, and 128 averages were accumulated for each spectrum, with a final acquisition time of 4.5 min. The water signal is suppressed during the acquisition, since it would dominate the other metabolite's peak. A third 1H spectrum of a triglyceride solution inside a glass sphere, positioned within the extremity coil next to the calf, is also obtained during the same session in order to have an external standard acquired in the same conditions as the subject's spectra. Postprocessing of the data, executed with the Sage/IDL software, consists of high-pass filtering, spectra apodization, zerofilling, Fourier transformation, and phasing of the spectra. The integral of the area under the peak is calculated using a Marquardt fitting with Lorentzian functions of the peaks of interest. The integral of the methylene signal (CH_2) at 1.35 parts/million is used to calculate intramyocellular triglyceride content expressed in arbitrary units (AU) as the ratio to the integral of the peak of the external standard × 1,000 (Luzi et al. 2003).

This useful method for evaluation of triglycerides in the skeletal muscle can be used as an index of insulin resistance; in fact, the intramyocellular lipid concentration inversely correlates with insulin sensitivity.

Probably, the retroviral infection, in combination with HAART (including both NRTIs and PIs), is responsible for the metabolic defect, which is associated with abnormal fat distribution. Recent publications point to a selective impairment of GLUT4 activity by PI drugs, and genetic manipulation of GLUT4 expression has shown a role of this protein in adipose tissue metabolism (Hruz 2006).

In summary, different human diseases (other than HIV) associated with lipodystrophy are characterized by major metabolic derangements, such as insulin resistance and dyslipidemias. In particular, the diagnosis of lipodystrophy can be very difficult using only anthropometric measures (waist: hip ratio, skinfold thickness, and weight and height); therefore, a radiological test can be very useful to assess the real body composition.

154.4 Previous Experience with GH Treatment and Potential Risks

Optimization of growth hormone (GH) replacement during childhood is likely to be a key factor for normal skeletal development in GH-deficient (GHD) children. In the past, GH replacement for childhood-onset growth hormone deficiency has been discontinued at completion of linear growth. However, GH replacement in GHD adolescents and adults is increasingly believed to have beneficial effects on a number of biological endpoints, including skeletal health. After epiphyseal closure, skeletal effects of GH replacement in GHD subjects include improvements to a perturbed bone remodeling cycle. The resulting beneficial effects on bone mineral density (BMD) may be crucial before the attainment of peak bone mass, which may not occur until the beginning of the fourth decade. Additional beneficial effects, including improvements in lean body mass, muscle strength,

exercise capacity, cardiac performance, and psychological well-being, will result in inevitable benefits to the young-adult skeleton (Mukherjee et al. 2003).

Growth hormone (GH) secretion from anterior pituitary is regulated by the hypothalamus and by the mediators of GH actions (Table 154.2). Factors including GH-releasing hormone (GHRH), somatostatin (SRIF), GH endogenous peptide with GH-releasing properties (ghrelin), and insulin-like growth factor (IGF-I) modulate GH secretion. The principal physiological regulatory mechanisms of GH secretion are neural endogenous rhythm, sleep, stress, physical exercise, and nutritional and metabolic signals. GH deficiency results from various hereditary or acquired causes, which may take place in isolation or in combination with other pituitary hormone deficiencies.

The use of recombinant human GH has expanded the narrow indication of treating children with severe GH deficiency (GHD) to include a broader target population of children with growth retardation and short stature and adults with hypopituitarism and severe GHD (Mauras et al. 2000). More recently, some authors speculated about use of recombinant human GH in obesity and in the metabolic syndrome (Shadid and Jensen 2003).

In subjects with hypothalamic–pituitary disease, the adult GH-deficiency syndrome (GHD) is typically characterized by changes in body composition, including a reduction in lean mass and bone mineral density (only in patients with GHD of childhood onset) and an increase in fat mass, with a preponderance of central adiposity and increased waist circumference. Muscle strength and exercise performance decline. An impaired sense of well-being and the alteration of other psychological complaints are common. The excess abdominal fat accumulates mainly in the viscera. In epidemiological studies, this abdominal fat distribution has been associated with a higher risk of mortality and morbidity due to cardiovascular disease. Using various methods, few studies have demonstrated decreased bone mass at several skeletal sites in patients with GHD when compared with healthy control subjects (Carroll et al. 1998).

GH and cardiovascular risk. There are many reports in the medical literature on the increased cardiovascular mortality rates associated with GHD, supporting the hypothesis that long-standing GH deficiency in adults predisposes to the development of premature atherosclerosis and hypercoagulability. Moreover, adults with GHD are likely to be insulin resistant. Using a hyperinsulinemic euglycemic clamp (40 mU/m^2·min), Johansson et al. (1995) found a lower glucose infusion requirement in 15 adults with GHD than in matched controls, demonstrating their reduced insulin sensitivity, which was associated with the central obesity and increased intra-abdominal adiposity typical of GHD. Most studies utilizing the hyperinsulinemic euglycemic clamp have confirmed the presence of insulin resistance in GHD (Carroll et al. 1998). Higher concentrations of total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), and apolipoprotein B (ApoB) were observed in GHD patients compared with age- and sex-matched controls. High-density lipoprotein cholesterol (HDL-C) levels are lower and triglycerides (TG) levels are higher than in healthy controls.

Central adiposity, insulin resistance, diabetes mellitus, and hyperlipidemia are common in adults with hypopituitarism. The consensus statement of the Endocrine Society of Evaluation and Treatment of Adult Growth Hormone Deficiency in 2006 showed that there are benefits of GH therapy including improvements in body composition, exercise capacity, skeletal integrity, lipids, and quality of life. Although it has been suggested that GH treatment may reduce the increased vascular mortality associated with hypopituitarism, this has not yet been proved. It should be emphasized that long-term clinical-outcome studies on hard endpoints, such as fractures, clinical heart disease, cancer, and mortality are still lacking at present. The KIMS study demonstrated that GH replacement is associated with an improvement in central fat mass and mean reductions in serum total and LDL cholesterol, which may be compared to those achieved with HMG CoA reductase inhibitors. These beneficial effects are maintained for at least 2 years after the beginning of the therapy. In particular, there was a reduction in central adiposity, both in men and women, when the GH dose was adjusted

to achieve a serum IGF-I level between the median and the upper value of the age-related range of reference. The net effects of GH replacement on cardiovascular risk are likely to derive from the reduction of central adiposity and lipid metabolism combined with an improvement in insulin resistance (Monson 2003).

Thus, all the metabolic alterations of GHD are partially reverted by short-term rGH therapy (about 1 year) (Carroll et al. 1998), although its real impact on vascular damage and endothelial dysfunction is still unknown. Recent reports showed the improvement of metabolic picture and of flow-mediated vascular dilatation in patients treated with hrGH (Benedini et al. 2006). Surprisingly, Lp(a) seems to be increased after GH therapy in a population of men with abdominal obesity, but, regarding cardiovascular risk, the effects on total cholesterol, LDL, and Apo B are probably of more importance than the moderate increase observed in serum Lp (a) concentration.

The data reported so far are encouraging and indicate the beneficial cardiovascular effects of GH in the short term as one of the major factors supporting this treatment in hypopituitary GHD adults. Furthermore, consistent evidence derived from GHD studies suggests a physiological role for the GH/IGF-I axis in the control and regulation of several metabolic cardiovascular risk factors (Benedini et al. 2006).

GH deficiency during childhood is associated with severe growth retardation, resulting in marked impairment of adult height.

GH and tumors. There is increasing evidence that the growth hormone/insulin-like growth factor-I axis may provide a major link between these factors and the development of cancer through its influence on the regulation of normal cell proliferation, differentiation, and apoptosis (Jenkins et Bustin 2004).

The question of the impact of GH therapy on tumor growth has often been raised, particularly in reference to populations of children previously treated for childhood malignancies. Because interpretation of tumor recurrence data is complicated by biases introduced by the selection of children for GH therapy, careful matching of control populations is necessary. In a condition such as acromegaly (constantly high GH concentrations), there is little evidence that cancer risk is increased, and one possible explanation of this fact is that, in acromegaly, both IGF-1 and IGFBP-3 are high and, hence, the GH-binding protein is able to modulate negatively the role of IGF-1 in cell growth. Both single-center studies and large-multicenter surveillance studies have failed to show any increase in the incidence of de novo malignancies during GH replacement (Benedini et al. 2008). A recent updated analysis confirms that childhood cancer survivors treated with GH appear to have an elevated risk of developing a secondary solid tumor compared with survivors not treated. However, the elevation of risk resulting from GH use appears to decrease with increasing length of follow-up, and the overall risk remains small. This risk should be carefully weighed against the potential benefits of GH therapy in cancer survivors (Table 154.3).

GH and diabetes mellitus. Fasting glucose levels were shown to rise after the commencement of GH therapy in children, and there have been reports of development of diabetes mellitus during treatment. Data from the National Cooperative Growth Study (NCGS) (Blethen et al. 1996) and KIMS (Pharmacia International Growth Database) have not suggested an increase in the incidence of type 1 diabetes, but the KIGS database did demonstrate a higher than expected incidence of type 2 diabetes in a heterogeneous population including children treated with GH for short stature not due to GHD (Cutfield et al. 2000). this incidence in children and adolescents was, very small (34 cases per 100,000 yr of GH treatment), and it was postulated that the higher rates may indicate an acceleration of the disorder in predisposed individuals.

The diabetogenic effect of GH arises from the (direct or indirect) ability of GH to enhance endogenous glucose production and to inhibit cellular glucose uptake, thus raising plasma glucose concentrations (see Table 154.1).

Table 154.1 GH therapy: side effects

Arthralgia
Peripheral edema
Generalized edema
Pseudotumor cerebri
Myalgia
Carpal Tunnel Syndrome
Paraesthesia
Hyperglycemia

In this table are summarized the most common side effects of GH therapy

Insulin resistance and type 2 diabetes have been reported in a few patients in the early, large clinical trials (Svensson et al. 2002). Thus, with current treatment dose, there may be a moderate increase of the risk to develop diabetes mellitus. Careful monitoring of diabetic patients for changes in medication needs is appropriate.

154.5 GH Therapy in Lipodystrophy

Reduced secretion of GH is associated with excess total body fat in obese non-HIV- infected patients (Carroll et al. 1998; Benedini et al. 2006). However, GH dynamics have not previously been characterized in patients with HIV lipodystrophy in whom weight and total body fat are normal but visceral fat is increased in association with reduced subcutaneous fat. Our data demonstrate normal GH pulse frequency but significantly reduced mean GH concentrations, basal GH concentrations, and GH pulse amplitude (Luzi et al. 2005). In the past, many studies demonstrated a significant reduction in GH secretion in patients with HIV-related lipodystrophy (Koutkia et al. 2005; Luzi et al. 2005). Visceral adiposity seems to be the most significant predictor of reduced GH concentrations in this population.

In the past, many treatments were proposed to improve lipodystrophy (for example, drugs, such as metformin, that improve insulin sensitivity), but all had only minor beneficial effects on the metabolic picture (Saint-Marc and Touraine 1999).

In our recent study, we showed that low-dose GH treatment improves body fat distribution and is devoid of metabolic side effects (Luzi et al. 2005). Previous works suggest a reversal of positive effects on fat distribution after cessation of GH treatment. For this reason, even in the light of the results of previous studies, we foresee the possibility of proposing short periods of low-dose GH treatment (6 months in our experience) combined with a program of physical training (to be performed continuously both during the treatment and the wash-out periods) (Luzi et al. 2005). The quoted results may also be relevant for future studies aimed to assess the effect of low-dose GH treatment in clinical conditions (other than HIV lipodystrophy) characterized by visceral obesity. The known metabolic effects of higher doses of rhGH on glucose and lipid metabolism should always be taken into consideration (Luzi et al. 2003) (see previous section).

Approximately 20% of HIV-infected patients with lipodystrophy and increased visceral adiposity have inadequate GH response to GHRH/arginine using a stringent cutoff threshold of 3.3 ng/ml and, therefore, may be considered functionally GH deficient. Those patients may benefit from GH administration in terms of improving body composition and metabolic parameters, although further studies are necessary to test the efficacy of low-dose GH therapy. Use of a less stringent cutoff threshold may increase the number of patients failing the GH stimulation test but will decrease the specificity of the test. Additional studies are needed to optimally identify the cutoff for HIV patients with

reduced GH secretion and to assess, therefore, whether lipodystrophic patients might benefit from GH replacement (Koutkia et al. 2005).

Kotler et al. suggested that 4 mg of rhGH administered daily for 12 weeks significantly reduced visceral adipose tissue, trunk fat, dorsocervical fat, non-HDL cholesterol, and related cardiovascular risk parameters in carefully selected HIV patients with excess visceral adipose tissue. The optimal regimen to sustain these effects over time awaits determination (Kotler et al. 2004). With high-dose rhGH replacement, Lp (a) increases, glucose metabolism may become impaired, increasing the cardiovascular risk (in particular in males). High-dose GH therapy cannot be continued for more than a few months without incurring in the risk of cancer and impaired glucose tolerance or overt diabetes.

The presence of different sensitivity to GH of target tissues and of different GH response after GH administration in HIV-infected patients with and without lipodystrophy are yet presumed. In particular, IGF-I-producing tissues in lipodystrophic HIV-infected patients seem to be much more sensitive to injected GH than those in HIV-infected patients with wasting. In a interesting pilot study, Andersen and associates performed a 16-week open-label prospective study in six male patients with HIV-associated lipodystrophy syndrome using an s.c. low-dose hGH (0.7 mg/day). After treatment, the patients demonstrated significant increases in total and free plasma IGF-I, and a trend toward a favorable change in fat distribution was suggested. The low-dose hGH treatment was not associated with the side effects observed with the higher doses of hGH. Despite these results, the authors await placebo-controlled, randomized studies before extending the indication of hGH therapy in lipodystrophic HIV-infected patients (Benedini et al. 2008).

Also, GH administration in the absence of true GH deficiency did not show metabolic benefits in a study conducted in obese patients without HIV lipodystrophy (Shadid and Jensen 2003). By contrast, almost all studies reporting the effects of GH administration on glucose metabolism in obesity show trends toward worsening of insulin resistance. Thus, if visceral fat loss was truly achieved, the possible benefits (a primary incentive for GH administration) could be lost; however, any demonstrable effects on body composition were minimal, not necessarily attributable to the GH administration, and present only when isocaloric diets were given. Although GH administration attenuated nitrogen loss, this effect was lost after a few weeks, whereas it did not convincingly affect other parameters related to lean body mass. Troublesome non-metabolic side effects of GH treatment include fluid retention, arthralgia, and carpal tunnel syndrome (see Table 154.3).

Perhaps not surprisingly, GH returns to normal after weight reduction in obesity. This finding strongly suggests that low GH is a consequence, not a cause, of central obesity. Considering the high costs and the lack of a full knowledge of the long-term consequences of GH treatment of obesity, we argue against its use for this purpose, at present.

It is possible that the exogenous administration of GH can promote the deactivation of 11beta-hydroxysteroid dehydrogenase type 1 (11ß-HSD1), an important enzyme highly expressed in the visceral adipose tissue. This enzyme is able to decrease the autocrine generation of cortisol by cortisone in adipose tissue. Cortisol is well known to be able to interfere with normal fat distribution and cell proliferation (Benedini et al. 2008).

A low concentration of GH in the basal condition and after stimulation could be related to an high urinary cortisol level secondary to excessive activation of 11ß-HSD type 1. In fact, 11ß-HSD1 is highly expressed in human adipose tissue. It is conceivable that decreased 11ß-HSD1 activity represents a compensatory mechanism to the adverse metabolic profile in obesity. Although the effects of cortisol excess on adipose tissue mass are well recognized, as shown in patients with Cushing's syndrome, the impact of the autocrine generation of cortisol on fat mass regulation is less clear. Cortisol promotes adipocyte differentiation and inhibits preadipocyte proliferation, and it was previously shown that limiting cortisol availability to the glucocorticoid receptor (GR) through inhibition of 11ß-HSD1 inhibits adipocyte differentiation and promotes preadipocyte proliferation.

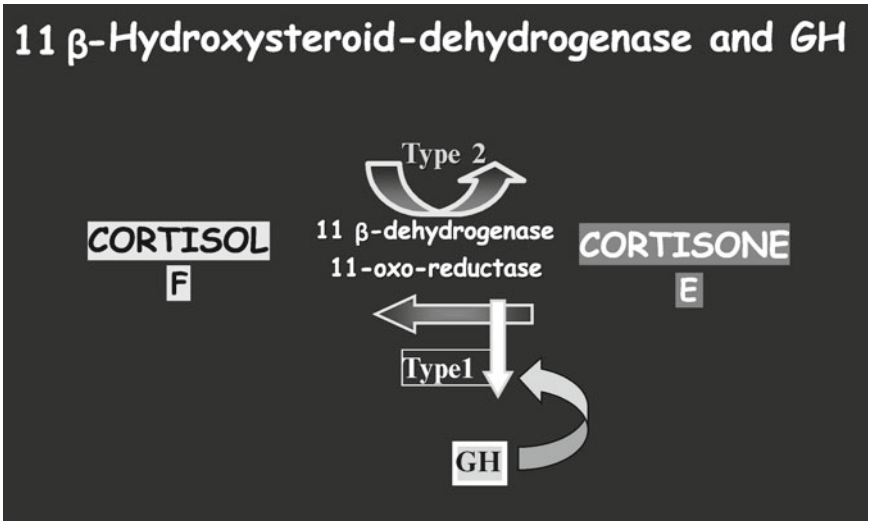

Fig. 154.3 11-Beta-hydroxysteroid dehydrogenase type 1 and GH. This figure explains the action of GH on 11-ß-HSD1 and the link between GH and steroid action

Therefore, it is possible that inhibition of 11ß-HSD1 by GH will decrease the autocrine generation of cortisol within adipose tissue, reduce adipocyte differentiation, and enhance preadipocyte proliferation. Once again, there is a delicate balance of actions between increasing and decreasing adipose tissue mass, and this may explain why GH did not alter absolute fat mass, despite inhibiting 11ß-HSD1 (see Fig. 154.3). In fact, a recent paper by Filipsson and colleagues showed the impact of different glucocorticoid regimens in patients with hypopituitarism (KIMS population) after 1 year of GH treatment (Filipsson et al. 2006). It is possible that increased tissue exposure to GC, as a result of increased 11ß HSD1 activity, which occurs in replaced ACTH-deficient and GHD subjects, promoted adipocyte differentiation and preadipocyte proliferation. A similar hormonal picture is present in HIV patients with lipodystrophy, who have relative hypercorticism and associate metabolic and nutritional alterations.

In summary, human growth hormone (hGH) was demonstrated to increase lean body mass in HIV wasting syndrome, but its long-term efficacy in patients with HIV-lipodystrophy is uncertain. Prospective studies documented hGH's role in reducing fat and increasing lean mass, especially in the trunk, without changing overall body weight significantly. The response is usually nearly complete by 12 weeks of therapy and reverses rapidly upon discontinuation (Hoffman et al. 2005).

154.6 Conclusions

Both nucleoside reverse transcriptase inhibitors (NRTIs) and the protease inhibitors (PIs) are considered causes of the lipodystrophic syndrome in HIV.

These drugs have significantly improved the survival and prognosis of HIV-infected individuals. However, side effects, such as lipodystrophy and metabolic disturbances, have appeared in past years (Carr et al. 1998).

Table 154.2 Key features of growth hormone

1. GH is a protein hormone of 190 amino acids that is synthesized and secreted by the acidophil cells of the anterior pituitary gland.
2. The pituitary gland is responsible for the production of eight hormones; GH secretion is largely regulated by the hypothalamus.
3. GH is a major participant in the control of several physiologic processes, including growth and metabolism.
4. The major role of growth hormone in stimulating body growth is to stimulate the liver and other tissues to secrete IGF-I.
5. IGF-I stimulates the proliferation of chondrocytes (bone growth), but also appears to be the key player in muscle growth and decreasing fat accumulation.
6. GH and IGF-1 stimulate amino-acid uptake and protein synthesis in muscle and other tissues and also stimulate lipolytic activity of adipose tissue in combination with a reduction of triglycerides' accumulation (inhibition of lipoprotein lipase activity).
7. GH exerts profound effects on whole-body- and district-body composition through a combination of anabolic and lipolytic actions.

This table lists the actions of growth hormone, including site of production, regulation, and the principal effects on body composition
IGF-I insulin-like growth factor I

Table 154.3 Absolute contraindications to recombinant human Growth Hormone (rhGH) therapy

Contraindication of GH therapy
• Active malignancy
• Benign intracranial hypertension
• Proliferative or preproliferative diabetic retinopathy
• Pregnancy after first trimester

This table lists the major contraindications for using recombinant human growth hormone in adult patients

Much remains to be learned about the HIV lipodystrophy syndrome. Although, morphologically, there are distinctive and recognizable markers of this metabolic pattern. There is compelling evidence that the NRTIs, particularly stavudine, play a facilitative, if not primary, role in its development. PI use appears to be responsible for the metabolic manifestations, but, again, the mechanism(s) responsible is(are) undefined for both drugs. Aside from the effect on quality of life, the short-term consequences of lipodystrophy are manageable. However, there is concern about the potential long-term risks, especially for atherosclerotic disease. At present, the metabolic complications are, to an extent, treatable with standard therapies or possibly with substitution for the PI component of therapy. Among other therapies, hGH and metformin may reduce lipodystrophy (Kravcik 2000).

Low value of GH in basal condition and after stimulation could be related to high value of plasma and urinary cortisol. In fact, the role of 11beta-hydroxysteroid dehydrogenase type 1 (11ß-HSD1) in the pathogenesis of human obesity and the regulation of adipose tissue mass is not fully explained. 11ß-HSD1 is highly expressed in human adipose tissue. It is plausible that decreased 11ß-HSD1 activity represents a compensatory mechanism to the adverse metabolic profile in obesity. Although the effects of cortisol excess on adipose tissue mass are well recognized, the impact of the autocrine generation of cortisol on fat-mass regulation is less clear. It is clear that there is a delicate balance of actions between increasing and decreasing adipose tissue mass; this may explain why GH did not alter absolute fat mass despite inhibiting 11ß-HSD1. Furthermore, the degree of inhibition mediated by IGF-I may not be sufficient to truly limit the availability of cortisol to the glucocorticoid receptor. Other factors that may explain the lack of effect of GH on fat mass in this study also need to be considered.

Although GH treatment may not represent an effective therapy in simple obesity because of its many complex actions and perhaps because of its lack of potency as an inhibitor of 11ß-HSD1, selective, potent inhibition of 11ß-HSD1 may represent a novel therapeutic strategy for insulin sensitization (Tomlinson et al. 2003). Patients with central obesity but with no evidence of hypopituitarism have relative GH deficiency and it is exciting to speculate that low-dose GH treatment in this group, by inhibiting cortisol generation within omental fat, may offer a novel therapeutic approach.

This important action on endocrine picture suggests that GH treatment could be an important support in HIV-related lipodystrophy. The question, which is still open, is the duration of the GH treatment. Previous work suggests the reversal of effects on fat distribution after cessation of GH treatment. For this reason, we foresee the possibility of proposing short periods of low-dose GH treatment combined with a program of physical training. Recent preliminary data show that two to three sessions of aerobic exercise performed for 3 months at 40–60% of VO_2 max improve insulin secretion and reduce TNF-α and MCP-1 in HIV-1-infected patients with lipodystrophy. The use of low-dose hGH showed favorable change in fat distribution (Luzi et al. 2005). Also, in adults with GH deficit after more than 6 months of GH therapy, lipid profile, insulin resistance, and flow-mediated dilatation improved (Benedini et al. 2006). A point that seems unclear is the real impact on cardiovascular risk secondary to elevation of Lp (a) after GH therapy. In fact, in patients with abnormal lipid profile, the positive impact on cardiovascular risk of GH treatment could be offset by the rise of Lp (a), particularly in males. Regarding the potential worsening of lipid profile in patients on GH therapy, many authors emphasized the positive effect on cardiovascular risk of this therapy in patients with GH deficit (Benedini et al. 2006). In HIV-related lipodystrophy, there is a lipid profile very similar to patients with GH deficit and the use of GH therapy could improve dyslipidemia and, consequently, cardiovascular risk. Some authors have suggested also the use of more physiologic strategy, which involves the use of growth-hormone-releasing hormone (GHRH) to augment growth hormone secretion, leading to a reduction of abdominal fat accumulation (Grinspoon 2006).

In conclusion, hrGH therapy is able to change the fat distributions, as stated in a recent paper by Haugaard et al. (2006a) and seems to improve also metabolic picture[3]. However, before suggesting hGH therapy in selected HAART-treated patients with HIV-related lipodystrophy, we would like to stress the importance of further studies (placebo-controlled, randomized studies) with the aim to better define the strategies to revert lipodystrophy and to minimize the side effects of GH therapy.

Summary Points

- The growth hormone exerts profound effects on whole-body- and district-body composition through a combination of anabolic and lipolytic actions playing a central role in human metabolic homeostasis.
- Different human diseases (other than HIV) associated with lipodystrophy are characterized by major metabolic derangements, such as insulin resistance and dyslipidemias.
- In the past, many treatments were proposed to improve lipodystrophy, but all of these had only partial beneficial effects on the metabolic picture.
- Even if GH/IGF-1 therapy does result in a small increase in cancer risk compared with untreated patients with GH deficiency, it is likely that the eventual risk will be the same as in the general population.
- Human growth hormone (hGH) was demonstrated to increase lean body mass in HIV wasting syndrome, but its role in patients with lipodystrophy is not very clear.

Key Points

- HIV-related lipodystrophy is associated with peripheral fat wasting and central adiposity, dyslipidemia, insulin resistance, and increased intramuscular fat accumulation.
- In literature, there are some pilot studies in patients having HIV with lipodystrophy showing that low-dose GH treatment improves body fat distribution and is devoid of metabolic side effects.
- hGH was demonstrated to stimulate redistribution of fat in HIV with lipodystrophy. However, before suggesting hGH therapy in selected HAART-treated patients with HIV-related lipodystrophy, the importance of further studies with the aim to better define the strategies to revert lipodystrophy and to minimize the side effects of GH therapy needs to be stressed.

- In HIV-infected patients with lipodystrophy, hrGH therapy is able to change the fat distributions and seems to also improve the metabolic picture.

Chapter 155
Digital Three-Dimensional Photogrammetry: Craniofacial Applications to Facial Growth, Orthognathic and Reconstructive Surgery, and Morphometrics

Nada M. Souccar, Chung How Kau, and Seth M. Weinberg

Abstract Three-dimensional (3D) surface imaging systems have been extensively used in the past three decades by orthodontists and maxillofacial surgeons. The principal advantages of these devices are their quick image acquisition time, non-invasiveness and ease of application, which make them particularly suitable for children and patients with disabilities. In addition, they have been validated against anthropometry for precision, accuracy, bias and reproducibility. The generated models are easy to store and manipulate, making them a unique tool for diagnosis, treatment planning, surgical evaluation and longitudinal studies. Three-dimensional photogrammetry has multiple applications: The creation of average faces has been described and allows age, gender and racial comparison. Monitoring and quantitation of post-surgical changes in reconstructive surgery and orthognathic interventions is also possible using surface imaging. Moreover, it is a powerful morphometrics method used to identify phenotypic markers associated with genetic risk for a particular condition such as non-syndromic cleft lip and palate. Finally, a virtual face can be created by combining surface imaging with cone beam computed tomography.

CT	Computed tomography
CBCT	Cone Beam Computed Tomography

155.1 Introduction

For centuries, the human face has inspired artists and challenged the medical profession. Over the past three decades, three-dimensional surface-imaging devices that allow a realistic capture of the craniofacial complex have been developed. This chapter will present some craniofacial applications of surface-image acquisition to facial growth, orthognathic and reconstructive surgery, and morphometrics.

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_155,

Cranial dimensions were traditionally used in anthropometry to determine normal proportions in selected similar individuals. Distances and angles were measured directly on defined cranial and facial landmarks, generally using calipers (Farkas 1994). With the evolution of three-dimensional imaging technology, it is now possible to capture craniofacial surface images for diagnosis, treatment, and research purposes. This technology enables clinicians and researchers to study the soft tissue of the face in a faster and less invasive way than direct examinations. The acquired data are a collection of points, each defined by x, y and z coordinates and, therefore, represent a mathematical expression of the human face. If color and texture information are gathered at the same time, they will be added over the produced 3D model. It then becomes possible to define soft-tissue landmarks, measure distances, and compare proportions on this newly created geometrical model (Lane and Harrell 2008; Kau et al. 2007b).

155.2 Validation of Systems

Weinberg and Kolar (2005) define at least four equally important aspects of measurement error to evaluate 3D anthropometry: the magnitude of error associated with multiple observers/repeated measurements (precision), the degree of similarity between the device and conventional techniques (accuracy), the tendency of the device to systematically under- or overestimate values (bias), and the device's ability to capture data in a consistent manner (reproducibility). Studies have been conducted to validate various 3D surface morphometric systems:

Aldridge et al. (2005) identified facial landmarks on 3D images from a sample of 15 children and adults obtained with the 3-dMD system (3dMDface, Atlanta, GA) and tested precision, measurement error, and repeatability of image acquisition. They showed that the average error associated with landmarks placement was submillimeter. Precision was high (error below 1 mm) and repeatability exceeded 95% for most identified landmarks. Weinberg et al. (2006) compared the precision and accuracy of two structured light systems, the Genex FaceCam (Kensington, MD) and 3dMD systems, with anthropometrics. They used 18 mannequin heads with marked facial landmarks to measure 12 linear distances. The measurements were taken twice with each method to evaluate intra-observer reliability. They reported submillimeter-level accuracies and good precision, regardless of the employed method. In a publication by Wong et al. (2008), the 3dMD system was tested against direct anthropometry by taking linear measurements in 20 normal adults. Most measurements were found to be reliable (mean $r = 0.91$) and precise (high correlation between direct and digital values, $r = 0.88$). Computerized stereophotogrammetry (C3D), another type of structured light system, was extensively researched by a team of orthodontists and maxillofacial surgeons. Their findings indicate that the precision of facial landmark identification of 21 facial stone models of patients with cleft lip was within 1 mm (Ayoub et al. 2003). As a result, they validated the use of this device in infants, children, for surgical procedures, and orthodontic models. Laser light systems were also tested for validity. The accuracy of Minolta VI-900 scanners (Konica Minolta, Tokyo, Japan) was found to be 0.56 ± 0.25 mm and the error in computerized registration of left and right scans was 0.13 ± 0.18 mm (Kau et al. 2005).

Because of the ease of data acquisition, storage, manipulation, and image superimposition over different time points, 3D imaging is now widely used for various craniofacial applications such as:

1. Facial averages;
   1.1 Gender analysis
   1.2 Facial morphology in different populations;

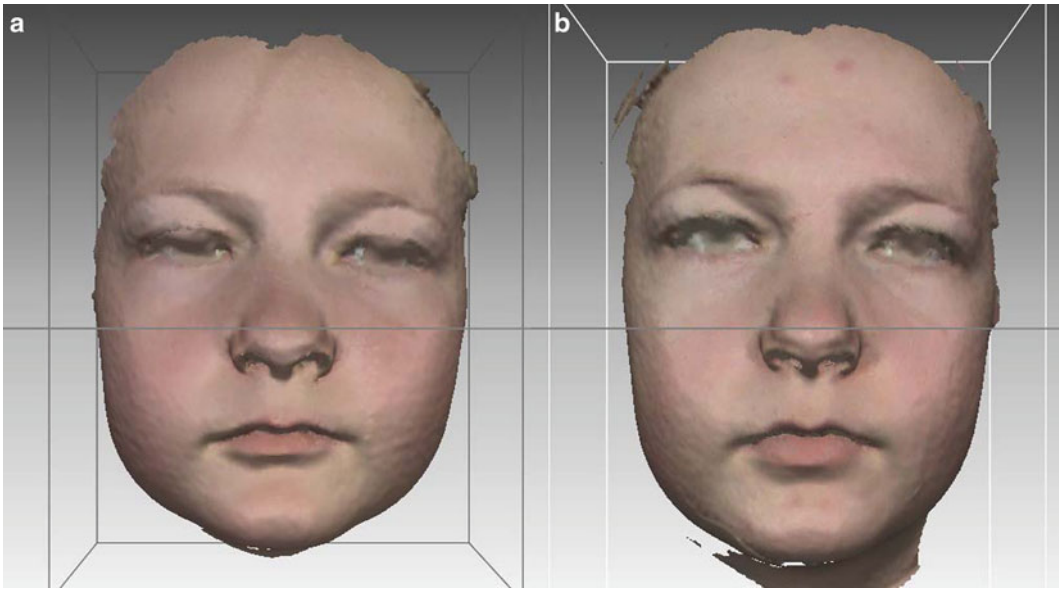

Fig. 155.1 Three-dimensional surface reconstruction of a female patient. Three-dimensional laser reconstruction of a female patient taken at two different time points. (**a**) Time 1: height = 145 cm, weight = 39.0 kg and (**b**) time 5: height = 155 cm, weight = 48.3 kg

2. Facial growth;
3. Orthognathic and reconstructive surgery;
4. Morphometrics; and
5. The virtual face.

155.2.1 Facial Averages

Our modern society emphasizes the importance of esthetics. However, the concept of beauty, although related to proportions and harmony, varies from population to population. Therefore, it is of prime importance to understand the characteristics of faces across diverse cohort groups and posit specific norms for each of them. Just as cephalometric averages vary according to age, gender, and ethnicities (Bishara et al. 1990), a targeted three-dimensional soft-tissue template would allow clinicians to treat a particular group to a particular norm, within the limits of biology and stability.

A three-dimensional construction of the average face can be done in the following sequence (Kau et al. 2006a):

1. Pre-aliging images by determining the principal axes of rotation (based on computing the tensor of inertia of each 3D image);
2. Manual positioning, when necessary, to improve the previous stage;
3. Applying best-fit alignment using inbuilt algorithms;
4. Averaging coordinates of the images normally to a facial template;
5. Point-cloud triangulation to obtain an average face;
6. Improving the average face by filling in small holes and removing possible mesh defects; and
7. Applying color texture (Fig. 155.1).

This process allows the comparison of intergroup average faces in addition to the analysis of an individual face against his/her corresponding gender/age group mean. Gender analysis, population comparisons, and growth studies are possible applications for this method.

155.2.1.1 Gender Analysis

Female and male morphologies are intrinsically different. One can visually determine that females present a rounder, thinner, and softer face than males who often have larger bones and overall facial dimensions. However, it would be much more interesting to be able to quantitate gender variation. In a study by Kau et al. (2006b), a set of left and right scans was taken from 80 healthy males and females (mean age 24.5 years) using two laser-scanning devices assembled as a stereopair (Minolta VI900, Osaka Japan). The resulting images were merged to form a composite 3D soft-tissue reconstruction of the face (a surface shell). Sex differences in facial morphology were then measured and visualized using shell-to-shell deviation color maps. The average difference between the male and female facial templates was 1.28 ± 1.02 mm. The areas of greatest deviation included supraorbital, zygomatic, and lower mandibular regions.

155.2.1.2 Comparisons Among Various Ethnic/Racial Groups

The three-dimensional face average is a unique tool to investigate morphologies and identify common features across populations. A series of studies conducted on subjects from five different countries (Wales, UK; Houston, TX, USA; Slovenia; and Egypt) illustrates this concept (Bo Ic et al. 2009; Seager et al. 2009; Gor et al. 2010; Kau et al. 2010). Two stereophotogrammetric systems were used: Minolta VI-900 and 3dMDface. The generated images were superimposed and a complex mathematical algorithm created one average composite female and one average composite male face per subgroup. Each obtained 3D shell was compared on the basis of gender to the other populations, in order to quantify facial similarities. The findings show that facial morphologic differences are greatest when very different populations are evaluated (Slovenia and Egypt for women, Houston and Egypt for men). Also, even though Europeans and Northern Americans show high concordance percentages, their differences are more concentrated in areas of the face that can be altered by orthodontic treatment. These results highlight the need to establish 3D norms inherent to each population. Since clinicians are relying more and more on soft-tissue appearance to decide treatment modalities, three-dimensional databases would allow them to have averages specific to each cohort group. Furthermore, being aware of the norms will help better understand the extreme variations of facial deformities.

155.2.2 Facial Growth

Growth and development of the human face have always been a major issue for the medical profession in general, and for orthodontists in particular. Dentofacial orthopedics is believed to enhance the differential growth of the jaws and correct unbalanced faces. Patients are unconsciously classified as ‘good’ or ‘poor’ growers, based on treatment outcomes. Progress has traditionally been measured by superimposing lateral cephalograms taken a few months apart on stable landmarks, such as the cranial base. Since radiographs are a two-dimensional representation of a three-dimensional reality

and because of the associated risk of harmful radiations, many researchers have found 3D-surface imaging a very attractive tool to understand soft-tissue changes and their underlying growth concepts. A mixed longitudinal and cross-sectional design by Ferrario et al. (1999a) used automated infrared photogrammetry to investigate soft-tissue growth in both genders and create three-dimensional facial soft-tissues normative data. Selected linear and angular measurements as well as ratios were calculated and averaged for age and sex. Their findings show that the soft tissue, particularly the middle third of the face, continues its growth in boys after age 13. The lower face grows continuously in both genders, boys being always larger than girls. A three-dimensional mesh-diagram analysis by the same group demonstrated that boys and girls have the same pattern of growth between ages 6 and 11. The pattern changes after adolescence, and males end up having a larger forehead, longer and more vertical nose, more inferior and posterior gonia, more inferior and prominent lips, and a larger mouth than female faces of corresponding age (Ferrario et al. 1999b). In a cross-sectional trial, Nute and Moss (2000) used a surface laser to acquire facial images of 132 five- to ten-year-old children and created average scans for each age and sex subgroup. The scans were superimposed on identified landmarks using the Procrustes method. This method proved to be useful to track changes in both genders at each age and changes of the same gender at different ages. A longitudinal study followed a cohort of 12-year-old children over 2 years. Researchers compared 3D laser surface reconstructions (Vivid VI900, Minolta, Tokyo, Japan) taken six months apart (Kau and Richmond 2008). Shells were superimposed according to the best-fit method. Using the appropriate software (Rapidform 2004, INUS technology, Seoul, Korea), the differences between the two facial reconstructions were automatically generated. The findings confirm that surface changes are more important and occur at a later time in boys than in girls. Growth occurs in a downward forward direction. The areas that grow the most are the nose, brows, lips, and vertical dimension of the face. Overall, in both genders, the eyes deepen and the cheeks become flatter (Fig. 155.2).

These analyses prove that 3D imaging is a successful method to monitor the effect of growth on the human face.

155.2.3 Orthognathic and Reconstructive Surgery

Orthognathic and facial reconstructive surgery treatment usually brings together a team of oral and maxillofacial specialists. One approach to monitor soft-tissue changes is to use color codes on facial-deviation maps to distinguish groups of normal adults and those with facial disproportion (Mc Cance et al. 1997). Another way is to superimpose 3D images on identified landmarks with a best-fit Procrustes method. This method was tested for pre- and post-surgical asymmetries' evaluations (Hajeer et al. 2004). Guest et al. (2001) demonstrated that the most sensible results in superimposition and comparison of two surfaces were achieved by the closest-point and the correspondence-by-sensitivity-to movement algorithms. However, average values for 3D maxillofacial morphologies were calculated and tested to evaluate post-surgical treatment effects in women (Terajima et al. 2009). By superimposing scans and measuring shell-to-shell deviation, Kau et al. (2007a) have shown that the greatest reduction in postoperative swelling occurred within the first month after single- and double-jaw orthognathic surgery, and the mean percentage of improvement was approximately 60–70%. Based on this timetable, Alves et al. (2009) conducted a prospective study to analyze facial surface after surgery. Three-dimensional surface images of 30 adults were taken pre- and post-operation and superimposed on the forehead, as it is not affected by the procedure. The color-coded millimetric map they developed was successful in tracking soft-tissue changes. Moreover, patients

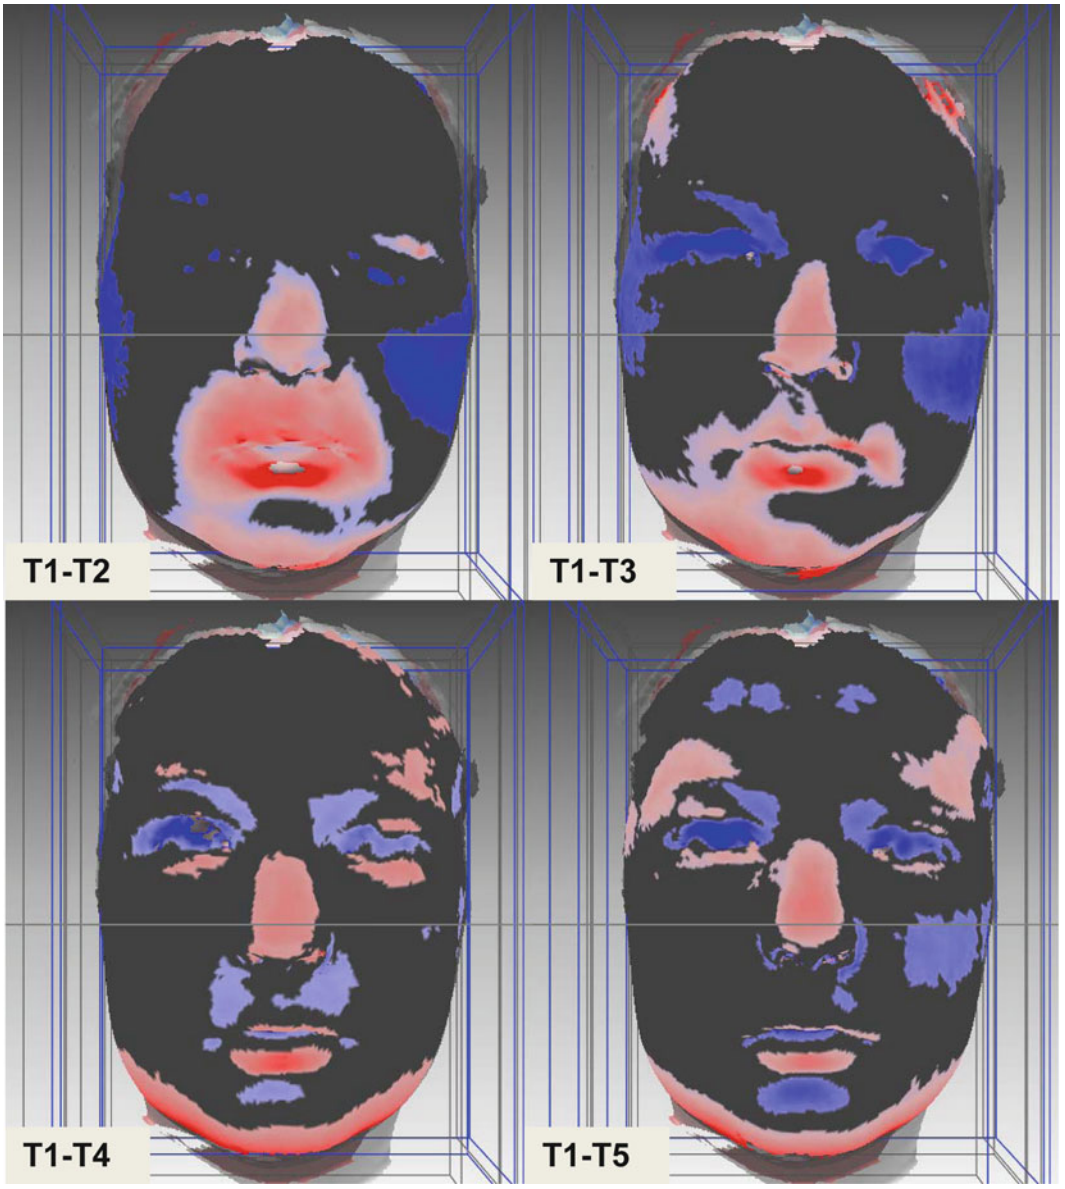

Fig. 155.2 Superimposition of two facial shells of a female patient obtained at four different time points to depict changes associated with orthodontic treatment and growth. The facial shells of the patient shown in Fig. 155.1 are superimposed to visualize the changes between T1 and four different time points (T2, T3, T4, and T5). Each time point is superimposed on the initial shell, obtained at T1. Red indicates positive changes (increase in prominence), blue indicates negative changes (retrusion), and black indicates similarities

with genetic syndromes requiring reconstructive surgery are excellent candidates for three-dimensional surface imaging. A review by Al-Omari et al. (2005) recommends the utilization of three-dimensional imaging for the diagnosis and evaluation of treatment outcome in cleft lip and palate patients. Additionally, the authors advocate the creation of a standardized method to assess cleft lip and palate affections, which will unify research protocols and allow a much more significant interpretation of results.

155.2.4 Morphometrics

Morphometrics aim at identifying phenotypic variations that could represent markers of genetic susceptibility. The combination of powerful statistical tools with three-dimensional surface acquisition allows investigators to precisely analyze the fine details of biological shape. One application is the investigation of morphometrics in non-syndromic cleft lip with or without palate (CL/P) patients. A meta-analysis of the cephalometric literature highlighted the following morphologic differences between unaffected parents of cleft lip and palate patients and controls: wider faces, interorbital and nasal cavity dimensions, narrower cranial vaults, longer cranial bases, and longer and more protrusive mandibles. The variations were subtle and gender specific (Weinberg et al. 2006). Recently, unaffected relatives of cleft lip and palate patients were compared to healthy controls (Weinberg et al. 2008). Using a selection of linear distance-based methods, the investigators observed a number of craniofacial differences between the two age- and sex-matched groups: increased upper and midfacial width, excess midface retrusion, increased lower facial height, and decreased upper facial height. Discriminant function analysis was able to correctly classify over 70% of female subjects and over 80% of male subjects, with facial width contributing most to group discrimination. Therefore, the assumption is that unaffected parents of CL/P patients present midface characteristics that differentiate them from the general population. If these traits are identified, they could serve as markers to classify 'at-risk' individuals. Therefore, morphometrics could assist genetic studies and improve recurrence risk estimation. A more recent study looked at face shape in unaffected parents with one or more cleft-affected children (Weinberg et al. 2009). Eighty parents were divided in two groups: 1. with a positive family history of cleft lip and palate, that is, an affected relative and 2. with a negative family history. A significant discrepancy was noted between unaffected parents and controls ($p < 0.01$). Parents with a positive family history of CL/P presented distinct midface retrusion, reduced upper facial height, increased lower facial height, and excess interorbital distance. In this group, it was also interesting to note that nasal dimensions were related to a specific gender pattern, with fathers having reduced and mothers having increased width.

These studies strongly indicate the need for the creation of a phenotype/genotype database to research morphologic characteristics and their associations with genetic disorders.

155.2.5 New Application: The Virtual Face

Surface imaging can be combined with hard-tissue imaging, such as the cone beam computed tomography (CBCT) to create a virtual patient. The idea is to start constructing the virtual face from the outside in, that is, from the soft tissue to the hard tissue. This concept is somewhat in opposition with the general idea of the face being a soft-tissue element resting on a hard-tissue structure. The major advantage is to capture the patient's natural head posture without any external aiding device. Consequently, by locking the CBCT inside the soft-tissue surface image, the CBCT can be reorientated, according to the patient's posture. The 3dMDvultus Software Platform allows the fusion of the 3dMD surface with three-dimensional hard-tissue imaging (CBCT, CT, or even dental models) (Fig. 155.3). In this complete reconstruction, it becomes possible to fully evaluate a patient and plan any treatment, including surgery. Surgical simulations are achievable and results can be anticipated. The software also permits surface distance and angle measurements with volume calculation. Volumetric analysis is critical for airway evaluation. Other applications include reconstructive surgery follow-up, such as in cleft lip and palate patients, aging changes, and non-surgical treat-

Fig. 155.3 The virtual face. Profile and Frontal view of a Cleft Lip and Palate patient. The 3dMDvultus Software Platform allows the fusion of the 3dMD surface with CBCT

ment evaluation. Prospective studies of facial development can also be conducted. Given all these features, we now have the tools to understand the mechanisms involved in craniofacial growth, development, dysmorphologies, and treatment. Research possibilities are therefore "virtually" endless.

Summary Points

- Surface-acquisition systems are noninvasive, inexpensive, and powerful tools to generate a three-dimensional model of the human face.
- They are particularly well suited for children and patients with facial deformities because of their quick acquisition and non-ionizing properties.
- The acquired data can be translated into a set of *x*, *y*, and *z* coordinates.
- Multiple quantitative comparisons between individuals at one or different time points render non-contact surface-imaging devices perfectly suited for research and clinical applications.
- Surface images can be superimposed to investigate the effects of growth and surgical treatment be used to track gender and ethnic differences.
- When used in morphometrics, 3D surface acquisition is a powerful tool to study subtle morphologic features that represent non-penetrant phenotype.
- The association of surface imaging with hard-tissue imaging, such as the CBCT, results in the creation of a virtual face. In addition to the above-mentioned applications, the virtual face can be the basis for future longitudinal craniofacial research.
- Comprehensive normative facial databases are needed and can be generated with surface imaging. Their purpose is to provide baseline reference dimensions for different ages, genders, and populations for direct morphologic comparisons and genetic studies and allow for inter-center research cooperation.

Key Facts on Cleft Lip and Palate

- Cleft lip with/without palate is the most common congenital craniofacial defect.
- It occurs in approximately 1 in 700 births.
- CL/P can be an isolated condition or be a part of an inherited disease or syndrome.
- Embryologically, the maxillary processes fuse with the frontonasal process at week 6. A failure of fusion results in a cleft lip.
- At week 8, the tongue is depressed and the palatal shelves migrate and fuse. Clefting of the palate results from the failure of the palatal shelves to fuse.
- Treatment of CL/P calls for a multidisciplinary approach: patients usually require multiple surgeries as well as extensive dental treatment to restore the lip, palate, and teeth, as needed. Patients also benefit from speech therapy and counseling.

Part XXIII
Anthropometry in Ethnic Groups and Cultural and Geographical Diversity

Chapter 156
Anthropometry in Ethnic Groups and Cultural and Geographical Diversity

Auricular Anthropometry of Newborns: Ethnic Variations

Wee Bin Lian

Abstract The human ear is important not just for its aesthetic value and hearing ability, but also helps to confer normality to a newborn. Developmental abnormalities can result in abnormal ear shape and size. Descriptive examination must therefore be supplemented by objective anthropometric measurements, to aid a complete diagnosis profile. Ethnic and race variations are well known to have an impact on various anthropometric measurements. The ear is likely to be no different. However, comparisons of ear measurements in different ethnic groups have been difficult and rarely carried out. Differences in methodologies and definitions have also made comparisons of reported studies challenging. Nevertheless, just as gestation is an important consideration when making such measurements, so is the ethnicity of the baby. Ear length by convention is most often defined as the maximum length measured from the superior to the inferior aspect of the external ear. By and large, the Caucasian ear appears to have a marginal edge on the Asian ear, with the Israeli and Turkish babies registering the longest ears. The impact of even minor differences in ethnicity is further realized in seeing that even Chinese of different historical roots may have different measurements, with the Hong Kong Chinese ear being somewhat smaller than the Taiwanese and Singaporean Chinese ear. Also interestingly, the longest ear need not necessarily be the widest ear. Ear width is defined as the transverse distance from the palpable anterior base of the tragus through the external auditory canal to the margin of the helical rim at the widest point. For this, the Japanese ear is supreme. Another aspect would be the placement of the ear which changes as the child grows. The few studies that evaluated this aspect of the ear concurred that it was normal to have at least a third of the ear above the intercathial medial line across the eyes, with the Asian ear appearing to be somewhat higher placed than the Caucasian ear. Knowing the size, shape and position of the normal ear lends more weight to terms such as microtia (small ear), macrotia and low-set ears, allowing the practicing clinician to pinpoint abnormalities and effect investigations and interventions more accurately, reducing unneeded parental anxiety.

156.1 Introduction

The human external ear, also known as the auricle, is embryologically derived from the pharyngeal arches, with the ear canal being derived from the branchial groove that joins the first pharyngeal pouch. Developmental defects of the 1st and 2nd arches or the groove would thus result in congenital malformations of the ear. Malformations of the pinna are relatively common conditions, reported to be in the range of 1 in 670 births, though external ear malformations and branchial sinuses and tags collectively are more common, with an incidence of 1 in 90 (Melnick et al. 1979). A whole range of ear abnormalities has been described, including abnormalities in size, shape and position (Table 156.1).

Ear development is also intrinsically related to the development of other organs being formed around the same embryological period. As such, abnormalities in the ear may herald a host of other significant abnormalities, which thus form the basis of the importance of dysmorphological examination of a newborn. The exclusion of any malformations or genetic syndromes is an integral part of the newborn screening process. It has become clear that the ear, besides being an aesthetic addition to the head, is an important organ not only for its function of hearing and equilibrium, but also as a diagnostic handle for dysmorphology and genetic disorders (Clark and Eteson 1991; Behrman et al. 2004; Jones 2006).

Table 156.1 Summary of types of ear malformation

Property	Abnormality	Description	Associated conditions
Size (Patil 2007)	Anotia/Agenesis	Absent ear (often with atretic ear canal)	Autosomal dominant (Gupta and Patton 1995), isoretinoin embryopathy (Clark and Eteson 1991), Treacher-Collins syndrome (Clark and Eteson 1991; Jones 2006), chromosomal anormalies, for example, trisomy 18
	Microtia	Small ears	Goldenhar syndrome (Clark and Eteson 1991), Hereditary autosomal dominant (Potter 1937), Down syndrome (Aase et al. 1973; Awwad et al. 1994; Thelander and Pryor 1966), rubella and other intrauterine infections
	Macrotia	Large ears	Hereditary (Rogers 1968), Fragile X syndrome (Butler et al. 1992; Hull and Hagerman 1993), Marfan syndrome (Jones 2006), De Lange type 2 (Verloes et al. 1996)
Shape	Cup-shaped	Small auricle cupped forward over the meatus	Pierre-Robin syndrome (Peterson and Schimke 1968), Autosomal dominant (Rogers 1968), Towns-Brocks syndrome (Jones 2006)
	Lop-shaped	Auricle lifting off the head at a greater angle	Autosomal dominant (Rogers 1968), Towns-Brocks syndrome (Jones 2006)
	Elfin	Pointed	Chromosomal anomaly (Golbus et al. 1973)
	Dysplastic	Abnormal shape	Trisomies 13–15, Treacher Collins (Clark and Eteson 1991; Jones 2006)
Position	Low set	Less than one-third of the ear length is above an arbitrary line drawn through both medial canthi of the eye	Noonan's syndrome (Sanchez-Casco 1983), Turner's syndrome (Horowitz et al. 1976), Down syndrome (Aase et al. 1973; Awwad et al. 1994; Thelander and Pryor 1966)
	Protruding	Ear sticks out/not flat against head	Foetal-alcohol syndrome (Jones 2006)

156.2 The Importance of Anthropometry in Newborn Assessment

Descriptions and anthropometric measurements of the ear are thus important to help establish norms for the purpose of comparison. Descriptions are important, especially in combination with visual cues but can sometimes be confusing, as there are many varied definitions as well as interpretations of definitions (Feingold and Bossert 1974; Saitta and Zackai et al. 2005; MedicineNet.com 2007; Patil 2007). Anthropometric measurements, on the other hand, using instruments, such as callipers, measuring tapes or specific purpose-built instruments, are systematised techniques which can provide quantitative values for qualitative descriptions. Using a combination of objective and subjective measures, it becomes possible to achieve some degree of consistency in dysmorphologic assessment.

156.3 Definitions

Ear length (EL) is usually defined as the maximum length measured from the superior to the inferior aspect of the external ear (Fig. 156.1). This definition has been employed by many authors across different ethnic populations (Sivan et al. 1983; Hall et al. 1989; Tateishi and Kaajii 1992; Chou et al. 2001; Fok et al. 2004; Agnihotri and Singh 2007; Lian et al. 2008), although, more specifically, Kalcioglu et al. (2006), described it as the length from the superaurale to the subaurale. Of particular significance was the landmark paper, by Farkas et al. (1992), who described EL as being the projective

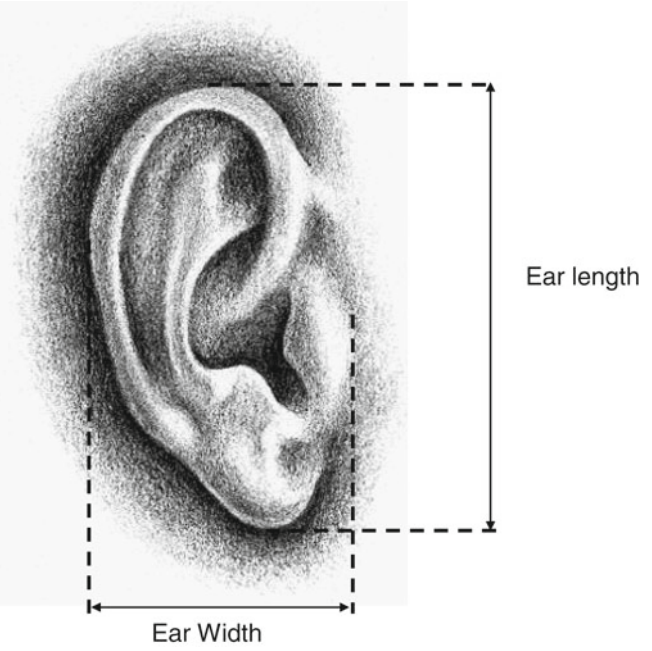

Fig. 156.1 Ear measurements. Ear length (*EL*) is usually defined as the maximum length measured from the superior to the inferior aspect of the external ear. Ear width (*EW*) is defined as the transverse distance from the palpable anterior base of the tragus through the external auditory canal to the margin of the helical rim at the widest point (Adapted from "Drawing the Ear" (www.artyfactory.com). With kind permission of John MacTaggart, art teacher from Glasgow, Scotland)

distance between the level of the highest point (superaurale) on the free margin of the auricle and the level of the lowest point (subaurale) on the free margin of the ear lobe. This was demonstrated in a schematic drawing, which, despite the similarly worded description, was different from that by Kalcioglu et al. (2006), who demonstrated a figure denoting a similar measurement as the other authors, using the maximal length measured between the most superior and inferior points. Such differences therefore need to be taken into account when comparing the results of the different studies.

Ear width (EW) is defined as the transverse distance from the palpable anterior base of the tragus through the external auditory canal to the margin of the helical rim at the widest point (Chou et al. 2001; Golalipour et al. 2003; Fok et al. 2004; Agnihotri and Singh 2007) (Fig. 156.1). This corresponds to the description and schematic drawing by Farkas et al. (1992). Kalcioglu et al. (2006), on the other hand, defined it as the distance from the tragus to the helix but denoted the posterior edge of the tragus to the helical rim in the accompanying figure. Minor differences may not make much difference in an older child or adult but would certainly make a difference amongst newborn infants. It is thus important to be aware of such differences when making comparisons, particularly amongst newborns.

156.4 Impact of Gestation and Age

In almost every newborn measurement, gestational age plays a significant role. Birth weight is classically linked to gestation, as is head circumference. Physical measurements, such as bone length and body proportions, are also related to gestation and therefore cannot be simply taken on their absolute values without information on gestation. This is important when making comparisons between studies. Shimizu et al. (1992) reported a linear relationship between foetal ear length and width and gestational age in an ultrasonographic study of 124 normal singleton pregnancies. The measurements quoted in this article generally have been based on measurements in term infants carried out soon after birth (Table 156.2). Also, as the baby grows, changes in facial structure and ear growth would have an impact on subsequent measurements (Farkas et al. 1992). Figure 156.2 (Fok et al. 2004) depicts the impact of gestation on ear length amongst Hong Kong Chinese populations. Figure 156.3 (Chou et al. 2001) also demonstrates the impact of age on the ear lengths amongst the Taiwanese Chinese babies and children. In this last study, an attempt had been made to compare the Caucasian ear and the Chinese ear in the older children, though no studies have thus far reported direct comparison across gestation in the newborn period.

It is well known that maturation and growth of the ear continues throughout the early years of a child's life, reaching mature size at between 7 and 13 years in the males and between 6 and 12 years in the females, with further growth toward maximal size in adulthood past 18 years (Farkas et al. 1992; Chou et al. 2001). As such, one wonders whether measurements at birth were different amongst the different ethnic groups and races, to have then become influenced by environmental and geographical changes, diminishing the differences as the child grows. The proportion of growth could also differ in different populations. A German study reported annual growth of 0.66 and 0.46 mm in boys and girls, respectively, and developed a nonlinear regression model only for EL, commenting that EW, conversely, was rather independent of age in both sexes (Pelz and Stein 1990). It was noted in the study by Farkas et al. (1992) that EW rapidly expands in early childhood and EL continues to expand beyond a year, despite reaching 75% of its adult size by 1 year. Consistent with that, Itoh et al. (2001) reported that rapid growth was observed until late teenage and significant growth

Table 156.2 Comparison of ear length (EL) of term infants amongst different ethnic populations

Author	Year	Country	Gestation (weeks)	Ethnicity (n)	Mean EL ± SD [Range] (cm)	Ear & time measured
Sivan et al.[a]	1983	Israel	Term	Caucasian males/ females[#] (48/39)	3.90 ± 0.30 [–]	Right ear[#]
Merlob et al.[a]	1984		27–41			36–60 h

				Japanese males (50)[#]	3.6 ± 0.25 [3.0–4.0]	
				Japanese females (50)[#]	3.5 ± 0.25 [2.8–4.0]	
Adeyemo et al.	1998	Nigeria	Term, AGA	Nigerian males/ females[#] (200)	3.2 ± 0.3 [–]	–
el Shanti et al.	2000	Jordan		Jordanian (158)	3.62 ± 0.29 [–]	Within 24 h
Chou et al.[b]	2002	Taiwan	Term	Chinese males(156)[#]	3.5 ± 0.8 [–]	Right ear[#]
				Chinese females (128)[#]	3.5 ± 0.6 [–]	Newborn
Fok et al.[a]	2003	Hong Kong	Term	Chinese males/ females[*] (2095)	3.19 ± 0.30 [–]	Within 48 h
Kalcioglu et al.[a]	2005	Turkey	40, Term	Turkish males[#] (20)	3.84 ± 0.64 [Upper limit 3.96]	Right ear Within 24 h
				Turkish females[#] (20)	3.84 ± 0.72 [Upper limit 3.71]	
Agnihotri and Singh[a]	2007	India	'newborn babies'	North Indian males (30)	3.76 ± 0.224* [–]	After 48 h
				North Indian females (30)	3.52 ± 0.261* [–]	
Lian et al.[b]	2008	Singapore	39, Term	Chinese/Malay/Indian/ Others[#] (83)	3.64 ± 0.27[#] [2.95–4.36]	Both ears[#] Within 36 h
			Term	Chinese (50)	3.59 ± 0.30[#] [2.4–4.0]	

[a] EL = length from superaurcle to subaurale or from most superior point on the helix to the inferior point of the external ear
[b] EL = greatest vertical axis
* Significantly different between groups within study
[#] No significant difference between groups within study (either race/gender/different-sided ears)

continued thereafter until advanced age. It is therefore highly debatable whether differences, seen or unseen, at older ages, would transpose into differences at the newborn age.

156.5 The Impact of Race and Geography

Yet one other factor casts further confusion on an already problematic field. Racial, geographical and ethnic variations have long been seen to make a difference in anthropometry, lending a huge diversity to life. For instance, comparisons in anthropometry show that Asians had more subcutaneous fat than did whites and had fat distributions different from whites (Wang et al. 1994). Race was also shown to have a significant and differential effect on the bones in the axial and appendicular skeletons

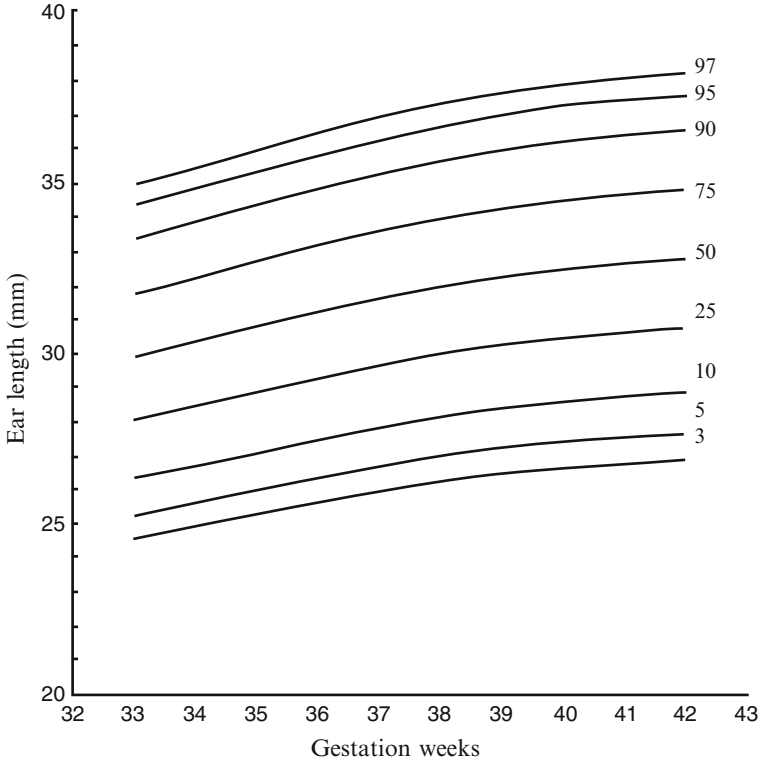

Fig. 156.2 Ear length versus gestation for Hong Kong Males. There is a corresponding increase of ear length with increasing gestation (Reproduced from Fok et al. (2004). With kind permission from Wiley-Blackwell, Oxford, UK)

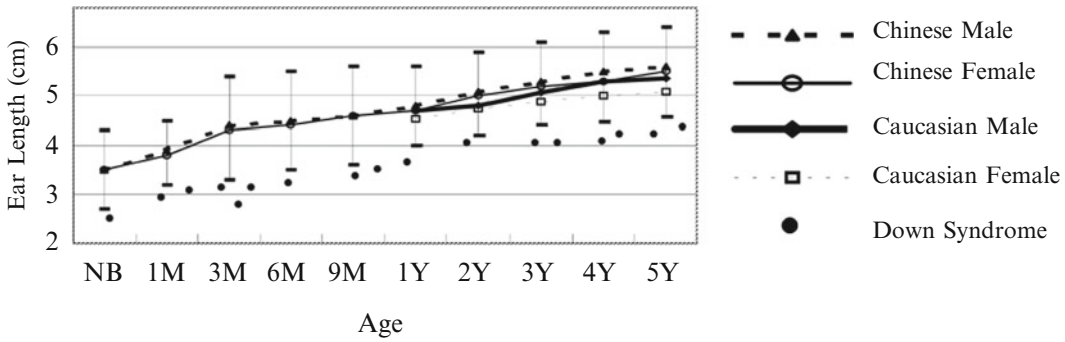

Fig. 156.3 Ear length of normal Chinese neonates, infants and preschool children (Reproduced from Chou et al. (2002). With kind permission from Tsai FJ)

(Glisanz et al. 1998). Similarly, such differences are also likely to be present with regard to anthropometric measurements of the face.

Despite previous work by physical anthropologists documenting differences in facial measurements among races and ethnic groups, this has only been systematically investigated in recent years (Dawei et al. 1997; Farkas et al. 2000; Le et al. 2002). Farkas et al. (2005), who had done much anthropometric work, observed that, with the influx of numerous peoples into North America, the significance of the broader spectrum of races and ethnic groups became important for craniofacial

surgeons and other medical professionals whose work involved the analysis and correction of head and face abnormalities. His study was drawn from 14 measurements in 1,470 subjects of 25 national groups hailing from Europe, the Middle East, Asia, Africa and North America belonging to four races. Interestingly, the regions with single measurements (head, mouth and ear) showed almost no differences though ethnic / racial differences in those regions with multiple measurements (orbits, facial width, etc.) were observed between vertical and horizontal measurements. These nevertheless remained adult studies.

156.6 Anthropometry in Different Populations

There are to date only limited reports of ear anthropometry studies done in different ethnic populations amongst the newborn. Methodologies also differ with the adoption of somewhat varied definitions. To permit reasonable comparison, the methodologies employed should be similar between studies. Despite such restrictions, it is still useful to place studies of different population side by side to give an idea of ethnic and racial variations.

156.7 Methodologies

Early researchers tended to rely on Western studies. Feingold and Bossert (1974), presented one of the earliest papers to aid syndrome delineation. For the purpose of ear anthropometry, the authors, with their cohort of 356 cases, described the use of an instrument made from a pre-calibrated transparent film. Both sides of the instrument were divided into millimetres to allow measurement of both the right and left ears by the same instrument. This method was employed in the Israeli study by Sivan et al. (1983). This method was also adopted by Lian et al. (2008), in a more recent study carried out in Singapore (an Asian country). This therefore permits comparison of values between these ethnically different cohorts. Both Sivan et al. (1983) and Lian et al. (2008) validated their findings by having two independent observers. Hall et al. (1989) recommended the use of a tape measure or a transparent calibrated ruler. Tateishi and Kaajii (1992), employed the use of a sliding calliper in his Japanese cohort. Agnihotri and Singh (2007) as well as Fok et al. (2004) similarly used a vernier calliper in their study of Indian and Hong Kong Chinese babies, respectively. Chou et al. (2001) in his Taiwanese study described the use of a calliper ruler. Golalipour et al. (2003) used a Martins sliding calliper in his cohort of two ethnic groups, the Turkman and the Native Fars groups in the Iran-Gorgan area.

156.8 Ear Length

Not many authors have reported on EL amongst different ethnic groups within the same geographical location (Table 156.2). Lian et al. (2008), in a recent study, revealed no significant differences amongst four different racial groups of different ancestry within the same Asian country. However, it would appear amongst studies with similar methodologies that across the board, although the means of EL measurement amongst different ethnic populations do not vary widely, there remained likely subtle differences, with the Caucasian ear slightly longer than the Asian ear. The upper limits of normality for the Caucasian ear are also higher than the Asian ear. The Israeli and Turkish ears are reportedly amongst the largest newborn ears. Sivan et al. (1983) and Merlob et al. (1984) (Israeli)

reported a mean of 3.90 ± 0.30, whereas Kalcioglu et al. (2006) (Turkish) reported a mean of 3.84 ± 0.64 cm for males and 3.84 ± 0.72 cm for females, with upper limits of norms between 3.96 and 3.71 cm, respectively. By contrast, the African ear (Adeyemo et al. 1998) is closer to the Hong Kong Chinese ear (Fok et al. 2004), being amongst the smallest of the newborn ears. The Jordanian (el-Shanti et al. 2000), Japanese (Tateishi and Kaajii 1992), Indian (Agnihotri and Singh 2007), Taiwanese (Chou et al. 2001) and Singaporean (Lian et al. 2008) ears measure in between, somewhat closer to the Caucasian ear. Interestingly, this pattern is also borne out in the study by Lian et al. (2008), where the general mean EL across different ethnic groups was slightly larger than the Chinese mean, though not statistically significant.

Furthermore, even in exploring similar ethnicities of similar ancestral descent, such as amongst Hong Kong Chinese, Taiwanese and Singaporean Chinese, there also appeared to be differences in EL, with the latter cohort being closer to their Caucasian counterpart, similar to the Japanese ear. One wonders whether the heterogeneous nature of the cosmopolitan Singaporean population, with rising incidences of interracial marriages, has lent weight to anthropometrical changes, leading to narrowing of differences in anthropometrical measurements. By contrast, the Hong Kong Chinese remain a fairly homogeneous group. Notably, however, Taiwan, despite being also a fairly homogeneously Chinese group, albeit with the historical hybrid nature of its society, and possibly earlier Japanese and Western influence, appeared more similar to Singapore.

156.9 Ear Width

Even fewer authors have reported on EW amongst newborns. Some demonstrated graphs but the number of reported numerical values in their reports were too few to permit comparison. Interestingly, despite a relatively shorter ear compared to their Caucasian counterparts, the Japanese baby has the widest neonatal ear, with an EW that is considerably bigger at 2.7 ± 0.21 cm (Tateishi and Kaajii 1992). The Turkish neonate has a smaller EW at 2.01 ± 0.39 cm (Kalcioglu et al. 2006). Again, the Singaporean newborn was more in tandem with their Turkish counterpart (Lian et al. 2008; Kalcioglu et al. 2006). None of these three studies (Table 156.3) showed any significant difference between the genders.

156.10 Ear Position

There is little doubt that a standard ear does not exist. Not only are there differences in EL and EW when looking at different ethnicities, the ear position and setting lend further confusion to ear anthropometry. Hall et al. (1989) described the degree of protrusion of the ear as being measured by the angle that is subtended from the posterior aspect of the pinna to the mastoid plane of the skull. This measurement is seldom measured in the neonate due to the fact that the ear continues to change over the years in childhood before finally reaching a settled position and size in adult ears. Ear position is denoted by the location of the superior attachment of the pinna. Therein lies another potential area of confusion in ear assessment for normality. Hall also described the various ways that this can be studied. Some authors would use an imaginary line between the outer canthi of the eye and the most prominent part of the occiput and confer normality on the ear with the superior attachment of the pinna being on or above this line. Another method would be the use of yet another imaginary line through the inner and outer canthi of the eye, again with normality being conferred on the superior

Table 156.3 Comparison of ear width (EW) of term infants amongst different ethnic populations

Author	Year	Country	Ethnicity (n)	Gestation (weeks)	Mean EW ± SD [Range] (cm)	Ear and Time measured
Tateishi and Kajii[b]	1992	Japan	Entire cohort (100)	37–41,	2.7 ± 0.21 [2.2–3.1]	Left ear[#] 8–64 h (majority within 40 h)
			Japanese males (50) [#]	Term	2.7 ± 0.20 [2.3–3.1]	
			Japanese females (50) [#]		2.6 ± 0.20 [2.2–3.0]	
Kalcioglu et al.[b]	2005	Turkey	Turkish males[#] (20)	40, Term	2.01 ± 0.39 [-]	Right ear
			Turkish females[#] (20)	40, Term	2.00 ± 0.43 [-]	Within 24 h
Lian et al.[b]	2008	Singapore	Chinese/Malay/Indian/ Others[#] (83)	39, Term	2.06 ± 0.14[#] [1.74–2.40]	Both ears[#] Within 36 h

attachment of the pinna being on or above that line. The argument with both methods lies in the fact that the Asian eye is often with a natural upward slant. This would result in unfavourable comparisons with the Caucasian measurements.

A more readily adopted method would be the use of a line drawn through the inner canthi of both eyes (intermedial canthial line – IMCL) and extending it outwards, with normality conferred on the superior attachment of the pinna being on or above this line. This method was adopted by a number of authors, such as Feingold and Bossert (1974), looking at the definition of low-set ears. However, anthropologists more often favour the Leiber method (Hall et al. 1989; Fok et al. 2004), which is more complicated and involved more landmarking, a technique which would be difficult for the practicing clinician.

There is extremely limited literature on studies that look at ear position. The definition of 'low-set ears' has conventionally been taken as the ear which has less than 33% of the vertical ear height above the IMCL. The study by Sivan et al. (1983) was reportedly comparable with Feingold and Bossert (1974), marking approximately 30% above the eyeline. However, Lian et al. (2008) reported that the ears of the babies in their Asian multiracial cohort were 'higher set', at 49 ± 8% of the ear being set above the IMCL, than those of previously studied Caucasian babies. Notably, Golalipour et al. (2003) looked at a different measurement in his study of head shapes and faces amongst two ethnic groups of different ancestry presently living in the same geographical location. Using the term 'auricular height', defined as 'the vertical distance between vertex to external acoustic meatus', the study reported differences in ear placement between those who migrated from central Asia and those who were native to that area, with the former group demonstrating a significantly higher placed ear in relation to the vertex than the latter. This is the only study to date looking at different ethnic groups in the same geographical location. There is clearly room for more studies in this area of anthropometry.

156.11 Applications to Other Areas of Health and Disease

156.11.1 Investigations and Interventions for the Baby with the Abnormal Ear

With objective measurement norms now available for different populations, it would be important to apply these in clinical practice. An abnormal ear has a lot more implications than just the aesthetic value or for the craniofacial surgeon to adjust. It points to a need for full extensive examination of the baby and an attempt to delineate all the potential problems associated with it.

The work-up for the presence of an abnormal ear needs to take into account developmentally associated patterns. For instance, there is often a need to obtain a renal ultrasound to exclude renal abnormalities in the presence of an abnormal ear. There might be a need to explore the auditory tracks and pathways to ensure adequate hearing ability. There would be a need to involve a multidisciplinary team for better management of the child. Genetic counselling and the involvement of the geneticist become important in a suspected genetic disorder, should the abnormal ear form part of a larger syndrome. Management is often long term and, as such, an abnormal ear should only be labelled abnormal in the context of the appropriate population norms; hence, ethnic and racial variations may become significant, especially in multiracial populations.

156.11.2 Further Implications of Ethnic Variations

Just as in ear anthropometry, the impact of ethnic variations should also be considered in measurements of other aspects of the newborn. In particular and pertinent to daily practice would be the weight, length and head circumference of the newborn (Cortés et al. 1992; Schumacher et al. 1990; Golalipour and Heydari 2004/2005). Studies on other facial measurements have also looked at the impact of ethnicity (Madjarova et al. 1999; Fok et al. 2003). Even penile length has been shown to be different between and within populations (Lian et al. 2000; Fok et al. 2005). Ethnicity and race will always remain factors to be considered in anthropometry, even in the most minute part of the body. To be exact in one's science is to take every factor into consideration. Only then can we be sure that we have provided the best of services and care.

Summary Points

- The newborn ear is important for aesthetics, hearing and equilibrium maintenance, as well as serving as an indicator marker for dysmorphology.
- Descriptive examination must therefore be supplemented by objective anthropometric measurements, to aid a complete diagnosis profile.
- Ethnic and race variations are well known to have an impact on various anthropometric measurements.
- Ear length by convention is most often defined as the maximum length measured from the superior to the inferior aspect of the external ear.
- The longest newborn ear is reported amongst the Israeli and Turkish babies, with smallest amongst the Hong Kong Chinese babies.
- There are also differences amongst Chinese of different geographical origins, where Taiwanese and Singaporean Chinese demonstrate longer ears than Hong Kong Chinese babies.
- Ear width is defined as the transverse distance from the palpable anterior base of the tragus through the external auditory canal to the margin of the helical rim at the widest point.
- The longest ear is not necessarily the widest ear. The Japanese newborn ear is the widest amongst limited reports.
- In limited studies, the ear is generally at least one-third above the eyeline or the inter-cathal medial line across both eyes. A low-set ear implies abnormality and is related to many genetic conditions.
- The work-up for any anthropometric abnormality must take ethnic variations into consideration. In the newborn, gestation and in the infant/child, age should also be taken into account in any anthropometric assessment.

Key Points

- Both qualitative and quantitative assessments are important in the delineation of a normal newborn ear, essential to newborn screening and syndromic diagnosis. Ethnic and race variations are well known to have an impact on various anthropometric measurements.
- Ear length by convention is most often defined as the maximum length measured from the superior to the inferior aspect of the external ear. The Middle-Eastern babies tend to have the longest newborn ears. Even within the same ethnic group, EL appears to be impacted by country of origin.
- Ear width is defined as the transverse distance from the palpable anterior base of the tragus through the external auditory canal to the margin of the helical rim at the widest point. The longest ear is not necessarily the widest ear. The Japanese newborn ear is the widest amongst limited reports.
- In limited studies, the ear is generally at least one-third above the eyeline or the inter-cathal medial line across both eyes. A low-set ear implies abnormality and is related to many genetic conditions.

Chapter 157
Ethnicity and Facial Anthropometry

Mehrdad Jahanshahi

Abstract The term of ethnicity is also international and multilingual. An ethnic group or ethnicity is a population of human beings whose members identify with each other, either on the basis of a presumed common genealogy or ancestry.

The human face is a highly rich stimulus that provides diverse information for adaptive social interaction with people.

Cephalometry is one of the important parts of anthropometry, in which the dimensions of the head and face are measured. Cephalometric results are used in forensic medicine, plastic surgery, oral surgery, paediatrics, dentistry, and diagnostic knowledge between the patient and normal populations.

Some descriptive and cross-sectional studies which was set up to determine and compare the face shapes in Fars and Turkman ethnic groups of normal newborns and 17–20 years old males and females in Gorgan (North of Iran). The length and width of faces were determined by using classic cephalometery technique with usage a Martin spreading caliber, and the shape of faces in the ethnic group of Fars and Turkman in both sexes was compared.

Studies indicate that the Hypereuriprosopic type with 34.60% was dominant type in Turkman's male newborns and also dominant type of faces in Fars' male newborns was hypereuriprosopic with 71.9%. Also the mesoprosopic type with 36.01% was dominant in the Turkmans female newborns and the dominant type of face in native Fars female newborns was hypereuryprosopic with 71.22%.

The dominant type of face shape in the native Fars females was Euryprosopic (37.7%) and it was Euryprosopic (51.7%) in Turkman females.

The dominant type of face shape in the native Fars males was mesoprosopic (44%) and it was mesoprosopic (38.4%) in Turkman males.

157.1 Introduction

Studying intra- and interpopulation variations in different morphological characters have long been an interest of anthropologists (Ghosh 2007). The evaluation and measurement of human body dimensions are achieved by physical anthropometry (Chamella 1997). The dimensions of the human body are affected by ecological, biological, geographical, racial, gender, and age

factors (Imami-Mibodi 1996; Okupe et al. 1984; Hamill 1979). On the basis of the above factors, anthropometrical studies have been conducted on the age, gender, and racial groups in certain geographical zones (Afak et al. 1998; De Onis et al. 1998). The term 'ethnicity' is already huge and is constantly being added to. This term is also international and multilingual, large parts of it being regrettably inaccessible to readers who depend on English (or any other single language) for their familiarity with this topic.

The differences between regions and disciplines begin with the very definitions of the terms ethnicity, extending to all the ramifications of these terms for the social, psychological, economic, political, and cultural interactions within and between groups of human beings.

Some concepts of ethnicity and race are as follows:

An ethnic group or ethnicity is a population of human beings whose members identify with each other, on the basis of either a presumed common genealogy or ancestry.
Ethnicity connotes shared cultural, linguistic, or religious traits.
Ethnicity is defined in terms of shared genealogy.
The term 'race' refers to the concept of dividing people into populations or groups on the basis of various sets of characteristics and beliefs about common ancestry.
Race connotes shared biological (genetic or phenotypic) traits.
Race is defined in terms of shared genealogy.

Not only the meaning of 'race' has changed over many centuries, but also it is now generally accepted as something created by society. The American Anthropological Association's statement on race is that, "Physical variations in the human species have no meaning except the social ones that humans put on them." While we may not be different biologically, the color of our skin is the most visible difference among us, and it affects the way we interact with each other.

Racial encounters carry a long history of abuse from colonization, which saw the establishment of a major group and a minor group. This condition still thrives today but ethnicity, gender, and economic status further inform the experience of the minority. Ethnicity is best defined as the practices and traditions of a racial group, such as language, religion, behaviors, and culture.

Current understanding of racism can be traced back to the period of industrialization of Europe and the colonization of non-European peoples in the eighteenth century, when there were rapid scientific and technological developments. The ways and cultures of indigenous peoples and people of color were seen as inferior to the white explorers and colonizers, and were therefore exploitable (Enlow 1990; Farkas 1994).

Today, many countries are culturally diverse due to generations of immigration resettlement (refugees who have been selected to establish themselves in a country), diaspora (a dispersion of people from their original homeland), and forced displacement; however, race relations within a country remain tense and unstable. Racial and ethnic minority identities are shaped by the dominant culture, which controls the institutions of power (the legal and education system, media, etc.) that produce and maintain representations and stereotypes. In spite of this, ethnic and racial minorities are defining and creating their own identities.

Multicultural societies help promote cultural acceptance and pluralism (the state of having more than one culture in one geographic area), but they should be careful not to focus on the simple aspects of culture, such as food, dance, music, and clothing, as they do not represent a culture in its complexity and do not disturb the organization and power of the dominant culture.

The human face is a highly rich stimulus that provides diverse information for adaptive social interaction with people. Humans are able to process a face in a variety of ways to categorize it by its identity, along with a number of other demographic characteristics, including ethnicity (or race), gender, and age.

Over the past few decades, much effort has been devoted in the biological, psychological, and cognitive sciences areas, to discover how the human brain perceives, represents, and remembers faces. Computational models have also been developed to gain some insight into this problem. Anthropometrical statistics show the racial and ethnic morphometric differences in the craniofacial complex (Enlow 1990; Farkas 1994).

157.2 Applications to Other Areas of Health and Disease

Enlow in 1990 and Farkas in 1994, based on carefully defined facial landmarks, took 25 measurements on head and face to examine three racial groups (i.e., North American Caucasian, African-American, and Chinese). Farkas identified several differences in these three groups. For example, the Chinese group had the widest faces; the main characteristics of the orbits of the Chinese group were the largest intercanthal width. Further, the soft nose is less protruding and wider in the Chinese group and it had the (relatively) highest upper lip in relation to, for example, mouth width. Enlow also conducted research on the structural basis for ethnic variations in facial form (Enlow 1990; Farkas 1994).

The demographic features, such as race and gender, are involved in human face-identity recognition. Malpass and Kravitz in 1969 and also Brigham and Barkowitz in 1978 reported that humans are better at recognizing faces of their own ethnicity/race than faces of other races (Malpass and Kravitz 1969; Brigham and Barkowitz 1978). Golby et al. showed that same-race faces elicit more activity in brain regions linked to face recognition (Golby et al. 2001). They used functional magnetic resonance imaging (fMRI) to examine if the same-race advantage for face identification involves the fusiform face area (FFA), which is known to be important for face recognition (Puce et al. 1995). O'Toole et al. in 1994 investigate the differences in the way people perceive own- versus other-race faces. They found that the perceived typicality of own-race faces was based both on global shape information and on small distinctive feature markers, whereas the typicality of other-race faces related more to the presence/absence of local distinctive features (O'Toole et al. 1994). O'Toole et al. have shown that people categorize faces of their own-race by sex more efficiently than they categorize faces of another race by sex. The identification of race and gender can help the face-recognition system to focus more on the identity-related features and limit the number of entries to be searched in a large database, improving the search speed and efficiency of the retrieval systems. Ethnicity and gender are also useful for demographic statistics in many social applications. Unlike identity, ethnic categories are loosely defined classes. O'Toole reduces the ethnicity classification into a two-category classification problem, Asian and non-Asian, each of which has relatively distinct anthropometrical features (O'Toole et al. 1996).

Image-based face recognition has been drawing a great deal of attention over the past decade. A number of face-recognition algorithms have been investigated and several commercial face recognition products. In real applications, cross-race, cross-gender, and large-scale face-recognition tasks need to be solved (Zhao et al. 2000).

Cephalometry is one of the important parts of anthropometry, in which the dimensions of the head and face are measured. Cephalometric results are used in forensic medicine, plastic surgery, oral surgery, pediatrics, dentistry, and diagnostic knowledge between the patient and normal populations. Although anthropometric studies of newborns and other age groups and their relationship in health and disease have been achieved, there is currently a background for research in different geographical and racial groups.

157.3 Practical Methods and Techniques

The face measurements determined with a Martin spreading caliber (Fig. 157.1b) included:

- Face length = nasion – gnathion height (Fig. 157.1a-4).
- Face width = bizygomatic breath (Fig. 157.1a-2).

To compute the prosopic index, the following formula is used:

$$\text{Prosopic index} = \frac{\text{Face length}}{\text{Face width}} \times 100$$

The above index was determined on the basis of international anatomical descriptions. Based on this index, the types of face shapes were classified as the following (Banister et al. 1995).

Face Shape	Prosopic Index (PI) Range (%)
Hypereuriprosopic (very broad face)	75 < PI < 79.9 and PI < 75
Euriprosopic (broad face)	80 < PI < 84.9
Mesoprosopic (round face)	85 < PI < 89.9
Leptoprosopic (long face)	90 < PI < 94.9
Hyperleptoprosopic (very long face) (Fig. 157.2)	PI > 95

Distribution of face shapes in Turkman and Fars female newborns

Morphological features of different races and ethnic groups are not randomly distributed but appear in geographic clusters.

In the north of Iran (southeast of Caspian Sea), there are some different ethnic groups that have been residing for about two centuries. Some of them are: Native Fars, Turkman, and Sistani (Jahanshahi et al. 2008).

Turkman group: The Turkman populations have been living in this area for more than two centuries, having emigrated from central Asia. The Turkman people marry only among themselves because of religious and ethnic concepts. They are therefore almost a 'pure' ethnicity.

Native Fars group: The populations of native Fars were selected from three generations who have lived in this region.

Sistani group: This population emigrated from the east of Iran to the north about 80–100 years ago.

The morphological classification of the face shape in newborns in north of Iran (southeast of Caspian Sea) is depicted in Tables 157.1 and 157.2:

Table 157.3 17–20-year-old females

	Females

Total	200	100	198	100	

The shapes of face in 17–20-year-old males in Fars and Turkman group
NS not significant

According to Tables 157.1 and 157.2, the hypereuriprosopic type with 34.60% and the hyperleptoprosopic type with 0.90% were the dominant and the rare types in Turkman male newborns; the dominant and rare types of faces in Fars male newborns were hypereuriprosopic with 71.9% and hyperleptoprosopic with 2.5%, respectively (Golalipour et al. 2003).

In Table 157.2, the mesoprosopic type with 36.01% and the hyperleptoprosopic type with 1.89% were the dominant and the rare types in the Turkman female newborns, and the dominant and rare types of face in native Fars female newborns were hypereuryprosopic with 71.22% and hyperleptoprosopic with 4.24%, respectively.

It was concluded that there is significant difference between the dominant types of faces in the Turkman and native Fars ethnical groups.

The morphological classification of the face shape in adult females and males in north of Iran (southeast of Caspian Sea) is depicted in Tables 157.3 and 157.4:

The means and SD of prosopic index in Turkman males and females were 87.25 ± 5.18 and 81.48 ± 5.28, respectively.

The means and SD of prosopic index in Fars males and females were 88.22 ± 5.21 and 84.48 ± 5.85, respectively.

The dominant type of face shape in native Fars females was euriprosopic with 37.7%, and in Turkman females, it was euriprosopic with 51.7% (Jahanshahi et al. 2008).

The dominant type of face shape in native Fars males was mesoprosopic with 44% and, in Turkman males, it was mesoprosopic with 38.4%.

There were no significant differences between the dominant types in the two sex and racial groups.

Further, the rare type of face shape in native Fars females was hyperleptoprosopic with 5.8% and, in Turkman females, it was leptoprosopic with 3%.

The rare type of face shape in native Fars males was hyperleptoprosopic and hypereuryprosopic with 4% and, in Turkman males, it was hypereuryprosopic with 8.6% (Jahanshahi et al. 2008).

Another study in east of Iran, by Heidari et al. showed that the prosopic index was significantly different in Sistani and Baluchi women and the dominant type of face shapes was euryprosopic with a statistically significant difference between them. The rare types were hypereuryprosopic and hyperleptoprosopic in the Sistani and hyperleptoprosopic in the Baluchi groups (Heidari et al. 2006).

157.4 Conclusion

The study of the face shapes in different parts of Iran indicates that the geographical factor, similar to ethnical factor, can affect the form of the face. Normally, various facial types are encountered in every population so that a certain number of people have thin, broad, or small faces. In children, the PI is lower than in the adults, and through growing up, they gain a longer and narrower face.

Summary Points

- An ethnic group or ethnicity is a population of human beings whose members identify with each other, on the basis of either a presumed common genealogy or ancestry.
- Not only has the meaning of 'race' changed over many centuries, but it is now generally accepted as something created by society as well.
- Cephalometry is one of the important parts of anthropometry, in which the dimensions of the head and face are measured.
- Cephalometric results are used in forensic medicine, plastic surgery, oral surgery, pediatrics, dentistry, and diagnostic knowledge between the patient and normal populations.
- The dominant type of face shape in native Fars females was euriprosopic with 37.7% and, in Turkman females, it was euriprosopic with 51.7%.
- The dominant type of face shape in native Fars males was mesoprosopic with 44% and, in Turkman males, it was mesoprosopic with 38.4%.
- In conclusion, the face shapes in different parts of Iran indicate that the geographical factor, similar to ethnical factor, can affect the form of the face.

Chapter 158
Anthropometry in the Circumpolar Inuit

Tracey Galloway, T. Kue Young, and Peter Bjerregaard

Abstract The Inuit are an indigenous population whose homeland today comprises Chukotka in Russia, Alaska, northern Canada and Greenland, with an estimated global population of 165,000. The rapid social and economic changes especially over the past half century have been accompanied by a health transition, for which anthropometry is well suited to provide convenient and inexpensive indicators such as stature and obesity. The historical and early ethnographic literature reported the Inuit as characteristically short but with a high sitting height ratio. The Inuit morphology has been attributed to adaptation to the cold Arctic climate, however, secular trends in increasing height and reducing sitting height ratio, especially among children, have been documented. Obesity among the Inuit based on BMI, skinfold thicknesses, and waist circumferences had been uncommon up until the late 1970s and early 1980s. Recent surveys among children in some regions have found an alarming prevalence of obesity at 57% for boys and 45% for girls. Studies on the metabolic correlates of obesity among adult Inuit tend to show a lower degree of blood pressure, plasma glucose, insulin, and atherogenic lipids compared to Europeans at the same levels of BMI, however, imaging studies that localize abdominal fat distribution are lacking. Determining the health consequences of "obesity" classified according to international criteria requires longitudinal monitoring of defined cohorts. While field studies of anthropometry in the Arctic are faced with formidable logistical obstacles, they offer important information for monitoring the health and nutrition status of the population, and the planning and evaluation of health programs and services.

158.1 Introduction

The Inuit are indigenous residents of the circumpolar regions of North America, Greenland, and the Chukota Peninsula in Siberia (Table 158.1). The term 'Inuit' is the plural of 'Inuk', which means a person. The term is used to refer collectively to a number of linguistically closely related groups with a variety of regional names, such as Yuit, Yupik, Alutiiq, Inupiat, Inuvialuit, and Kalaallit. It has generally replaced the older term 'Eskimo', which is perceived to be derogatory in some regions, especially in Canada. While the total population of Inuit is low, it has risen rapidly in recent decades. It is estimated that, globally, there are over 165,000 Inuit in the early years of the twenty-first century, including approximately 51,000 in Canada, 57,000 in Greenland and Denmark, 55,000 in the USA, and 1,800 in Russia (Young and Bjerregaard 2008:126).

The age structure of the Inuit population is disproportionately weighted toward children and youth. In social terms, this means a majority of Inuit communities are characterized by relatively young populations whose need of health and social services is not matched by the infrastructure available to them. There are both geographic and political barriers to health and social development in the north, and economic development is unevenly distributed among geographically disparate communities.

In the past 40 years, acculturation to a Western lifestyle has proceeded in the Arctic at a rapidly increasing pace. Inuit communities have experienced a shift from nomadic hunting and gathering to a largely sedentary lifestyle and a transition to a wage-based cash economy. In some jurisdictions, government policy required the forcible removal of children from communities to attend residential schools, where Inuit language and other cultural activities were severely curtailed. Increasing availability of market goods and foods, combined with the impact of settlement and climate change on the availability of country foods, has led to enormous changes in dietary patterns.

There are some substantial differences in the overall health status of the Inuit and their national counterparts. Infant mortality is two to three times those of the non-Inuit population in the same country, and life expectancy at birth of the Canadian and Greenland Inuit is 10–14 years lower than among the non-Inuit. Other significant health problems include infectious diseases, such as tuberculosis and sexually transmitted diseases, and injuries, especially suicide among youths (Niclasen and Bjerregaard 2007). Social statistics too reflect the challenges facing Inuit communities. Poverty is widespread, and education and employment levels are low compared to national levels in Canada, Denmark, and the USA (Young and Bjerregaard 2008).

This chapter examines the use of anthropometric techniques to assess the health and nutrition of the circumpolar Inuit, and discusses some of the methodological challenges of such research.

Table 158.1 Key facts about the circumpolar Inuit

1. The Inuit are indigenous people whose traditional lands occupy the Arctic regions of Canada, Greenland, Alaska and Eastern Russia.
2. In these countries, the Arctic environment is relatively harsh compared with the south. Mean annual temperature is below freezing and the growing season is extremely short with limited rainfall.
3. Humans have occupied Arctic regions for 15 000 years. Today's Inuit are descendents of the Thule cultural group, which occupied Arctic regions 1000 years ago.
4. Historically, Inuit are nomadic hunters, following the migratory patterns of terrestrial and marine mammals, birds and fish. Depending on region and seasonal availability, traditional Inuit diet includes caribou, muskox, seal, walrus, whale, char, cod, halibut and herring.
5. Today, the majority of Inuit live in settled communities. Most Inuit towns have fewer than 1 000 residents. Larger administrative centres such as Iqaluit, Canada and Nuuk, Greenland have populations of 8 000 and 14 000 respectively.

This table lists key historical facts about the circumpolar Inuit history, subsistence pattern, and demography

158.2 Historical Studies of Stature and Body Proportion

There is an abundant ethnographic literature produced by polar explorers whose travels brought them into contact with circumpolar people, for example, the 1631 voyages to Hudson Bay by James and Fox, the 1776 voyage of Captain James Cook to the Pacific Northwest, and Lavrentiy A. Zagoskin's travels in Yukon and Alaska during 1842–1844. All contain similar descriptions of short, physically robust adults, lean and muscular from rigorous outdoor work in the cold Arctic climate (Michael 1967; Oswalt 1999).

Short stature, as a characteristic of Inuit morphology, was reported in early anthropometric studies by anthropologists Franz Boas (1888) and Ales Hrdlicka (1930, 1941). In a 1958 survey of Alaskan National Guardsmen, Mann et al. (1962) recorded adult height on average 2.5 cm shorter than that of the overall Canadian population. Reporting on studies undertaken in1968–1972 for the Human Adaptability Section of the International Biological Program (IBP), Auger et al. (1980) found that Inuit populations in USA, Canada, and Greenland had standing heights consistently below the 50th percentile of the US National Centers for Health Statistics (NCHS) reference. For both men and women, the statures of Alaskan Eskimo people followed the 25th percentile, those of Canadian Inuit ranged nearer the 5th centile, and those of Greenlandic Inuit were intermediate between the 5th and 25th percentiles of height-for-age.

Efforts were made to discover how early in ontogenic development the limitation on stature emerged. In their 1958 survey of Alaskan schoolchildren, Mann et al. (1962) observed that children's height tracked a Canadian population reference closely until the age of 6 years; children 7–19 years had heights significantly below the reference. Other studies found decreased stature evident even earlier in growth. In an examination of data collected by researchers and physicians in Canada and Alaska between 1928 and 1972, Jamison (1990) demonstrated that despite mean recumbent length at birth consistent with the 50th percentile of the NCHS growth reference, by 3 months of age the mean length of Inuit children fell to the 10th percentile of the NCHS and remained there through the first 36 months of life. Heller et al. (1967) and Maynard and Hammes (1970) reported declining length/height and rising weight-for-height percentiles among Alaskan infants within the 1st months of life that persisted into childhood.

A second noted feature of Inuit morphology was described by Danish anthropologist Kaj Birket-Smith, who accompanied the Fifth Thule Expedition of 1921–3. Commenting on the Caribou Eskimo, he wrote: "As a rule the Eskimos are powerfully built and plump without being fat. The trunk is comparatively long and the arms and legs short in relation to the total height" (Birket-Smith 1936, cited in Young 2007). This pattern of short arms and legs relative to total height was incorporated into anthropometric research through use of the sitting height ratio (sitting height/standing height). In a review of Arctic anthropometric data collected during 1880–1928, Stewart (1939) found sitting height values comparable with European and US references, whereas the sitting height ratio was comparatively high in Arctic populations due to their shorter legs. Subsequent studies of circumpolar populations bore this pattern out (Heller et al. 1967; Maynard and Hammes 1970; Auger et al. 1980). Johnston et al. (1982) found significantly shorter leg lengths and higher sitting height ratio among 84 Alaskan children ages 6–17 years when compared with US reference data.

High sitting height ratio complicates interpretation of weight-for-height, as the mass of the body trunk or core is relatively greater than that of the extremities. High weight-for-height has been observed in Inuit populations throughout the twentieth century. Jamison (1990) examined data from North American and Greenland studies as early as 1928, finding high weight-for-age across childhood. Heller et al. (1967), Auger et al. (1980), and Petersen and Brant (1984, cited in Jamison 1990) report high weight-for-height values in Alaskan children from 6 months to 20 years of age. Low stature and high relative sitting height complicate calculation of weight-for-height and other calculated indices of body composition, such as body mass index, in both historical and contemporary populations. As a result, anthropometric assessment of adiposity in circumpolar populations requires a combination of techniques and analytic approaches.

158.3 Inuit Morphology and Cold Adaptation

The pattern of stature and limb proportions in the North American and Greenlandic Inuit is widely interpreted as evidence of physiologic adaptation to cold climate. Inuit populations have been described as fitting the ecological 'rules' of Bergmann and Allen that relate size and shape of the body to climactic variation, as a result of natural selection (Johnston et al. 1982:400).

'Bergmann's rule' is often applied to explain variation in body size among human populations (Steegman 2007). Evolutionary anthropologists, such as Ruff et al. (2005), posit that the adaptive advantage of greater mass per unit of volume arises through the conservation of heat dissipation via limited body surface area per unit of mass in shorter, cold-adapted populations. Further, Ruff argues that this selective advantage is responsible for latitudinal variation in stature among both hominid and contemporary human populations. Steegman reviewed studies of cold adaptation since 1975 and failed to find consistent physiologic evidence in support of Bergmann's rule. For example, in a series of cold immersion studies, McArdle et al. (1984) and Toner et al. (1986) reported equivalent rates of core temperature loss in women and men of varying statures and surface area-to-mass ratios. Gustafsson and Lindenfors (2009) found no demonstrable relationship between latitude and stature across 124 human populations.

Population differences in limb-length proportions are viewed by evolutionary anthropologists as consistent with the thermoregulatory principle described by Allen's rule, which states that species living in warm regions tend to have longer extremities than those living in cold regions. Steegman challenged the heat-conservation advantage of foreshortened extremities. Because of peripheral vasoconstriction, little heat is lost from the distal extremities, regardless of body proportion differences within the human species (Steegman 2007:226). The driver of variability in extremity length and sitting height ratio in circumpolar populations may not be cold, as previously assumed, but a combination of environmental conditions, such as nutrition and infectious disease burden, an idea advanced as early as in 1939 by Stewart (1939:122). Steegman (2007) suggests that circumpolar populations may exhibit thermal adaptation related to both the insulative and metabolic properties of skeletal muscle. Although fat has higher insulative value than muscle, a thickly muscled individual will have much more muscle than subcutaneous fat, resulting in a higher absolute insulative value. Studies of Inuit body composition support ethnographic descriptions of circumpolar people as robustly muscular. Shephard et al. (1973) found that the Canadian Inuit had one-third more lean body mass per centimeter of height than did men from southern Canada. Johnston et al. (1982) observed significantly greater upper-arm circumference in Alaskan Eskimo children compared with a US reference, with mean values falling in the 74th percentile for boys and in the 94th percentile for girls. In this population, greater lean mass was interpreted as an increase in heat-producing tissue and a physiologic adaptation to cold. Other morphologic and physiologic features, such as centripetal fat distribution (Schaefer 1977), brown adipose tissue (Lean and James 1986), and basal metabolic rate (Leonard et al. 2002), offer avenues for investigation of human cold adaptation.

158.4 Adiposity in Historical Studies of Inuit

Historical ethnographic sources describe Arctic populations as relatively lean compared with their European and North American contemporaries. John Murdoch, in his report of the 1881–83 Point Barrow Expedition, described Eskimo people as "of medium height, robust and muscular, inclining rather to spareness than corpulence, though the fullness of the face and the thick fur clothing often gives

the impression of the latter" (Anderson and Eels 1935:26–7). A similar observation was made by Canadian anthropologist Diamond Jenness in his report of the 1913–18 Canadian Arctic Expedition. Jenness described Copper Eskimo people as "of about middle stature, and sturdy and robust in build. The fur clothing in which they are habitually enveloped gives them an exaggerated appearance of corpulence, whereas in reality they incline towards slenderness" (Jenness 1923, cited in Young 2007). These authors highlight a fundamental misconception about Inuit morphology that persists to the present day that historically their high adiposity was perhaps part of an adaptive mechanism for living in cold climate. Commenting on the results of a 1975 Nutrition Canada survey, Schaefer noted the "popular misconceptions of Eskimos eating lots of blubber and being jolly rotund fellows whose presumably ample subcutaneous fat padding helps them to withstand the Arctic cold" (Schaefer 1977:1623).

In fact, analysis of historical sources suggests that obesity was virtually nonexistent in circumpolar populations prior to the twentieth century (Michael 1967; Oswalt 1999). Anthropometric studies repeatedly demonstrated a pattern of low height, with overall body weight comparable to non-Inuit (Boas 1888; Hrdlicka 1930, 1941). The pattern of low prevalence of obesity appears to have continued into the mid-twentieth century. In a 1958 Survey for the US Interdepartmental Committee on Nutrition for National Defense, Mann et al. (1962) observed that obesity was rare among Eskimo men employed by the Alaskan National Guard and that weight in excess of 100% of US actuarial tables was an artifact of excessive bone and muscle mass rather than fat deposits (Mann et al. 1962:43–4). In addition, the low caloric intake reported in numerous nutrition studies suggests Inuit were morphologically lean (Schaefer 1977:1626).

As recently as 1973, researchers recorded very low prevalence of obesity among Greenland Inuit children (Schnohr et al. 2008). In a study of 1,000 adult Inuit conducted during 1964–1970, Schaefer (1977) reported triceps, subscapular, and suprailiac skinfold thicknesses significantly lower than those of the overall Canadian population. Measures of 84 Alaskan Eskimo children 6–16 years of age showed no difference in triceps skinfold thicknesses when compared with a US reference population (Johnson et al. 1982), despite high weight-for-height values. Retrospective analysis of anthropometric data from Greenland (collected between 1962 and 1964) reveals median Inuit BMI in the high percentiles of the WHO reference, despite overwhelming evidence that this was an extremely lean population by any standard (Andersen et al. 2004).

158.5 Secular Trend in Stature

Over the course of the twentieth century, researchers have recorded a secular trend of increasing stature among the Inuit. Schaefer (1970, cited in Jamison 1990) compared measures of children ages 2–14 years taken in 1938 (n = 176) and 1968 (n = 186) in the Eastern Canadian Arctic and found a significant increase in height during this period among both boys and girls. Jamison (1990) compared measures of 71 boys ages 2–13 years taken in 1968 with those of 70 boys taken in 1977 by Petersen and Brant (1984, in Jamison 1990) in Wainwright, Alaska and found that, in 1977, the boys were significantly taller up to age 11 than their 1968 counterparts. Rode and Shephard (1984) compared measures of 9–19-year-old children living in living in Igloolik, Canada, in 1970 (n = 110) and 1980 (n = 205). While in 1970, the authors reported increasing height values relative to earlier studies, they found no evidence of secular trend during the period 1970–80, concluding that secular trend had reached its zenith around 1970 in this population. For all age groups, the 1980 children's mean standing heights remained significantly below that of US, Canadian, and UK references. Subsequent measures taken in 1989 (n = 547) showed a resumption of the trend toward increasing height in this population, with significant differences evident between the 1980 and 1989 samples (Shephard and Rode 1995).

Zammit et al. (1993) compared results of a 1991 study of Labrador Inuit children and adults with historical stature data on Labrador Inuit collected between 1880 and 1928. Evidence suggested that secular trend in stature had occurred over this period, though in the modern study children's mean height still fell between the 10th and 50th percentiles of the NCHS reference. In a study of children from Maniitsoq, Greenland, of ages 5–19 years, Becker-Christensen (2003) compared standing height values from 1996–7 with measurements taken in 1964–5. In the roughly three decades between studies, there was an increase of at least 10 cm in standing height among 14-year-old children. A recent study of 3–5-year-olds from Nunavut, Canada, reported no difference in mean stature between Inuit children and the US Centers for Disease Control (CDC) growth reference (Galloway et al. 2010). It should be noted that some of the above studies incorporated small sample sizes and a wide variety of techniques and personnel. Interpretation of their findings is hampered by lack of methodological consistency. However, taken as a whole, they provide generally consistent evidence of stature increase in Inuit children over decades across a wide geographical area.

Interestingly, while children's standing height increased during the late twentieth century, this increase appears to be the result of a modification in the shape of a child's growth curve, with earlier maturation resulting in an earlier adolescent growth spurt. Rode and Shephard (1984) observed this phenomenon as early as 1984, reporting changes in the timing of growth spurts for height and body mass. Becker-Christensen (2003) reports that the mean height of Greenlandic boys measured in 1996–7 tracks that of their Danish counterparts up to the age of 14 years, when values fall below the reference, achieving a final attained standing height 7 cm below that of Danish boys. Similarly, the mean height of girls follows the Danish curve up to age 11 years, dropping after that point to a final attained height 5 cm below that of Danish children. This pattern of secular trend of earlier physical maturity is supported by data on menarcheal age among the Canadian (Schaefer et al. 1980) and the Greenland Inuit (Becker-Christensen 2003).

It is also interesting to note that, among the Inuit, secular trend in height has been accompanied by a decrease in sitting height ratio (Schaefer 1977), suggesting that children's increased height is the result of increasing leg length. This pattern reflects that observed in other European contexts and suggests that patterns of morphology previously typical of Inuit growth may be changing in response to the environmental stimuli accompanying Westernization.

One of the few studies that looked at childhood determinants of adult stature was conducted in Greenland. Among adults in Greenland assessed during 1999–2007 (n = 2302), height was associated with mother's place of birth, birth cohort, childhood residence, alcohol problems in childhood home, and education among both men and women (Bjerregaard et al. 2009).

158.6 Increasing Prevalence of Obesity

Inuit communities are experiencing the increase in obesity prevalence, which is characteristic of regions experiencing rapid socioeconomic development (Figures 158.1–158.7). Young (1996) has observed that, in past studies, the low prevalence of obesity among Inuit has set them apart from other North American Aboriginal populations. However, recent studies document a trend toward increasing prevalence of obesity among Inuit adults (Table 158.2). Young reports increasing BMI and skinfold thicknesses among Inuit from the Kivalliq region of the Canadian Arctic. According to the 2004 Nunavik Inuit Health Survey, 30% of Inuit adults were overweight (BMI 25–29.9) and 28% were obese (BMI ≥30) (Nolin et al. 2007). Among obese adults, more than one-third had BMI categorized as class II (BMI 35–39.9) or III (BMI ≥40), according to the WHO BMI classification system for adults.

Table 158.2 Selected studies of overweight and obesity in adult Inuit by gender, published 1990 onward

This table lists recent significant contributions to the literature on overweight and obesity prevalence among the circumpolar Inuit

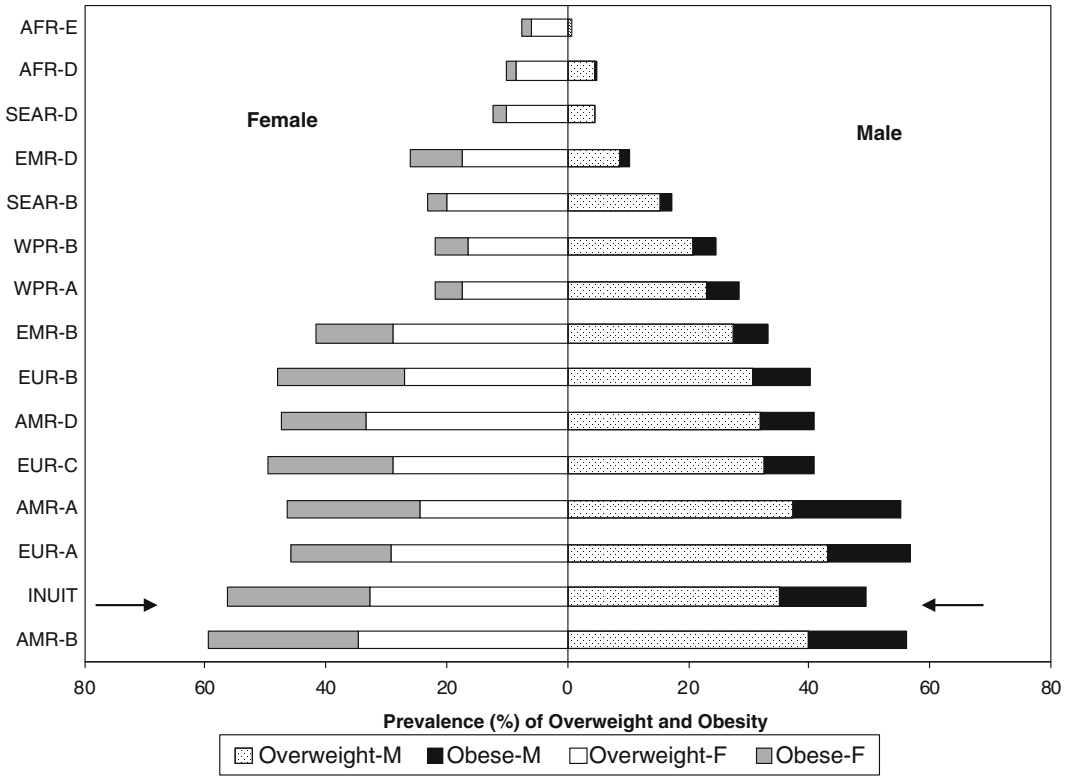

Fig. 158.1 Age-standardized prevalence of overweight and obesity among the Inuit compared to WHO Regions (*AFR* Africa; *SEAR* South East Asia; *EMR* Eastern Mediterranean; *WPR* Western Pacific; *AMR* Americas; *EUR* Europe). Inuit overweight and obesity prevalence is among the highest in the world for both males and females (Reprinted from Young et al. (2007). With permission)

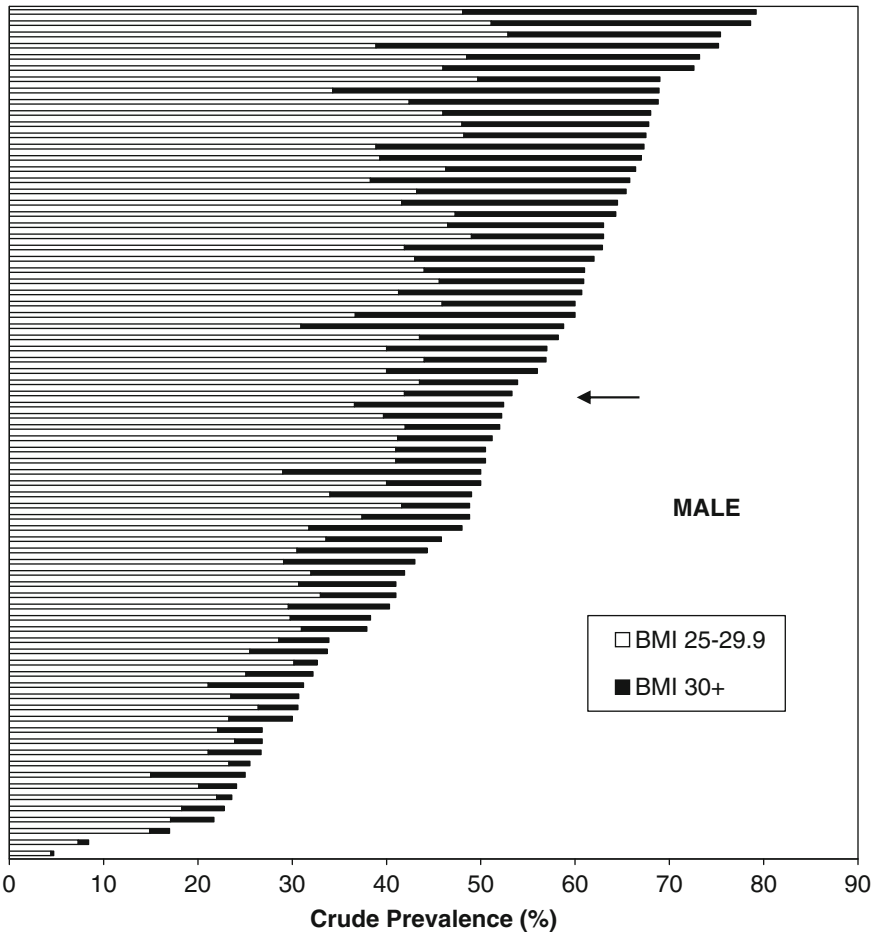

Fig. 158.2 Crude prevalence of obesity and overweight among Inuit men (*arrow*) in global perspective. This figure presents country data for males from the International Obesity Task Force database [www.iotf.org/media]; each *bar* represents a country; *arrow* indicates position of the Inuit (Based on Young 2007)

In a study of Inuit communities in the Bering Straits region of Alaska, Risica et al. (2000) reported that 36% of men and 28% of women were overweight, and 16% of men and 33% of women were obese. More recently, Mohatt et al. (2007) studied members of ten Inuit communities in the Yukon-Kuskokwim delta of Alaska: 32.5% of people ages 18+ years were overweight and 32% were obese ($n = 753$). Similarly, high prevalence of obesity was found among women ages 40–64 years ($n = 1334$) (Hiratsuka et al. 2007). Thirty-two percent of women were overweight and 47% of women were obese; 11% of women had BMI in the class III range. Jørgensen et al. (2003) report significantly higher indices of abdominal obesity (mean BMI, mean waist-to-hip ratio, and mean waist circumference) in Greenland Inuit men and women of ages 30–60 years ($n = 1118$) compared with a Danish reference (Figs 158.2 and 158.3).

An important observation is a pronounced difference in obesity prevalence between adult men and women. Many studies report disproportionately high prevalence of obesity (measured by BMI) and centripetal fat patterning (measured by waist circumference and waist–hip ratio) among Inuit women. Analysis of pooled anthropometric data (BMI and waist circumference) collected between 1990 and 2001 from Canada, Greenland, and Alaska ($n = 2545$) yielded obesity prevalence of 26%

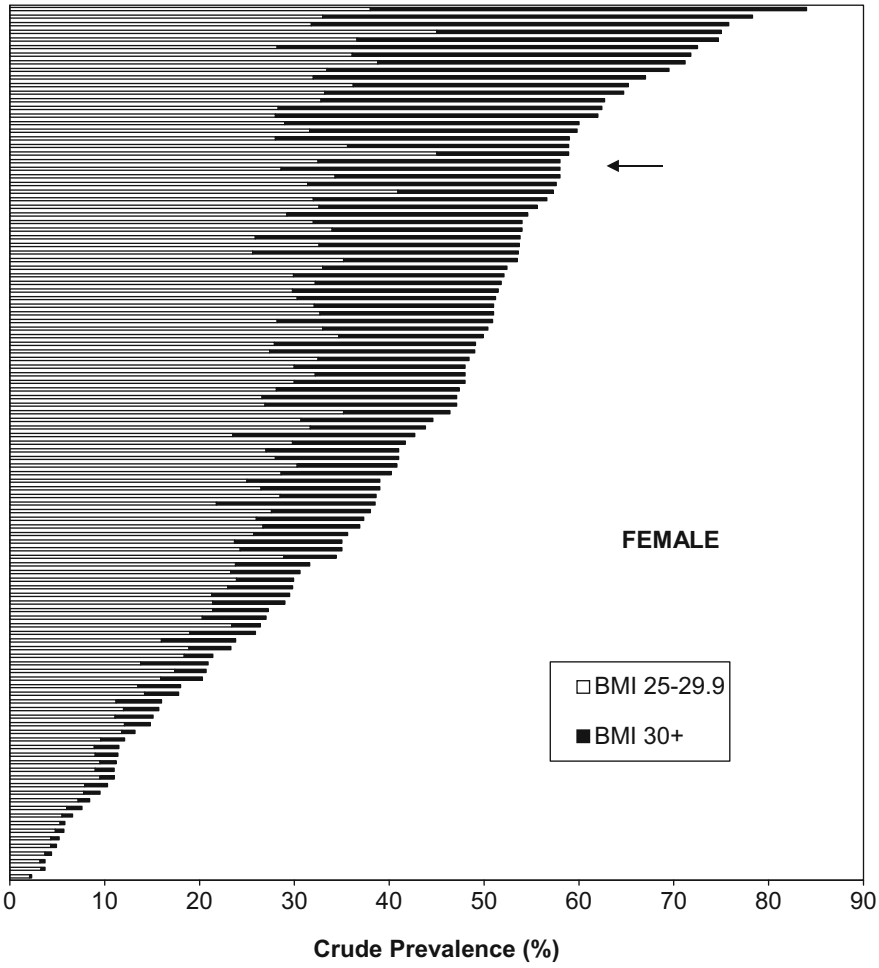

Fig. 158.3 Crude prevalence of obesity and overweight among Inuit women (*arrow*) in global perspective. This figure presents country data for females from the International Obesity Task Force database [www.iotf.org/media]; each *bar* represents a country; *arrow* indicates position of the Inuit (Based on Young 2007)

among Inuit women compared with16% among Inuit men (Young et al 2007). While there were no gender differences in overall overweight and obesity classification in the Nunavik Inuit Health Survey, the proportion of individuals with severe obesity (WHO classes II and III) was significantly greater in women (Nolin et al. 2007). The pattern of higher obesity prevalence in women appears to be somewhat less pronounced in the Greenland data. For example, there were no significant gender differences in the prevalence of central adiposity (defined by waist–hip ratio) among the Greenland Inuit measured during 1999–2002 (Jørgensen et al. 2006). Bjerregaard et al. (2002) report a gender difference in the opposite direction: adult Greenland Inuit men had significantly higher waist circumference than women. What is consistent in both Greenlandic and North American populations is the persistent increase in obesity prevalence among both men and women in recent decades.

It is increasingly recognized that many adult health problems have their origin in childhood, and socioeconomic factors operating during childhood have been shown to be associated with adult obesity among Greenlanders. For men, obesity during adulthood was also associated with their mother's place of birth, whereas for women, adult obesity was associated with alcohol problems at home during their childhood (Bjerregaard et al. 2009).

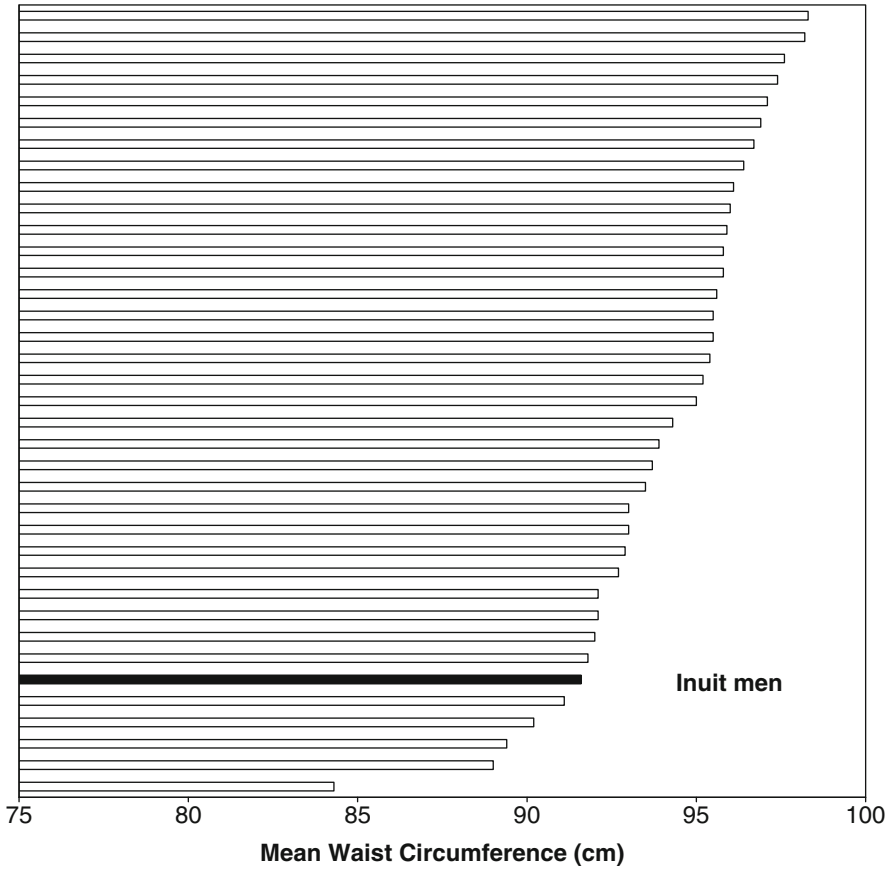

Fig. 158.4 Ranking of age-standardized mean waist circumference of Inuit men ages 35–64 years among MONICA survey populations. This figure presents waist circumference data on males from the WHO MONICA surveys conducted in the 1990s to monitor trends in cardiovascular diseases and relate trends to changes in risk factors and treatment in the population (Available from www.ktl.fi/publications/monica/surveydb/bmi/table635_summary.htm; Based on Young 2007)

The rise in adiposity among circumpolar populations is also evident among children (Table 158.3). Schnohr et al. (2008) report that the prevalence of overweight (using International Obesity Task Force [IOTF] cutoffs) among Greenland Inuit children of ages 2–15 years rose from 13% to 23% in boys and from 13% to 24% in girls between 1973 and 1992. Data on the 5–7-year age group show that the prevalence of overweight has risen from 7% in 1980 to 17% in 2004 (Schnohr et al. 2005). Obesity prevalence for the same age group has risen from 1% to 5% over the same period. Obesity prevalence among Greenlandic children is now among the highest in the world (Schnohr et al. 2008).

Greenlandic data also indicate that the age of onset of obesity is decreasing. Among cohorts of children measured between 1973 and 1992, the age at which 30% of children were overweight decreased from 9.7 to 7.3 years in boys and from 14.7 to 4.6 years in girls (Schnohr et al. 2008). There is evidence that this profile of decreasing age of overweight in onset is part of a constellation of biological processes (including earlier skeletal maturity, earlier adolescent growth spurt, and decreasing age at menarche) accompanying rapid acculturation to a Western lifestyle (Zammit et al. 1994; Becker-Christensen 2003).

Inuit child growth has followed a similar pattern in North America, with rates of overweight increasing dramatically in recent decades. The most recent data on child growth come from the Nunavut Inuit Health Survey, which measured 388 children of ages 3–5 years (Galloway et al. 2010).

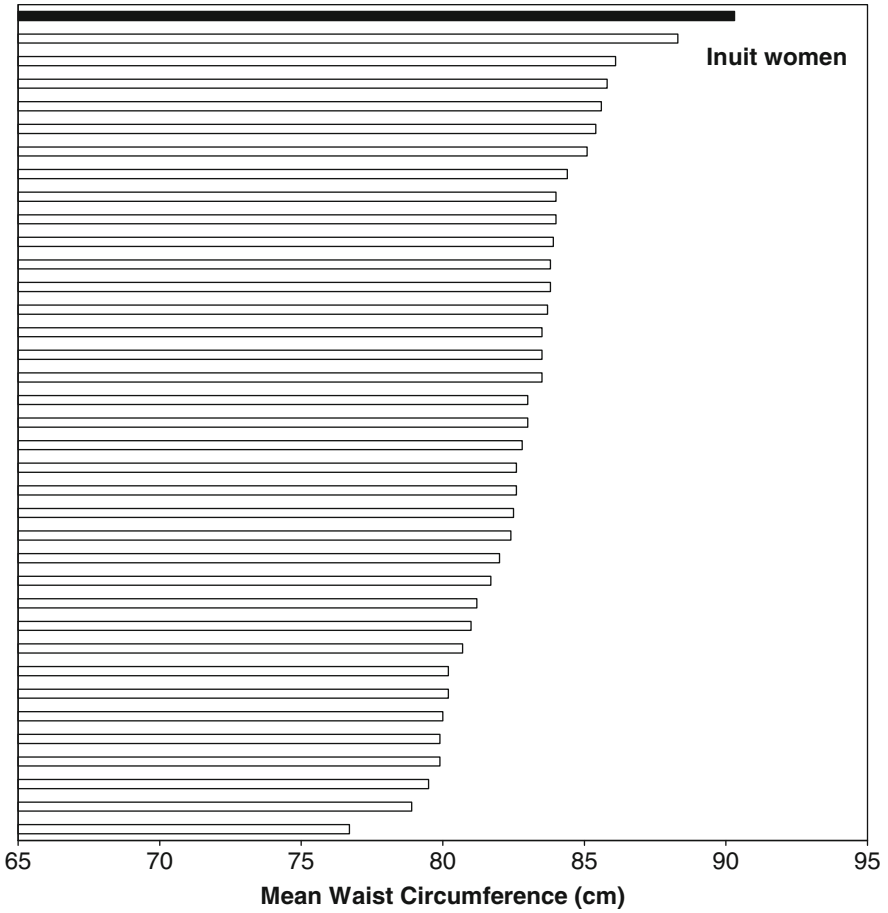

Fig. 158.5 Ranking of age-standardized mean waist circumference of Inuit women of ages 35–64 years among MONICA survey populations. This figure presents waist circumference data on females from the WHO MONICA surveys conducted in the 1990s to monitor trends in cardiovascular diseases and relate trends to changes in risk factors and treatment in the population (Available from www.ktl.fi/publications/monica/surveydb/bmi/table635_summary.htm; Based on Young 2007)

The prevalence of overweight was 27% in this preschool age group (using CDC cutoffs). The prevalence of obesity was 51%, with a gender difference indicating significantly greater obesity prevalence among boys (57%) compared with girls (45%). The large proportion of children in the obese category raises significant concern over future health and metabolic disease risk in children.

158.7 Metabolic Changes Accompanying Obesity

In North American and European populations, the rise in obesity has been accompanied by a concomitant rise in metabolic indicators, such as hypertension, glucose intolerance, and dyslipidemia. While this pattern generally holds true also for the Inuit, there is evidence that the relationship between abdominal obesity and its attendant metabolic changes is different (in the Inuit). Jørgensen et al. (2003) found that at each level of obesity, the Greenlandic Inuit had lower blood pressure, lower

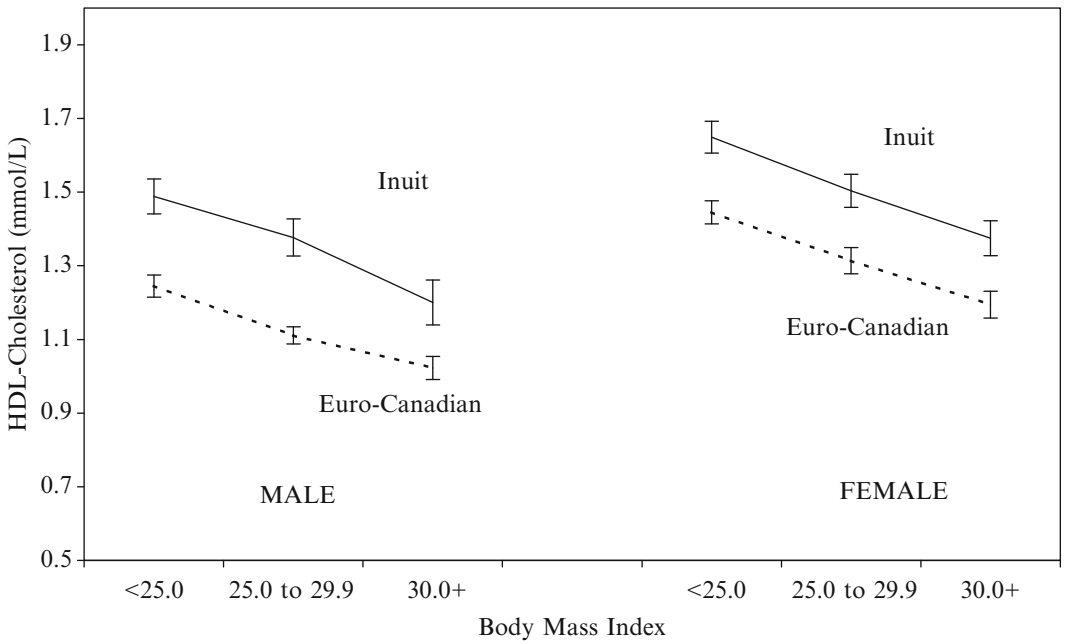

Fig. 158.6 Comparison of mean HDL-cholesterol values by categories of body mass index, sex, and ethnic category. This figure shows higher HDL-cholesterol levels at selected BMI ranges in Inuit compared to Euro-Canadian populations (Based on Young et al. 2007)

levels of 2-h glucose, insulin, and triglyceride, and higher levels of HDL cholesterol than the Danish subjects. This pattern is observed in other Inuit populations in Alaska and Canada (Young et al. 2007) (Fig. 158.6).

There is a dearth of body composition studies among the Inuit. Without imaging studies (e.g., dual X-ray absorptiometry, computed tomography, ultrasonography, and magnetic resonance imaging), it is not known whether the central obesity represented by high waist circumference is predominantly

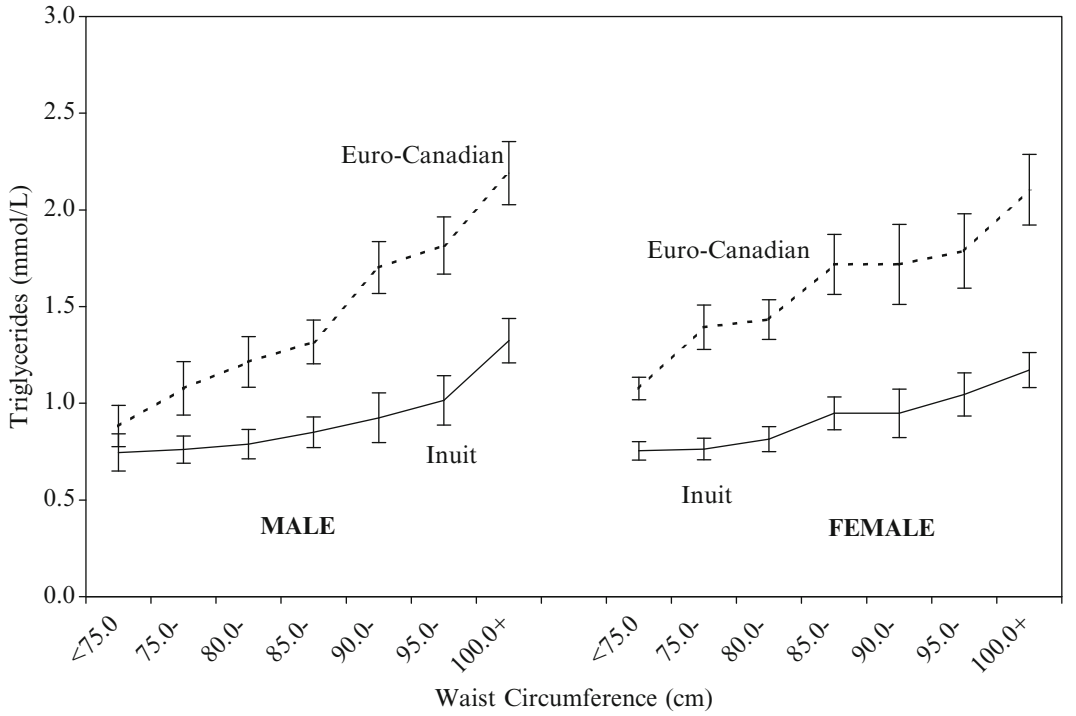

Fig. 158.7 Comparison of mean triglyceride values by categories of waist circumference, sex, and ethnic category. This figure shows higher triglyceride levels at selected categories of waist circumference in the Inuit compared to Euro-Canadian populations (Based on Young et al. 2007)

intra-abdominal or subcutaneous. Subcutaneous adipose tissue is poorly vascularized and therefore relatively metabolically inert, lacking the ability to store extra energy derived from dietary triglycerides. The accumulation of intra-abdominal or visceral fat is a marker of considerable metabolic risk (Fig. 158.7).

Attempts have been made to more accurately describe fat- and lean-mass distribution in the Inuit. Deuterium oxide dilution (Shephard et al. 1973) and underwater weighing (Rode and Shephard 1994) studies have been performed on samples of Canadian Inuit men. These studies report fat-mass estimates much higher than would be predicted from skinfold thicknesses in the same subjects. However, their interpretation is hampered by small sample sizes and a reliance on formulas developed in European populations. As a result, we know relatively little about fat distribution at various levels of BMI or waist circumference in the Inuit. Interpretation of the metabolic disease risk associated with various levels of adiposity is also difficult, prompting researchers to call for Inuit-specific cutoffs for central obesity measures associated with diabetes and cardiovascular disease outcomes (Jørgensen et al 2003; Young et al. 2007; Chateau-Degat et al. 2008). There is ample evidence that Inuit mortality from cardiovascular disease is at least as high as in non-Inuit populations and that Inuit mortality from cerebrovascular disease is significantly higher (Bjerregaard et al. 2003) (Table 158.4).

Table 158.4 Challenges to application of anthropometric reference standards to the Inuit

1. Studies done in the nineteenth and twentieth centuries established that the Inuit were significantly shorter in stature than US and Greenland populations
2. Much of the difference in stature was attributable to higher sitting height ratio in the Inuit. This means that leg length was much shorter in Inuit populations
3. Shorter leg length in the Inuit results in relatively greater body mass per unit of height. Therefore, anthropometric indices based on mass, such as BMI, may give falsely high estimates of adiposity in Inuit
4. While secular trend in height may have diminished differences in sitting height ratio between Inuit and non-Inuit populations, there is little data available on sitting height or fat and lean mass ratios among the contemporary Inuit
5. US, WHO, and IOTF reference standards for BMI in adults and children must be interpreted with caution in the Inuit

This table summarizes the challenges to interpreting anthropometric reference data in circumpolar Inuit, given differences in growth and body proportion, secular trend in height, and a lack of data on body composition

158.8 Methodological and Practical Issues

There are significant barriers to conducting anthropometric research in the circumpolar north, not the least of which is the severe climate. Apart from a few towns which serve as administrative capitals (e.g., Nuuk, Greenland, population 15,000 and Iqaluit, Canada, population 7,000), Inuit communities are widely dispersed throughout the far north. Travel costs are high and travel is dependent on seasonal access via air and sea. Small populations necessitate travel across a broad geographic area in order to compile data on adequate sample sizes. Jurisdictional issues are also relevant, as researchers must negotiate the various national, state, provincial, and territorial bodies that provide services in the north.

Although not unique to the Inuit, the use of 'racial' or 'ethnic' identity is not entirely neutral, as these are socially constructed categories. The methodological approach used to define an ethnic category needs to be in direct proportion to its explanatory power as a variable. Research reports should state clearly the reason for including ethnic categories within the research and how ethnic group classifications were made. For example, in their comparison of metabolic risk among resident Greenlanders and migrants to Denmark, Jørgensen et al. (2006) define 'Inuit' as persons with at least one Inuit parent. In this case, language and migration to Denmark are used as markers of the degree of Westernization, since previous studies have observed increasing metabolic disease risk among acculturated Inuit. The definition of Inuit employed here acknowledges the multifactorial nature of the processes underlying metabolic disease, which is influenced by economic and sociocultural, as well as biologic and genetic factors.

As in many populations where past studies have demonstrated patterns of growth unlike those in Europe and North America, the application of international reference values to Inuit contexts is a matter much discussed in the literature. Twentieth-century studies documenting robust muscularity and high sitting height ratios among the Inuit have led to calls for Inuit-specific growth reference and Inuit-specific norms for BMI, especially from among clinicians.

Secular trend in height has eliminated the need for Inuit-specific stature reference in children. However, recent findings of high obesity prevalence among Inuit children, and observed differences between the metabolic correlates of adiposity among Inuit adults, have led to speculation on whether international standards are appropriate in this context.

The Canadian Paediatric Society (CPS) recommends that the CDC-derived growth charts be used for all Canadian children, including First Nations and Inuit (CPS 2004). Greenland researchers have consistently used Danish or IOTF references, noting that it is overall trends in growth parameters that provide information useful for child health policy and programming (Schnohr et al. 2005, 2008).

The current state of knowledge about adult Inuit body composition is insufficient to the task of creating Inuit-specific cutoffs for obesity and metabolic disease risk. The use of WHO cutoffs facilitates

prevalence estimates and evaluation of temporal trends in Inuit populations. Until more is known about the distribution of fat and lean mass in the Inuit, and the degree of metabolic aberration associated with varying levels of adiposity, international references appear to be the most appropriate means of assessing growth and adiposity in Inuit adults and children.

Finally, there is a lack of methodological standardization that hampers comparisons of growth, body size, and body composition in the Inuit. The inclusion of sitting height in both child and adult studies would permit analysis of secular trend in this area (Charbonneau-Roberts et al. 2005). Standardized protocols incorporating hold-out samples and repeat measures would permit reporting of inter- and intra-observer error and technical error of measurement, features which are, unfortunately, rarely documented in anthropometric studies of the Inuit.

158.9 Applications to Other Areas of Health and Disease

Anthropometric techniques offer a relatively inexpensive, non-technical means by which to assess the health and nutrition status of populations, especially those such as the Inuit, who are undergoing a health transition as a result of rapid social and economic change. Methodologically rigorous anthropometric studies offer a way to:

1. Screen populations for health risks: A wide range of disease processes can be identified through intermittent monitoring of anthropometric status. The geographic isolation and relative dearth of health services in circumpolar regions make the monitoring of health status an ongoing priority for Inuit health policy and service providers.
2. Monitor infant and child growth: Early detection of diseases of infancy and early childhood can be achieved through regular monitoring of growth and nutrition status. In particular, infectious diseases and nutritional impairment are readily identified through regular growth assessment. The young age structure of Inuit populations makes child-growth monitoring a key priority for healthcare providers.
3. Directly monitor obesity prevalence: Obesity has been identified as a key health concern in Inuit populations. Monitoring of overweight and obesity prevalence permits identification of at-risk communities and direction of healthcare resources toward vulnerable populations.
4. Indirectly monitor metabolic changes which accompany obesity: Obesity is a valuable tool for identifying individuals at risk for other changes, such as elevations in plasma glucose, insulin, and atherogenic lipids. While the unique metabolic changes accompanying obesity in the Inuit necessitate caution in interpreting anthropometric indicators in this population, current research is exploring the association between obesity levels and cardiovascular disease risk.

158.10 Conclusion

Human biology in the circumpolar north requires a significant expenditure of resources. Given the high cost of Arctic travel and the logistic challenges of gathering extensive data in geographically isolated communities, anthropometry has served as an inexpensive and informative tool to assess the state of Inuit health and nutrition. Historical studies provided the foundation for the observations of secular trend in stature and BMI which have accompanied the relatively swift and recent changes in

Inuit lifestyle. Concurrent trends toward increasing risk of diabetes and cardiovascular disease have been illuminated by studies describing unique relationships between adiposity and metabolic indicators in Inuit adults. Future studies offer opportunities for monitoring health and nutrition interventions aimed at averting and addressing the major shifts in population health occurring in circumpolar populations.

Summary Points

- The 165,000 Inuit living in four circumpolar countries have undergone a substantial health transition, which can be monitored through anthropometry.
- Historical and ethnographic records indicate that Inuit adults had shorter stature and higher sitting height than European populations, but secular changes in the past half century have reduced or eliminated most of such differences.
- Obesity among the Inuit based on international criteria had been uncommon up until the late 1970s and early 1980s.
- Recent surveys among Inuit children in some regions revealed an alarming prevalence of obesity at 57% for boys and 45% for girls.
- Studies on the metabolic correlates of obesity among adult Inuit tend to show a lower degree of blood pressure, plasma glucose, insulin, and atherogenic lipids compared to Europeans at the same levels of BMI.

Chapter 159
Anthropometric Measures of Birth and Stature: Perspectives on Russian Mothers and Newborns

Boris N. Mironov

Abstract Using data from St. Petersburg hospitals on the length and weight of 64,087 infants born between 1980 and 2005 and the physical stature and weight of 15,819 mothers born between 1929 and 1989, we find that women's living standards, as measured by their height, improved steadily from the end of World War II up to 1990, which is when women born in 1972 reached adulthood. For mother cohorts born after 1972 and reaching adulthood in the early and mid-1990s, heights declined. Evidence on both the length and weight of babies corroborates this pattern as there is a noticeable connection between the height and weight of newborns and that of their mothers, on the one hand, and social and demographic indicators, on the other. In our data, we see their values trace a "U" shaped curve with troughs near the mid-1990s. Thus, the anthropometric evidence concerning newborns as well as mothers points to the impact of strains on living standards that were prevalent during the period of economic restructuring of the 1990s. This is a general result that confirms a recurring pattern: periods of economic transitions are almost always accompanied by biological stress.

In the Soviet and post-Soviet periods, newborns in Moscow and St. Petersburg were definitely inferior to European and white American newborns in weight and, most likely, in stature as well, as there is a close relationship between stature and weight.

159.1 Introduction

This paper estimates trends in the health and the biological standard of living of women and their newborn babies in St. Petersburg between 1980 and 2005. The data consist of the height and weight of mothers and their newborns, a robust indicator of living conditions (Ward 1993, p. 12). Since 1976, the World Health Organization has used average birth weight of babies as a standard indicator of women's quality of life (Ward 1993, p. 5). Obviously, the anthropometric indicators of the newborn also testify to the level of their physical development; less obviously, their length at birth also testifies to their prenatal conditions. Sensitive to the mother's living conditions throughout her pregnancy,

Table 159.1 Key features of Russia

1.	In 1992, Russia's population entered a period of negative growth. This was for the first time in the peacetime history of Russia
2.	As in many Western industrialized nations, Russia's fertility rate has fallen over the course of the twentieth century. In 1920, the average Russian woman was expected to give birth to about 7.5 children in her lifetime; in 2007, that number had fallen to 1.4
3.	In many Western countries, the peak childbearing age for women has increased and now falls between 25 and 29; by contrast, the peak age in Russia has become younger, occurring between ages 20–24
4.	This tendency toward fertility at younger ages is reflected in marriage patterns. Between 1960 and 2007, the average age at marriage of women in Russia fell by 2.7 years, from 26.2 to 23.5
5.	The decline in fertility is contributing to a rapid aging of the Russian population. Between 1960 and 2008, the proportion of males aged 60 and over and females aged 55 and over doubled and reached 21%
6.	The increased death rate, especially dramatic among working-age men, is an important indicator of demographic crisis in Russia
7.	Life expectancy in Russia has dropped. In 2007, Russia had the lowest life expectancy for males in a developed country (61.4 years) and the largest disparity in the world between male and female life expectancy (12.6 years)
8.	The increase in deaths from preventable causes points to problems in Russia's healthcare system

This table lists the key facts of current Russian demographic trends

the size of a fetus will also be affected to some degree by the mother's general living standards prior to conception. Despite gender inequality, women's living conditions undoubtedly reflect larger forces affecting the entire society.

The paper draws on the recumbent length and birth weight of 64,087 babies born in St. Petersburg between 1980 and 2005. In addition, we have data on the physical stature and weight of 15,819 mothers born between 1929 and 1989. The data embrace information from clinics on women of all nationalities, whose delivery lasted a normal length of time and ended in the birth of a singleton. The information was taken mainly from birth records and from archived annual accounts of maternity wards in the Maternity Hospital's archives in St. Petersburg. Nearly 74% of the women were from St. Petersburg, 26% were from the surrounding region (*oblast'*), and less than 1% from other Russian regions.

During the period under study, the mothers' average age increased from 25.3 to 26.8 years. Their average educational attainment was 11.8 years. The social profile of the women in the sample underwent major changes, as indicated in Table 159.1. The share of skilled blue-collar workers decreased from 37.3% to 13.3%, and the share of professionals decreased from 20.8% to 9.3%, while the share of housewives increased dramatically from 4.2% to 51.1%. Although we have no information on the profession and education of housewives, they probably belonged to the well-to-do stratum of the population: as it will be shown further, their biological potential was above average and this testifies to the fact that, at least by birth and by marriage, they belong to the well-to-do stratum of the population – to the socioeconomic class of professionals, top executives, and businessmen. From 91.2% to 95.4% of the women were ethnic Russians, and the rest were divided among 57 other ethnic groups. Thus, our sample consists mainly of information on relatively young, recently married women of ethnic Russian descent, who, by their educational level, material position, and social status, belonged to the middle stratum of St. Petersburg's population (the general characteristics of the sample: age structure, education, social profile, family status, and ethnicity are presented in the Tables 159.1–159.6 of Statistical Supplement).

Histograms, means, medians and modes, coefficients of asymmetry, excess kurtosis, and other characteristics of the distribution of newborns and their mothers by stature and weight show that the sampling data approximate a normal distribution.

159.2 Trends in the Biological Status of Women

There is a close relationship between the recumbent length and the weight of the newborn (correlation coefficient is 0.879). On the eve of perestroika, in 1982–1985, the average length of singleton, full-term (born 9 months after conception) newborns (both boys and girls) was 51.4 cm and weight 3,476 g (Fig. 159.1).

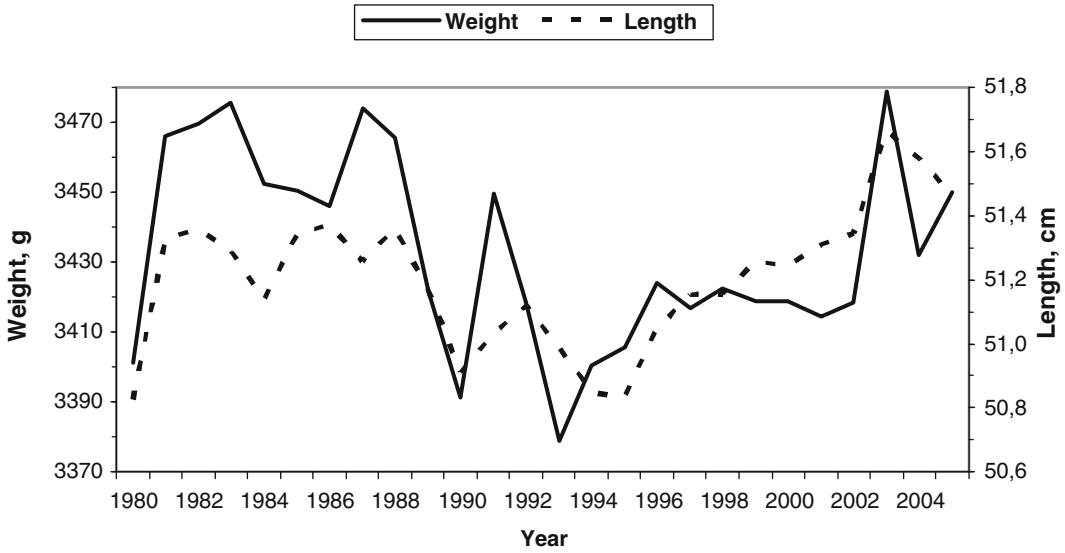

Fig. 159.1 The weight and stature of newborns in St. Petersburg, 1980–2005

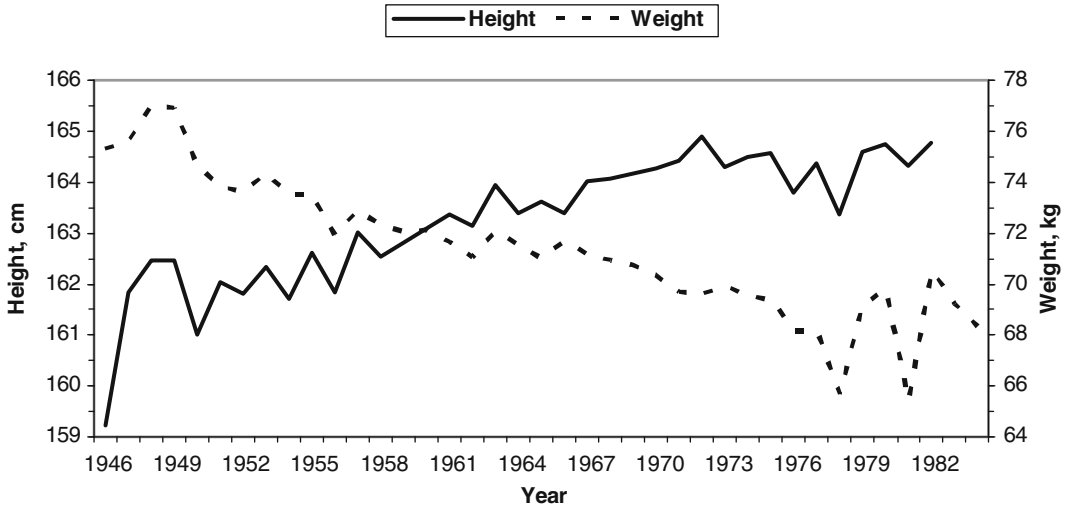

Fig. 159.2 Height and Weight of Women in St. Petersburg, 1946–1985

The following decade, which included both perestroika and the last years of Communism, saw a considerable decrease in both anthropometric attributes: the length of newborns reached a minimum of 50.8 cm in 1995 and weight 3,379 g in 1993. Then, an upward trend began. However, the increase in weight stopped in 1996–2001 and resumed only in 2002. By the end of the period under consideration, both length and weight were back where they started in the early 1980s in the pre-perestroika era: about 51.4 cm and 3,450 g.

For mothers by birth cohort, we find that, from the end of World War II to the early 1970s, their height increased by nearly 6 cm and then the trend changed (Fig. 159.2). The stature of women born in 1976–1978 decreased by about 1 cm and stabilized thereafter at about 164.5. Due to the lack of

information for those born after 1985, it is hard to say whether the trend actually continues or increases in connection with improved living conditions after the turn of the twenty-first century. To summarize, the data are robust in showing the decrease of the St Petersburg women's living standards in the 1990s.

Although there was a considerable reduction in average weight – by nearly 12 kg – this was not necessarily itself a measure of decrease in living standards because the increase in mothers' height of those born before 1976–1980 was more likely linked with the lower average age of this group. The average age at childbirth of women born in 1946–1950 was 35 years and, of those born in the 1980s, 17–20 years. Height naturally also had to decrease, since empirically, with aging, there is a gradual increase in weight. In order to test this conclusion, we selected women aged 25 or less and compared their average weight with that of all women (we can do this for 1956–1985) (Table 159.2).

The comparison shows that the age of these women did not affect their height (of course, since upon reaching 18–20 years of age, height does not increase) but did affect their weight: the younger women of the same year of birth weighed less. However, the lower weight cannot be fully attributed to a lesser age: the weight of women of approximately the same age also decreased from cohort to cohort. Hence, it follows that other factors played a role – above all, diet. Between the post-war period and 1970, the quality of nutrition in St. Petersburg improved markedly and then remained stable between 1970 and 1990 (Table 159.3).

Consumption of food containing high amounts of protein increased: meat – by 2.2 times, milk – by 2, eggs – by 2.9, fish – by 1.7, and vegetables – by 1.9 times. By contrast, consumption of food having less protein decreased: bread – by 28% and potatoes – by 24%. It should be emphasized that overall nutrition improved not only in a quantitative sense but also in terms of quality. At the same time, women expended less energy, since the role of manual labor diminished. Consequently, we conclude that the decrease in women's weight in 1941–1985 had nothing to do with the decrease in their living standards. We assume that the decrease in weight was most likely affected both by fashion – the slim female figure has firmly been established over the last 25 years – and by women's reduction of calories to make delivery easier, because a high-calorie diet increases the size of the fetus, potentially causing a difficult birth. Due to the systematic decrease in women's weight at a rate faster than the increase in height, women's body mass index declined from 28.3 to 24. However, this decline was within the range of normal dietary practice.

Women's living standards depended on many socio-demographic factors. With the available data, we can assess the effect of family status, education, socio-professional status, and ethnicity on their living standards (Table 159.4).

A relationship between socio-professional variables and living standards is more visible when communities are grouped by profession (Table 159.5).

Ethnicity affects anthropometrical indicators of women and their infants. On average, Russian mothers are 1.3 cm taller than their non-Russian counterparts (163.8 against 162.5), their weight is 1 kg more (68.2 against 67.2), and their infants are 0.1 cm taller (51.2 against 51.1) and weigh 25 g more (3,438 against 3,413). The body mass index of mothers is in the range of 24.47–27.04 (Table 159.6).

We explain women's living standards as the result of the interplay of various factors that were changing during the period under study (Table 159.7).

These data suggest three main trends:

1. There was a noticeable connection between the height and weight of newborns and that of their mothers, on the one hand, and social and demographic indicators, on the other;
2. Social and demographic determinants were changing during the period under review; and
3. Anthropometrical indicators were also changing during the same period, sometimes for the worse, sometimes for the better.

Table 159.7 The trend of the main characteristics of mothers and newborns in St. Petersburg, 1980–2005 (Sources: The archives of St. Petersburg hospitals, 1980–2005)

2000	26.7	11.8	86.7	1.49	71.8	68.4	164.9	25.2	3,419	51.2
2001	26.8				72.1	68.7	164.8	25.3	3,415	51.3
2002	26.7				72.0	68.6	164.7	25.3	3,418	51.3
2003	26.9				72.0	68.5	164.6	25.3	3,479	51.7
2004	27.0				72.1	68.7	164.8	25.3	3,432	51.6
2005	27.0				72.2	68.8	164.9	25.3	3,450	51.5
1980–2005	26.0	11.7	91.8	1.5	71.5	68.1	163.7	25.4	3,433	51.2

This then leads to an important question: Was the shift in the anthropometric parameters of St. Petersburg women and their newborns caused by a change in the quality of life of the mothers or by changes in other characteristics (education, occupation, social status, age, and ethnicity)?

159.3 Women's Height: Multiple Regression Analysis

Table 159.8 presents the results of multiple regression analysis of the determinants of mean height for individual data. The explanatory variables are birth cohort, occupational category, marital status, and ethnicity. The regression constant refers to a single, white-collar, Azeri woman, born in 1981–85. Since all variables are dummies, the estimated coefficients should be interpreted group differences from the reference category. The number of cases corresponding to each condition is given in the right-hand column.

Table 159.8 Factors affecting the mean height of women (cm): regression coefficients

The category ‘professionals’ indicates individuals with a university education. Sources: archives of St. Petersburg hospitals, 1980–2005.

The mean height of women born between 1929–1940 and 1971–1975 was increasing; that of women born from 1976 to 1985, by contrast, was decreasing. Mean heights varied by 5.13 cm between the mothers born in the period 1929–1940 and those born in the period 1971–1975. The women born in the period 1971–1975 were 1.74 cm taller than those born in the period 1981–1985. Mean height varied by 3.11 cm between the shortest Jewish women and the tallest Byelorussian women. Professionals were taller than blue-collar workers by 1.39 cm. Women whose marital status was ‘unlawful’ (that is, women in couples that were not officially registered as spouses) were 0.4 cm shorter than those who were legally married. A comparison of paired and multiple coefficients of determination shows that year of birth, ethnicity, and social and marital status account for roughly 3% of the variation in mothers’ height. Also, a comparison permits ranking of factors included in the analysis: year of birth, social status, and ethnicity were more important, and marital status was less. It played the very modest role (Table 159.9).

Table 159.9 Estimation of the determinants of women's mean height: paired and multiple coefficients of determination

159.4 Women's Weight: Multiple Regression Analysis

Multiple correlation analysis leads to the conclusion that mother's weight variation was accounted for by age, year of birth, social status, ethnicity, and marital status (in order of significance) approximately by 5% (Table 159.10).

Table 159.11 presents the results of multiple regression analysis of the determinants of mean weight for the individual data. The regression constant refers to a 41 and more year old, white-collar, Azeri woman, born in 1981–1985.

The mean women's weight varied by 3.19 kg between the mothers born in 1946–1950 and those born in 1976–1980. The women born in 1976–1980 weighed 1.39 kg less than those born in 1981–1985. The mean weight varied by 9.24 kg between the stoutest Georgian and the slimmest Tatar women. The professionals weighed roughly 1 kg less than the blue-collar workers. The slimmest 14- to 16-year-old mothers weighed 5.78 kg less than the stoutest 31- to 35-year-old mothers.

159.5 Birth Length: Multiple Regression Analysis

Paired and multiple coefficients of determination allow the ranking of factors, as follows: we find that the weight and height of mothers, the gender of newborn, the order of delivery, and the year of birth had the greatest effect, while other factors played modest roles. The combined influence of the

five factors explains infants' height variation by approximately 8.4%, as the multiple determination coefficient shows. The influence of all ten factors accounts for 8.6% of the variation in infants' height (Table 159.12).

Table 159.13 presents the results of multiple regression analysis of the determinants of birth length. The regression constant refers to a boy born in 2000–2005 by the slimmest and shortest mother.

The mean birth height increased between 1980 and 1989 and between 2000 and 2005, while it decreased between 1990 and 1999. The mean height varied by 0.3 cm between the infants born in 1985–1989 and those born in 1990–1999. It varied by 1 cm between the shortest and the tallest women, and it varied by 1.4 cm between the slimmest and stoutest mothers. Boys were 0.3 cm longer than girls.

With regard to social factors, mean height at birth varied by 0.25 cm between infants born by students versus those born by professionals, by 0.27 cm between those born by women with legal

versus unofficial marital status, and birth height varied by 1.68 cm between those born by Jewish versus by Ukrainian women (Table 159.14).

159.6 Birth Weight: Multiple Regression Analysis

Our analysis of determinants of mean birth weight offers results analogous to the ones reached above. Paired and multiple coefficients of determination allow a hierarchal ranking of factors: weight and height of mothers, gender of newborn, order of delivery, and year of birth; others played a modest role. The combined influence of the five key factors explains roughly 10% of the variation in birth weight. The influence of all ten factors accounts for 10% of the variation in mean birth height (Table 159.15).

The results of multiple regression analysis of the determinants of mean birth weight are summarized in Table 159.16. The regression constant refers to a boy born to a mother of minimal weight and weight between the years 2000 and 2005.

Mean weight at birth decreased in 1980–1999 and increased in 2000–2005. Mean weight varied by 64.05 g between the infants born in 1980–1984 and those born in 1995–1999. It varied by 349.88 g between the slimmest and the stoutest mothers and by 123.96 g between the shortest and the tallest women. Boys were heavier than girls by 63.17 g.

With regard to social factors, mean weight of infants varied by 66.5 g between students and professionals, by 30.09 g between women with legal versus unregistered marriages, and by 352.65 g between Jewish versus Ukrainian women (Table 159.17).

Hence, overall statistical analysis shows a tendency toward increase in the stature and weight of newborns and their mothers in the Soviet period and a tendency toward decrease in their stature and weight in the post-Soviet period, along with the recovery of both in the period between 2000 and 2005. Our analysis also suggests that these trends were determined by changing conditions in overall quality of life and not by a change in the social and demographic profiles of the mothers themselves.

159.7 St. Petersburg Newborns in a Historical and Comparative Perspective

It is of interest to look at St. Petersburg newborns in a historical and comparative perspective. The available information for 1933–2005 shows that, in Moscow and St. Petersburg, the stature and weight of children varied synchronously and also that newborns in St. Petersburg have always been inferior in size and weight to Muscovite newborns (Table 159.18).

There is nothing surprising in the synchrony of the newborns' stature and weight variations: the residents of both cities experienced approximately similar living conditions. From the available information for Moscow during the 1875–1930 period, we can see some of the changes affecting living standards of newborns and their mothers in St. Petersburg. Between 1875 and 1914, there was a tendency toward increase in the stature and weight of newborns, with maximum indicators of both achieved on the eve of World War I. In the 1920s, the stature and weight of newborns began to decrease and this continued until the mid-1940s. Then, in the post-World War II period, anthropometrical indicators began to improve again. The pre-World War II level was achieved by the early 1950s and the pre-Soviet level – in the 1960s. Then, the tendency changed again, and indicators continued to decrease up to the beginning of the twenty-first century. During the period between 2001 and 2005, weight and height at birth reached parity with measurements for the 1950s.

Let us compare the St. Petersburg birth weight with all-Russian birth weight (Sukhanova 2006, p. 124) (Fig. 159.3).

Between 1998 and 2004, live-born children in Moscow were only 31 g or 0.9% heavier than their counterparts in St. Petersburg and 33 g or 1% heavier than newborn babies in Russia as a whole. Hence, it may be suggested that the female standards of living in St. Petersburg and Russia were

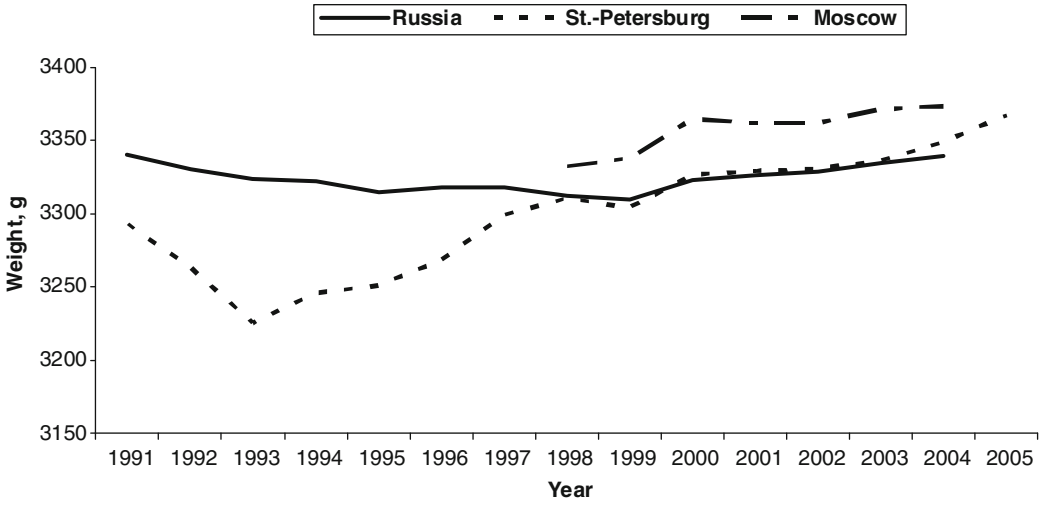

Fig. 159.3 Mean weight of children born in Russia, St. Petersburg, and Moscow, 1991–2005. Stillbirths are not included (Source: Archive of the Central Research Institute on Information, the Ministry of Health of the Russian Federation, Moscow; Sukhanova 2006, p. 124)

nearly equal, and they were inferior to the living standards of Moscow women. The dynamics of the mean weight in Russia, St. Petersburg, and Moscow were synchronous.

International comparisons are difficult due to the incomparability of the data. Our data for Russia allow us to measure children born alive, single, and at term, while available foreign data usually only provide information on live births (Table 159.19).

Between 1980 and 2005, the average weight of all St. Petersburg live-born infants was 5–7% less than those born at term, and according to the information for 2001–2005, their stature was 2.2% smaller (Table 159.20).

If we decrease the weight of Russian newborns by 5–7% and stature by 2%, then we can see that newborns in Moscow and St. Petersburg in the 1970–1980s are inferior to West-European and white American newborns both in stature and weight. From the last third of the nineteenth to the first third of the twentieth century, corrections should be even greater, as the share of children with low birth weight at that time was greater than in 1980–2005. According to the calculations made by Peter Ward, the share of children with low-birth-weight deficit in 1870–1930 in Austria, Great Britain, USA (whites), and Canada was within the interval from 5.7% to 15.2% and, in the 1970–1980s, from 3.6% to 7.7%, that is, almost a twofold decrease (Ward 1993, p.134). Between 1870 and 1899, Moscow children born at term were only 3% heavier than American whites and 7% heavier than British, Canadian, and Irish children. Corrections in Russian data eliminate the advantage of the Moscow infants and the more so of the St. Petersburg children who have always been less in stature and weight than the Moscow infants. It is possible that, in 1900–1913, the difference in weight between Moscow and West-European infants somewhat smoothed out, but, nevertheless, equality did not follow. In the Soviet and post-Soviet periods, Moscow and St. Petersburg newborns were definitely inferior to European and white American newborns in weight and, most likely, in stature, as there is a close relationship between stature and weight. Between 1870 and 1980, the stature and weight of newborns in the West increased. In Russia, this favorable tendency was observed until 1913, but, during the Soviet period, it was replaced by a tendency toward decrease.

159.8 Discussion and Conclusion

Based on the data on the physical stature and weight of women and the length of birth weight of newborns, we conclude that the living standards of women in St. Petersburg steadily improved after World War II. The height of women increased until the birth cohorts of ca.1972 (Fig. 159.2), who reached adulthood near 1990. Women born thereafter reached their final height at a time when the Soviet era was drawing to a close. The height of these women who reached their final height in the 1990s declined by as much as 1.3 cm, implying that their living standards decreased in the post-Soviet era. Essentially, the height of women traces an inverse 'U'-shaped curve.

This pattern is corroborated by the fact that, during the transition from the command economy to a market economy from 1990 to 1996, per capita gross domestic product decreased by nearly 39% (Gaidar 2005, p. 381). In addition, life expectancy of women peaked in 1967 at 74 years, a level maintained until 1987, when it then began to decline. By 1993, when it reached its lowest level, it had declined to 71 years. Thereafter, it began to slowly rise again to 72 years in 2002–2005 (Eliseeva and Gribov 2003, vol. 2, p. 81). Furthermore, in 1995–1999, there was also a marked increase in the number of premature births (by a factor of 1.9 compared to 1980–1984) and of retarded births (by a factor of 5.4). There was also a rise in the number of pregnant women with anemia (by a factor of 16.4) and women having abnormal births (by a factor of 2.3) (Table 159.20). Yet, the weight and BMI of the women was also in decline during most of the period under consideration, which was a positive development as the women had been rather overweight at the outset.

The decrease in the women's living standards in the 1990s resulted from the worsening of diet (Table 159.3) as well as a decline in real income and wages. According to the official data in St. Petersburg from 1991 to 1999, the buying power of the average income decreased by a factor of 2.4 (Eliseeva and Gribov 2003, vol. 3, p. 26). Although official data on incomes do not take secondary or shadow earnings into full account (and these sometimes represented as much as 40% of total family income), the anthropometric data, an indicator of total actual consumption and, consequently of all income, suggest that full income must have been decreasing as well. There is further supporting evidence of a widespread subjective feeling of dissatisfaction that also impacted overall living standards (Zdravomyslov and Iadov 2003, pp. 464–479; Patrushev 2001; pp. 120–129).

In addition to the height of mothers, we have provided evidence here that both length and weight of babies trace a 'U'-shaped curve with troughs near the mid-1990s with amplitudes in the annual data of ca. 0.6 cm and 70 g (Fig. 159.1). Thus, the anthropometric results for newborns as well as for their mothers point to the stress on standards of living that was experienced during the restructuring of the Soviet economy. This is a general result that we can recognize as a recurring pattern: economic transitions are almost always accompanied by biological strains. This was the case during the Neolithic agricultural revolution, during the Industrial Revolution, and also, it seems, in the post-Communist 'velvet Revolution' in St. Petersburg as well (Komlos 1998).

159.9 Applications to Other Areas of Anthropometry

This inquiry is set in four distinct but interrelated contexts: history of human growth, living standards and nutrition, inequality and poverty, and women's economic status. Weight and length at birth are strongly conditioned by the health and nutritional status of mother and, therefore, they are linked to circumstances specific to women. Because weight and length at birth are sensitive to environment factors acting during the 9 months of gestation as well as to the long-range effects of changes in living conditions, they reflect both short- and long-term trends. The analysis of newborn weight and length complements studies on growth patterns and achieved height in the past.

Summary Points

The analysis above allows us to draw the following conclusions:

- A tendency toward increase in the length and weight of newborns was observed in the Soviet period and a tendency toward decrease in both was observed in the post-Soviet period: the average length of single-born boys and girls decreased from 51.4 to 50.8 cm and weight from 3,476 to 3,379 g between the early 1980s and the early 1990s.
- By 2000–2005, both length and weight had nearly returned to where they started in the early 1980s in the pre-perestroika era.
- Variation in mean height and weight of infants can be attributed to their mother's weight and height, the child's gender, the order of delivery, and the year of their mothers' birth. The key factors account for about 8% of the variation in newborns' height and roughly 10% of the variation in weight.
- For mothers by birth cohort, from the end of World War II to the early 1970s, height increased by nearly 6 cm, while decreasing by about 1 cm for birth cohorts from 1973 to 1978.
- A reduction in average women's weight in 1945–1985 by nearly 12 kg was most likely affected both by changes in fashion (the slim female figure has firmly been established over the last 25 years) and by an overall reduction in calories by women, which made delivery easier.
- Variation in women's mean height and weight was determined by year of birth, social and marital status, ethnicity, and age. The key factors account for up to 3% of the variation in women's height and up to 5% of the variation in women's weight.
- Anthropometric indicators of newborns and their mothers point to women's living standards steadily improving from the end of World War II through to the early 1980s. Thereafter, they declined until the late 1990s.
- Other indicators point to a serious slump in the women's living standards in the 1990s: per capita gross domestic product decreased by 39%; and life expectancy of women declined from 74 in 1960s to 71 years in the early 1990s. Meanwhile, the number of women having abnormal births drastically increased.
- These negative trends in women's living standards were determined by changing conditions of life rather than by any significant change in the women's social and demographic profiles. The most important factor affecting these negative trends in female standards of living was the worsening diet and decline in real incomes and wages.
- There is a noticeable connection between the height and weight of newborns and that of their mothers, on the one hand, and social and demographic indicators, on the other.

- In the Soviet and post-Soviet period, the Moscow and the St. Petersburg newborns were definitely inferior to European and white American newborns in weight and, most likely, in stature, as there is a close relationship between stature and weight.
- Russian anthropometric results confirm the view that economic transitions are almost always accompanied by stresses and challenges to health and other biological indicators of well-being.

Chapter 160
Body Composition in a Multiethnic Community in New Zealand

Elaine Rush

Abstract This chapter summarizes evidence of ethnic differences in body composition from a multiethnic community in Auckland, New Zealand. The people measured were apparently healthy, aged 18–82 years and selected for a range of body mass index (BMI) within each age group. Because the measurement of body composition was by a single dual xray absorptiometry (DXA) machine, strong evidence has been provided for ethnic differences in the relationship between BMI and percentage body fat. Furthermore there are marked differences in both men and women by ethnicity of regional fat distribution, leg length and appendicular skeletal muscle mass.

The ethnic comparison is limited by the absence of concurrent measurements of chronic disease risk associated with BMI and fat distribution, however national health surveys clearly demonstrate that South Asian, Pacific and Maori have a higher prevalence of risk than European. The relationship is confounded by the concurrent evidence that lower socioeconomic status is associated with increased obesity and risk. Within an ethnicity, and by sex, risk increases with body weight for height, BMI. BMI may help inform international comparisons and public health *action points* within a population. BMI should not be used as an arbitrary cutoff point to label a person; ethnic origin should also be considered and further tests administered.

Further evidence is provided from longitudinal studies that within an ethnicity, weight for height tracks from birth, throughout childhood and into adulthood, providing support for the developmental origins of health and disease and the importance of early intervention.

WHO World Health Organisation

160.1 Introduction

160.1.1 Body Mass Index

Using evidence for association of body mass index (BMI) with risk factors for morbidity and mortality, the World Health Organization (WHO) has set standard desirable BMI values for populations (WHO Consultation on Obesity 1999). Evidence for association of increased mortality with increasing BMI continues to accumulate. Recently, strong evidence that mortality is lowest at a BMI of 22.5 to 25 kg/m^2 has been provided from 57 prospective studies of 900,000 Western European and North American adults(Whitlock et al. 2009). Furthermore, this collaborative analysis shows that for the same BMI, yearly deaths of males are almost twice the yearly deaths of female; yearly deaths from ischemic heart disease are three times higher than stroke and yearly deaths of current smokers are twice as high as nonsmokers. The evidence also very clearly shows that BMI is a strong predictor of overall mortality above and below 22.5 to 25 kg/m^2 and that the progressive excess mortality above this range is related to vascular disease. No clear cutoff values for increased risk were seen making precise definitions of overweight and obesity dubious.

160.2 Obesity

While the WHO definition of obesity (a BMI above 30 kg/m^2) is used for monitoring populations over time and comparing country statistics, it is often used as a risk factor for identifying individuals at risk. Obesity is more accurately defined as having an excess of body fat – however, the exact amount of fat has not been determined and is confounded by variations in risk being dependent on where in the body the fat is located. In particular, it is the accumulation of intra-abdominal fat and the closely associated waist measurement that has been found to improve the sensitivity for prediction of risk.

160.3 Geographical Origins

Globally, there is large variation in body size and shape (Ruff 2002) and the pattern of disease risk and mortality also varies widely. Due to a global increase in longevity, the prevalence of chronic diseases that are associated with aging and increased weight for height are increasing. In general, for an increase in BMI the proportion of body fat also increases. Interpretation of the variation in body size among populations becomes more difficult with migration and intermarriage. New Zealand, relatively geographically isolated in the South Pacific, is an example of a country where body composition in relation to ethnicity and the effects of migration can be studied.

160.4 Ethnicity in New Zealand

New Zealand, once predominantly Māori (the indigenous people) and European now, has an increasingly multiethnic population; in the 2006 census, 67.6% of the population identified themselves as European in origin, 14.6% Maori, 6.9% Pacific Island, and 9.2% as Asian (Statistics New Zealand 2006). Most Asian were of Chinese (3.8%) and Indian (2.7%) origin. Some people identified with more than one ethnicity so figures do not always sum to 100%. In 2006 more than one in five New Zealand people were born overseas, the median age was 36 years compared with 26 years in 1971 and life expectancy at birth had increased to 78 years for males and 82 years for females. However, as in many countries, there are large disparities among ethnic groups in health and life expectancy which are associated with both ethnicity and socioeconomic status (Ministry of Health and Statistics New Zealand 2009). Europeans live longer compared with Māori and Pacific and have higher socioeconomic standing (Table 160.1).

Ethnicity is defined, by Statistics New Zealand (Statistics New Zealand 2005), as "the ethnic group that people identify with or feel they belong to" and as such "is a measure of cultural affiliation, as opposed to race, ancestry, nationality or citizenship." Māori and Pacific peoples have the highest incidence and age-adjusted prevalence obesity, cardiovascular disease, and type 2 diabetes (Ministry of Health 2002, 2004). Maori and Pacific children appear to follow the same trend of increased size and associated risk (Ministry of Health 2008). In the census and in health statistics, ethnicity is by self-identification. Consequently, the analysis of associations among body size, ethnicity, socioeconomic status, and health risks has many errors and assumptions. An understanding of the differences in body composition among ethnic groups may contribute to a better understanding of the associations with disease risk. In particular, it is important to consider the lean component of body composition, a large proportion of which is found in skeletal muscle tissue. Skeletal muscle tissue plays a large role in the regulation of metabolism, particularly with increased physical activity.

The choice of method of measurement of body composition is limited by availability of equipment, access, cost, invasiveness, and the suitability of the measurements to address the research question. Over a number of years on a single dual energy X-ray absorptiometry (DXA) machine (model DPX + with software version 3.6y; Lunar Radiation Corp., Madison, WI, USA), we have undertaken a number of studies to answer questions about ethnic differences in the relationships between body fatness and body size, fat distribution, muscularity, bone mineral mass, and leg length. The following sections describe the practical methods used and, in particular, compare Pacific and Asian-Indian men and women, ethnic groups arguably at opposite extremes in terms of muscularity and fatness and very different in geographic origin.

Table 160.1 Independent life expectancy at birth of the Maori population compared with Non-Maori

	Non Maori		Maori	
	Males	Females	Males	Females
Life expectancy	79.0	83.0	70.4	75.1
Independent life expectancy	68.8	70.4	62.0	64.2
Healthy life expectancy	71.5	74.6	64.2	67.6

This table describes the disparity between Maori and Non Maori in the number of years expected to be lived free of functional limitation needing assistance (independent life expectancy) and the equivalent number of years of full health that a person can expect to live (healthy life expectancy) Material adapted from Ministry of Health and Statistics New Zealand (2009)

160.5 Practical Methods and Techniques

160.5.1 Sample Selection

When comparisons of body composition between ethnic groups are made, it is important that the subjects measured within each group cover the range of ages and body compositions of interest. This means that subjects are not randomly drawn from the population or are similar in proportions, but that they are selected to represent a range of age, BMI, and fatness.

160.5.2 Measurement

One relatively direct way of measuring body composition (fat mass (FM), fat-free soft tissue (lean), and bone mineral content (BMC)) is using a single DXA machine with the subjects lying supine in light clothing. The rising prevalence of increased body size means that for some studies both arms of a person may exceed the scanning area of the DXA. This may be overcome by positioning the subject so that one arm is not completely scanned. Subsequently, the data from the completely scanned arm are used to replace the data from the incomplete arm (Micklesfield et al. 2007).

Fat-free mass (FFM) is calculated as the sum of lean and BMC. Percentage of fat mass FM was calculated as FM/(FM + FFM) * 100. A quality-control check of DXA data is to compare body mass determined from DXA measurements (FFM + FM) with the actual body mass determined by weighing the subject.

160.5.3 Fat Distribution

Increased waist circumference as a measure of abdominal obesity is recognized as a marker of dysfunctional adipose tissue (Despres and Lemieux 2006) and, moreover, the ratio of waist-to-hip girth measurements has been shown to be a stronger predictor of myocardial infarction than BMI in a number of ethnicities, including European and Asian-Indian (Yusuf et al. 2005). The comparison among ethnic groups of the amount of FM, lean, and BMC in these areas of the body may provide further insights into ethnic differences in the underlying body composition that determines risk. DXA scans are limited in that they are two dimensional and assumptions are made within the manufacturers software algorithms about the amount and type of tissue behind the radio-opaque bone (Table 160.2). Therefore to examine the abdominal and hip area, regions of interest selected had minimal bone included within their borders. The hip measurement is closely related to the thigh measurement and the top of the thighs is where the largest mass of muscle in the body is located. More lean and less fat in the upper thigh area would translate into reduced metabolic risk (Snijder et al. 2003). Because of the following three factors – reduced bone mass, abdominal fat purportedly representing increased metabolic risk, and increased thigh area representing increased muscle mass and reduced fat mass – the two regions of interest below (illustrated in Fig. 160.1) were selected to examine ethnic differences in body composition.

Based on the criteria of Ley et al. (1992), abdominal fat was obtained from the analysis of a region of interest positioned with the lower horizontal border on top of the iliac crest and the upper border parallel and approximately passing through the junction of the T12 and L1 vertebrae. The sides of

Table 160.2 Features of DXA scans

While DXA scans are a reference method for measurement of lean, bone mineral, and fat components of body composition, there are limitations and strengths of this technique
At an equipment level, the reliability of a single machine is good but between machines and manufacturers the differences may be large. Machines are not portable and require expert operation. Reference phantoms are expensive, not easily portable and may not match the population of interest in size and composition
Manufacturers do not provide the equations used to derive body composition and validation against four compartment models of body composition
The gray-scale scan has two dimensions, and the composition within (e.g., the head) and behind bone (e.g., the superior gluteal region and the neck) is assumed
Strengths of the technology are that the scans have a very low dose of radiation; the time taken for the scans is relatively short and they are not invasive. Regional body composition analysis is possible and appendicular muscle may be derived. The use of DXA for validation of field techniques such as bioimpedance, for ethnic comparisons, and for longitudinal studies provides useful information

This table describes features of DXA scans, which are used to measure the lean, bone mineral and fat components of body composition
DXA dual energy X-ray absorptiometry

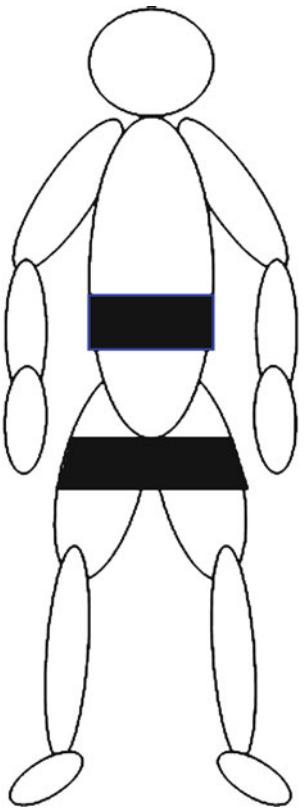

Fig. 160.1 Regions of interest of the whole-body DXA scan. Cartoon to demonstrate the regions of interest (*shaded black*) of the abdominal and thigh regions of the whole-body DXA scan. DXA = dual energy X-ray absorptiometry. Unpublished figure from the author

this region were adjusted to include the borders of the abdominal tissue scanned, and the fat content of this total region was reported as abdominal fat. A region of interest of identical height was placed over the thighs with the upper horizontal border positioned immediately below the ischial tuberosities and the lateral margins were adjusted to follow the shape of the thighs. The fat content of this region was reported as thigh fat.

160.5.4 Appendicular Skeletal Muscle Mass

Appendicular skeletal muscle mass (ASMM) was derived from the DXA scans as total limb mass minus the sum of limb fat and wet bone mass, estimated as BMC divided by 0.55. In this model, mass of the skin and associated dermal tissues is assumed to be negligible relative to the skeletal muscle component (Heymsfield et al. 1990).

160.5.5 Leg Length

Relative to height, a longer leg length is associated with greater muscle mass (Gallagher et al. 1997). Total subject skeletal, femoral, and tibial lengths were measured on the right side using the pixelated DXA image. Total skeletal length (DXA height) was measured as the distance from the apex of the cranium to the plantar surface of the calcaneus bone. Femur bone length was measured from top of the femoral head (greater trochanter) to middle patellar surface, and tibia bone length was measured from the superior intercondylar eminence to the inferior surface medial malleolus. Dimensions were measured in pixels and converted to centimeters based on a DXA scan of a standard ruler. Leg length was determined as the sum of the lengths of the femur and tibia bones. The ratio of leg length to DXA height was used as an index of relative leg length.

160.6 Ethnic Variations in Body Composition

160.6.1 Relationship Between BMI and Body Fat

We have been able to show that, generally speaking, for the same body size, height, and weight, a European adult has more fat and less muscle than a Maori or Pacific person (Table 160.3; Rush et al. 1997, 2009). On the other hand, an Asian-Indian person has more fat and less muscle than a European for the same size.

Examination of Fig. 160.2 emphasizes some fundamental patterns of difference. First of all, it can be clearly seen that for the same BMI, in general, a woman of any ethnicity has more body fat than a man; about 10% more of the total body mass of a women is fat compared to a man. The plateau of body fatness in women in these groups was about 50% of body mass while in men very few were seen to have body fat more than 40%. Similarly very few women had less than 15% body fat but for men a number were below 15%. Therefore, the differences in body fat by sex are a fundamental, biological difference.

The second feature of Fig. 160.2 that should be noted is that the BMI scale is logarithmic. Even with this transformation to linearize the relationship with PBF, some curvilinearity can be observed with a plateau of total PBF as BMI increases. This is because as fat mass increases, the fat-free mass required to maintain this extra mass also increases (Kyle et al. 2006).

Furthermore, in a study across two countries and five ethnic groups (summarized in Table 160.2; Rush et al. 2007), it was shown that for a BMI of 30 kg/m^2, Pacific Island women had the lowest PBF (~38% BF) and Asian-Indian women the greatest PBF (~48% BF). South African black women, European, and Māori had similar values of total PBF for a BMI of 30 kg/m^2 (40% BF). The explanation for these ethnic differences in the relationship may lie in linear body proportions and quantity and location of adipose tissue, skeletal muscle, and bone mineral content.

Table 160.3 Comparison of BMI and corresponding percent total body fat in different ethnicities

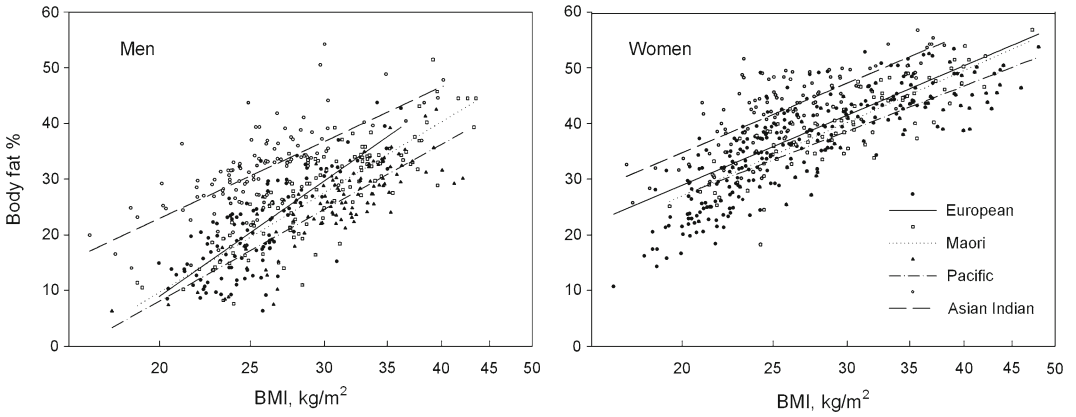

Fig. 160.2 Relation between percent body fat and BMI in different ethnicities. Relation between PBF and BMI of European (*closed circles*), Maori (*open circles*), Pacific Island (*closed triangles*), and Asian-Indian (*open triangles*) men (*upper panel*) and women (*lower panel*). The linear regressions are: PBF = 117.7log$_{10}$(BMI) – 144.2 (SEE = 5.2%, r^2 = 0.61, n = 124) for European men (*solid line*); PBF = 101.3log$_{10}$(BMI) – 122.0 (SEE = 4.6%, r^2 = 0.74, n = 109) for Maori men (*dashed line*); PBF = 93.6log$_{10}$(BMI) – 113.6 (SEE = 4.1%, r^2 = 0.68, n = 104) for Pacific Island men (*dotted line*); PBF = 78.6log$_{10}$(BMI) –79.4 (SEE = 5.0%, r^2 = 0.52, n = 117) for Asian-Indian men (*dash-dot line*); PBF = 103.5log$_{10}$(BMI) – 09.7 (SEE = 4.8%, r^2 = 0.72, n = 186) for European women (*solid line*); PBF = 74.8log$_{10}$(BMI) – 70.3 (SEE = 3.9%, r^2 = 0.72, n = 90) for Maori women (*dashed line*); PBF = 65.2log$_{10}$(BMI) – 57.8 (SEE = 4.1%, r^2 = 0.65, n = 97) for Pacific Island women (*dotted line*); and PBF = 71.0log$_{10}$(BMI) – 57.7 (SEE = 4.4%, r^2 = 0.60, n = 107) for Asian-Indian women (*dash-dot line*). PBF = percent body fat, BMI = body mass index, SEE = standard error of the estimate Material of the author (Rush et al. 2009)

160.6.2 Fat Distribution

DXA technology was developed and validated against a chemical model of fat (all that is soluble in ether), lean, and BMC. Therefore, the analysis is not able to differentiate between what is adipose tissue and the fat content of other tissues. Skeletal muscle cells contain more droplets of fat in both athletes and sedentary, obese people (Goodpaster et al. 2001). In the abdominal area, there is a relatively small proportion of muscle and fat measurement in this region of interest includes both the fat content of subcutaneous adipose tissue and the intra-abdominal fat. There are marked ethnic variations of the quantity of abdominal fat. In our study (Rush et al. 2009) after adjustment for height, weight, and age, fat mass in the abdominal area was higher for Asian-Indian men and women than all other ethnic groups. Conversely, Pacific men and women had the lowest amount of abdominal fat. The same differences between Asian-Indian and Pacific were observed for adjusted thigh fat mass. Thigh fat mass also includes subcutaneous and inter- and intramuscular fat content. Thigh fat mass was significantly higher in Europeans than the other ethnic groups. The ratio of abdominal to thigh fat mass was lowest in European and highest in Asian-Indian men, whereas in women, this ratio was also the lowest in European but Asian-Indian women had a lower value than Pacific. These ethnic and sex patterns of difference in fat distribution were still seen after adjustment for age and did not completely eliminate the ethnic differences in the relationship of percentage total body fat to BMI.

160.6.3 Appendicular Skeletal Muscle Mass

For both men and women, the highest ASMM was observed in the Pacific group and the lowest ASMM in the Asian-Indian group, both before and after adjustment for age, height, and weight. ASMM did not differ between Maori and European men or women after adjustment. Inclusion of ASMM in the PBF–BMI regression models reduced but did not completely eliminate the ethnic differences.

160.6.4 Leg Length

In the women studied, adjusted for height, age, and weight, Asian-Indian and Pacific women had the longest legs and Māori women the shortest. European, Maori, and Asian-Indian men had legs of a similar length and Pacific men had the longest legs. The significant difference in leg lengths was about 1 cm – with average leg length in women about 75 cm and in men 82 cm. Leg length and height, when added to the percentage of BF–BMI regression models, did not significantly affect the ethnic differences observed.

160.6.5 Age

Longitudinal studies to show changes in total body fat and ASSM with aging are difficult. This cross-sectional study of healthy adults showed after adjustment for height and weight that in both men and women, within ethnicity, the percentage of total body fat increased with age. The exception was in Asian-Indian men where no relationship of percentage total body fat with age was able to be shown.

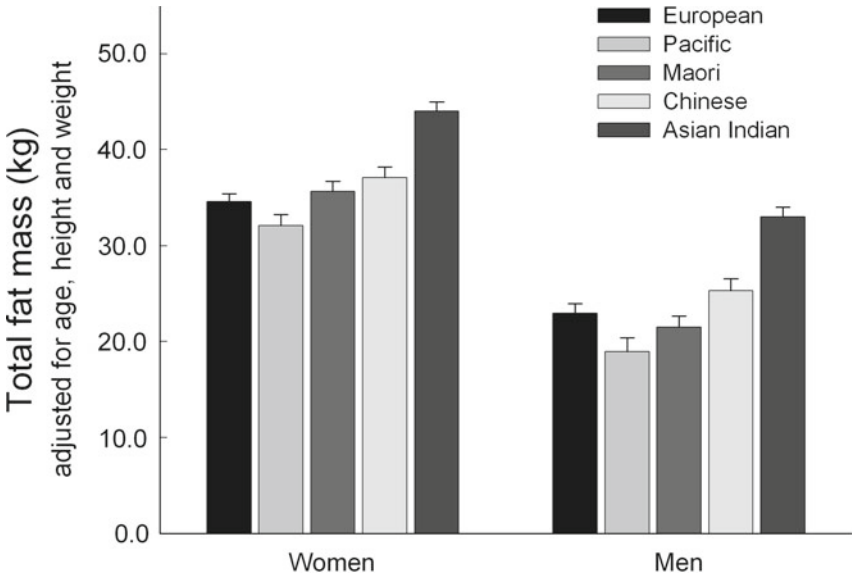

Fig. 160.3 Differences in total fat mass (kg) for European, Pacific, Maori, Chinese, and Asian-Indian men and women adjusted for age, height, and weight (Chinese data adapted from (Wen 2008), all other data adapted from (Rush et al. 2009))

ASMM, after controlling for weight and height, decreased linearly with age in European and Māori men and women but not in Pacific or Asian-Indian men or women. Abdominal fat as a percentage of total fat and the ratio of abdominal to thigh fat increased with age in all ethnic groups, men and women.

160.6.6 Chinese and Asian-Indian Differences

Recently, as a follow-up to the previous study, using measurements on the same DXA machine, we have been able to add 43 (M20, F23) New Zealand Chinese, aged 30–39 years and compare with the existing data for European (M29, F37), Maori (M23, F23), Pacific (M15, F23), and Asian-Indian (M29, F25) for the same age range (Wen 2008).

For a fixed BMI, Chinese had a higher PBF than European and less PBF than Asian-Indian. At a PBF equivalent to a BMI of 30 kg m^{-2} in Europeans, BMI values for Asian-Indian and Chinese women were 5.8 and 2.2 BMI units lower than European, respectively, and for Asian-Indian and Chinese men, BMI values were 8.2 and 3.0 units lower (Table 160.2). In addition, Chinese had a significantly higher central-to-appendicular fat ratio than both Asian-Indian and European ($P < 0.001$). Chinese men and women had relatively more central fat than European and Asian-Indian.

The relationship between total PBF and BMI for Asian-Indian and NZ Chinese differs from Europeans and from each other, which indicates that different BMI thresholds for obesity, defined by PBF, may be required for these Asian ethnic groups**.**

In this multiethnic subsample (Wen 2008) adjusted for age, height, and weight, Asian-Indians had the highest total FM and Pacific the lowest (Fig. 160.3), while Chinese had an intermediate value. Yet, Pacific and Asian-Indian people in New Zealand have higher rates of type 2 diabetes mellitus and other vascular diseases than European (Ministry of Health 2008).

160.7 Applications to Other Areas of Health and Disease

It must be emphasized that measurement of body size is not a functional measure. BMI may help inform *action points* for a population rather than being an arbitrary cutoff point to label a person. There is a limit to all health budgets and when an action point is decided then it infers that there is budget and expertise to be able to provide treatment. What is known is that increasing body mass for height in general is accompanied by an increase in risk for all ethnic groups. There is also increased risk for those who are underweight – as in all physiological systems there is an optimal, homeostatic equilibrium. Functional capacity of the population must be considered as well as physical size and body composition.

The prevalence of obesity and type 2 diabetes follows a socioeconomic gradient. In New Zealand, as in other countries, highest rates of chronic disease are observed among groups with the lowest levels of education and income and in the most deprived areas. Inequitable access to healthy foods is one mechanism by which socioeconomic factors influence the diet and health of a population. With the current recession and global food shortage, incomes drop and prices rise, and energy-dense foods that are nutrient poor become the only way to provide daily calories at an affordable price. By contrast, nutrient-rich foods and high-quality diets not only cost more but are consumed by more affluent groups (Solomons 2009). Affluence and deprivation tend to track through life as do food and activity patterns. Therefore, the pattern of differences shown among ethnic groups is confounded by economic status. Furthermore, there is an intergenerational effect, epigenetics, and culture that influences the body composition of future generations.

From conception, the diet and activity of the mother influence the environment for the child. Seventy-five percent of cell divisions take place before birth, and birthweight is a strong predictor of the future growth trajectory of the child. This has been shown clearly in the Pacific Island family study where birthweight is a strong predictor of body weight at the age of 6 years (Rush et al. 2009).

At 2 years of age, body fatness was determined by bioimpedance analysis in 142 children, 78 girls and 64 boys. The mothers' of these children were diagnosed and treated for gestational diabetes (Rowan et al. 2008). In these children body fatness differed by sex, with girls having more fat than boys. Body fat also differed by ethnicity, and adjusted for age, height, and weight; Asian-Indian children had the most body fat and European the least Fig. 160.4 (unpublished data). Birthweight was positively associated with body weight at 2 years ($r = 0.47$, $P < 0.0001$). Both birthweight and weight at 2 years were positively related to the mothers' weight 2 years post-partum ($r = 0.35$, $P < 0.0001$ and $r = 0.32$, $P < 0.0001$, respectively). Birthweight is a retrospective marker of the intrauterine availability of nutrients, oxygen, and hormones that program tissue development (Fowden et al. 2006). The developmental origin of health and disease (DOHaD) concept is an emerging paradigm for relating evolutionary biology to contemporary health issues such as increased body mass and fat accumulation.

It is clear that adaptations to the environment are initiated in utero and in early life, and this is referred to as programming. At a molecular level, the mechanism is epigenetic, which results in permanent structural and metabolic changes which occur because of the way DNA is expressed. On a macro-level, the public health consequence of programming challenges the one-size-fits-all norm and shows the need for prescreening prior to some interventions. In some cases, individualized, rather than collectively applied, preventive, or remedial measures will be the safest option.

Particularly in a multiethnic community, it must not be assumed that the path to obesity is the same or a simple case of exercising too little and eating too much. For example, in Asian-Indian mothers, low-vitamin-B12 and -protein intake during pregnancy have been shown to be associated with increased adiposity and cardiovascular disease risk factors in the 6-year-old offspring (Yajnik et al. 2008). Vegetarianism has been practiced for many generations in the majority of Indian communities. While the Asian-Indian New Zealand population is only 2.5% of the total population,

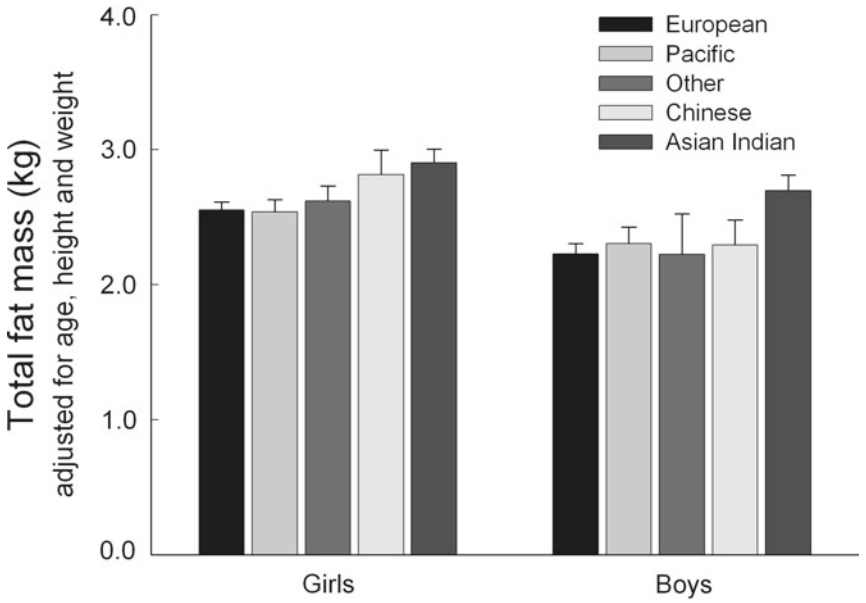

Fig. 160.4 Differences in total fat mass (kg) in 2-year-old children by sex and ethnicity. Differences in total fat mass (kg) adjusted for height, weight, and age in European, Pacific, Other, Chinese, and Asian-Indian girls and boys aged 2 years. All children's mothers were diagnosed with gestational diabetes mellitus during pregnancy (Rowan 2009 unpublished data)

hospitalization and mortality rates due to cardiovascular disease and the prevalence of self-reported diabetes are two and three times higher than that of the total population (Ministry of Health 2006).

Another example of intergenerational effect is gestational diabetes mellitus (GDM). GDM has a higher prevalence in non-European NZ ethnic groups. Children of mothers with GDM are born larger and are more likely to be obese and have type 2 diabetes in later life. The problem therefore may compound with successive generations. More studies and modeling are required to be able to target treatment to the most at-risk populations, with the greatest chance of reducing the risk and breaking the cycle. In the meantime, ethnic-specific measures of body composition may help identify those at higher risk and inform public health initiatives and health care across the lifespan.

Summary Points

- The relationship between BMI and body fatness is not linear, and varies by ethnicity.
- An understanding of the relationship between BMI and body-fat percentage in different ethnicities will enable a better prediction of disease risk.
- In general, women have about 10% more of their body weight as fat compared with men.
- BMI is more useful as a tool to help inform action points for populations, rather than as an arbitrary cutoff point for individuals.
- Increased weight for height is a risk factor for chronic disease in later life.
- The developmental origins of health and disease paradigm emphasize the importance of the intrauterine environment for future health.
- Birthweight is a strong predictor of future weight and therefore risk for vascular disease, as well as other diseases associated with increased weight for height.

Chapter 161
Anthropometric Measurements in Australian Aborigines

Srinivas Kondalsamy-Chennakesavan, Leonard S. Piers, Sidya Raghavan, and Kerin O'Dea

Abstract Aborigines have inhabited Australia for many thousands of years. They led a 'hunter-gatherer' lifestyle prior to European contact. They are known to have lower sitting-height to stature ratio with long legs, relatively short trunks and narrow across the torso and hips (a 'linear' body build). European expeditions in the early twentieth century confirm that overweight and obesity was rarely observed. In the second half of the twentieth century, the traditional lifestyle of Aborigines had transitioned to a westernised lifestyle. Associated with such a transition to western lifestyle is the epidemic of non-communicable chronic health conditions such as diabetes, cardio-vascular diseases and renal failure.

Average weight and Body Mass Index (BMI) of Aborigines have increased over time. However, this increase is not uniform across Aboriginal Australia. There are major differences in the body habitus profile between different clan groups/communities. In spite of these variations, the pattern of preferential central obesity in both men and women is uniform in almost all the communities. This could have provided a survival advantage under conditions of traditional lifestyle (with its 'feast-and-famine' pattern of food intake) experienced by Aborigines prior to European contact.

Our studies have shown that BMI significantly underestimated overweight and obesity when compared to other indices of body fat. Aborigines have preferential central fat deposition and exhibit consistently higher waist-hip ratios when compared to other Australians. Also, prevalences of overweight and obesity depend on the anthropometric definitions used. The relationship of surrogate estimates of body composition such as S4 for subcutaneous fat and height^2/resistance for FFM (fat free mass) to body weight and BMI are significantly different between Aboriginal people and European Australians.

Even at lower levels of body habitus profiles, Aborigines have increased risk for chronic conditions. Also, anthropometric characteristics differ substantially among different Aboriginal communities and stereotyping and generalisations should be avoided.

161.1 Introduction

This chapter provides an overview of anthropometry amongst Australian Aborigines. Even though there are a number of measurements used in anthropometry, we have focussed on easily obtainable and commonly used measurements in clinical practice. This chapter is organised into three distinct parts. The first part deals with a review of published findings on anthropometric measurements (height, weight, and derived measurements such as BMI) by time period, age and gender. The second part examines the relationship of adiposity and body-fat distribution to BMI in Australians of Aboriginal and European ancestry. The final part addresses applications to other areas of health and disease.

161.2 Part 1: A Brief Background

Aborigines have inhabited Australia for many thousands of years. They have adapted to the harsh environmental conditions that vary from warm and humid tropical climate in the north to colder climate in the south. They had led a hunter-gatherer, nomadic life in the past. However, their lifestyle has undergone dramatic changes since European settlement, and contemporary Aborigines, with few exceptions, lead a westernised way of life. A number of studies have shown that the anthropometric

measurements of Aborigines are different when compared to other ethnic groups. The relationships of these measurements to health and diseases are also different amongst Aborigines when compared to non-Aborigines. The current health status of Aborigines is one of the poorest in the developed world with major disparities in life expectancy when compared to the Australian population.

For part one, a literature review was conducted to retrieve information on anthropometric measurements. The traditional lifestyle of Australian Aborigines changed most dramatically in the latter half of the twentieth century. This necessitated reviewed studies to be classified as those done prior to the year 1970 where the impact of westernisation was much less pronounced and those done later. This arbitrary cutoff also serves to assess the changes in body habitus profiles of contemporary Aborigines in comparison with the profiles documented earlier. Studies conducted prior to the 1970s collected a number of anthropometric features ranging from skeletal measurements to the commonly used measures of height and weight. These studies had different aims, with some trying to elucidate the origin of Aborigines or trace their ancestry, whereas others focussed on evaluation of health status. We have also obtained and analysed original data on 383 Aborigines (203 men and 179 women) collected by Abbie between 1957 and 1963 and used in his seminal publications (Abbie 1957, 1968; Macho and Freedman 1987).

As this part of the chapter focuses on commonly used measurements that are clinically useful, we have extracted details on height and weight and calculated BMI. The methods and the environment in which these measurements were taken differed significantly between the studies. It is beyond the scope of this chapter to illuminate the similarities and differences in the methodology and readers are advised to consult the original publications for detailed information.

Similar measurements from studies conducted after 1970 have also been reviewed to provide an overview of anthropometric measurements of contemporary Australian Aboriginal adults. The survey conducted by the Australian Bureau of Statistics (ABS) in 1994 is the only national survey of Aborigines where height and weight were measured and collected. Apart from this survey, a number of researchers have conducted independent studies on a smaller scale in different geographical regions. The objectives of these smaller studies varied greatly – some were community-wide health assessments and others were targeted studies evaluating risk factors for diabetes, cardiovascular disease and/or other health-care conditions. Most studies have focussed on Aborigines living in remote areas, despite over 70% of the Indigenous population living in urban centres.

Detailed information on anthropometric measurements from nine major studies was used for this review. Six of these studies were conducted prior to 1970 and will be presented first followed by studies done later. Amongst these six, four studies included Aborigines in the Northern Territory (NT) (Campbell et al. 1936; Howells 1937; Macho and Freedman 1987); the fifth study included Aborigines in the NT and Western Australia (WA) (Prokopec 1977) and the sixth study was conducted in Queensland (Douglas 2005). Norgan (1994) reviewed five of these studies and compiled information related to body mass indices and provided detailed interpretation of low BMI in Australian Aborigines. Norgan's work shows that the mean BMI amongst men varied from 18.8 kg/m^2 in Beswick to 23.8 kg/m^2 in the southeast. Similarly, average BMI amongst women varied from 17.6 kg/m^2 in Arnhem Land to 23.2 kg/m^2 in Yalata. Overall, men and women had an average BMI of 20.3 and 19.2 kg/m^2, respectively. The only other study prior to 1970 but not included in Norgan's review was conducted in 1965 amongst Cape York Aborigines. This study reported that the average BMI amongst men and women was 18.7 and 19.9 kg/m^2, respectively (Douglas 2005). Even though these studies were conducted amongst different clan groups and communities from a wide geographical area, the uniform pattern of slender build with low average BMI remains uniform.

Figure 161.1 shows the results of our reanalyses of Abbie's data collected between 1951 and 1963 by age group and gender. As expected, men were taller than women. While heights fluctuated across the age groups, numbers were small. Men were generally lean with a mean BMI fluctuating around

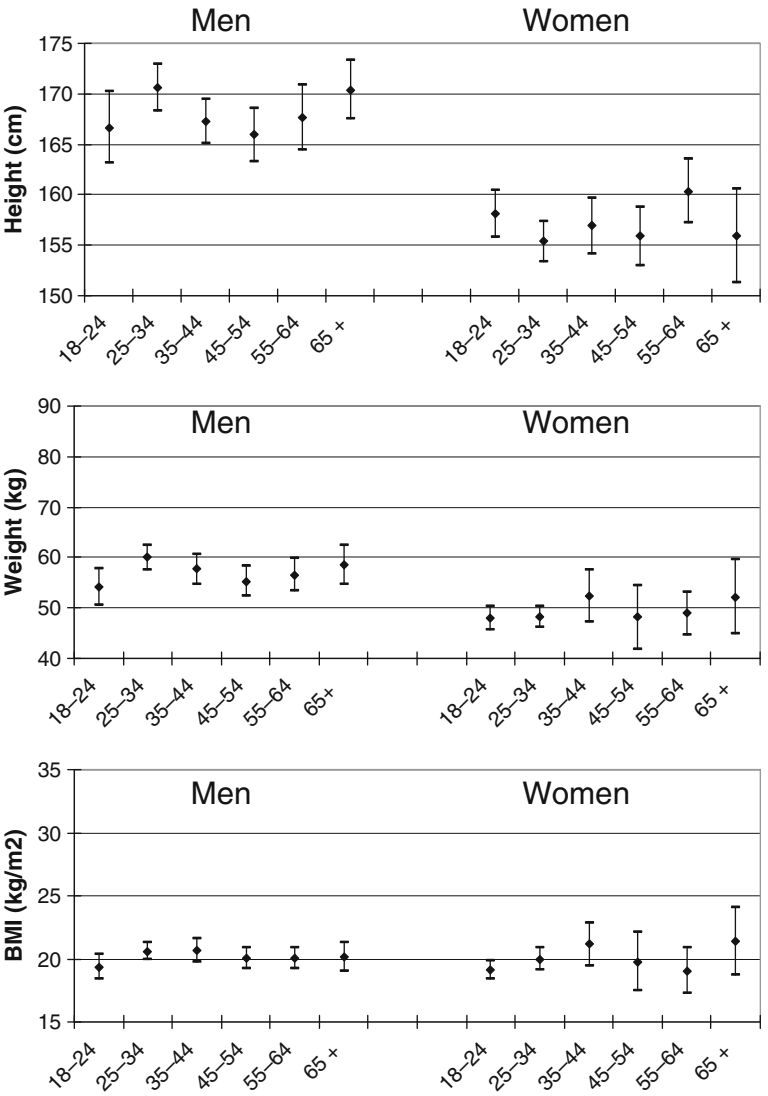

Fig. 161.1 Mean height, weight and BMI with 95% CI by sex and age groups. (Source: Data collected by Abbie between 1957–1961 and obtained from http://www-personal.une.edu.au/~pbrown3/resource.html)

20 kg/m^2. BMI in women also fluctuated around 20 kg/m^2, and varied more widely in the older age groups. None of the variations with age were statistically significant.

As noted above, we have presented anthropometric measurements from three of the studies conducted after 1970. One of these three was a national survey of Aboriginal and Torres Strait Islanders conducted by the Australian Bureau of Statistics in 1994 (Cunningham and Mackerras 1998), whereas the other two were our studies in remote NT and central Australia between 1995 and 2003 (Kondalsamy-Chennakesavan et al. 2008a; Piers et al. 2003).

Figure 161.2 shows height, weight and BMI by age groups and gender based on the national survey of Aboriginal and Torres Strait Islanders (Cunningham and Mackerras 1998). Height in Aboriginal males tended to fall slightly with age until age 65+. Females were shorter with a trend towards shorter stature from the age of 45 years. Amongst males, weight and BMI rose up to the age of 44 years after which there were declines. In women, weight and BMI increased steadily up to the age of 64 years after which they fell.

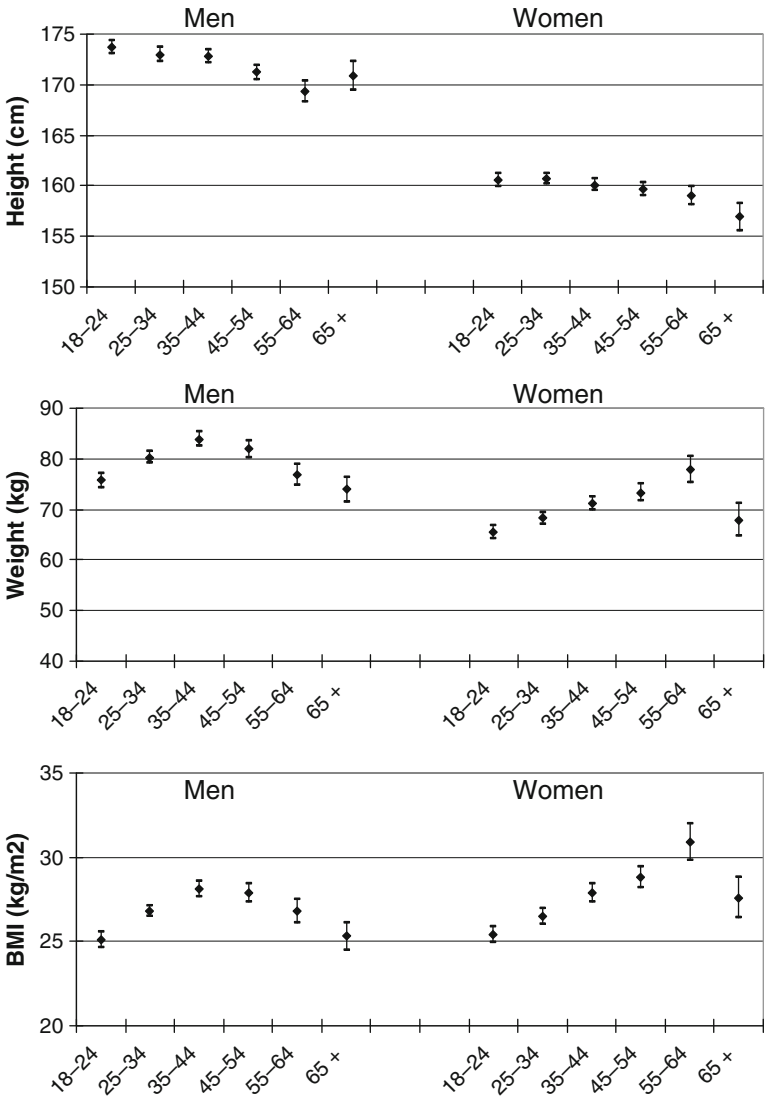

Fig. 161.2 Mean height, weight and BMI with 95% CI by sex and age groups (Source: NATSIS 1994)

We have previously published information on anthropometric measurements of Aborigines living in three remote communities (Wadeye, Nauiyu and Borroloola) and compared them with a nationally representative survey (AusDiab) in Australia (Kondalsamy-Chennakesavan et al. 2008a). In brief, these communities were in the Top End of the Northern Territory. Body habitus profiles were collected using standardised methods as part of a chronic disease screening and management program. Figure 161.3 shows the extent to which these Aboriginal communities differ in their anthropometric measurements. The average differences in waist circumference between communities were as high as 12 cm amongst men and 6 cm amongst women. Similarly, average differences in weight were as high as 19 kg in men and 16 kg in women. The most striking differences between the Aboriginal populations and AusDiab were the marked differences in body-fat distribution. In contrast to AusDiab participants, in the Aboriginal populations both men and women exhibited a central fat deposition with little difference between the sexes.

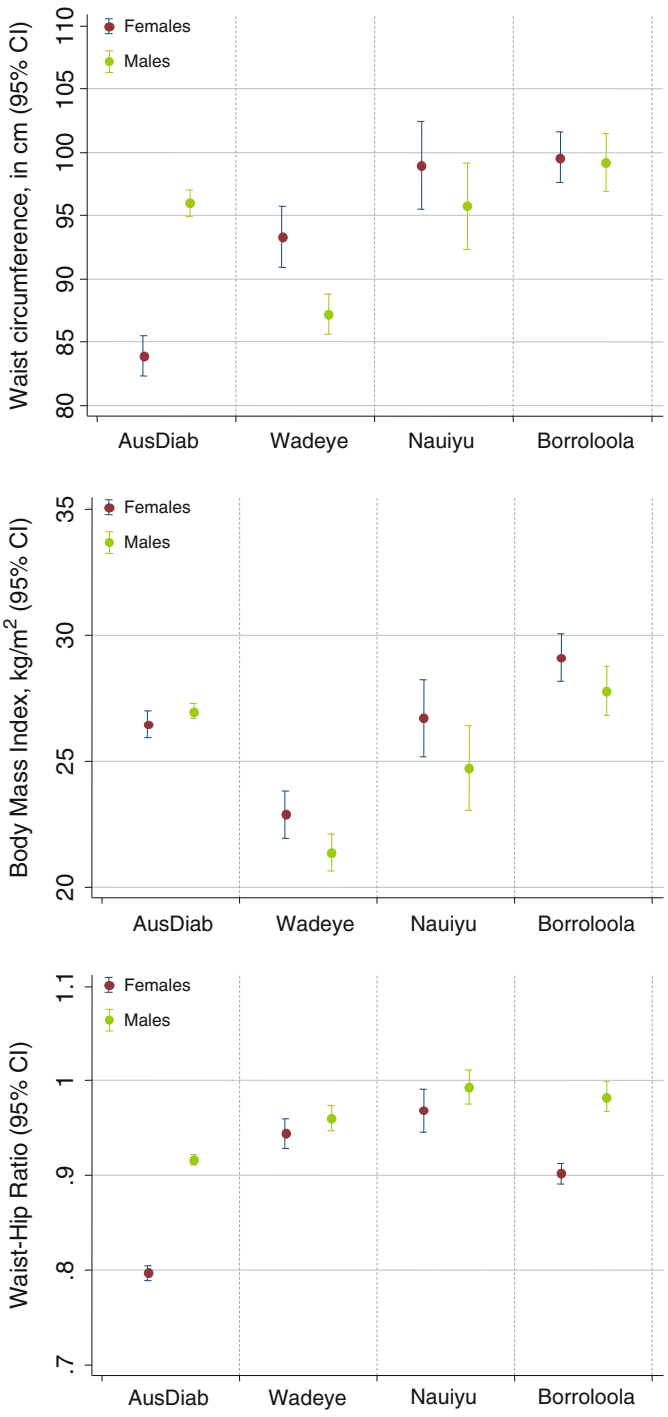

Fig. 161.3 Selected anthropometric measurements by sex and community (Source: Kondalsamy-Chennakesavan et al. (2008a) (printed with permission))

Table 161.1 shows rates of overweight and obesity by community and gender. Amongst females, when compared to their AusDiab counterparts, Aboriginal women from all the three communities had significantly ($P < 0.001$) higher rates of overweight and/or obesity by any definition, with the exception of females in Wadeye who had a lower prevalence by BMI. When compared to their AusDiab

BMI Body Mass Index; *WC* Waist Circumference; *WHR* Waist-Hip Ratio

[a]Significance test for differences in the distribution

counterparts, Aboriginal males in Wadeye and Nauiyu were significantly ($P < 0.001$) less overweight and/or obese by BMI and waist circumference. In contrast, using the waist–hip ratio criterion, Aboriginal males from all the three communities were significantly ($P < 0.001$) more overweight and/or obese. In aggregate, the proportions of Aboriginal and AusDiab females with BMI ≥25 were similar. In contrast, proportionally less Aboriginal males had BMI ≥25 than their AusDiab counterparts (37% vs. 68%, $P < 0.001$). Waist circumference classified many more Aboriginal than AusDiab women as overweight or obese (89.7% vs. 56%, $P < 0.001$), but fewer Aboriginal than AusDiab men (41.2% vs. 54.7%, $P < 0.001$). By waist–hip ratio, almost all Aboriginal people of both sexes were overweight or obese, at levels vastly higher than the AusDiab data, 95.6% vs. 45.3% for females ($P < 0.001$), and 78.7% vs. 58% for men ($P < 0.001$) (Kondalsamy-Chennakesavan et al. 2008a).

There are a number of factors influencing the nutritional status of contemporary Aborigines. Some of these factors are probably genetic; however, there are important socio-environmental and lifestyle-related influences. Age also seems to be a strong determinant of body habitus profiles. Lower body weight in those aged 65+ amongst both men and women may suggest a 'cohort phenomenon' related to different social-environmental influences early in their lives. It is also possible that this phenomenon represents a 'healthy survivor' effect as more than half the Aboriginal population died by the age of 55 years (Kondalsamy-Chennakesavan et al. 2008a).

To summarise, when compared to the studies conducted prior to 1970, recent studies have shown that the average weight has increased significantly in recent years. There is also a significant difference in average waist–hip ratios between Aborigines and non-Indigenous Australians. However, these changes and differences are not uniform across Aboriginal Australia and there are wide variations between Aboriginal communities.

161.3 Part 2: The Relationship of Adiposity and Body-Fat Distribution to Body Mass Index (BMI) in Australians of Aboriginal and European Ancestry

161.3.1 A Brief Background and Methods

Body mass index (BMI) and the waist-to-hip circumference ratio (WHR) are now used conventionally as indices of obesity and fat distribution in epidemiological studies. Although some general limitations of these indices are recognised, there are others that affect their use in relative risks for disease which are not well recognised. For example, differences in sex, ethnicity and especially age can result in substantial misclassification of obesity and fat distribution (Baumgartner et al. 1995). Cutoff points for obesity as defined by the WHO are based on BMI values. However, these cutoff points are based on studies on the relationship between BMI and morbidity and mortality in Western populations (Lew and Garfinkel 1979; WHO 1990).

We have previously shown that BMI has poor sensitivity and positive predictive value in identifying overweight/obese individuals when classified by per cent body fat, measured using deuterium dilution, in Australians of European ancestry (Piers et al. 2000). In recent years, several studies have shown a different relationship between BMI and per cent body fat amongst ethnic groups. For example, Gurrici et al reported that Indonesians had, for the same per cent body fat, a BMI about 3 units lower than Dutch Europeans (Gurrici et al. 1998). A meta-analysis of available data likewise showed that there were differences in the relationship of BMI to per cent body fat between various ethnic groups (Deurenberg et al. 1998).

Australian Aboriginal people have an extremely high and increasing prevalence of obesity, with its associated health problems (Cunningham and Mackerras 1998). Amongst adults aged 18 years or more, about 25% of Aboriginal men and 28% of Aboriginal women may be classified as obese based on measures of BMI (McLennan and Madden 1999). Furthermore, in addition to the absolute amount of body fat, anatomical distribution is important as it is a known risk factor for ill health. While BMI, WHR and waist circumference have been shown to be powerful independent predictors of type 2 diabetes (Carey et al. 1997; Ledoux et al. 1997), there is evidence that WHR is a better screening measure for type 2 diabetes risk than BMI (Haffner et al. 1992).

As body-fat distribution may also vary between ethnic groups (Baumgartner et al. 1995; Gasperino 1996; Lovejoy et al. 2001), we were interested in determining if body weight, BMI and body-fat distribution were related in the same manner to body composition in young (18–35 years of age), healthy (non-diabetic) Australians of Aboriginal and European ancestry. The methods used and detailed results have been published earlier (Piers et al. 2003). In brief, we analysed data from 397 participants: 250 Aboriginal people (120 women and 130 men) and 147 European Australians (100 women and 47 men). Participant characteristics are presented in Table 161.2.

161.3.2 Results

161.3.2.1 Differences in Anthropometric Measurements Between Aborigines and Europeans

Aboriginal people were significantly shorter and weighed less than their European Australian counterparts. While mean BMI was similar in women ($P = 0.285$), Aboriginal women had significantly greater mean waist circumference and mean waist-to-hip ratios ($P < 0.0005$) compared to European Australian women. In contrast, mean BMI was significantly lower in Aboriginal men compared to European Australian men ($P = 0.011$), and waist-to-hip ratio was significantly ($P = 0.007$) higher in Aboriginal men compared to European Australian men.

Skinfold thickness (SFT) measurements are said to provide an estimate of the size of the subcutaneous fat depot, which in turn provides an estimate of total body fat (Durnin and Rahaman 1967). Such estimates are based on two assumptions: (a) the thickness of the subcutaneous fat reflects a constant proportion of the total fat and (b) the skinfold sites selected for measurements, either singly or in combination, represent the average thickness of the entire subcutaneous tissue (Lukaski 1987). In addition, it is still unclear if ethnic-specific equations are required to estimate FFM (fat-free mass) and FM (fat mass) using bioelectrical impedance analysis (BIA) (Ellis et al. 1999) as there is evidence of population specificity in the validity of BIA (Chertow et al. 1997). As such, we chose to compare directly measured variables (SFT and height^2/resistance) rather than derived estimates of FM and FFM using regression equations generated from data that did not include Aboriginal people. We also restricted the analysis to healthy young people aged between 18 and 35 years, analysed data from women and men separately, and excluded pregnant women altogether.

161.3.2.2 Differences in Skinfold Thickness Between Aborigines and Europeans

The mean sum of the four skinfold thicknesses (S4) was higher in Aboriginal women compared to European Australian women ($P < 0.0005$). While their mean trunk SFT was significantly higher ($P < 0.0005$), the limb SFT of Aboriginal women tended to be lower than that of European Australian

Table 161.2 Participant characteristics

[a]Significantly different ($P < 0.05$) from European Australians of same sex

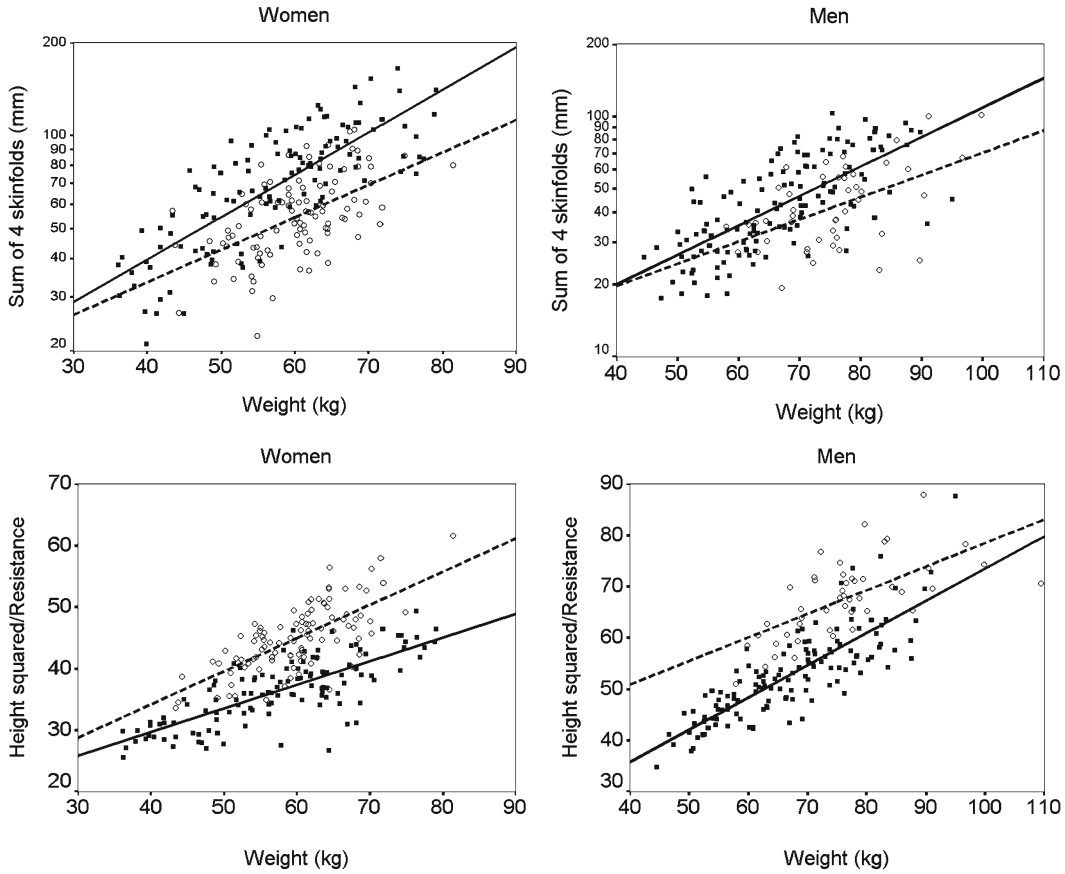

Fig. 161.4 Relationship of body weight to surrogate measures of fat mass (Sum of 4 skinfold thicknesses) and fat-free mass (height^2/resistance) in Australians of Aboriginal (*filled squares*, *solid line*) and European (*open circles*, *broken line*) ancestry

women ($P = 0.06$). There was no significant difference in S4 between Aboriginal and European Australian men ($P = 0.485$), nor were there significant differences in limb and trunk SFT. Both Aboriginal men and women had significantly higher ($P < 0.0005$) mean resistance values, but significantly lower ($P < 0.0005$) height^2/resistance ratios compared to their European Australian counterparts.

161.3.2.3 Relationship of Body Weight and BMI to Surrogate Measures of Fat Mass and Fat-Free Mass

Figures 161.4 and 161.5 show the relationships of body weight and BMI to $\log_{10}$ S4, and height^2/resistance, by sex and ethnicity. On modelling body weight in women as a function of ethnicity, $\log_{10}$ S4, height^2/resistance, height and their interactions, there was no significant interaction between ethnicity and any of the other independent variables ($P > 0.05$). However, the coefficient for ethnicity was significant ($P = 0.01$), with Aboriginal women being 2.0 kg heavier, for the

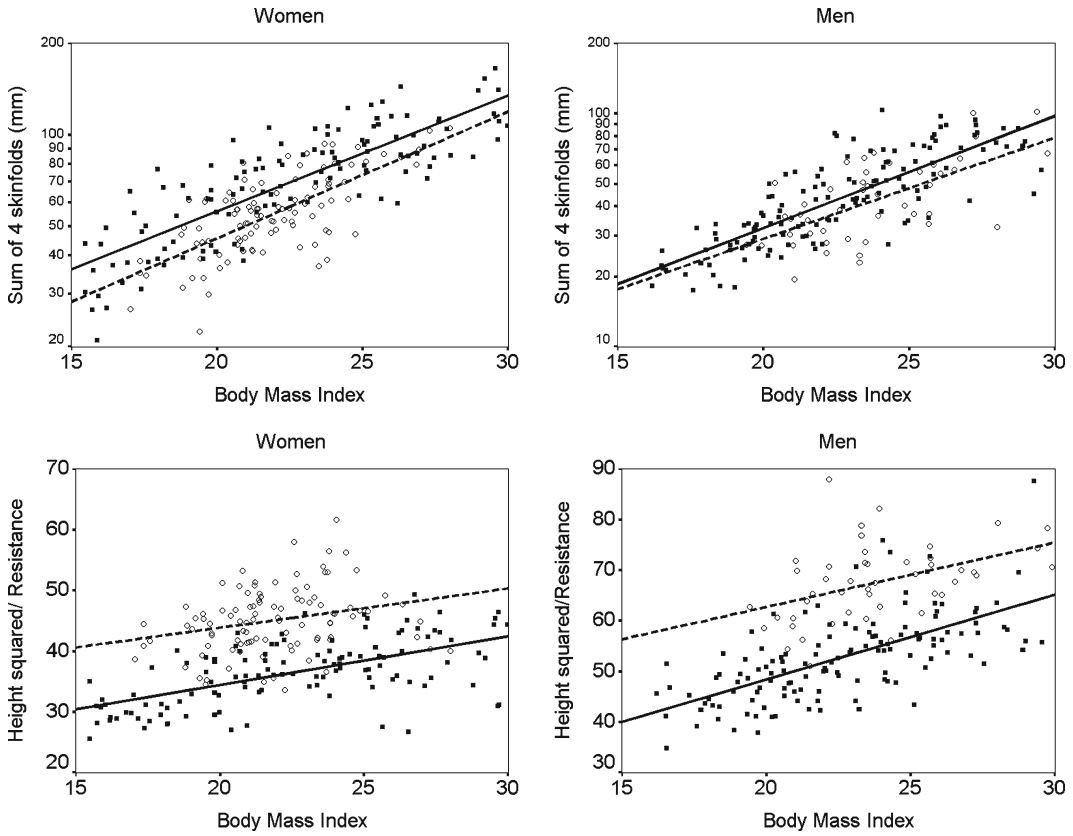

Fig. 161.5 Relationship of body mass index (kg/m^2) to surrogate measures of fat mass (sum of 4 skinfold thicknesses) and fat-free mass (height^2/resistance) in Australians of Aboriginal (*filled squares*, *solid line*) and European (*open circles*, *broken line*) ancestry

same height, $\log_{10}$ S4 and height^2/resistance values, than their European Australian counterparts. On modelling body weight in men as a function of ethnicity, $\log_{10}$ S4, height^2/resistance, height and their interaction terms, there was no significant interaction between ethnicity and any of the other independent variables ($P > 0.05$). However, the coefficient for ethnicity was significant ($P < 0.00005$), with Aboriginal men being 3.8 kg heavier, for the same height, $\log_{10}$ S4 and height^2/resistance values, than their European Australian counterparts (Fig. 161.4).

On modelling BMI in women as a function of ethnicity, $\log_{10}$ S4, height^2/resistance and their interactions, there was a significant interaction between $\log_{10}$ S4 and ethnicity ($P < 0.01$). Because of this interaction, the coefficient of the ethnicity variable could not be interpreted, except to say that the relationship of $\log_{10}$ S4 and height^2/resistance to BMI was different between the two ethnic groups (Fig. 161.5). On modelling BMI in men as a function of ethnicity, $\log_{10}$ S4, height^2/resistance and their interactions, the interaction terms were not significant ($P > 0.05$). However, the coefficient for ethnicity was significant ($P < 0.05$). Hence, for any given combination of S4 and height^2/resistance, Aboriginal men had a BMI that was ~1.2 kg/m^2 higher than European Australian men (Fig. 161.5). As the analysis was restricted to those who were 18–35 years of age, 'age' was not included in any of the analyses.

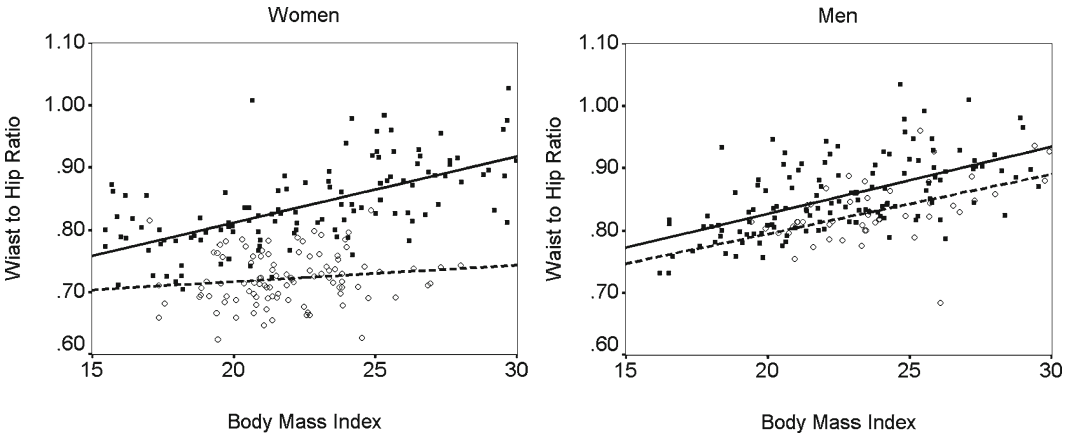

Fig. 161.6 Relationship of waist-to-hip circumference ratio with body mass index (kg/m^2) in Australians of Aboriginal (*filled squares*, *solid line*) and European (*open circles*, *broken line*) ancestry

161.3.2.4 Relationship of Waist-to-Hip Circumference to Body Mass Index

Figure 161.6 shows the relationship of WHR to BMI in Aboriginal and European Australian men and women. On modelling WHR as a function of BMI and ethnicity in women, Aboriginal women had significantly greater WHR ($P < 0.0005$), but as there was significant interaction between ethnicity and BMI ($P = 0.01$), this difference could not be quantified. Aboriginal men had a WHR that was 0.036 units higher for any given BMI compared to European Australian men ($P < 0.0005$).

161.3.3 Discussion

If one accepts that S4 is a surrogate marker of subcutaneous FM and height^2/resistance representative of FFM, then for the same S4, height^2/resistance and height, both Aboriginal men and women had a higher body weight, by 3.8 and 2.0 kg, respectively, compared to their European Australian counterparts. We assume that part of this difference in body weight was due to non-subcutaneous fat, as this component of FM was not accounted for in the regression model. Given the significantly higher WHR, in both Aboriginal men and women when compared to the corresponding European Australian group, we speculate that this unaccounted body weight was probably intra-abdominal visceral fat. Direct methods of body composition, such as computer assisted tomography (CAT) and/or magnetic resonance imagining (MRI), would be required to confirm this.

Our results indicate that this group of Aboriginal women was shorter and proportionately less heavy than European Australian women, and consequently had a similar mean BMI. However, while Aboriginal men were also shorter, they weighed considerably less than European Australian men and therefore had a significantly lower mean BMI. Nevertheless, for any given combination of S4 (subcutaneous fat) and height^2/resistance value (fat-free mass), Aboriginal men had a BMI that was approximately 1.2 kg/m^2 greater than European Australian men. This would indicate that for any given BMI, the ratio of FM to FFM was greater in Aboriginal men. The significant interaction of ethnicity and body composition variables in women indicated that the relationship of these surrogate measures of body composition to BMI was significantly different in the two ethnic groups. However, the magnitude of the difference could not be assessed.

The data support the results of the WHO consultation on obesity which, while recommending BMI be used to classify obesity, recognise that Aboriginal Australians "…*tend to have a deceptively low BMI; a healthy BMI for this range appears to be between 17 and 22*, …" (WHO 1998). Subsequently, the WHO also released provisional recommendations that overweight and obese BMI cutoff points for Asian populations in the Asia-Pacific region be reduced to 23 and 25 kg/m^2, respectively (WHO 2000).

Differences in SFT and WHR between Aborigines and Europeans are more pronounced in women than in men. Indeed, the differences in body build/composition between women and men are much less apparent amongst Aborigines than amongst Europeans. This is consistent with the chronic disease risk profiles: Aboriginal women have little, if any, gender protection against CVD and diabetes (O'Dea et al. 1993). Aboriginal men in this study (Piers et al. 2003) had significantly narrower hips, an observation that has been made before (Abbie 1957), but had a similar mean waist circumference compared to European Australian men. A difference in hip circumference between Aboriginal and European Australian women was not evident; but Aboriginal women had a significantly greater waist circumference. Consequently, both Aboriginal men and women had significantly greater mean waist-to-hip circumference ratios, as compared to their European Australian counterparts, suggesting that they have a greater mass of abdominal fat even at this young age. This difference was evident at any level of BMI (up to 30 kg/m^2). The health risks associated with centrally deposited fat are well documented (Pi-Sunyer 1993). Our observations on waist circumference and WHR are in keeping with observations made in an earlier study involving Aboriginal Australians (Rowley et al. 1997). They are also consistent with the significantly higher prevalence and incidence of risk factors in Aboriginal Australians for the insulin resistance syndrome, as compared to the general Australian population (Daniel et al. 1999). Wang and Hoy, after investigating waist circumference, waist-to-hip ratio, BMI, and weight and hip circumference as risk factors for type 2 diabetes in Aboriginal Australians, also concluded that waist circumference is the best body-size measurement in predicting diabetes in Aboriginal people (Wang and Hoy 2004). This is consistent with most studies in homogeneous populations. However, when making comparisons across different ethnic groups, the best differentiator is WHR as it better accounts for differences in body build (Maple-Brown et al. 2007a, b).

161.3.3.1 Comparison with Other Studies in Australian Aborigines

In 16 Australian Aboriginal women and 16 healthy age- and weight-matched Caucasian women using dual-energy X-ray absorptiometry, Raja et al reported that body composition showed no significant ethnic differences in height, total body bone mineral density, total and appendicular skeletal muscle mass, and per cent body fat (Raja et al. 2003). The lack of difference may have been related to significant non-Aboriginal (European) admixture in this very small group of urban Indigenous women. Most other reports have reached different conclusions. For example, Kagawa et al compared ethnic differences in anthropometry, including size, proportions and fat distribution, and body composition in a cohort of 70 Caucasian Australian (44 boys, 26 girls) and 74 urban Australian Indigenous (36 boys, 38 girls) children (aged 9–15 years) (Kagawa et al. 2009). Anthropometric measures (stature, body mass, eight skinfolds, thirteen girths, six bone lengths and five bone breadths) and body composition assessment using dual-energy X-ray absorptiometry were conducted. Body composition variables, including total body-fat percentage and percentage abdominal fat, were determined and, together with anthropometric indices, including BMI (kg/m^2), abdominal:height ratio (AHtR) and sum of skinfolds, ethnic differences were compared for each sex. After adjustment for age, Indigenous girls showed significantly ($P < 0.05$) greater trunk circumferences and proportion of overweight and obesity than their Caucasian counterparts (Kagawa et al. 2009).

Furthermore, Sellers et al recently described the prevalence and clinical characteristics of the metabolic syndrome (MetS) in a cohort of Australian Aboriginal children (Sellers et al. 2008). They measured BMI, waist circumference, skin fold thickness, body-fat percentage, insulin resistance and the prevalence of metabolic syndrome in 486 children aged 9–14 years from the Darwin Health Region in the Northern Territory. Using an age- and sex-specific definition, 14% of the children in the cohort had metabolic syndrome, 6.4% were overweight, 4.9% were obese and 26.2% had an elevated waist circumference. Waist circumference was significantly associated with insulin resistance as measured by the 'Homeostasis Model Assessment of Insulin Resistance' ($P < 0.001$). They concluded that measurement of waist circumference may help identify Aboriginal children at high risk for metabolic syndrome (Sellers et al. 2008).

161.3.3.2 Comparison with Similar Studies on Aboriginal People in Other Countries

Leslie et al carried out a study to determine if ethnic differences in body composition affect differences in bone mineral density (BMD) between Canadian white and Aboriginal women (Leslie et al. 2008). An age-stratified population-based sample of 206 Aboriginal women and 177 white women underwent multisite bone density measurements and total body soft tissue composition analysis. The authors reported that the ratio of lean mass to fat mass was lower in Aboriginal than white women ($p < 0.001$). When BMD was adjusted for body composition variables, no significant difference was observed between Aboriginal and white women. Apparent ethnic differences in weight- and BMI-adjusted BMD between Canadian white and Aboriginal women were explained by a lower ratio of lean mass to fat mass in Aboriginal women, combined with a smaller increment in BMD from fat mass versus lean mass in both populations (Leslie et al. 2008). In another Canadian study, Silha et al compared the relationship between body composition, insulin resistance and inflammatory adipokines in Aboriginal Canadian women, who are at high risk of vascular disease, with white Canadian women. A subgroup of the First Nations Bone Health Study population, consisting of 131 Canadian Aboriginal women and 132 matched white women, was utilised. Body composition was determined by whole-body dual X-ray absorptiometry, and blood analytes were measured after an overnight fast. First Nation (Aboriginal) women were more insulin resistant than white women, and this was explained by trunk fat, but not total fat. Despite the increased insulin resistance, inflammatory adipokines are not significantly increased in First Nation (Aboriginal) women compared with white women (Silha et al. 2007).

Lear and co-workers investigated if body-fat distribution differs across ethnic groups in Canada (Lear et al. 2007a). They compared the relation between abdominal adipose tissue and total body fat amongst persons living in Canada of Aboriginal, Chinese and South Asian origin with persons of European origin. They reported that BMI significantly underestimated visceral adipose tissue (VAT) in all non-European groups. Throughout a range of total body fat mass, VAT was not significantly different between the Aboriginals and the Europeans. With total body fat >9.1 kg, Chinese participants had increasingly greater amounts of VAT than did the Europeans. The authors concluded that compared with Europeans, the Chinese and South Asian cohorts had a relatively greater amount of abdominal adipose tissue, and this difference was more pronounced with VAT. No significant differences were observed between the Canadian Aboriginals and the Europeans. In a related study, Lear et al hypothesised that VAT was an independent risk factor for atherosclerosis (Lear et al. 2007b). They studied healthy men and women ($n = 794$), matched for ethnicity (Canadian Aboriginal, Chinese, European and South Asian), and BMI range (<25, 25 to 29.9, or ≥30 kg/m^2) and assessed VAT (by computed tomography scan), carotid atherosclerosis (by ultrasound), total body fat, cardiovascular risk factors, lifestyle and demographics. They observed that VAT was associated

with carotid intima-media thickness (IMT), plaque area and total area (IMT area and plaque area combined) after adjusting for demographics, family history, smoking and per cent body fat in men and women. In men, VAT was associated with IMT and total area after adjusting for insulin, glucose, homocysteine, blood pressure and lipids. This association remained significant with IMT after further adjustment for either waist circumference or the waist-to-hip ratio. In women, VAT was no longer associated with IMT or total area after adjusting for risk factors. The authors concluded that VAT is the primary region of adiposity associated with atherosclerosis and likely represents an additional risk factor for carotid atherosclerosis in men. Most, but not all, of this risk can be reflected clinically by either the waist circumference or waist–hip ratio measures (Lear et al. 2007b).

161.3.3.3 Studies from Multi-Ethnic Populations

Rush et al investigated body-size and body-fat relationships and fat distribution in young healthy men drawn from New Zealand European, Pacific Island, and Asian Indian populations (Rush et al. 2004). A total of 114 healthy men (64 European, 31 Pacific Islanders, 19 Asian Indian) aged 17–30 years underwent measurements of height, weight and body composition by total body dual-energy X-ray absorptiometry (DXA). For the same BMI, per cent body fat (%BF) for Pacific Islander men was 4% lower and, for Asian Indian men, was 7–8% higher, compared to Europeans. Compared to European men for the same %BF, BMI was 2–3 units higher for Pacific Islanders and 3–6 units lower for Asian Indians. The ratio of abdominal fat to thigh fat, adjusted for height, weight and %BF, was significantly higher for Asian Indian men than European ($P = 0.022$) and Pacific Island ($P = 0.002$) men. Appendicular skeletal muscle mass (ASMM), adjusted for height and weight, was highest in Pacific Island and lowest in Asian Indian men. The authors concluded that the relationship between %BF and BMI is different for European, Pacific Island and Asian Indian men which may, at least in part, be due to differences in muscularity. Asian Indians have more abdominal fat deposition than their European and Pacific Island counterparts. Use of universal BMI cutoff points is not appropriate for comparison of obesity prevalence between these ethnic groups (Rush et al. 2004).

Rush et al also investigated body composition differences, especially the relationship between BMI and per cent body fat (%BF), amongst five ethnic groups of women (Rush et al. 2007). Seven hundred and twenty-one apparently healthy women aged 18–60 years (BMI: 17.4–54.0 kg/m^2) were from South Africa (SA, 201 black, 94 European) and New Zealand (NZ, 173 European, 76 Maori, 84 Pacific, 93 Asian Indian). Anthropometry, including waist circumference, and total, central and peripheral body fat, bone mineral content and ASMM derived from dual X-ray absorptiometry were obtained. The authors reported that at a BMI of 30 kg/m^2, SA European women had a %BF of 39%, which corresponded to a BMI of 29 for SA black women. For a BMI of 30 kg/m^2 in NZ Europeans, equivalent to 43% body fat, the corresponding BMIs for NZ Maori, Pacific and Asian Indian women were 34, 36 and 26 kg/m^2, respectively. Central fat mass was lower in black SA than in European SA women ($P < 0.001$). In NZ, Pacific women had the lowest central fat mass and highest ASMM, whereas Asian Indian women had the highest central fat mass, but lowest ASMM and bone mineral content. The authors concluded that the relationship between %BF and BMI varies with ethnicity and may be due, in part, to differences in central fatness and muscularity. Use of universal BMI or waist cut-points may not be appropriate for comparison of obesity prevalence amongst differing ethnic groups, as they do not provide a consistent reflection of adiposity and fat distribution across ethnic groups (Rush et al. 2007).

Duncan et al. have proposed several factors to help explain the dependency of the BMI/per cent body fat relation on ethnicity (Duncan et al. 2004). The first factor they propose is body build/frame

size (as measured by wrist and knee girths), which tends to vary amongst different ethnic groups. A number of studies have noted that ethnic populations with relatively high levels of BF at a given BMI also have a more slender build (Deurenberg et al. 1999; Gurrici et al. 1999). Furthermore, Deurenberg et al found that correcting for body build eliminated most of the ethnic-specific differences associated with per cent body fat prediction equations for bioelectrical impedance analysis (BIA) in Chinese, Malay and Indian Singaporeans (Deurenberg et al. 2002). A second factor that may contribute to ethnic-specific relationships between BMI and %BF is variation in sitting height relative to total height. Australian Aborigines with long legs (low sitting height) generally have a lower BMI and, as such, per cent body fat may be underestimated from BMI – particularly for those in the 'normal weight' range (Norgan 1994). Finally, there may be differences in physical activity level amongst ethnic groups. More active individuals are likely to have a higher proportion of muscle mass and, therefore, the potential for overestimation of per cent body fat from BMI (Deurenberg et al. 1999).

Indigenous Australians, however, are a diverse group of people and these results are not necessarily generalisable to all Aboriginal Australians. The Aboriginal people we studied were from central Australia and north Queensland. Rutishauser and McKay have observed similar characteristics in the Kimberley region of Western Australia (Rutishauser and McKay 1986). They found that for a given sum of skinfold thickness, Aboriginal women from north-western Australia had a mean BMI that was 2 units lower than age-matched Caucasians, suggesting a greater proportion of body fat. Comparable data from south-eastern Australia is not available, although greater WHR in Aboriginal people in the 'healthy' BMI range was reported in at least one study (Guest and O'Dea 1993). Body-fat distribution may be modulated by a number of factors, including neuroendocrine responses (Bjorntorp 1999) and it should not be assumed that the present observations arise only from genetic characteristics.

Our study indicates that Aboriginal Australian people have a very different body-fat distribution, consistent with a greater amount of abdominal fat compared to their European Australian counterparts – and that this is particularly evident in women. Because of the much smaller differential in body-fat distribution between Aboriginal men and women than between men and women in populations of European origin, gender specific cutoffs derived from European populations are unlikely to be appropriate for Indigenous populations. In addition, the relationship of surrogate estimates of body composition, S4 for subcutaneous fat and height^2/resistance for FFM, with body weight and BMI is significantly different between Aboriginal people and non-Indigenous Australians. Therefore, the currently recommended classification of weight status, based on BMI, may be inappropriate for use in the Australian Aboriginal population.

161.4 Part 3: Applications to Other Areas of Health and Disease

Anthropometric measurements are useful to monitor changes in body habitus profiles and develop strategies to minimise risks associated with such adverse changes. These measurements are also used to assess the nutritional status of hospitalised patients and to provide appropriate intervention to improve their status. Anthropometric measurements can also be used as independent predictors of certain chronic conditions and to develop validated models of risk assessment.

We have reviewed the associations of body-size measurements with chronic health conditions and found that the relationships are different amongst Aborigines when compared to other population groups. We have "shown that waist to height ratio was a better predictor for proteinuria amongst Aborigines whereas waist–hip ratio was the best predictor amongst Australians. For cardiovascular

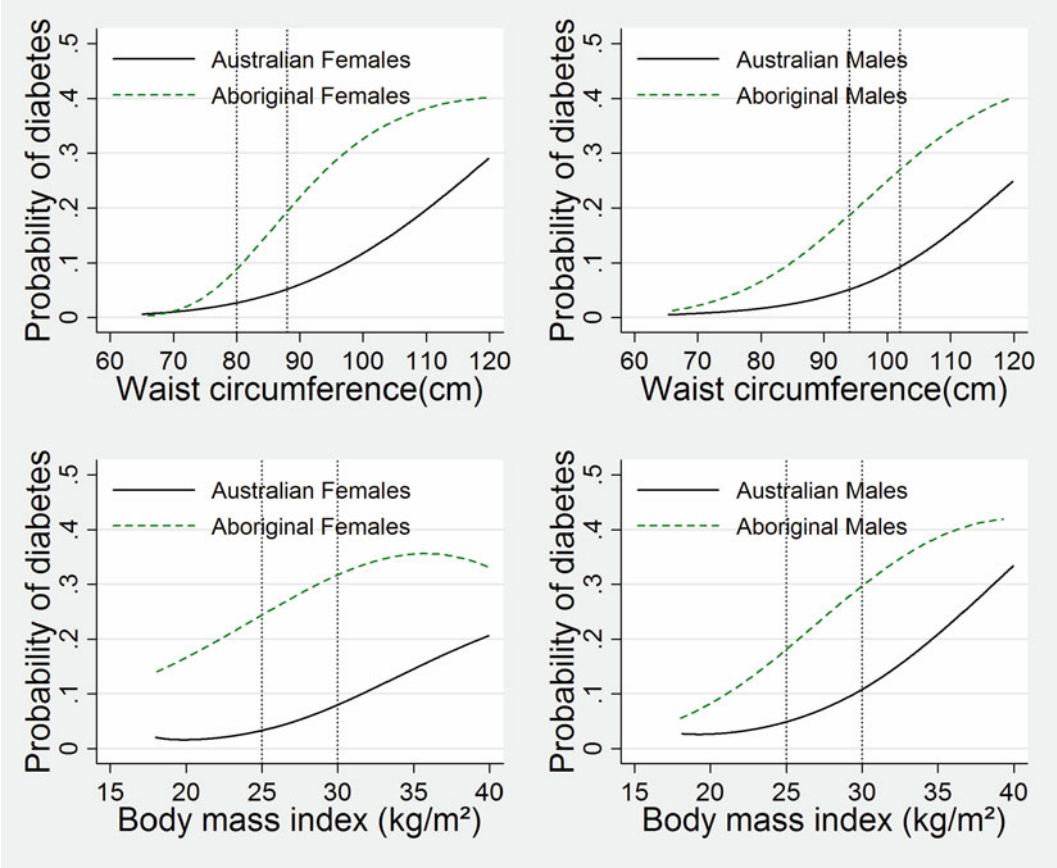

Fig. 161.7 Waist circumference and BMI, and predicted probabilities of diabetes (Source: Kondalsamy-Chennakesavan et al. (2008b))

events, waist circumference had better predictive abilities amongst Aborigines whereas waist–hip ratio had better predictive abilities amongst Australians. For diabetes, waist circumference was the best predictor amongst Aborigines whereas amongst Australians, waist–height ratio was the best predictor. Coronary heart disease risk functions predicted using Framingham calculations underestimate the risk amongst Aboriginal people and cannot be readily used in remote Aboriginal settings" (Kondalsamy-Chennakesavan et al. 2008a).

Risk for certain chronic conditions can be quantified using body-size measurements. We have quantified the risk of diabetes by body habitus profiles (Kondalsamy-Chennakesavan et al. 2008b) amongst Aborigines and compared them to the nationally representative Australian dataset (AusDiab). Even at lower levels of body-size measurements, Aborigines tend to exhibit elevated risk for diabetes (Fig. 161.7). Similarly, elevated risk at lower levels of body habitus profiles amongst Aborigines is also evident for hypertension and proteinuria. Such differences in risk profiles and differential association of body habitus measurements with disease conditions indicate that public health interventions need to be targeted at prevention of excessive weight gain in order to tackle the epidemic of chronic conditions amongst Aborigines and to close the health gap between Aborigines and other Australians.

Summary Points

- The average weight (and BMI) of contemporary Aborigines has increased significantly when compared to the average weight (and BMI) documented in studies conducted prior to 1970.
- Aborigines have preferential central fat deposition and exhibit consistently higher waist–hip ratios when compared to the general Australian population.
- Prevalences of overweight and obesity depend on the anthropometric definitions used.
- There is a wide variation in body habitus profiles between Aboriginal communities.
- The relationship of surrogate estimates of body composition, S4 for subcutaneous fat and height^2/resistance for FFM, with body weight and BMI is significantly different between Australian Aborigines and Australians of European origin.
- Increases in body habitus profiles elevate the risk of chronic conditions such as diabetes.

Key Features of Australian Aborigines

- Aborigines are the original inhabitants of Australia. In the past, they led a hunter-gatherer lifestyle.
- Associated with westernisation, their body habitus profiles show significant changes.
- Caution must be exercised when overweight and obesity are defined amongst Aborigines using cutoffs derived from other populations.

Chapter 162
Secular Changes in Anthropometric Indices of Children and Adolescents: Studies from Korea

Joong-Myung Choi and Ji-Yeong Kim

Abstract This chapter assesses the secular growth changes in anthropometric measures with reference to Korean children and adolescents during the last four decades. The review describes the data from 68,790 boys and 62,557 girls that were recruited across the nation in 2005. Anthropometric measures included weight, height, and etc. This review compared the results of previous nationwide growth studies with the present study. It is indicated in this chapter that the growth and developmental status of Korean children and adolescents has been changed substantially compared with those in 1965, 1975, 1984 and 1997. The data presented in this chapter show a distinct secular increase in growth in body height and weight of Korean children and adolescents spanning this period. A nationwide survey every 5 years would be beneficial to establish a reference standard for the growth of children and adolescents according to the socioeconomic, environmental and nutritional changes.

162.1 Introduction

The term 'secular trend' is used to describe a slow, continuous change in growth and development over successive generations in the same regions (Ulijaszek et al.1998). Secular changes are best documented by body height and weight and weight-for-height (Hauspie et al.1997). Height is the physical attribute that is currently being analyzed most frequently (Vignerová et al. 2006). Although the mechanisms underlying a secular trend in growth measures are not fully understood, previous studies suggest that environmental and nutritional improvements are important causes of the secular increase (Malina 1979, 1990; Taranger 1983; Susanne 1985; Van Wieringen 1986; Tanner 1992). Genetic components also play a role in growth regulation, even though few studies have demonstrated that genetic factors have a major effect on the extent of growth. Secular changes in growth and maturation have been observed in many countries during the past two centuries (Van Wieringen 1986; Eveleth and Tanner 1990; Malina 1990; Hauspie et al. 1996), and studies of many countries have revealed a gradual increase in the mean height of adults, as well as children and adolescents (Vignerová et al. 2006). During the course of the past two centuries in many industrialized countries, striking increases in the mean stature and an earlier sexual maturation, usually called positive

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_162,

secular growth change, have been observed (Hauspie et al. 1996). Nevertheless, recent studies show that secular trends in growth and maturation are more pronounced in less advantaged groups of a population, such as those living in rural areas or from lower socioeconomic backgrounds, compared with more advantaged groups (Hauspie et al. 1996, 1997). Studies carried out in developing countries, especially in the past two decades, reveal a sharp and significant secular trend in growth (Zellner et al. 2004). The results of two anthropometric studies undertaken in Turkey in 1993 and 2003 revealed that Turkish children between the ages of 7 and 15 consistently demonstrated positive secular growth trends. In all of the age groups, both Turkish boys and girls in a 2003 survey were taller and heavier than their peers from the 1993 survey (Simsek et al. 2005). Further longitudinal studies are still needed to interpret the relationship between the socioeconomic status and anthropometric growth in developing countries. Unlike developing countries, the rate of secular growth change has gradually diminished in developed nations, including in Western European countries, Japan, and North America (Simsek et al. 2005), which means that societal improvements cannot fully explain secular trends in some populations in spite of continued improvements in quality of life and health (Ducros 1980; Henneberg and van den Berg 1990; Hauspie et al. 1997; Henneberg 1997; Pretty et al. 1998; Tracer et al. 1998). According to Zellner and Jaeger in a study published in 2004, a leveling off in the height trends of German schoolchildren is consistent with a wide range of studies from other European countries, which also indicate a slowing down or recent halt of the secular changes in the height of schoolchildren at the end of the twentieth century (Zellner et al. 2004). Diminishing secular increases in developed countries may indicate that the adult stature has almost reached a plateau (Hauspie et al. 1997).

The southern part of the Korean peninsula has experienced one of the most rapid economic growth developments since the Korean War in the 1950s. It has been suggested that Korean children and adolescents have showed positive secular changes in anthropometric profiles that are associated with significant improvements in the standards of healthcare, hygiene, nutrition, socioeconomic status, social welfare, and education during the past four decades. However, few studies are available to support this suggestion. In 1965, 1975, 1984, and 1997, nationwide cross-sectional growth studies were performed, showing that Korean children and adolescents had become taller and heavier than children in previous generations. In this study, we expected to observe distinct positive secular changes in the anthropometric profiles of Korean children and adolescents resulting from the rapid socioeconomic development.

In this review, we present growth data for height and weight from the fifth nationwide growth study in 2005 and compare the results of all five nationwide growth studies to assess secular growth changes in Korean children and adolescents during the past four decades. We also compare the results from Korean surveys with Japanese data to analyze the different growth patterns of children in developing and developed countries.

162.2 Methodological Considerations

The first nationwide cross-sectional anthropometric survey in Korea was carried out during the summer months of 1965 and included 16,213 boys and 16,612 girls (Moon and Yun 1978). The second nationwide study was conducted in June 1975 and consisted of 40,149 boys and 37,865 girls (Moon and Yun 1978).

The third study, conducted from April to October 1984, included 61,780 boys and 59,393 girls (Shim and Ko 1986). There have been limitations in analyzing and interpreting the historical data because the studies that were conducted in 1965, 1975, and 1984 recorded only the means and sample sizes.

We gathered these data from previous publications. The fourth survey was conducted from January 1997 to August 1998 and included 57,449 boys and 51,965 girls. In the fifth study, 68,790 boys and 62,557 girls aged between 0 and 20 years were recruited across the nation. Data collection for the fifth survey took place from April 2005 to March 2006. Quality control of the data from the fourth and fifth surveys was done with the cooperation of all the organizations involved in these studies, such as the Korea Center for Disease Control and Prevention, the Korean Society of Pediatrics, and the Medical School of Kyunghee University. Staffs from the Korea Center for Disease Control and Prevention were sent to the schools where surveys were conducted to check whether trained researchers were measuring the children in an appropriate way. The Korean Society of Pediatrics supervised the part of the surveys that was conducted at the hospitals for infants. Academic personnel, including medical professors, junior doctors in the residency of preventive medicine, and other researchers, such as statisticians at the Medical School of Kyunghee University, performed quality control for the data. They received all the data from hospitals and schools, eliminated outliers from the data set, and analyzed the data statistically.

Exclusion criteria were provided for each study. Details about the exclusion criteria applied to the first three studies have been published previously (Moon and Yun 1978; Shim and Ko 1986). Infants with a birth weight <2,500 g were excluded from the fourth and fifth studies. Children whose disorders were diagnosed as a growth hormone deficiency, growth-related disorder, or other chronic debilitating conditions were also excluded from the sample of the last two surveys. Children who were twins or had non-Korean parents were not included in these surveys.

The sample was stratified according to age, sex, and province. Infants aged 0–2 were measured at well-baby clinics in 26 university hospitals. From the age of 2–20, subjects were measured at day-care centers, kindergartens, elementary schools, middle schools, high schools, and universities.

The ages of all of the children were assessed from the hospital and school registers, based on birth certificates. In the first year of life, babies were divided by 1-month intervals. From the age of 1–2, infants were categorized at intervals of 3 months. Preschool children aged 2–7 were divided by 6-month intervals. For the ages of 7–20, the intervals were of 1 year.

The trained researchers measured the stature and weight of the subjects while they were in light clothing and no shoes. The height of infants up to 2 years of age was measured to 0.1-cm sensitivity in the supine position. The international standard measuring instrument, SECA 210 (Germany), was used. From the age of 2, standing height was measured to the nearest 0.1 cm using the standard measuring instrument (SECA 225, Germany). Infants aged 0–2 were weighed on calibrated baby scales. The weights of older children and adolescents were measured using calibrated mechanical step-scales. Weight was recorded to the nearest 0.1 kg.

Descriptive statistics were utilized to interpret the age- and gender-specific means of the height and weight. SAS (Statistical Analysis System, SAS Inc., USA) version 9.1 was used to perform statistical analysis. Curves were created using Microsoft Office Excel 2003.

162.3 Anthropometric Changes in Children and Adolescents from 1965 to 2005 in Korea

The mean heights of boys and girls revealed by surveys performed in 1965, 1975, 1984, 1997, and 2005 are represented in Tables 162.1 and 162.2. These tables also include a summary of the differences between the mean heights of the 1965 survey and the remaining surveys. A comparison among these five national surveys shows a positive secular trend in the mean heights for Korean boys (Table 162.1) and girls (Table 162.2) aged 0–20 years. The most remarkable changes are apparent

Table 162.1 Mean height of boys (cm) and changes relative to 1965 (The source of data regarding the years of 1965, 1975, and 1984 are from Moon and Yun (1978) and Shim and Ko (1986). With permission)

The mean heights of boys revealed by surveys performed in 1965, 1975, 1984, 1997, and 2005 are represented in the table. Results are expressed as mean ± SD for the years of 1997 and 2005

Standard deviations for the first three studies are not available

[a]*SD* standard deviation

during the growth spurt period of puberty. As for boys, the greatest difference in mean height was evident at the age of 13 (143.4 cm, 1965; 162.0 cm, 2005). Thirteen-year-old boys have grown an average of 18.6 cm taller during the past four decades. The most significant height change in boys from 1965 to 1984 occurred at the age of 14 (143.4 cm, 1965; 159.2 cm, 1984). Between 1965 and 1975, the greatest height change in boys was only 5.2 cm, which was found at the age of seven (Table 162.1). Between 1965 and 2005, the mean height of 12-year-old girls increased by 15.5 cm, which is the most remarkable difference in mean height in girls (138.7 cm, 1965; 154.2 cm, 2005). Girls aged 12 years had grown taller by 12.2 cm between 1965 and 1997 (138.7 cm, 1965; 150.9 cm, 1997). Between 1965 and 1975, the greatest height change in girls was 4.9 cm, which was found at the age of 7 (Table 162.2). The mean heights of boys and girls have also changed at the age of 17 (boys, 165.9 cm in 1965 and 173.1 cm in 2005; girls, 155.5 and 160.2 cm, respectively). An increase in the mean height is found in other age groups too.

Tables 162.3 and 162.4 describe the positive secular trend in the mean weights for Korean boys (Table 162.3) and girls (Table 162.4) aged 0–20 years. Between 1965 and 2005, for boys, we found that the greatest relative increase in weight occurred at 14 years of age (39.7 kg, 1965; 60.9 kg, 2005). Boys of any age group did not gain more than 3 kg between 1965 and 1975. The most remarkable increase in weight for boys was 7.7 kg at the age of 14, from 1965 to 1984 (39.7 kg, 1965; 47.4 kg, 1984) (Table 162.3). The most significant change in mean weight in girls (an increase of 14.7 kg) during the past 40 years (36.2 kg, 1965; 50.9 kg, 2005) occurred at the age of 13. The greatest weight

Table 162.2 Mean height of girls (cm) and changes relative to 1965 (The source of data regarding the years of 1965, 1975, and 1984 are from Moon and Yun (1978) and Shim and Ko (1986). With permission)

change in girls from 1965 to 1984 occurred at the age of 14 (39.8 kg, 1965; 46.8 kg, 1985) (Table 162.4). During the past four decades, the mean weight of 20-year-old boys increased by 12.8 kg, whereas that of girls increased by 4.1 kg. During the past 40 years, the weight of girls has changed less than that of boys.

During the past 40 years, the mean height of the Korean population shows more variation than that of the Japanese population (Figs. 162.1 and 162.2) (Japanese Ministry of Education, Culture, Sports, Science and Technology 2007). Japanese children have undergone more stable and slower secular changes in growth development than Korean children have during the past 40 years. A comparison of the heights of Korean children younger than 13 years in 2005 with those of children in 1965 shows that present-day Korean children reach similar heights 3 years earlier. However, current Japanese children attain similar heights at only 1 year earlier compared with Japanese children in 1965 (Figs. 162.1 and 162.2).

162.4 The Implications of Anthropometric Changes

The data presented in this review show a distinct secular increase in body height and weight of Korean children and adolescents during the past four decades. The growth and developmental status of Korean children and adolescents has changed substantially compared with those in 1965, 1975,

Table 162.3 Mean weight of boys (kg) and changes relative to 1965 (The source of data regarding the years of 1965, 1975, and 1984 are from Moon and Yun (1978) and Shim and Ko (1986). With permission)

[a]*SD* standard deviation

1984, and 1997. This review provides valuable findings about secular trends in growth because all the data analyzed in this research were from five cross-sectional anthropometric surveys involving subjects recruited across the whole nation.

Anthropometrical studies of conscripts and schoolboys show that an increase in the height of 17-year-old boys commenced in the nineteenth century (Lintsi and Kaarna 2006). It has commonly been understood that secular changes in growth result from the combined effect of changes in overall body size at all ages and changes in the period of time needed for the completion of growth (Hauspie et al. 1997). Usually, a positive secular growth change is accompanied by an advance in sexual maturation (Fredriks et al. 2000).

If the largest gain in height or weight over the period examined occurs around pubertal age, this reflects earlier puberty and thus a shortening of the growth period (Loesch et al. 2000). In this review, there has been a trend toward increased height among Korean boys and girls aged 0–20 years since the 1965 data were collected. Height is determined in part by genetics and in part by childhood living conditions, including nutrition, housing conditions, the occurrence of diseases, and strenuous work at young ages (Nyström-Peck and Lundberg 1995). Persistent international differences in the mean height across birth cohorts demonstrate continuing differences in childhood living conditions between countries (Cavelaars et al. 2000; Komlos and Kriwy 2002; Krawczyski et al. 2003; Gyenis and Joubert 2004; Sander 2004). In Korea, between 1965 and 2005, significant improvements were observed in the socioeconomic conditions and health of the population. Evaluation of socioeconomic and health indicators in the southern part of the Korean peninsula during the past four decades

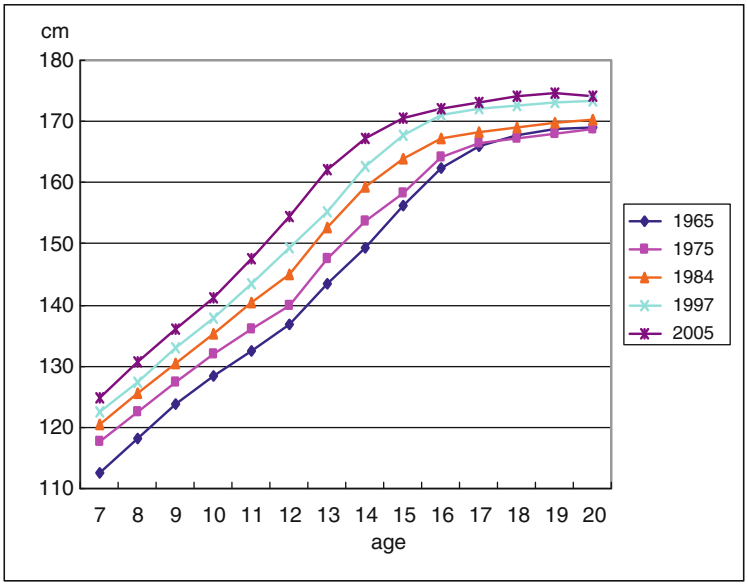
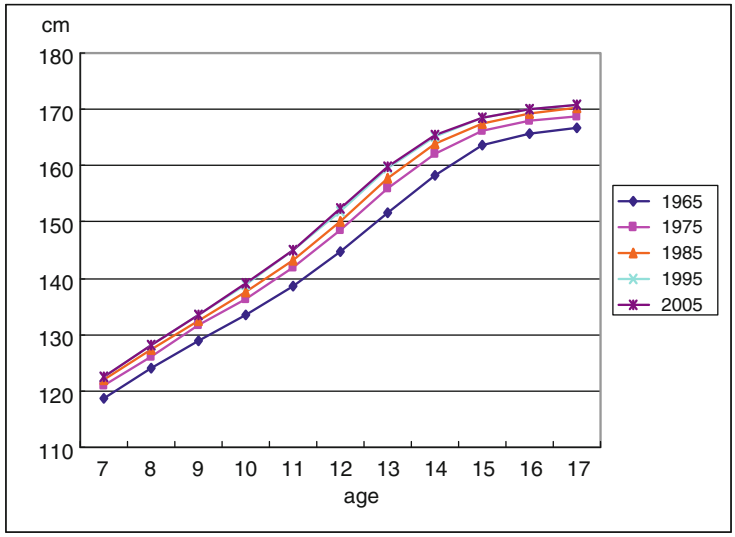
is represented in Table 162.5 (Korea National Statistical Office Internet 2007). The period between 1965 and 1984 is characterized by a positive trend in the difference in the mean height of Korean children and adolescents of all ages, more significantly for boys aged 0–11 years and girls aged 0–14 years. After 1984, the increase in mean height of boys older than 11 years and girls older than 14 years exceeded the changes in height taking place between 1965 and 1984 (Fig. 162.3). This change means that there has been an increase in the average height of the Korean population from one generation to another. This increase in the mean height in infants and younger children (0–11-year-old boys and 0–14-year-old girls) occurred more drastically during the period between 1965 and 1984, which experienced a very rapid development in the Korean economy and living conditions after the Korean War. It is generally assumed that an improvement in the quantity and quality of food is the most important cause of secular growth change (Fredriks et al. 2000). After 1984, in Korea, the general wealth of the population has increased considerably and significantly more children had easy access to food. Easier access to infant healthcare and the institution of a vaccination program also affected secular growth change in a positive way during this period. In many studies, the differences in somatic development between children from various social backgrounds were evaluated (Drachler et al. 2002; Langnäse et al. 2002; Armstrong et al. 2003). Socioeconomic status and the quality of healthcare and nutrition are regarded as factors, which, in combination with genotype, have the strongest impact on the growth and development of an individual (Vignerová et al. 2006). Such improvements in the socioeconomic and socio-hygienic conditions and the public-health status of



(Korean boys)



(Japanese boys)

Fig. 162.1 The comparison of mean height between Korean and Japanese boys during past four decades. The figure shows the mean heights for Korean boys aged 7–20 years during past 40 years in the comparison with those of Japanese boys (The source of data regarding Japanese boys is the Japanese Ministry of Education, Culture, Sports, Science and Technology (2007). the Korean population occurred more remarkably between 1965 and 1984 than during the period between 1984 and 2005. This may explain why the positive secular trend in height has diminished in Korean infants and younger children after 1984. A secular trend in the mean weight of Korean children and adolescents during the past four decades is different in pattern from that of the height. The increase during the past two decades (1984–2005) in the mean weight of boys older than 7 years and girls older than 5 years exceeded the changes in weight that occurred between 1965 and 1984 (Fig. 162.4). A pattern of secular trend in the Korean children's weight shows a sharp increase between 1984 and 2005. Unlike the pattern for stature, the secular trend of increased weight occurred mostly during the past two decades (Figs. 162.3 and 162.4).

162.5 Further Considerations

A significant secular increase in height and weight measurements were found in Korean infants, children, and adolescents aged 0–20 years during the past four decades. In all of the age groups, both boys and girls in the 2005 survey were taller and heavier than their peers from the 1965 study.

This secular trend may have important implications for other developing countries with many changes in socioeconomical conditions. The comparison between Korean and Japanese data in this research also supports the effect of rapid socioeconomic changes in less developed nations on the secular growth trend of children. The positive secular changes of children observed in developing countries (in this research, Korea) are more distinct than those in developed world (in this research, Japan), and this supports the necessity of regular nationwide growth survey for children, especially in less developed areas. The positive secular change in both the height and weight of Korean children underscores the need for an update in growth standards. Regular research studies of anthropometrical characteristics are an essential and relatively inexpensive component of the follow-up analysis, allowing for the examination of the health of a population of children and adolescents

(Vignerová et al. 2006). Thus, a nationwide survey every 5 years would be beneficial to such analysis by establishing a reference standard for the growth of children and adolescents according to the socioeconomic, environmental, and nutritional changes.

Summary Points

- Korean children and adolescents have showed positive secular changes in anthropometric profiles that are associated with significant improvements in the standards of healthcare, hygiene, nutrition, socioeconomic status, social welfare, and education during the past four decades.
- A secular trend in the mean weight of Korean children and adolescents during the past four decades is different from that of the height in pattern.
- A pattern of secular trend in the Korean children's weight shows a sharp increase between 1984 and 2005. Unlike the pattern for stature, the secular trend of increased weight occurred mostly during the past two decades.
- During the past 40 years, the mean height of the Korean population shows more variation than that of the Japanese population.
- The positive secular changes of children observed in developing countries are more distinct than those in developed world, and this supports the necessity of regular nationwide growth survey for children, especially in less developed areas.

Key Features of Secular Changes

Table 162.6 Key features of secular changes

1. Secular change means a long-term and steady variation
2. The anthropometric indices are the measurements of the human individuals, such as weight, height, and circumferences
3. Changes in nutrition, socioeconomic status, and the quality of healthcare lead to secular changes in anthropometric measurements of the population

This table lists the key features of secular changes including the meaning of the secular change and the anthropometric indices. This also briefly explains the association between the social backgrounds and the secular changes in anthropometric measurements

Chapter 163
Determinants of Central Adiposity: An Iranian Perspective

Leila Azadbakht, Ahmad Esmaillzadeh, and Pamela J. Surkan

Abstract Although obesity is a major health problem, most recent studies suggest that the pattern of body fat distribution is more important than overall body mass. Abdominal obesity has been associated with a substantially elevated risk of chronic diseases and mortality. While most risk factors are shared worldwide, both non-dietary and dietary determinants of abdominal adiposity can vary across populations. Iranian studies reveal that physical activity, unemployment, menopause, marriage, smoking and depression are the most important non-dietary factors. Regarding the dietary determinants of central adiposity, three classes of exposure include dietary patterns, food groups/foods, and nutrient intake. According to studies in Iran, a healthy dietary pattern mainly based on whole grains, fruits, vegetables, and unhydrogenated vegetable oil, is inversely associated with central adiposity. Also, based on Iranian studies, dairy consumption as well as fruit and vegetable intake are inversely correlated with central adiposity as well as with metabolic syndrome, for which one of the major components is large waist circumference. Hydrogenated vegetable oil is directly correlated with central adiposity and with metabolic syndrome both in Iranians and some other populations. Factors that appear to be protective for central fat accumulation among Iranians include high fiber, vitamin C and calcium consumption. Insulin resistance is one of the major problems related to central adiposity; therefore, individuals with central adiposity are at risk for other diseases, such as type 2 diabetes and cardiovascular disease. Being physically active and consuming a diet with a low glycemic index that is rich in whole grains, fruits, vegetables, and unhydrogenated vegetable oil are recommended to prevent central adiposity for Iranian population.

163.1 Introduction

Obesity has become an important health problem, which is correlated with increased risk of many chronic diseases (Wei et al. 1997). However, current evidence suggests that attention should be placed on the pattern of body fat distribution rather than on simply overall body weight or obesity (Wei et al. 1997). One reason is that central adiposity is a better indicator of other chronic diseases, such as metabolic syndrome, type 2 diabetes, and cardiovascular diseases as well as increased mortality (Janssen et al. 2004). To assess central adiposity, most researchers have used the World Health Organization (WHO) cutoffs or the Adult Treatment Panel III (ATP III). These utilize waist circumference and waist-to-hip ratio as two major criteria in determining central fat accumulation (Reeder et al. 1997).

The prevalence of central adiposity is rising at an alarming rate worldwide (Reeder et al. 1997). According to a population-based study of adolescents and adults over 15 years old living in the 28 provinces of Iran, abdominal obesity was present in 43.4% of women, 9.7% of men, 28.5% of urban residents, and 23.0% of rural residents (Kelishadi et al. 2008). In Tehran, the capital of Iran with the most industrialized lifestyle, 67% of women and 33% of men older than 20 are centrally obese (Azadbakht et al. 2005a). A study of secular trends in central fat accumulation in Iran showed a 6% and 9% increase of central adiposity between 1998 and 2002 in men and women, respectively (Azizi et al. 2005). Compared to the US population, the mean of both waist circumference (WC) and waist-to-hip ratio (WHR) among Iranian women is higher than among American women (Sarrafzadegan et al. 2009). The prevalence of central obesity is about 38.6% (46.3% in females and 29.8% in males) in USA (Ford et al. 2002), 65% in Oman (Al–Riyami and Afifi 2003), 63% in a sample of Japanese Brazilians (Barbieri et al. 2009), and 55% in Indian women (Beegom et al. 1995).

Although obesity has genetic determinants, social and environmental factors also contribute to the problem. Among the factors important in different populations, socioeconomic status, gender, marital status, physical activity, educational level, and dietary habits can be mentioned (Al–Riyami and Afifi 2003; Beegom et al. 1995; Azadbakht and Esmaillzadeh 2008).

Regarding diet, research has focused on dietary patterns, food groups/specific foods, and nutrients. Given that central adiposity is a risk factor for severe chronic diseases, understanding its determinants is critical. Therefore, in this chapter, we discuss the non-dietary and dietary determinants of central adiposity mainly based on studies of the Iranian population.

163.2 Non-dietary Determinants of Central Adiposity

Aging and genetics are two important non-dietary determinants of central adiposity but are not amenable to behavioral intervention, underscoring the importance of lifestyle factors related to this problem. However, these lifestyle-related risk factors can be very similar to those for obesity, resulting in high correlations and actually colinearity between central adiposity and obesity. Physical inactivity

Table 163.1 Important non-dietary determinants of central adiposity among Tehranian adults

Lifestyle factors	Odds ratio	95%CI
Physical activity		
Light[b]	2.11[a]	1.40–2.53
Moderate[c]	1.13	0.91–1.42
Heavy[d]	1.00	–
Parity		
0	1.00	–
One to two	1.02	0.83–1.42
Three or more	1.31	1.18–1.62
Marital status		
Single	1.00	–
Married	1.31	1.10–1.82

[a] $P < 0.05$

[b] Those who had a sedentary lifestyle: considered as a light physical activity level

[c] Those with maximum daily 30 min exercise: considered as moderate lifestyle

[d] Those with active lifestyle and doing more than 30 min exercise: considered as heavy physical activity level

is one of the most important risk factors for central adiposity, both in Iran and in other parts of the world (Hajian-Tilaki and Heidari 2007; Al–Riyami and Afifi 2003). The role of increased daily physical activity in minimizing age-related increases in abdominal obesity has also recently been highlighted (Holcom et al. 2004). Both depression and unemployment in Iranian women were associated with higher odds ratios of being centrally obese (Azadbakht and Esmaillzadeh 2008). One interpretation is that unemployed women's poor control over household economic resources may be a cause of depression and may also be linked to women's lack of activities, including physical activities apart from housework. Furthermore, easy availability of food at home might encourage obesity in the unemployed female population, which largely consists of housewives (Azadbakht and Esmaillzadeh 2008). Therefore, these factors may contribute to the central fat accumulation. Consistent with the literature from other countries (Al–Riyami and Afifi 2003; Moreira and Padrao 2006; Beegom et al. 1995), results of the Iranian Adults Study showed that socioeconomic status is also correlated with central adiposity (Azadbakht and Esmaillzadeh 2008). As observed elsewhere (Shimokata et al. 1989), smokers in Iran have higher probability of being centrally obese (Azadbakht and Esmaillzadeh 2008). A longitudinal study in USA has also shown that smokers gained more weight on the waist and less on the hips than predicted from gain in body mass, producing a gain in WHR (Shimokata et al. 1989). Menopause is also a risk factor related to central fat accumulation, which is thought to be associated with the role of sexual hormones, such as higher levels of testosterone during this period (Azadbakht and Esmaillzadeh 2008). Married Iranian women are more centrally obese compared to single ones (Azadbakht and Esmaillzadeh 2008), a finding that may possibly be explained by weight gain after each pregnancy and/or lactation. Multiparous Iranian women also had higher waist-to-hip ratios (WHR), which lends credence to the potential role of pregnancy and lactation in increasing the risk of central adiposity.

A recent study in the north of Iran also showed that similar factors were associated with central obesity: more sedentary behavior, low education, high parity, a family history of obesity, marriage at earlier age, and aging (Hajian-Tilaki and Heidari 2007). Given the multiethnic nature of Iran, comparing the results of studies from different parts of the country can be useful to form a national overview. In Table 163.1, odds ratios are displayed for the most important lifestyle factors related to central adiposity.

163.3 Dietary Determinants of Central Adiposity

Regarding the dietary determinants of central adiposity, we will consider three classes of exposures: (1) dietary patterns, (2) food groups and foods, and (3) nutrient intake.

163.3.1 Dietary Patterns and Central Adiposity

Studying central adiposity with an approach based on dietary patterns that reflects individual dietary behaviors can provide information about the nutritional etiology of obesity. Due to colinearity between food and nutrient intakes, a multivariate approach that specifies dietary patterns has the potential to resolve concerns about confounding factors and interactions between foods and nutrients (Esmaillzadeh et al. 2008). The links between dietary patterns and different forms of obesity are especially relevant in the case of Iran because of the high prevalence of a particular type of obesity, the so-called Middle-Eastern pattern, which makes Iranians particularly susceptible to increased risk of obesity-related comorbidities. The predominant characteristic of this pattern of obesity is central fat accumulation and enlarged waist circumference (WC), particularly among women (Esmaillzadeh and Azadbakht 2008a).

Limited data are available linking dietary patterns to obesity among Iranians. Through factor analysis, three major dietary patterns, Western, healthy, and Iranian, have been identified among Iranian female teachers (Esmaillzadeh and Azadbakht 2008). Individuals with scores in the top quintile of the healthy pattern were less likely to have general obesity (defined as BMI ≥30) and to have central adiposity, whereas those in the upper quintile of the Western pattern had greater odds for both general and central obesity (Table 163.2).

Although the Iranian dietary pattern and overall obesity were not associated, individuals in the top quintile of the Western dietary pattern had greater odds of being centrally obese (Esmaillzadeh and Azadbakht 2008a). These findings agree with other studies from both developing and developed settings. Overall, it seems that the nutrition transition in developing countries helps to promote Western dietary patterns, which, in turn, might account for the high prevalence of obesity in these countries. To date, no further reliable studies are available regarding dietary patterns and obesity among Iranians. Prospective studies will need to be conducted in Iran to confirm the current available findings.

163.3.2 Food Group, Food Intake, and Central Adiposity

Among Iranians, dietary intake of foods and food groups has also been related to the prevalence of overweight and obesity. In a cross-sectional study of Iranian adults, it has been reported that dairy intake was inversely associated with body mass index (BMI) and prevalence of obesity. Specifically, there was a lower likelihood of obesity for those in the top quartile of dairy intake (OR = 0.73, 95%CI = 0.40–0.83 for men and OR = 0.69, 95%CI = 0.34–0.80 for women) compared to those in the lowest quartile (Mirmiran et al. 2005). Fruit and vegetable intakes are also inversely related to obesity and central adiposity. Compared to individuals in the lowest quintile, those in the highest quintile of fruit intake are less likely to be obese (43% vs. 23%, $P < 0.05$) and to have a smaller waist circumference (98 ± 10 cm vs. 86 ± 11 cm, $P < 0.01$). This influence on waist circumference was also the case for those in the highest quintile of vegetable intake versus those with the lowest intake

Table 163.2 Adjusted odds ratios (95% CI) for general and central obesity in Iranian women across quintiles of dietary pattern scores[a,b]

	Healthy pattern score			*P* for	Western pattern score			*P* for	Iranian pattern score			*P* for
	1 (*n* = 97)	3 (*n* = 97)	5 (*n* = 97)	trend[c]	1 (*n* = 97)	3 (*n* = 97)	5 (*n* = 97)	trend	1 (*n* = 97)	3 (*n* = 97)	5 (*n* = 97)	trend
General obesity[d]	1.00	0.76 (0.38, 1.29)	0.41 (0.20, 0.75)	<0.05	1.00	1.85 (0.94, 3.41)	2.48 (1.20, 4.61)	<0.01	1.00	0.81 (0.54, 1.59)	0.88 (0.49, 1.45)	0.74
Central obesity[e]	1.00	0.66 (0.37, 1.11)	0.48 (0.27, 0.67)	<0.05	1.00	2.42 (1.34, 4.59)	5.33 (2.85, 10.6)	<0.01	1.00	2.08 (1.09, 3.65)	1.61 (0.94, 2.61)	0.41

[d] General obesity: BMI >=30 kg/m^2

[e] Central obesity: WC >88 cm

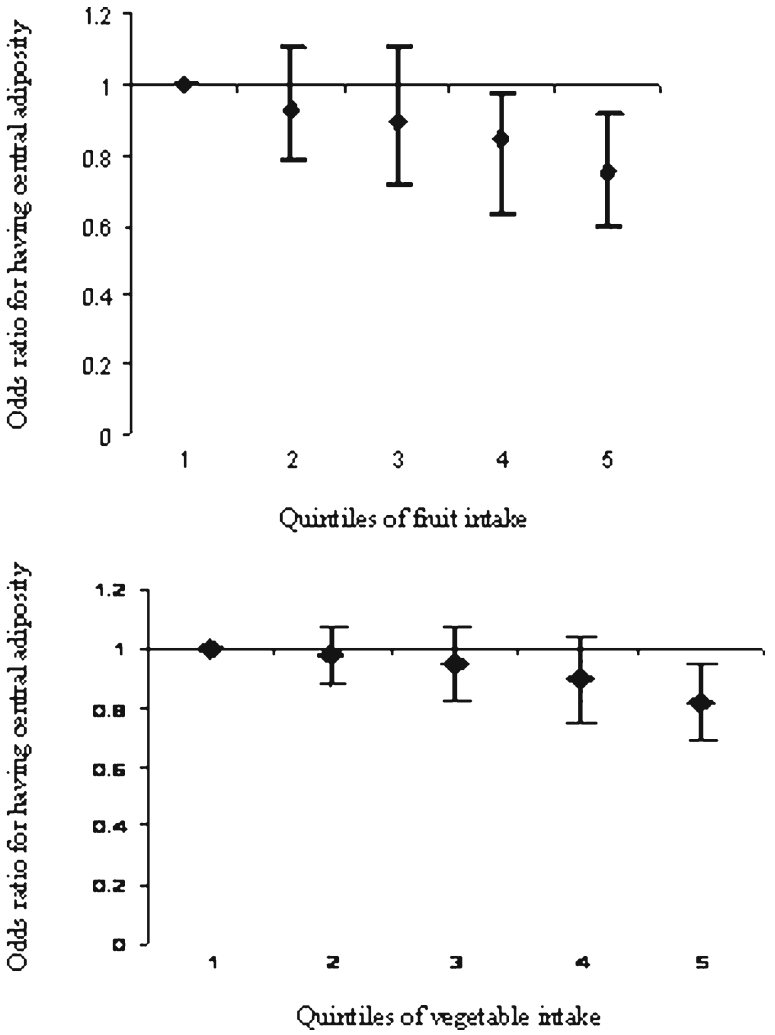

Fig. 163.1 Risk of central adiposity across quintiles of fruit and vegetable intake in Iranian women. Central adiposity was defined as having waist circumference >88 cm

(88 ± 12 cm vs. 97 ± 12 cm, $P < 0.01$) (Esmaillzadeh et al. 2006). The risk of central adiposity in Iranian women across different quintiles of fruit and vegetable intake is shown in Fig. 163.1.

Whole and refined grains have also been related to the risk of central obesity among Iranians. A hypertriglyceridemic waist phenotype has been defined as concurrently having serum triglyceride concentration (TG) ≥ 150 mg/dl and waist circumference (WC) ≥80 cm for men and TG≥150 mg/dl and WC ≥79 cm for women. In a cross-sectional study of 827 Iranian adults aged 18–74 years, a significant decreasing trend was observed for the risk of having a hypertriglyceridemic waist phenotype across quartile categories of whole-grain intake (odds ratios among quartiles: 1.00, 0.95, 0.90, and 0.78, respectively, P for trend = 0.02). Higher consumption of refined grains was associated with higher odds of having a hypertriglyceridemic waist phenotype (1.00, 1.38, 1.65, and 2.1, P for trend = 0.01). However, no significant association was observed with obesity generally (BMI >=30 kg/m^2) (Esmaillzadeh et al. 2005).

Table 163.3 Risk of central obesity according to levels of calcium and vitamin C intake in Iranian adults.

Nutrient intake (mg)	Odds ratio	95% CI
Vitamin C intake		
0–56	2.31*	1.25–4.25
57–80	1.82*	1.08–3.06
81–116	1.36	0.78–2.36
>116	1.00	–
Calcium intake		
0–398	1.30*	1.07–3.78
399–579	1.13	0.78–2.36
580–773	1.12	0.731.86
>773	1.00	–

These results are derived from a cross-sectional study on 926 women in Iran. The vitamin C intake or calcium intake was categorized according to the quartiles of these nutrients intake in the population
*$P < 0.05$

Few data are available showing the relation between food type and central adiposity. A cross-sectional study among Iranian women concluded that red-meat intake was not significantly associated with central adiposity (Azadbakht and Esmaillzadeh 2009). However, it was inversely correlated with metabolic syndrome (Azadbakht and Esmaillzadeh 2009). In a study of Japanese-Brazilians, those in the highest tertile of red-meat intake had the lowest risk of being centrally obese (OR = 0.50; 95%CI: 0.30; 0.82) (Barbieri et al. 2009). In light of the limited research on this topic, further prospective studies are needed to better define the relationship between red-meat intake and central adiposity.

Another study with Iranian women revealed that those with hydrogenated vegetable oil consumption (HVO) in the highest quintile had the largest WHR compared to those with consumption levels in the lowest quintile (Esmaillzadeh and Azadbakht 2008). HVO consumption is widespread in Iran, exposing the population to large quantities of trans fatty acids (TFAs). The TFA content of HVOs used in Iranian households is 23–36%. Trans-fat intake is associated with abdominal adiposity and insulin resistance (Kavanagh et al. 2007). In fact, 4.2% of all calories consumed by Iranians are derived from TFAs, which is about twice the amount consumed in many developed countries (Mozaffarian et al. 2007).

163.3.3 Nutrient Intake and Central Adiposity

Regarding the correlation between nutrient intake and central adiposity, results from research in Iranian adults showed that consumption of vitamin C, calcium, and fat was either positively or negatively related to central fat accumulation (Azadbakht and Esmaillzadeh 2008). Vitamin C as well as calcium can reduce fat absorption and may reduce the abdominal adiposity. Calcium can inhibit fat and fatty-acid absorption. Furthermore, it can affect the levels of agouti, a signaling peptide expressed in human adipocytes that stimulates calcium flux into the cells. The resulting effects on lypolysis and lypogenesis can trigger the deposition of fat in adipocytes. Agouti itself increases fatty acid synthetase activity and inhibits lipolysis (Azadbakht and Esmaillzadeh 2008). High quantities of refined carbohydrate intake and simple sugars are also directly correlated with abdominal adiposity (Esmaillzadeh et al. 2005). In Table 163.3, the odds ratios for having central adiposity among Iranian adults by different group of nutrient intake are displayed.

163.4 Application to Other Areas of Health and Disease

Central adiposity is directly associated with insulin resistance and, as such, insulin disturbance is the core problem associated with central obesity. Central adiposity is also one of the components of the metabolic syndrome, such that subjects with central obesity are at risk for type 2 diabetes and cardiovascular diseases (Reeder et al. 1997). It is possible that central adiposity might be correlated with increasing inflammation and oxidative stress biomarkers, which are the new risk factors for cardiovascular diseases. If so, by preventing central adiposity, we can protect against cardiovascular diseases, coronary problems, metabolic syndrome, and type 2 diabetes. According to research from Iran, there was an inverse association between fruit and vegetable intake and metabolic syndrome as well as between fruit and vegetable intake and C-reactive protein (Esmaillzadeh et al. 2006).

Figure 163.2 shows the risk of metabolic syndrome by quintile of the fruit and vegetable intake in the Iranian population.

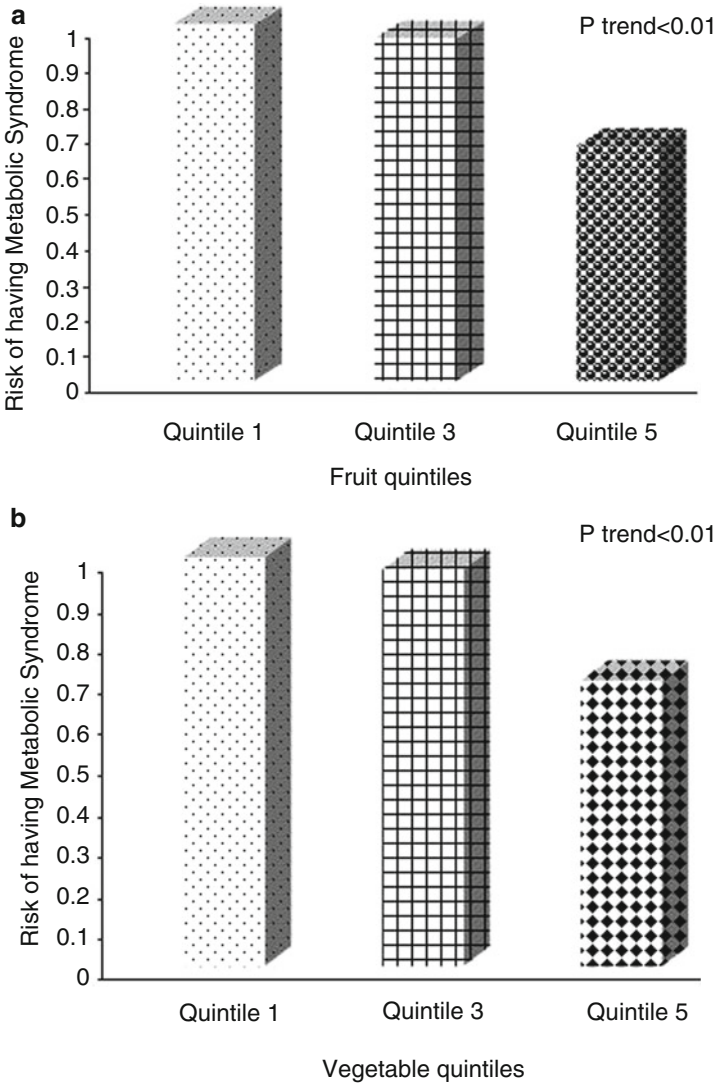

Fig. 163.2 Risk of metabolic syndrome by quintile of fruit and vegetable intake in the Iranian population. Those with the highest quintile of vegetable intake have a 30% lower chance of having the metabolic syndrome compared to those with intake in the lowest quintiles. Persons with fruit intake in the highest quintile had a 34% lower risk of having this syndrome compared to those with intake in the lowest quintile

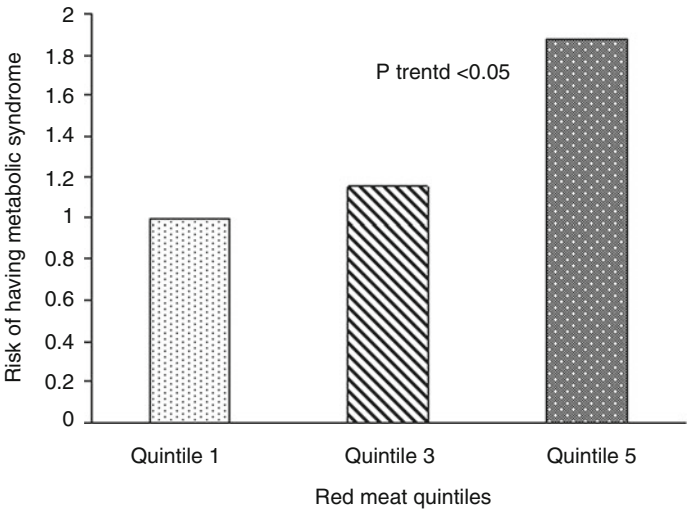

Fig. 163.3 Adjusted odds ratios for metabolic syndrome across quintile categories of red-meat intake. Individuals with the highest quintile of red-meat intake are at highest risk for metabolic syndrome

Whole-grain intake (Esmaillzadeh et al. 2005) and dairy consumption (Azadbakht et al. 2005b) were also inversely associated with the metabolic syndrome. However, there was a direct positive correlation between red-meat intake (Azadbakht and Esmaillzadeh 2009) and hydrogenated vegetable oil (Esmaillzadeh and Azadbakht 2008a, b) with metabolic syndrome. Figure 163.3 presents the odds ratios for metabolic syndrome by quintile of red-meat intake.

163.5 Practical Guidelines

To reduce the prevalence of abdominal adiposity, physical activity and dietary modification might be useful for the Iranian population. Therefore, we recommend a low glycemic index diet containing a large quantity of vegetables, whole grains, fruits, and low-fat dairy products with moderate amounts of non-hydrogenated vegetable oil, olive oil, fish, and poultry, and a low amount of red meat and refined grain as well as doing regular daily exercise. Our recent publications in Iran revealed that Dietary Approaches to Stop hypertension (DASH) eating pattern has a beneficial effects on reducing waist circumference and cardiovascular risks (Azadbakht 2011a, b). Increasing the dietary diversity especially regarding the fruit and vegetable and whole grain could also be related to lower waist circumference among this population (Azadbakht 2011c)

Summary Points

- Having a low physical activity level, unemployment, depression, smoking, being postmenopausal, and married are some important determinants of central adiposity, especially among the Iranian population.
- Eating a diet rich in vegetables, fruits, whole grains, and low-fat dairy products might be associated with lower risk for having central adiposity, based on Iranian studies.
- Calcium and vitamin C intake in sufficient quantities can reduce the risk of abdominal adiposity among Iranians.

- Hydrogenated vegetable oil can increase the risk of having central adiposity among Iranian adults.
- Central adiposity is a risk factor for metabolic syndrome, type 2 diabetes, and cardiovascular diseases.
- There is an inverse association between fruit-, vegetable-, dairy-, and whole-grain intake and metabolic syndrome among the Iranian population. However, red-meat intake and hydrogenated-vegetable-oil consumption are directly associated with this syndrome in Iran. Central adiposity is a major component of metabolic syndrome.

Key Features of Central Adiposity

Table 163.4 highlights key points related to the determinants of central adiposity.

Table 163.4 Key points: determinants of central adiposity

• Physical activity can reduce the risk of being centrally obese among Iranians
• Eating a diet rich in whole grains, vegetables, and fruits and containing low quantities of trans fats, hydrogenated fats, refined grains, and red meat is recommended for the prevention of central adiposity in Iran
• Low calcium intake and low vitamin C intake can be related to abdominal adiposity among Iranians

Chapter 164
Anthropometry and the Prevalence of Child Obesity in China and Japan

Liubai Li, Hui Li, and Hiroshi Ushijima

Abstract Despite the huge socioeconomic differences between China and Japan, the rapid increase of child obesity in both countries is alarming. The prevalence of overweight and obesity in children has increased two to four fold in the two countries over the past three decades.

In the 2002 China National Nutrition and Health Survey (2002 CNHS), the prevalence of overweight and obesity in children and adolescents was 3–4 times to that 30 years ago. In children aged 0–6 years, 3.4% of the children were overweight and 2.1% were obese, according to WHO recommended weight-for-height *Z*-score (WHZ) criteria (overweight: 2< WHZ ≤3,obesity: WHZ >3). For Chinese children and adolescents aged 7–17 years, the prevalence of overweight and obesity in 2002 CNHS were 4.5% and 2.1%, respectively, analyzed by using body mass index (BMI) cut-offs for Chinese children and adolescents (made by the Chinese Obesity Work Group, COWG). Using the same criterion, prevalence of overweight and obese students aged 7–22 years in 2005 were 8.72% and 5.01%, respectively, in urban areas, and were 4.61% and 2.63% in rural areas. Urban children have a higher risk of being overweight and obese than rural children.

Prevalence of overweight and obese children in Japanese is estimated by using the Percentage Overweight or Percentage of Standard Weight for Height (POW). The prevalence of overweight and obesity in boys and girls increased from 6.1% to 7.1%, respectively, in the time-period from 1976 to 1980, to 11.1% and 10.2% in 1996 to 2000 estimated by using the 85th percentile BMI cut-off values.

Overall, boys have a higher prevalence of being overweight and obese, and the increasing trend was most evident in 9–11 year old children in both countries.

Weight-for-height *Z*-scores and BMI cut-offs for Chinese children and adolescents are frequently used for child overweight and obesity screening in China. POW is usually used for child overweight and obesity screening in Japan. In this chapter, we present obesity related anthropometrical indices in population and the cut-offs for child overweight and obesity in the two countries.

164.1 Introduction

Obesity has become an epidemic in many parts of the world (including Asia) in the past three decades. Its impact on children's health and their later life is becoming a greater concern. Despite the large socioeconomic differences between China and Japan, the rapid increase of child obesity in Chinese and Japanese children is alarming. Obesity prevention has become an important public, health issue both in China and Japan.

Identifying children in high risk of overweight and obesity is important in obesity control. The World Health Organization (WHO) has established body mass index (BMI) (BMI = weight (kg)/height[m]^2) cutoffs for defining child overweight and obesity in the world (Cole 2000). However, ethnic differences in body composition limit its worldwide use. For actual reporting, the identification of child overweight and obesity in China and Japan is often based on their national criteria.

In this chapter, we report the prevalence of child overweight and obesity in China and Japan, and present the anthropometric indices relating to child overweight and obesity identification in the two countries.

164.2 Prevalence of Child Obesity

164.2.1 Prevalence of Overweight and Obesity in Chinese Children

The rapid socioeconomic development and urbanization in China transitioned nutrition toward the lifestyle in Western society (high-fat food, high-energy intake, sedentary lifestyle, etc.) and resulted in the child, obesity epidemic. In the 2002 China National Nutrition and Health Survey (2002CNHS) data sets, the prevalence of overweight and obesity in children and adolescents was three to four times that 30 years ago. About one-fourth of Chinese children are now overweight or obese (Wang 2005). In children aged 0–6 years, 3.4% of children were overweight and 2.1% were obese, according to

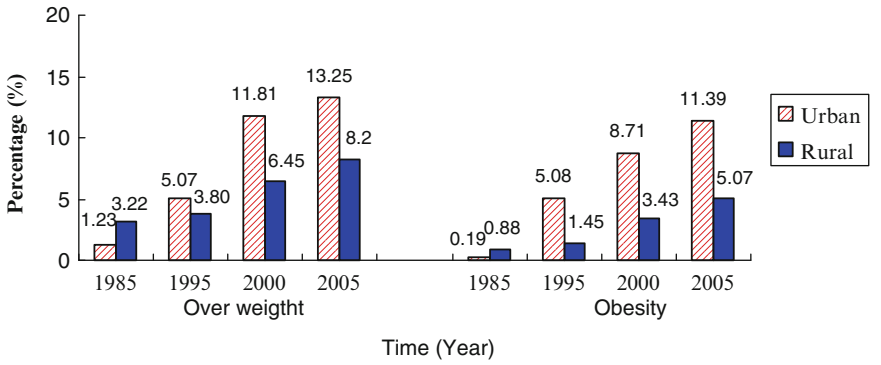

Fig. 164.1 Trends of overweight and obesity prevalence in Chinese boys aged 7–22 years from 1985 to 2005. Prevalence of overweight and obesity increased rapidly both in urban and rural areas (estimated by using the WHZ criterion for Chinese children). Sample size: $n > 200{,}000$ in 1985, $n > 100{,}000$ in 1995, $n > 100{,}000$ in 2000, and $n = 152201$ in 2005 (Research group on the physical fitness and health in Chinese students 2007)

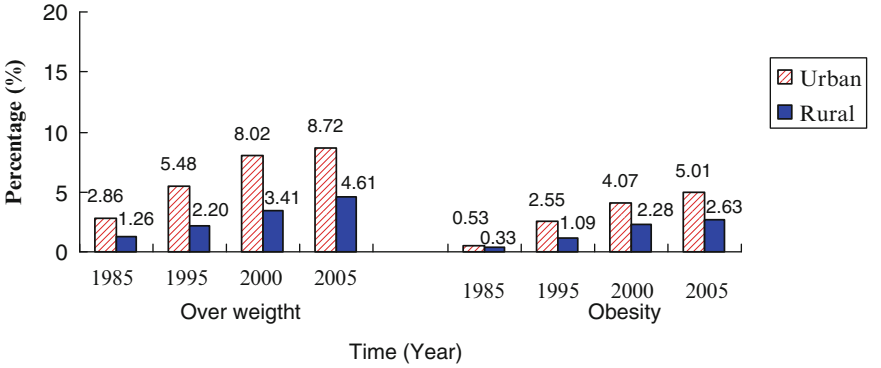

Fig. 164.2 Trends of overweight and obesity prevalence in Chinese girls aged 7–22 years from 1985 to 2005. Prevalence of overweight and obesity increased rapidly both in urban and rural areas (estimated by using the WHZ criterion for Chinese children). Sample size: $n > 200{,}000$ in 1985, $n > 100{,}000$ in 1995, $n > 100{,}000$ in 2000, and $n = 151{,}162$ in 2005 (Research group on the physical fitness and health in Chinese students 2007)

WHO-recommended weight-for-height *Z*-score (WHZ) criteria (overweight: 2 <WHZ ≤3, obesity: WHZ >3) (De Onis et al. 1996). In children and adolescents aged 7–17 years, the prevalence of overweight and obesity in 2002 was 4.5% and 2.1%, respectively – as analyzed by using BMI cutoffs for Chinese children recommended by The Chinese Obesity Work Group (COWG) (The Chinese Obesity Work Group 2004). The secular trends in the prevalence of child overweight and obesity were frequently reported. In a nine-city child growth survey of 112,945 urban children in 2005, about 6.25% of children aged 0–7 years were reported to be overweight and 3.19% were obese, according to the weight-for-height definition in the NCSH/WHO reference (over 10% as overweight and over 20% as obese). The prevalence of obesity has increased 2.78 times in the past 20 years, and the annual incremental rate was 6.9% (The Ministry of Health, China 2008).

In China, there are significant residential and gender differences in the prevalence of overweight and obesity in children. Urban children had a relatively higher prevalence than rural children, and boys had a higher prevalence than girls. Figures 164.1 and 164.2 show the increasing secular trends of childhood overweight and obesity in children and youths aged 7–22 years by using data of The National Survey on Chinese Students' Constitution and Health (in 1985, 1995, 2000, and 2005)

(Research group on the physical fitness and health in Chinese students 2007). Rates were estimated by using the WHZ criterion for Chinese children (Ministry of Education, China 2003).

The prevalence of overweight and obesity in 1985 was only 0.2% and 0.1% in boys and girls, respectively. This has increased to 25.4% for boys aged 7–9 years and 25.5% for boys aged 10–12 years. These numbers have increased to 17.0% in girls aged 7–9 years and 14.3% in girls aged 10–12 years. The prevalence was comparable to the average level seen in some developed countries (Cheng-Ye 2007).

164.2.2 Prevalence of Overweight and Obesity in Japanese Children

Westernized food pattern and lifestyles may account for the increasing rate of child overweight and obesity in Japan. The annual school health body check results showed the current prevalence of child overweight and obesity in Japanese children (Fig. 164.3) and described its secular trends (Fig. 164.4). Child overweight and obesity have increased rapidly in recent decades (School health statistics 2008).

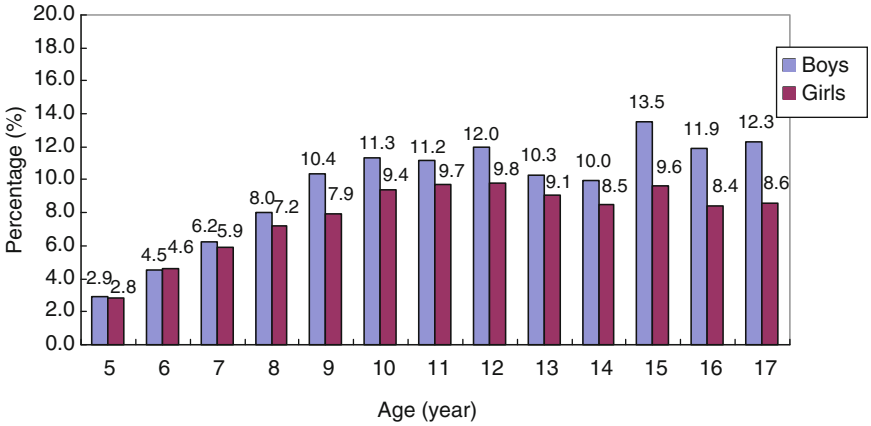

Fig. 164.3 Prevalence of child overweight and obesity in Japanese children in 2008. Prevalence of overweight and obesity was around 10% in most age groups of Japanese children in 2008 (School health statistics 2008)

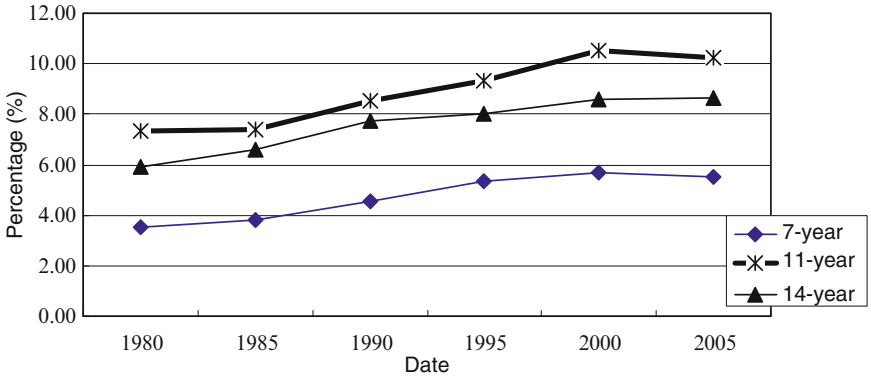

Fig. 164.4 Secular trends in the prevalence of overweight and obesity in Japanese children from 1980 to 2005. The prevalence of overweight and obesity in Japanese children increased rapidly from 1980 to 2005 (School health statistics 2008)

It was estimated that the mean (age-adjusted) BMI increased by 0.32 kg/m^2 per 10 years in boys and by 0.24 kg/m^2 per 10 years in girls, and the increases were remarkable in small towns (Yumi et al. 2004).

Overall, in both countries, prevalence of overweight and obesity was higher in boys than in girls, and the increasing trend was most evident in 9–11-year-old boys and girls.

164.3 Anthropometry of Chinese Children

The most frequently measured anthropometric indices are height, body weight, waist girth, hip girth, and skinfold thickness (usually triceps and subscapular skinfold thickness for body-fat estimation). We will present some anthropometric indices relating to the screening criterion for childhood overweight and obesity as well as its application to Chinese children.

164.3.1 Weight-for-Height Z-Scores and BMI Cutoffs

The prevalence of overweight and obesity in children owing to overnutrition can be measured either by the proportion of children with weight-for-height above +2 *Z*-score (WHZ>2), or with BMI above the 85th and the 95th percentiles of the same gender and age (WHO 2006; The Ministry of Health, China 2008). In China, both criteria are used in child overweight and obesity screening. Tables 164.1–164.3 display the mean (SD) and percentile values of weight-for-length/height and BMI for Chinese children under 7 years of age. The data were obtained in 2005 from well-nourished healthy children with rate of malnutrition (both undernutrition and overweight) less than 4% (The Ministry of Health, China 2008).

For children over 7 years, the previously used WHZ criterion (Ministry of Education, China 2003) is now being gradually replaced by the BMI-based criterion since the construction of the BMI cutoff values for child overweight and obesity screening by the COWG in 2004 (The Chinese Obesity Work Group 2004). The new BMI cutoff criterion was based on national data sets of 24,257 Chinese children and adolescents aged 7–18 years in 2000. The reference data excluded data of the malnourished children and used health outcomes (blood pressure, blood lipids, etc.) as predictive disease variables. The BMI cutoffs were constructed using the LMS method, and made the curve pass through BMI cutoff values for Chinese adults (24 kg/m^2 for overweight and 28 kg/m^2 for obesity) (The Chinese Obesity Work Group 2004). The criterion is now widely used in overweight and obesity screening in Chinese children and adolescents. In 2009, BMI cutoffs for overweight and obesity screening in Chinese children aged 2–18 years were established using the LMS methods and the two national data sets (Hui Li et al. 2009). Table 164.4 displays BMI distributions in Chinese Han ethnic children in Beijing areas in 2000 (combined urban and rural children).

Table 164.1 Weight-for-length (kg) for Chinese children under 7 years old (45–105 cm) (used in 0–3-year-old children) (Data source: Ministry of Health of China et al. 2009. With permission)

164.4 Anthropometry of Japanese Children

164.4.1 Percentage Overweight (POW) (% OW)

For defining obesity in childhood, the Ministry of Health, Labor and Welfare of Japan has adopted percentage overweight (POW) as the parameter in overweight and obesity screening. Box 164.1 shows the calculation of POW and the cutoff values of the criterion.

Table 164.4 Mean (SD) and percentiles of BMI (kg/m^2) for Chinese children aged 6–17 years

Data of the physical fitness and health surveillance of Beijing school students, measured in 2000

Box 164.1 Calculation of POW and the Cutoffs of Child Overweight and Obesity

1. Calculation of POW(% OW):
   % OW = 100 × (measured weight-standard weight-for-height)/standard weight-for-height
   Standard weight-for-height = a × measured height (cm) – b
   Here, 'a' and 'b' are coefficients. Both 'a' and 'b', as well as *Standard weight-for-height values* are available in the website of the Japanese government (School health statistics 2008)
2. The criteria for overweight and obesity screening (Japan society for the study of obesity 2004)
   Overweight and obesity are defined as *POW ≥15%* for children before school age (6 years), and *POW ≥20%* thereafter
   Normal weight: – 20% < %OW < +20%
   Mild obesity: +20% ≦ %OW < +30%
   Moderate obesity: +30% ≦ %OW < +50%
   Severe obesity:+50% ≦ %OW

In 2003, The Japanese Society for the Study of Obesity issued a new clinical diagnostic criterion for 'obesity disease'. According to the new criteria, obesity in childhood (<18 years old) was defined as: POW >20% and percent body fat (PBF) >25% for boys, POW >20% and PBF >30% for girls younger than 11 years, and PBF >35% for girls aged 11 years or older (Kohtaro et al. 2003).

164.4.2 BMI Reference Values for Japanese Children

In some studies, reference values of BMI for Japanese children were constructed by using data in the national school health check (Tables 164.5 and 164.6) (Mikako et al. 2007b).

164.4.3 Body Composition in Japanese Children and Adolescents

Obesity definitions according to fat% cutoff values in Japanese children are as follows (Japan Society for the Study of Obesity 2004), regardless of the measurement technique:

All boys: fat% >25%;
Girls <11 years: fat%>30%; girls ≦ 11 years: fat% >35%

164.4.4 Central Obesity

In Japan, either waist circumference (WC) ≥80 cm or visceral adipose tissue area ≥60 cm^2 in children is defined as obese (Kohtaro et al. 2003, 2005). Table 164.7 displays the adjusted WC means for children at different ages. The WC reference was prepared from national health check data. WC_1 was measured at the level of maximum waist narrowing and WC_2 was measured at the level of the top of the iliac crest (Mikako et al. 2007a).

WC_1: measured at the level of maximum narrowing waist narrowing
WC_2: measured at the level of the top of the iliac crest

164.5 Applications to Other Areas of Health and Disease

Child overweight and obesity relate to many health problems and diseases. Overweight can be a consequence of an original disease and is also related to a number of non-communicable chronic diseases (e.g., hypertension, diabetes, metabolic syndromes, and cancer). Obesity adversely affects virtually every organ system. The following clinical correlates may be related to overweight and obesity.

164.5.1 Clinical Correlates

- Acquired hypothalamic lesions: infectious (sarcoid, tuberculosis, arachnoiditis, and encephalitis), vascular malformation, neoplass, and trauma.
- Cushing's syndrome: hypercortisolism.
- Growth hormone (GH) deficiency: impaired production of GH (pituitary) or GHRH (hypothalamus).
- Hypothyroidism: hypothalamic, pituitary, or thyroidal.
- Behaviors: child eating disorder (binge eating).
- Cardiometabolic abnormalities.

164.6 Practical Methods and Techniques in BMI Calculation and WC Measurement

164.6.1 BMI Calculation

BMI correlates well with body fat and is relatively unaffected by height. BMI is calculated as either the body weight (kg) divided by the stature (height [m]) squared (wt/ht^2) or body weight (lb) × 703 divided by the height (stature) squared (wt [lb] × 703/[Ht(in)^2]).

164.6.2 Measuring Waist Circumference

To measure the waist circumference, locate the upper hip bone and the top of the right iliac crest. Place a measuring tape in a horizontal plane around the abdomen at the level of the iliac crest. Before reading the tape measure, ensure that the tape is snug but does not compress the skin and is parallel to the floor. The measurement is made at the end of a normal expiration.

164.7 Key Points of Different Screening Criteria

164.7.1 Weight-for-Height Z-Score (WHZ) and BMI Z-Score in Chinese Children

There were no significant differences in the prevalence estimation when using the two criteria (WHZ and BMI *Z*-score derived from data of Chinese children) in identifying overweight Chinese

children. For example, the prevalence of overweight boys and girls was 3.62% and 2.91% by using WHZ and was 3.72% and 2.76% by using BMI *Z*-score, respectively, in the nine-city child (0–7 years) nutrition survey, 2006.

Similarly, there was no significant difference between WHZ of China and WHO in the overweight prevalence estimation. Prevalence of child (under five) overweight in the above data sets was 2.98% and 3.07%, respectively, when using WHZ of China and WHO, as screening criteria.

For BMI *Z*-scores, significant difference was found using BMI *Z*-scores of China and the WHO in overweight prevalence estimation. In the above data sets, the prevalence of overweight was 3.26% and 2.94%, respectively, when using BMI *Z*-scores of China and WHO (Capital institute of pediatrics 2009).

164.7.2 POW and BMI Percentiles in Japanese Children

In screening child overweight and obesity, the two systems (POW and BMI percentiles) differed in the prevalence estimation. The traditional standard weight system, POW, underestimated the prevalence of child obesity when compared to the 95th BMI percentile systems (Mikako 2009).

164.8 The Chinese Obesity Work Group (COWG)

The Chinese Obesity Work Group (COWG) has greatly promoted works in obesity prevention and control in China. Table 164.8 shows the key facts of COWG.

Table 164.8 Key facts of the Chinese Obesity Work Group (COWG)

1. The Chinese Obesity Work Group (COWG) was established after a symposium titled 'Obesity in China' by the International Life Science Institute Focal Point in China (ILSI Focal Point in China) was presented in July 2000. The threat of an obesity epidemic in China and the urgent need for identifying BMI cutoff values for obesity screening and preventive strategies spurred its formation
2. The commission of COWG provides technical support for policy making in obesity and obesity-related disease prevention and control in China
3. COWG is composed of 13 medical institutions (and 46 other cooperating institutions), universities, and disease prevention and control institutions in China. Experts working in various fields (e.g., clinical medicine, public health, and bioinformatics and so on) are commissioned members to the group
4. Using available national health survey data sets, COWG has set BMI cutoffs for overweight and obesity screening both for Chinese adults and children. Cross-sectional data covering 240,000 people and longitudinal data of 620,000 people were analyzed for identifying the health risks of obesity
5. After 9 months, ILSI Focal Point in China held a symposium titled 'Obesity and disease risks in China' in June 2001. In this symposium, the BMI cutoffs for Chinese adults were issued. BMI cutoffs are defined as follows: healthy weight: $18.5 \leq \text{BMI} < 24.0$, overweight: $24 \leq \text{BMI} < 28.0$, and obesity: $\text{BMI} \geq 28$
6. COWG issued BMI cutoffs for overweight and obesity screening in Chinese children and adolescents in 2004. The cutoffs were determined based on the analysis of national data sets on physical fitness and health surveillance of Chinese school students
7. COWG is now continuing work on strategies of obesity and obesity-related disease prevention and control

This table lists the key facts of The Chinese Obesity Work Group including the establishment, the commission, and the contributions of COWG in China.

Summary Points

- Prevalence of child overweight and obesity in China and Japan increased rapidly in the past three decades.
- The most commonly used anthropometric indicators in child overweight screening are WHZ and BMI percentiles, which are determined, respectively, either by 2 < WHZ ≤3 for overweight and WHZ >3 for obesity or by BMI >85th percentile values in the same age and sex populations.
- Prevalence of child overweight and obesity may be significantly different when using different screening criteria.
- Waist and hip circumferences and WHR are important indices for obesity-related diseases.
- Thresholds of anthropometric indices (weight-for-height and BMI) may be used for guidance by decision makers to select nutrition-related interventions. However, they must be used with caution in the clinic settings for individual patients, taking into consideration contextual and trend analyses.
- Children with BMI percentiles >85th should be educated on the risks of being overweight.

Chapter 165
Optimal Waist Circumference Cutoffs for Abdominal Obesity in Chinese

Weiping Jia and Jiemin Pan

Abstract Obesity has become a global epidemic and is a major risk factor for the development of metabolic abnormalities and cardiovascular disease. With the rapid economic development in China, the prevalence of overweight and obesity has been rising, estimated 22.4% of the adult population is overweight and 3.01% is obese in 1990s. It is categorized as abdominal obesity if fat is accumulated in the abdomen. Theoretically, abdominal obesity should be determined by visceral adipose tissue (VAT) precisely measured by magnetic resonance imaging (MRI) or computerized tomography (CT) scanning. While, waist circumference is widely used clinically to estimate the abdominal fat for its convenience and strong correlation with VAT. The waist circumference increased with aging in Chinese population and was quite similar in men and women especially in the subgroup with age over 60 years. Based on a cross-sectional survey, the accumulation of visceral fat at the level of visceral fat area (VFA) over 80 cm^2 in Chinese linked with high prevalence of the metabolic syndrome (MetS). The corresponding waist circumference cut-offs were 87.5 cm in men and 84.3 cm in women. Therefore, it was demonstrated that the optimal cut-offs of waist circumference were 90 cm in men and 85 cm in women. Another prospective study demonstrated that the MetS based on the Chinese Joint Committee for Developing Chinese Guidelines on Prevention and Treatment of Dyslipidemia in Adults (JCDCG) definition was a significant predictor for the development of CVD in total subjects. This study furthermore confirmed that the waist circumference cut-offs with 90 cm in men and 85 cm in women were more suitable than the IDF recommended in Chinese population.

Abbreviations

BMI	Body mass index
CRP	C-reactive protein
CT	Computerized tomography
CVD	Cardiovascular disease
FFAs	Free fatty acids
FPG	Fasting plasma glucose

165.1 Introduction

The prevalence of obesity is rising rapidly worldwide. Although obesity may be considered as a disease in its own right, it is also one of the key risk factors for a wide range of illness and diseases. It has been listed as one of the ten major contributors to the global disease burden. Additionally, obesity can lead to social problems and psychological disorders. Obese individuals generally have an increased volume of adipocytes and abnormal high body fat percentage (body fat%) and fat deposits in certain parts of the body. It is categorized as 'central' or 'abdominal' obesity if fat is accumulated in the abdomen, which has metabolic influences. It has been demonstrated that obesity, especially abdominal obesity, plays an important role in the development of the metabolic syndrome (MetS) and cardiovascular diseases. With the rapid economic development in China since its reform and opening-up policy, the prevalence of overweight and obesity has been rising; an estimated 22.4% of the adult population was overweight and 3.01% obese in the 1990s. In 2000, the Working Group on Obesity in China conducted a meta-analysis of available data that included body mass index, waist circumference, hypertension, and serum lipid and glucose from more than 240,000 subjects located in 21 provinces, municipalities, and autonomous regions in China. On the basis of the meta-analysis, a BMI of 24 was recommended by the group as the cutoff point for overweight and a BMI of 28 for obesity; waist circumferences of 85 cm for men and 80 cm for women were recommended as the cutoff points for central obesity (Chinese Center for Disease Control and Prevention 2004, Table 165.1). Recently, the Chinese Joint Committee for Developing Chinese Guidelines on Prevention and Treatment of Dyslipidemia in Adults (JCDCG) proposed a new definition of MetS, in which abdominal obesity is defined as the waist circumference >90 for men and >85 cm for women (JCDCG 2007, Table 165.2). The optimal cutoff of waist circumference was based on data from several Chinese population studies. This review discussed the prevalence and features of obesity in China and summarized the available data on the linkage between central obesity and the risk of diabetes mellitus (DM), cardiovascular disease (CVD), and MetS.

Table 165.1 BMI combined with WC cutoff points and risk for disease[a] in Chinese adults

		Waist circumference (cm)		
Classification	BMI (kg/m^2)	Men:<85 Women:<80	Men:85–95 Women:80–90	Men: ≥95 Women: ≥90
Underweight[b]	<18.5	Ö[b]	Ö[b]	Ö[b]
Acceptable range	18.5–23.9	Increased	Increased	Moderately severe
Overweight	24.0–27.9	Increased	Moderately severe	Very severe
Obesity	≥28	Moderately severe	Severe	Very severe

This table lists the recommendations for BMI and WC cutoff points for overweight and obesity in Chinese and the assessment of obesity-related disease using these two measurements
BMI body mass index; *WC* waist circumference
[a]Related diseases are hypertension, diabetes mellitus, dyslipidemia, and clustering of risk factors
[b]Underweight may be a sign of other health problems

Table 165.2 Definition of MetS according to 2007 JCDCG criteria

MetS was defined as having at least three of the following metabolic abnormalities	
Abdominal obesity	Waist circumference >90 cm for men and >85 cm for women
Hypertriglyceridemia	Serum triglycerides ≥1.7 mmol/L
Low high-density-lipoprotein cholesterol	High-density-lipoprotein cholesterol <1.04 mmol/L for both men and women
Elevation of blood pressure	Blood pressure ≥130/85 mmHg or known treatment for hypertension
Impaired glucose tolerance or diabetes	FPG ≥6.1 mmol/L and/or 2h-PG ≥7.8 mmol/L and/or diagnosed diabetic mellitus

This table illustrates the components of MetS and the definition of each metabolic disorder according to 2007 JCDCG criteria
MetS metabolic syndrome; *FPG* fasting plasma glucose; *2h-PG* 2h plasma glucose

165.2 The Feature of Abdominal Obesity in Chinese

Body fat is mainly composed of cells that contain triglyceride stores. It can be divided into two main parts: subcutaneous and intra-abdominal (Ronti et al. 2006). Most of the visceral fat is located in the intra-abdominal space including intraperitoneal and retroperitoneal space, which is commonly influenced by gender, age, ethnicity, and physical activity (Klein et al. 2007).There has been a general trend that Chinese people with obesity tend to abdominal obesity rather than generalized obesity. Theoretically, abdominal obesity should be determined by visceral adipose tissue (VAT) precisely measured by magnetic resonance imaging (MRI) or computed tomography (CT) scanning, which is suggested as a standard method by the International Diabetes Federation. A single slice at the L4–L5 intervertebral level is used to measure the amount of fat, expressed in cubic centimeters (Alberti et al. 2006). The Japan Society for the Study of Obesity used visceral fat area (VFA) more than 100 cm^2 to define abdominal obesity (Examination Committee of Criteria for 'Obesity Disease' in Japan 2002). In Korea, VFA over 103.8 cm^2 was associated with an increased risk of obesity (Kim et al. 2006). In a cross-sectional study on the relationship between abdominal obesity and waist circumference in a Chinese population, VFA over 80 cm^2, which was calculated at the cross-sectional MRI scan between L4 and L5 vertebrae, was linked with high prevalence of MetS (Bao et al. 2008).

165.3 Waist Circumference: An Anthropometrical Measurement of Abdominal Obesity

As mentioned earlier, increased visceral adipose tissue, which is also called abdominal fat, is closely related with increased risk for cardiometabolic diseases. Though MRI or CT scanning is a widely accepted measurement of abdominal obesity, the inconvenience and high cost limit the 'platinum standard' measurement in clinical use and epidemiological survey. By contrast, anthropometrical measurements including body mass index (BMI), waist-to-hip ratio (WHR), and waist circumference (WC), used as surrogate markers for abdominal fat mass to discriminate for the presence of abdominal obesity, are simple and noninvasive for assessing visceral fat accumulation. We analyzed the area under receiver operating characteristic (ROC) curve of the anthropometric measurements in 690 Chinese adults (305 men and 385 women) for the determination of visceral obesity. The results showed that waist circumference had an excellent correlation with VAT ($r = 0.73–0.77$) and, in terms of sensitivity and specificity, waist circumference had better accuracy for measuring abdominal obesity and in diagnosing abdominal obesity in Chinese adults, compared with BMI and WHR (Jia et al. 2003).

165.4 Practical Methods and Techniques: The Accurate Method of Measuring Waist Circumference

Different anatomic landmarks are used to measure WC including the midpoint between the lowest rib and the iliac crest, the umbilicus, the narrowest or widest WC, just below the lowest rib, and just above the iliac crest. A recent systematic review evaluated the influence of different WC protocols on the relationship to morbidity and mortality (Ross et al. 2008). The most commonly used landmarks were the minimal waist (33%), the midpoint between the lowest rib and the iliac crest (26%), and the umbilicus (27%). However, WC protocol did not influence outcome of all-cause and CVD mortality, CVD, and DM. Thus, different anatomic landmarks seem not to influence clinical outcomes. In order to measure waist circumference precisely, the subject is required to stand straight with his/her feet spread 30–40 cm apart and arms hanging freely. The measurement is made at the end of a normal expiration. A soft, inflexible, measuring tape is placed perpendicular to the long axis of the body and horizontal to the floor and applied with tension, ensuring that the tape is clinging to but not pressing the skin. The tape measurement is read with 1-mm accuracy. The guidelines for prevention and control of overweight and obesity in Chinese adult used the WHO 1998 protocol (WHO 1998), the midpoint between the lowest rib and the iliac crest, as the WC measurement protocol in China (Chinese Center for Disease Control and Prevention 2004).

165.5 The Characteristics of Waist Circumference in the Chinese

The Chinese have smaller waist circumference levels compared with the Caucasians. We compared the waist circumference of the Chinese population with that of Caucasians from the multinational monitoring of trends and determinants in cardiovascular disease (MONICA) project and found that the waist circumference in the Chinese, particularly in men, was much smaller than that in Caucasians. From 1998 to 2000, a group of 2,776 randomly selected adults aged from 20 to 94 years living in Shanghai was investigated. Among this survey population, the prevalence of overweight (determined

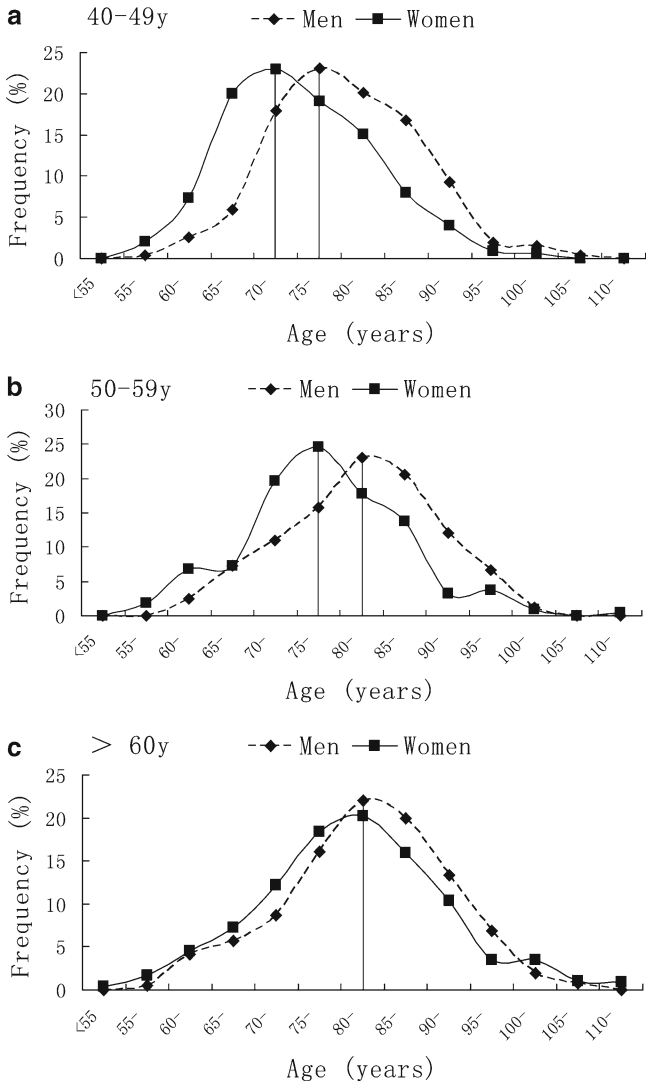

Fig. 165.1 Frequency distribution of waist circumference (WC) in the urban population survey in Shanghai, China (n = 2776, means ± SD). This figure shows frequency distribution of waist circumference in each sex in a Shanghai urban Chinese population survey and the characteristics of each subgroup after age and gender stratification. (**a**) age 40–49 years subgroup, men 80.3 ± 8.5 cm, women 74.6 ± 8.5 cm; (**b**) age 50–59 years subgroup, men 81.8 ± 8.5 cm, women 77.5 ± 9.2 cm; (**c**) age > 60 years subgroup, men 82.6 ± 9.5 cm, women 81.0 ± 10.6 cm. *Solid line*: women; *dotted line*: men (Reprinted from Jia et al. (2002). With permission from John Wiley & Sons)

by WHO definition) was 29.5% and obesity was 4.3%, with a greater number of women being obese than men. The average waist circumference in this study was 80.8 cm in men and 76.2 cm in women. After age stratification, the peak frequency distribution of waist circumference was shifted to the right with aging, and this phenomenon was more obvious in women. The difference of waist circumference between men and women less than 60 years of age was about 5 cm, regardless of different mean WC values within different age groups. Among women older than 60 years, the waist circumference further increased so that the average waist circumference was similar in men and women, at 82.6 and 81.0 cm, respectively (Jia et al. 2002, Fig. 165.1). Thus, the WC cutoff recommended by IDF could overestimate the difference between men and women.

165.6 Application to Other Areas of Health and Disease: The Relationship Between Waist Circumference and the Metabolic Syndrome

The MetS is composed of a cluster of metabolic disorders, such as hyperlipidemia, hypertension, elevated blood glucose level, insulin resistance, and microalbuminuria, associated with increased risk for cardiovascular disease and DM. Abdominal obesity, in particular, is considered as a fundamental element of the MetS. The more visceral fat accumulates, the more metabolic components increase (Reaven 1988; Kaplan 1989). A number of expert associations recommended different definitions for the MetS, in which most components were identical except for the obesity cutoff. Many epidemiological studies were conducted in China on the prevalence of MetS using different definitions. All these studies indicated that the MetS had become very common in China and that the frequency of the syndrome differed with definitions and regions in China (Feng et al. 2006; He et al. 2006; Yang et al. 2007). In the unified worldwide definition of MetS proposed by the International Diabetes Federation (IDF) in 2005, central obesity was regarded as a predominant element, and waist circumference cutoffs differ with gender and ethnicity. Waist circumference cutoff of 90 and 80 cm was proposed for Chinese men and women, respectively. The gender variation was larger than in our previous study. However, the IDF left the optimal cutoffs open for better data to link them to risk (Alberti et al. 2005). We carried out a cross-sectional study, which enrolled 1,140 individuals (525 men, 615 women) aged from 35 to 75 years to analyze VFA and the frequency of MetS. There was a linear increase in the number of metabolic syndrome components in those individuals with VFA less than 80 cm^2, and the prevalence of diabetes, dyslipidemia and of the aggregation of diabetes, dyslipidemia, and hypertension, components of the MetS had reached a plateau with VFA over 80 cm^2. Thus, it was suggested that the accumulation of visceral fat at the level of VFA over 80 cm^2 in the Chinese is linked with high prevalence of the MetS. The corresponding waist circumference cutoffs were 87.5 cm in men and 84.3 cm in women. Therefore, it was demonstrated that the appropriate cutoffs of waist circumference were 90 cm in men and 85 cm in women, which were associated with high risk of the MetS (Bao et al. 2008, Fig. 165.2, Table 165.3). Given the evidence above,

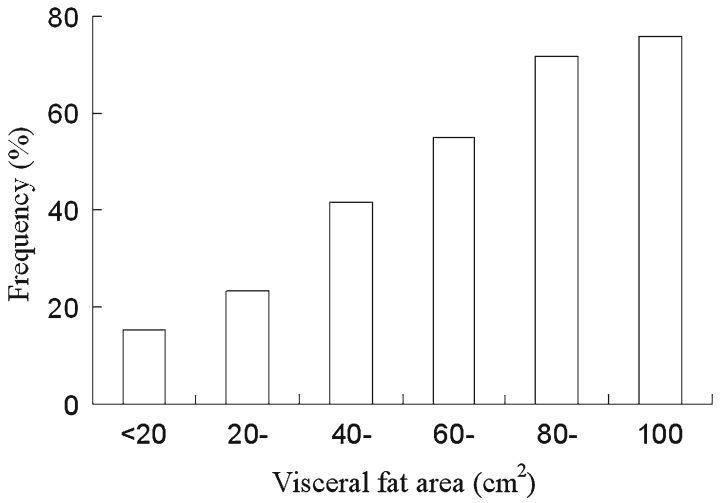

Fig. 165.2 The frequency of two or more components of the metabolic syndrome including hyperglycemia, hypertension, and dyslipidemia, except body fat parameters (waist circumference or BMI, $n = 1140$). This figure reflects the relationship between visceral fat area and the metabolic syndrome. The subjects were divided into six VFA subgroups from VFA <20 cm^2 to VFA ≥100 cm^2. The frequency of two or more components of the MetS without anthrometric indices of overweight/obesity was elevated with increased VFA. In individuals with VFA over 80 cm^2, the frequency was close to those with VFA over 100 cm^2 (Reprinted from Bao et al. (2008). With permission from Elsevier)

Table 165.3 Sensitivity and specificity of waist circumference to identify VFA in association with the MetS (n = 1140) (Reprinted from Bao et al. (2008). With permission from Elsevier)

			Waist circumference					
	n	VFA (cm^2)	Cutoff (cm)	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	J value
Men								
Total	525	80	87.5	75.9	78.1	90.2	60.8	0.54
Age <50	174	80	87.5	72.0	81.4	90.4	67.5	0.53
Age ≥50	351	80	88.3	71.3	83.8	92.5	53.0	0.55
Women								
Total	615	80	84.3	75.8	75.8	86.0	67.2	0.52
Age <50	208	70	81.5	77.2	72.3	78.6	74.7	0.50
Age ≥50	407	90	86.3	74.4	72.4	84.5	64.9	0.47

This table shows the best cutoffs of WC corresponding to the visceral fat area in association with the MetS. The corresponding cutoffs were selected by the largest Youden index which indicated the best trade-off between sensitivity and specificity by ROC curves

MetS metabolic syndrome, *NPV* negative predictive value, *PPV* positive predictive value, *VFA* visceral fat area

Table 165.4 Key Facts of the Chinese Joint Committee for developing Chinese guidelines on prevention and treatment of dyslipidemia in adults (JCDCG)

1. Dyslipidemia is lipid metabolic disorder. As an atherogenic factor, it is correlated with diabetes and metabolic syndrome
2. Chinese epidemiological studies demonstrated that dyslipidemia was an independent risk factor for cardiovascular disease in the Chinese population and a multifactorial estimation could improve the prevention and treatment of dyslipidemia
3. The guidelines were drafted by Chinese Society of Cardiology, Chinese Diabetes Society, Chinese Society of Endocrinology, and Chinese Society of Laboratory Medicine, based on several large-scale clinical trials
4. The guidelines consist of the subsections including lipid profile testing, classification of dyslipidemia, cardiovascular risk evaluation, trials-based evidence in lipid-lowering therapy, and treatment of dyslipidemia

This table lists the key features of the Chinese Joint Committee for Developing Chinese Guidelines on Prevention and Treatment of Dyslipidemia in Adults (JCDCG) including the basic concept of dyslipidemia, the purpose of the guidelines, the composition of the joint committee, and the subsections of the guidelines

in 2007, JCDCG proposed a set of criteria to define the MetS. In the revised definition, the WC cutoff points of 90 and 85 cm were suggested for Chinese men and women in order to detect abdominal obesity (Table 165.4).

165.7 Application to Other Areas of Health and Disease: The Optimal Waist Circumference Cutoffs in the Prediction of Diabetes and Cardiovascular Disease

Adipose tissue is viewed not only as an energy depot, but also as an active endocrine organ. Abdominal obesity is one of risk factors for CVD. Though the etiology of increased cardiovascular risk in patients with abdominal obesity is not known clearly, there are many potential theories on the issue. Increased levels of free fatty acids (FFAs) due to obesity and VAT worsen insulin resistance. The increase in VAT mass possibly reflects the lack of capacity of the subcutaneous tissue to store the energy excess that accumulates in liver, muscle, and pancreas, worsening insulin resistance (Despres et al. 2006). An inflammatory factor, C-reactive protein (CRP), produced by the liver and

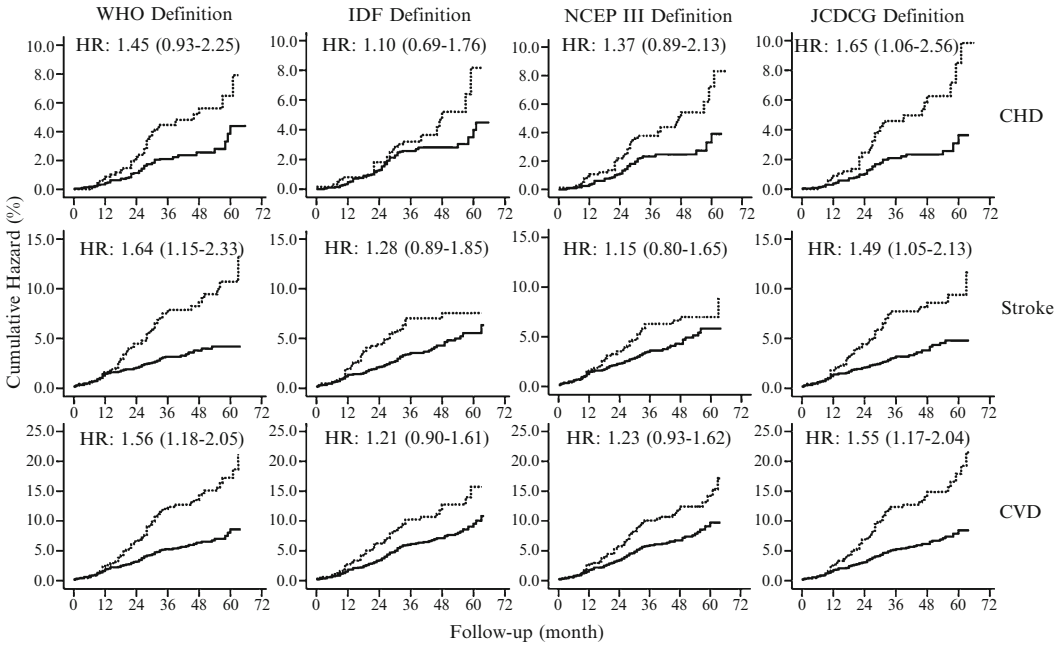

Fig. 165.3 The evaluation of MetS based on different definitions to predict future CVD events with age-adjusted Cox proportional hazard model ($n = 2788$). This figure shows the cumulative hazard of cardiovascular disease (*CVD*), coronary heart disease (*CHD*), and stroke in 2,788 Chinese subjects with and without metabolic syndrome, defined by the WHO, the IDF, the National Cholesterol Education Program Adult Treatment Panel III (NCEPIII), and the Joint Committee for Developing Chinese Guidelines on Prevention and Treatment of Dyslipidemia in Adults (*JCDCG*) definitions, using multivariate Cox regression analysis. *Solid line*: without metabolic syndrome; *dotted line*: with metabolic syndrome. *HR* hazard ration; *CHD* coronary heart disease; *CVD* cardiovascular disease (Reprinted from Wang et al. (2010). With permission from Elsevier)

correlating with atherosclerosis, is increased obviously in patients with visceral obesity (Lemieux et al. 2001). A prospective cohort study in a middle-aged and older Chinese population suggests that elevated high-sensitivity CRP (≥2.0 mg/L) is an effective predictor of the risk of composite CVD events during a 5.5-year period (Jiang et al. 2009). Additionally, several adipokines, including adiponectin, leptin, retinol binding protein4 (RBP4), and visfatin, derived from adipose tissue mediate glucose, lipid metabolism, and insulin sensitivity (Scherer 2006; Jia et al. 2007). Further investigations will be needed to illustrate the comprehensive pathophysiology. A community-based cohort study prospectively evaluated the predictive value of the MetS for CVD in a Chinese population using different MetS definitions including those from the World Health Organization (WHO), the IDF, the National Cholesterol Education Program Adult Treatment Panel III (NCEPIII), and JCDCG. Totally 2,788 subjects were included and followed up for 5.5 years. The results showed that the prevalence of MetS, according to JCDCG definition, was similar to those by the WHO, the IDF, and the NCEPIII definitions. While the MetS based on the JCDCG or WHO criterion was a significant predictor for the development of CVD in total subjects, the MetS based on the IDF or the NCEPIII criterion was not (Wang et al. 2010, Fig. 165.3). In addition, a 7.8-year follow-up study was conducted to identify the appropriate VAT cutoff and the corresponding waist circumference cutoffs for defining abdominal obesity in predicting diabetes. At the end of the study, 290 participants were followed up. The optimal waist circumference cutoffs were 88 cm in men and 82 cm in women, quite similar to the cutoffs JCDCG recommended (Ye et al. 2009). These results furthermore confirmed that the waist-circumference thresholds of 90 cm in men and 85 cm in women are more suitable for obesity-related risk assessment than the IDF recommended in the Chinese population.

Summary Points

- With the rapid economic development in China, the prevalence of overweight and obesity has been rising.
- Waist circumference is correlated with risk for DM, CVD, and MetS.
- Waist circumference is a widely used anthropometric measurement to estimate abdominal fat due to its convenience and strong correlation with visceral fat.
- Waist circumference increased with aging in Chinese population and was quite similar in men and women, especially in the subgroup with age over 60 years.
- The optimal cutoff of WC is 90 cm in men and 85 cm in women in the Chinese population.

Chapter 166
Usefulness of Skinfold Thickness Measurements for Determining Body Fat Distribution and Disease Risk for Japanese Men and Women

Hironori Imano, Akihiko Kitamura, Masahiko Kiyama, Tetsuya Ohira, Renzhe Cui, Isao Muraki, Yuji Shimizu, Mitsumasa Umesawa, Kenji Maeda, Masatoshi Ido, Takeo Okada, Masakazu Nakamura, Hiroyuki Noda, Kazumasa Yamagishi, Shinich Sato, Takeshi Tanigawa, Yoshinori Ishikawa, and Hiroyasu Iso

Abstract Subscapular and triceps skinfold thickness (SSF and TSF) as well as body mass index (BMI) were investigated as indices for body fat distribution between 1976 and 2007 in rural and urban communities in conjunction with the Circulatory Risk in Communities Study (CIRCS). Mean BMI did not change between 1976 and 1987 and increased thereafter for men of every age group in both rural and urban communities. There were no remarkable changes in BMI levels for women of any age groups, except for rural women aged 40–49 and urban women aged 40–59 whose mean BMI declined over time. Mean SSF and TSF did not change from between 1976 and 1987 and increased thereafter for men and women of every age group in both rural and urban communities, except for urban women aged 40–59 whose mean SSF declined over time. BMI, SSF and TSF correlated positively with systolic and diastolic blood pressures and total cholesterol in each survey period for both men and women of rural and urban communities. BMI and SSF correlated positively with serum glucose for rural women and for urban men and women in every survey period, but not for rural men, for whom correlations were weak between 1976 and 1991 and became stronger thereafter. The skinfold thickness measurement is useful to obtain a clearer picture of long-term trends for body fat distribution as well as for its influence on cardiovascular risk factors, which would be difficult to obtained with BMI measurement only.

Abbreviations

BMI	Body mass index
SF	Skinfold thickness
SSF	Subscapular skinfold thickness
TSF	Triceps skinfold thickness
TC	Serum total cholesterol
GL	Serum glucose
FGL	Fasting serum glucose
CIRCS	The Circulatory Risk in Communities Study

166.1 Introduction

The Japan National Nutrition and Health Survey (Ministry of Health, Labor and Welfare 2009) has provided data on long-term trends for mean body mass index (BMI). Mean BMI has increased in men aged 30–79 years and in women aged 60–79 years since the 1950s and either has not changed substantially or has actually declined in women aged 30–59 years since the 1970s. However, no national data on trends for skinfold thickness are available. The Circulatory Risk in Communities Study (CIRCS, Table 166.1) has investigated cardiovascular risk factors, incident cardiovascular disease, and their long-term trends in Japanese communities (Imano 2009). In that study, not only BMI but also subscapular and triceps skinfold thickness (SSF and TSF) were measured as indices for body-fat distribution. This chapter deals with (1) long-term trends for BMI, SSF, and TSF between 1976 and 2007 and (2) correlations between these indices and cardiovascular risk factors in Japanese men and women of rural and urban communities.

166.2 Methodological Considerations

The subjects were residents aged 40–79 years from two communities: Ikawa town (Kitamura et al. 2008; Shimamoto et al. 1989), Akita Prefecture (a northeastern rural community) and the Minami-Takayasu district (Kitamura et al. 2008), Yao City, Osaka Prefecture (a southwestern urban community). Annual cardiovascular risk surveys were conducted in those communities since 1963 as part of the CIRCS (Imano et al. 2009).

Table 166.1 Key features of the Circulatory Risk in Communities Study (CIRCS)

1. CIRCS is a new generic name of the prior and ongoing epidemiological study consisting of five Japanese communities' studies
2. The study started in 1963 for the prevention of cardiovascular disease, which was the most common cause of death for Japanese
3. The five communities are as follows
   (a) Ikawa town, Akita Prefecture: a northeastern rural community
   (b) Ishizawa and Kita-utetsu district, Yurihonjo City, Akita Prefecture: a northeastern rural community
   (c) Minami-Takayasu district, Yao City, Osaka Prefecture: a southwestern urban community
   (d) Noichi district, Konan City, Kochi Prefecture: a southwestern rural community; and
   (e) Kyowa district, Chikusei City, Ibaraki Prefecture: a central rural community
4. The study consists of Akita-Osaka Study, Ikawa Study, and Kyowa Study
5. The main research topic of the study is to investigate cardiovascular risk factors, incident cardiovascular disease (stroke, coronary heart disease, and sudden death) and their long-term trends
6. Study implementation institutes are Osaka Medical Center for Health Science and Promotion and the departments of public health in three universities, that is, Osaka University, University of Tsukuba, and Ehime University School of Medicine
7. The measurement of cardiovascular risk factors has been standardized by the same research institute, the laboratory of the Osaka Medical Center for Health Science and Promotion, an international member of the US National Cholesterol Reference Method Laboratory Network
8. The ascertainment system for cardiovascular disease has used the same diagnostic criteria throughout all study periods
9. The study found that stroke, especially cerebral hemorrhage, strongly related to hypertension and also related to low serum cholesterol levels
10. The incidence of stroke has declined substantially, while that of coronary heart disease remained low in those communities

This table lists the key features of the Circulatory Risk in Communities Study (CIRCS)

The study period was divided into eight terms of 4 years each: (1) 1976–1979, (2) 1980–1983, (3) 1984–1987, (4) 1988–1991, (5) 1992–1995, (6) 1996–1999, (7) 2000–2003, and (8) 2004–2007. The earliest individual datum was used within each term of the surveys as well as age- and sex-specific numbers of participants in conjunction with measurements of BMI, SSF, and TSF in rural and urban communities throughout the study period (Table 166.2).

Height in stockinged feet and weight in light clothing were measured. Body mass index (BMI) was calculated as weight (kilograms) divided by height (meters) squared. Keys calipers were used for measuring SSF and TSF to the nearest millimeter. SSF was measured about one centimeter below the tip of the inferior angle of the right scapula, at an angle of about 45° to the vertical. TSF was measured over the midpoint of the muscle belly, midway between the olecranon, and the tip of the acromion of the right upper arm, with the upper arm hanging vertically (Durnin and Rahaman 1967).

Age- and sex-specific trends for BMI, SSF, and TSF were investigated in rural and urban communities during the past three decades, from 1976 to 2007.

Blood was drawn from seated participants into a plain, siliconized glass tube followed by separation of the serum. Fasting was not required. Serum glucose was measured with the cupric-neocuproine method between 1976 and September 1986 and with the hexokinase method, thereafter. Glucose values (mmol/L) obtained using the first method were adjusted with the formula: 0.047 × (glucose concentration in mg/dL) - 0.541, as we reported previously (Iso et al. 2004).

Serum total cholesterol was measured at the laboratory of the Osaka Medical Center for Health Science and Promotion, an international member of the US National Cholesterol Reference Method Laboratory Network (Nakamura et al. 2003).

Systolic and diastolic blood pressures (SBPs and DBPs, Table 166.3) in the right arm were measured by trained physicians using standard mercury sphygmomanometers, based on the unified epidemiological methods (Kirkendall et al. 1980; Shimamoto et al. 1989). The participants were seated and had rested for 5 min prior to the blood-pressure measurements.

This study described age- and sex-specific mean values and sex-specific age-adjusted means of BMI, SSF, and TSF, and sex-specific Spearman correlations of BMI, SSF, and TSF with cardiovascular risk factors, such as SBP, DBP, serum total cholesterol and glucose. These calculations were performed for every survey period for participants in both rural and urban communities. The correlations between these indices and serum glucose levels were also calculated but only in fasting (time after meal >=8 h) samples. For 32% of the participants, fasting serum glucose data were available. All analyses were conducted with the SAS System for Windows (version 9.1; SAS Inc., Cary, NC). All p-values for statistical tests were two tailed, and values of <0.05 were regarded as statistically significant.

166.3 Trend for BMI, SSF, and TSF

Tables 166.4–166.6 show age- and sex-specific trends for mean values of BMI, SSF, and TSF in rural and urban communities. Mean BMI did not change from 1976–1979 to 1984–1987 and increased thereafter for men of each age group in both rural and urban communities (Table 166.4 and Fig. 166.1). For men aged 40–79, age-adjusted mean BMI was 22.9 kg/m^2 in 1976–1979, 22.9 kg/m^2 in 1984–1987, and 23.9 kg/m^2 in 2004–2007 in the rural community, and the corresponding values for the urban community were 22.4, 22.6, and 23.9.

There were no remarkable changes in BMI levels for women of all age groups except for rural women aged 40–49 and urban women aged 40–59 whose mean BMI declined gradually over time.

Table 166.2 Age- and sex-specific numbers of participants with measurement of body mass index (BMI) and skinfold thickness (SF) in rural and urban communities between 1974–1976 and 2004–2007

Age- and sex-specific numbers of participants were shown with measurements of body mass index (*BMI*), subscapular skinfold thickness (*SSF*), and triceps skinfold thickness (*TSF*) in rural and urban communities. The earliest individual data was used within each term of individuals who participated in the surveys

Table 166.3 Key facts of systolic and diastolic blood pressures

1. Systolic blood pressure is the highest arterial blood pressure by systole of the left ventricle of the heart
2. Diastolic blood pressure is the lowest arterial blood pressure during diastole of the heart
3. Higher blood pressure levels cause higher risk of stroke and coronary heart disease
4. CIRCS showed the shift of stroke burden from severe/moderate hypertension to mild hypertension
5. The early management of hypertension and primary prevention of high blood pressures have become important for the prevention of stroke

This table lists the key facts of systolic and diastolic blood pressures relating to cardiovascular disease

Mean SSF did not change from 1976–1979 to 1984–1987 and increased thereafter for both men and women of every age group in both rural and urban communities, except for urban women aged 40–59 whose mean SSF did not change materially over time (Table 166.5 and Fig. 166.2). For men aged 40–79, age-adjusted mean SSF was 11.4 mm in 1976–1979, 11.2 mm in 1984–1987, and 15.7 mm in 2004–2007 in the rural community and 13.7, 12.9, and 16.2 mm in the urban community. The corresponding mean SSF for women aged 40–79 was 17.5, 18.5, and 22.3 mm in the rural community and 18.6, 18.3, and 19.2 mm in the urban community. The increase in mean SSF was thus more evident for rural than for urban women.

Mean TSF did not change from 1976–1979 to 1984–1987 and increased thereafter for men and women of every age group in both rural and urban communities, except for urban women aged 40–59 whose mean TSF did not change materially over time (Table 166.6 and Fig. 166.3). For men aged 40–79, age-adjusted mean TSF was 6.6 mm in 1976–1979, 7.1 mm in 1984–1987, and 8.8 mm in 2004–2007 in the rural community and 8.5, 7.7, and 10.0 mm in the urban community. The corresponding mean TSF for women aged 40–79 was 15.1, 16.0, and 19.5 mm in the rural community, and 17.5, 16.0, and 18.3 mm in the urban community.

As mentioned earlier, in both a rural and an urban Japanese community, mean BMI in men of all age groups in the 40–79-year age bracket showed an increasing trend between the 1980s and the early 2000s. For women, however, there was no remarkable change in mean BMI, except for an actual decline in mean BMI for middle-aged rural and urban women. These BMI trends were generally comparable with national trends, according to the Japan National Nutrition and Health Survey (Ministry of Health, Labour and welfare 2009).

Mean SSF and TSF levels increased between the 1980s and early 2000s for men and women of all age groups in both the rural and urban community. This increasing trend was more evident for rural than for urban women. In Japan, there have been major changes in lifestyles since the 1960s, as a result of westernization along with socioeconomic development. Total energy intake has declined consistently since the 1970s mainly because of a reduction in carbohydrate intake, whereas fat intake increased from the 1960s to the 1970s but reached a plateaue thereafter. As a result, fat intake as a percent of energy has increased from the 1960s to the 1990s. The increase in mean SSF and TSF for both men and women may thus be attributable to this increase in fat intake as a percent of energy and to a decline in physical activity due to motorization and/or mechanization.

The increase or stabilization in mean SSF and TSF in spite of the declining trend for mean BMI among middle-aged women is an interesting phenomenon. It may reflect a reduction in muscle mass and a relative increase in body fat, probably due to the reduction in physical activity for both rural and urban women aged 60–79 years, that is, mostly postmenopausal women. The increase in mean SSF and TSF and in SSF in particular was more pronounced when compared with that for middle-aged women, but mean BMI remained stable or increased slightly. This phenomenon may be partly due to the depletion of estrogen hormone, which leads to changes in body fat distribution (Folsom et al. 1993).

Mean body mass index (BMI) did not change from 1976–1979 to 1984–1987 and increased thereafter for men of each age group in both rural and urban communities. There were no remarkable changes in BMI levels for women of all age groups, except for rural women aged 40–49 and urban women aged 40–59 whose mean BMI declined gradually over time

SD standard deviation, *SE* standard error

Mean triceps skinfold thickness (TSF) did not change from 1976–1979 to 1984–1987 and increased thereafter for men and women of every age group in both rural and urban communities, except for urban women aged 40–59 whose mean TSF did not change materially over time

SD standard deviation; *SE* standard error

[a]Age-adjusted

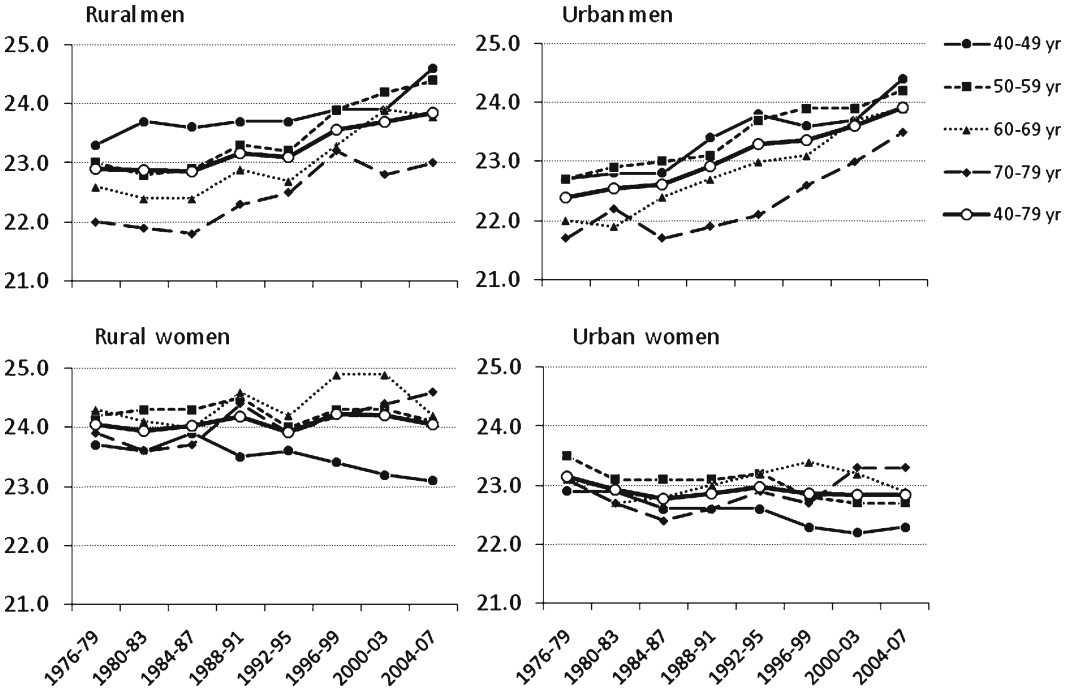

Fig. 166.1 Age- and sex-specific trends for body mass index (kg/m^2) in rural and urban communities. Mean body mass index (BMI) did not change from 1976–1979 to 1984–1987 and increased thereafter for men of each age group in both rural and urban communities. There were no remarkable changes in BMI levels for women of all age groups, except for rural women aged 40–49 and urban women aged 40–59 whose mean BMI declined gradually over time

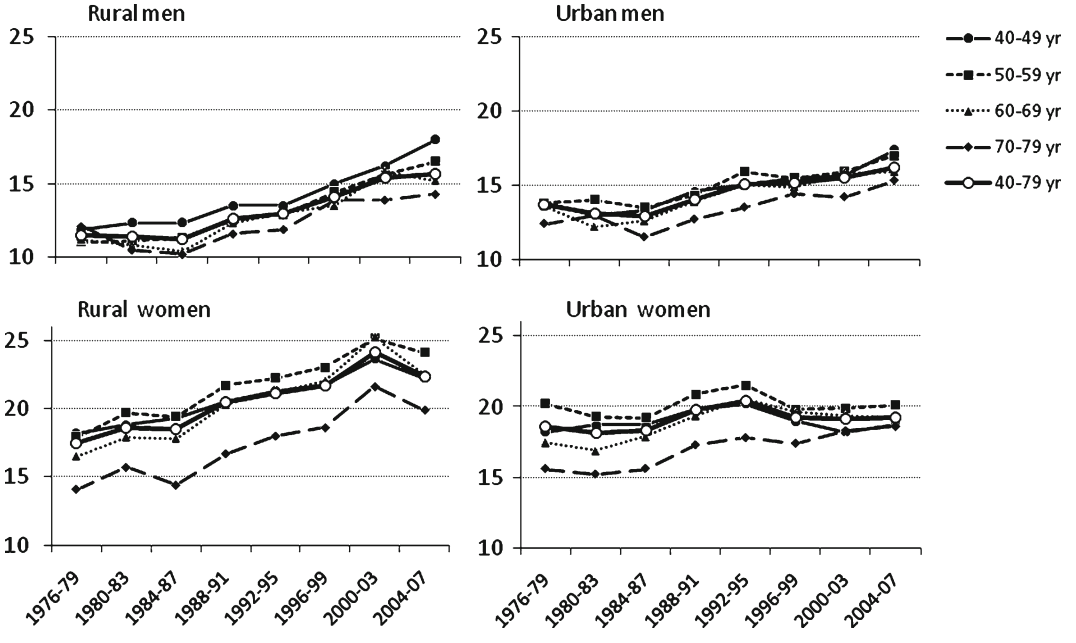

Fig. 166.2 Age- and sex-specific trends for subscapular skinfold thickness (mm) in rural and urban communities. Mean subscapular skinfold thickness (SSF) did not change from 1976–1979 to 1984–1987 and increased thereafter for both men and women of every age group in both rural and urban communities, except for urban women aged 40–59 whose mean SSF did not change materially over time

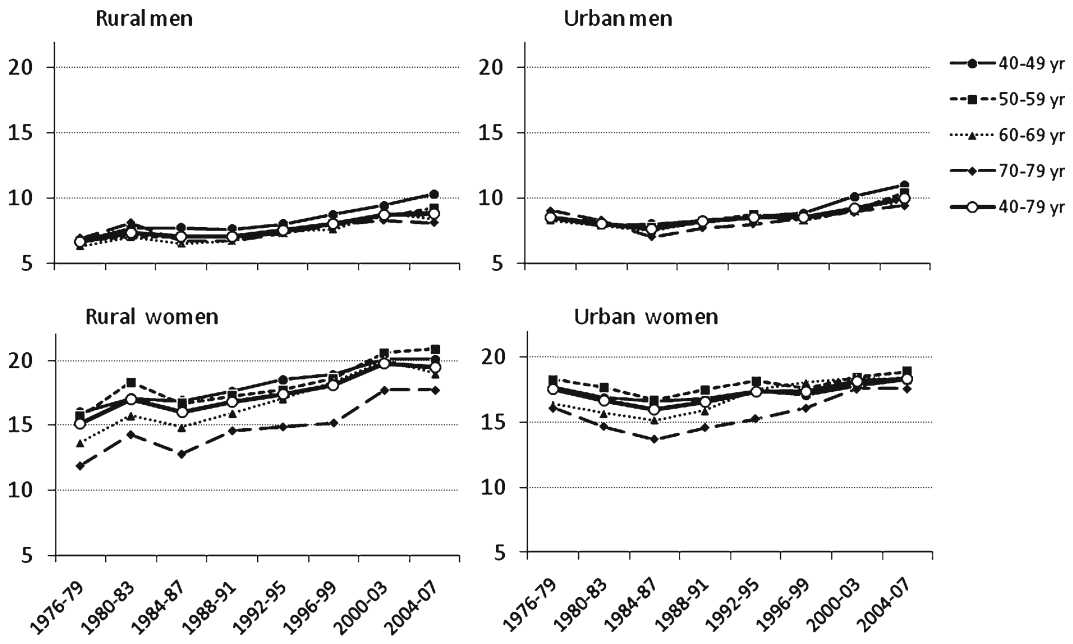

Fig. 166.3 Age- and sex-specific trends for triceps skinfold thickness (mm) in rural and urban communities. Mean triceps skinfold thickness (TSF) did not change from 1976–1979 to 1984–1987 and increased thereafter for men and women of every age group in both rural and urban communities, except for urban women aged 40–59 whose mean TSF did not change materially over time

166.4 Correlations of BMI, SSF, and TSF with Cardiovascular Risk Factors

Sex-specific Spearman correlations of BMI, SSF, and TSF with systolic blood pressure, diastolic blood pressure, serum total cholesterol, and serum glucose for men and women aged 40–79 in rural and urban communities are shown in Table 166.7. BMI, SSF, and TSF correlated positively with systolic and diastolic blood pressure and serum total cholesterol for both men and women in rural and urban communities in every survey period. BMI and SSF appeared to correlate positively with serum glucose levels for rural men and women and for urban women from 1992–1995, when means of these indices for the general population started to increase. Correlations between TSF and serum glucose levels for either men or women were weak or non-existent in every survey period. When we limited the analysis to fasting samples, the trends for the correlations of BMI, SSF, and TSF with serum glucose levels were essentially the same, but they became stronger than for total subjects.

Putting it all together, consistent correlations of BMI, SSF, and TSF with systolic and diastolic blood pressures and serum total cholesterol for both men and women aged 40–79 in the rural and as well as in the urban community throughout almost the entire study period. The correlations of BMI, SSF, and TSF with serum glucose were weak between 1976–1979 and 1988–1991, but increased thereafter for rural men and women and for urban women.

Skinfold thickness measurement is useful to obtain a clearer picture of long-term trends for body-fat distribution which would be difficult to obtain with BMI measurement only. An accumulation of central body fat, represented by an increase in mean SSF, may increase the likelihood of abnormal glucose levels in the general population.

Table 166.7 Sex–specific Spearman correlations of body mass index (BMI) and subscapular and triceps skinfold thickness (SSF and TSF) with cardiovascular risk factors among men and women aged 40–79 in rural and urban communities

Body mass index (BMI) and subscapular and triceps skinfold thickness (SSF and TSF) correlated positively with systolic and diastolic blood pressures and serum total cholesterol for both men and women in rural and urban communities in every survey period. BMI and SSF appeared to correlate positively with serum glucose levels for rural men and women, and for urban women from 1992–1995

*$p < 0.05$; †$p < 0.01$, ‡$p < 0.001$

SBP systolic blood pressure; *DBP* diastolic blood pressure; *TC* serum total cholesterol; *GL* serum glucose; *FGL* fasting serum glucose

Summary Points

- Mean body mass index (BMI) increased for both rural and urban men between the 1980s and early 2000s.
- Mean BMI of either rural or urban women did not change, except for a decline in middle-aged women.
- Subscapular skinfold thickness (SSF) increased consistently for both men and women in rural and urban communities between the 1980s and early 2000s.
- The correlation between SSF and serum glucose started to become stronger in the 1990s.
- Measurement of skinfold thickness is useful for identifying long-term trends for fat distribution and its influence on cardiovascular risk factors.

Acknowledgements The authors wish to thank Emeritus Professors Yoshio Komachi and Takashi Shimamoto (University of Tsukuba), Dr. Minoru Iida (Osaka Medical Center for Health Science and Promotion), Late Emeritus Professor Masamitsu Konishi (Ehime University School of Medicine), Professor Yoshihiko Naito (Mukogawa Women's University), Dr. Tomoko Sankai (University of Tsukuba) and Professor Tomonori Okamura (Keio University) for their support for long-term cohort studies. We also thank the research staff of the Osaka Medical Center for Health Science and Promotion and health professionals in the survey communities.

Chapter 167
Socioeconomic Status, Anthropometric Status and Developmental Outcomes of East-African Children

Amina Abubakar and Fons van de Vijver

Abstract The aim of the current review is to critically evaluate existing evidence on the relationship between socio-economic status, anthropometry and child development. We observed that socio-economic variables (e.g. maternal and paternal educational level, occupation and income, and wealth index, which is a composite of various wealth indicators) were positively associated with anthropometric status. Additionally, it was observed that children who had poor anthropometric status (i.e. stunted or underweight) performed more poorly on measures of child development compared to peers with proper growth. Relationships between SES and developmental outcomes are consistently found; with some studies reporting a direct and others an indirect relationship. We propose a mediation model in which SES has an influence on developmental outcomes through various more proximal variables, such as maternal caring capacity, anthropometric status, and ill-health. Potential pathways of the influence of SES on anthropometric status include inadequate food intake, ill health and sub-optimal parenting behaviour. Anthropometric status also influences developmental outcomes through multiple pathways, such as potential brain damage and lowered activity levels. It is concluded that parental SES influences child's physical growth which in turn affects their developmental outcomes. Implementing intervention measures to improve the anthropometric status of children living in poverty can be expected to improve developmental outcomes.

Poor physical growth is rampant in developing countries where approximately 27% and 32% of children under the age of 5 years are underweight and stunted, respectively (Stephenson et al. 2000). Given the high human cost (mortality, morbidity and disability) associated with malnutrition, tackling this problem has been a key aspect of the first millennium development goal (MDG). One of the targets of the first MDG was to reduce malnutrition by at least half from their 1990s proportion, by 2015 (De Onis et al. 2004). Unfortunately, a combination of several factors, such as slow economic growth and the spread of human immunodeficiency virus (HIV), have challenged the development of East-African countries (defined here as the members of the East African Community: Tanzania, Kenya, Uganda, Rwanda and Burundi) and they are unlikely to meet their millennium targets. In a review of progress, it was noted that prevalence rates of underweight children have either stagnated or decreased very slowly in all East-African countries (De Onis et al. 2004); Fig. 167.1 presents relevant summary statistics from different countries in East Africa.

	Kenya	Rwanda	Uganda	Tanzania
Underweight (percentage) 1990	17,6	24,3	21,5	25,3
Underweight (percentage) 2000	16,5	18	16,4	16,7

Underweight (percentage) 1990 Underweight (percentage) 2000

Fig. 167.1 Prevalence of underweight in East-African countries. The prevalence of underweight children in four East-African countries is presented, based on data collected in 1990 and 2000. Burundi has only data for 2000, hence its exclusion. The figure was generated based on data extracted from the WHO database on child growth and malnutrition

Table 167.1 Key features of developmental outcomes and their assessment

1. Developmental outcomes as referred to in this chapter entail several interdependent domains of child development, including sensorimotor, cognitive and social–emotional outcomes
2. Developmental outcomes can be assessed by three main approaches: (a) naturalistic observations; (b) standardised assessments that involve child participation in a variety of tasks and (c) assessment made through parent or caregiver reports
3. Approaches to and the complexity of the assessment will largely be determined by a child's age

A definition of developmental outcomes is provided alongside a discussion on how developmental outcomes can be assessed and how the child's age influences the type and complexity of developmental assessment

Poverty and its co-occurring factors place children at an elevated risk of experiencing growth failure (Walka and Pollitt 2000), with poor developmental and cognitive outcomes (Walker et al. 2007). Furthermore, children who are experiencing growth failure have been found to perform poorly on measures of developmental and cognitive outcomes (Grantham-Mcgregor 2002), independent of their SES. The current review aims at critically evaluating the existing evidence from East Africa on the relationship (and possibly, pathways) between socioeconomic indicators, anthropometrics status and developmental outcomes (Table 167.1 presents a brief description of developmental outcomes and its assessment). Specifically, the review aims at answering the following research questions:

1. What is the relationship between SES and anthropometric status among East-African children?
2. What are the relationships between SES and anthropometric status and between SES and developmental outcomes among East-African children?
3. Does existing evidence from East Africa provide support for the pathways suggested in the literature?

167.1 SES and Anthropometric Status

SES has traditionally been and still remains a subject of great interest in the social sciences; yet, there is no consensus on how it should be conceptualised and measured (Bradley and Corwyn 2002). In Europe and North America, the most common approach to assessing SES involves developing an index based on parental educational levels, income and/or occupation. However, numerous challenges in developing countries, such as limited variability in income, difficulties in estimating income in subsistence-based economies and limited variability in educational level or massive differences in educational quality across schools (challenging the adequacy of years of schooling as a useful measure) have rendered Western indicators inadequate. Several alternative approaches have been proposed, including the evaluation of assets owned by the family. Our review employs various SES indicators. Table 167.2 presents a summary of identified studies on SES and anthropometric status, highlighting some of the key findings in each study.

Maternal and paternal educational levels have been associated with anthropometric status in various studies in East Africa. Children of mothers and fathers with low educational status were more likely to be stunted or underweight compared to those whose parents had high educational levels (Kikafunda and Tumwine 2006). Vella et al. (1995) investigated the effects of parental education; in a stepwise regression, they found that parental education was associated with anthropometric outcomes. Fathers' education was positively associated with weight-for-age z-scores (WAZ) ($\beta = .03$, $p < 0.01$) and weight-for-height z-scores (WHZ) ($\beta = 0.02$, $p < 0.05$), while maternal education was positively associated with height-for-age (HAZ) ($\beta = 0.04$, $p < 0.05$). Several studies have consistently reported the influence of parental characteristics on children's anthropometric status, although

Table 167.2 Summary of studies and results from East Africa

Author	Country	Sample size (n)	Age range	Prevalence	Main findings
Abubakar (2008)	Kenya	204	24–35 months	19.6%[a] 49.0%[b]	Maternal education and a wealth Index were both associated with WAZ and HAZ
Bloss (2004)	Kenya	175	0–60 months	30.0%[a] 47.0%[b]	Mothers' education and family size were associated with poor nutritional outcomes
Chesire et al. (2008)	Kenya	384	6–12 years	14.9%[a] 30.2%[b]	Anthropometric status was predicted by monthly household income and food prices among other factors
Kikafunda et al. (2006)	Uganda	41	3–6 years	29.3%[a] 46.0%[b]	Fathers' education predicted anthropometric status, with better educated parents having children with better outcomes. Children from higher-income families had lower prevalence of growth restriction
Kikafunda et al. (1998)	Uganda	261	0–36 months	24.1%[a] 23.8%[b]	Rural residence, lack of access to clean water, poor personal hygiene, low SES and low maternal education predicted growth restriction
Kogi-Makau (1992)	Kenya	1,042	0–19 years	62%[c]	Amount of land owned, size of the household and monthly expenditure on food predicted anthropometric status
Kulwa et al. (2006)	Tanzania	100	6–24 months	22%[a] 43%[b]	Numbers of hours mothers worked outside the house negatively predicted child's anthropometric status
Nyaruhucha (2006)	Tanzania	250	0–59 months	31.0%[a]	Maternal education predicted the relative risk of being underweight
Ogden (1993)	Rwanda	965	0–59 months	16%[a] 43.8%[b]	Poor anthropometric status was associated with maternal education and female-headed households
Tumwine (2002)	Uganda	932	6–59 months	17.0%[a] 49.8%[b]	Low maternal and paternal education significantly increased the risk of growth restriction
Vella et al. (1992)	Uganda	1,178	0–59 months	24.8%[a] 42.4%[b]	Poverty, low parental education and lack of sanitation were found to be significant predictors of poor anthropometric status

Details on studies from East Africa investigating the relationship between socioeconomic indicators and anthropometry are presented alongside key findings from these studies

[a] Prevalence of underweight

[b] Prevalence of stunting

[c] Presents the number of households with at least one stunted member

different studies have shown slightly differing patterns of relationships. For instance, Kikafunda and Tumwine (2006) reported that neither maternal age nor maternal education had a significant association with WAZ and HAZ. The education of the father, however, had a significant ($p = 0.017$) association with WAZ; children whose fathers had lower than tertiary-level education showed WAZ values below the median.

Other parental characteristics, such as marital status (Nyaruhucha et al. 2006), occupational status (Kamau-Thuita et al. 2002) and income (Bhargava 2000), have also been found to influence anthropometric status. The influences of socioeconomic factors have also been described at the household level. Kogi-Makau (1992), working among a population living in a semi-arid area in Kenya, found that anthropometric status was predicted by household characteristics, such as household size, size of owned land, labour shortage and monthly cash food expenditure.

Assessing family assets has been widely used to evaluate the SES of families in East-African studies. These studies have consistently reported a positive association between children's anthropometric status and family assets. Ownership of land and types of vegetables and other foods harvested are also positively associated with anthropometric status. Quality of housing, access to clean water and access to adequate, clean latrines have also been positively associated with anthropometric status in all East-African countries (Vella et al. 1995; Bloss et al. 2004; Abubakar et al. 2008).

In summary, socioeconomic variables, whether measured as parental education, parental occupational status, family assets or living conditions, have been found to consistently predict childhood outcomes in East Africa. Regardless of the method by which SES was estimated, its influence on child's anthropometric status was significant and consistent in that children from less advantaged home environments were more likely to experience growth restriction (i.e. stunting and being underweight). Yet, in several cases, there were differences in the factors that predicted being underweight and those that predicted stunting. Variation in results could also be expected, given that the various studies had different methodologies. This variation arises because of the use of different, not interchangeable, measures of SES and, conversely, the use of both HAZ and WAZ as indicators of anthropometric status. HAZ and WAZ represent different forms of nutritional deprivation and potentially different aetiology (Frongillo et al. 1997); HAZ scores reflect chronic malnutrition, while WAZ scores reflect acute malnutrition.

167.2 SES, Anthropometric Status and Developmental Outcomes

Compared to the number of studies investigating the relationship between anthropometric status and SES, fewer studies have addressed the relationship between both anthropometric status and socioeconomic variables and psychological outcomes (Table 167.3 presents a description of some of the developmental and cognitive measures used in the studies reviewed here). In a series of studies in Embu, Kenya, the relationship between SES, anthropometric status and cognitive abilities among a largely lower-middle-class community has been investigated over a long period of time (Sigman et al. 1989a, b, 1991; Whaley et al. 1998). The authors evaluated the manner in which anthropometric status, family characteristics and toddler characteristics influence performance on cognitive tasks at 5 years of age. Anthropometric measures taken at toddlerhood influenced performance at the initial assessment (weight: $r(81) = 0.28$, $p < 0.05$; height: $r(81) = 0.21$, *ns*) and correlated with cognitive scores at 30 months of age (weight: $r(84) = 0.25$, $p < 0.05$; height: $r(81) = 0.23$, $p < 0.05$) and at 5 years. When the same sample was assessed at school age (age 7–8 years), cognitive scores were significantly related to SES and anthropometric status (Sigman et al. 1989a). Bhargava et al. (2005) collected data from Tanzanian schoolchildren aged 6–9 years. Using regression, the children's cognitive test scores (composite score of digit span, matrices, arithmetic and word meaning) were predicted by SES and income. In summary, the results obtained in these studies indicate that children with poor anthropometric status came from poorer homes and had lower scores in cognitive tasks.

In a study carried out among preschool children in two low-income settings in Kenya, we set out to investigate if anthropometric status mediates the relationship between SES and psychomotor outcomes (Abubakar et al. 2008). The study involved 204 children aged 24–35 months and two indicators of SES (an index of wealth and maternal education) were used. The wealth-index measure was developed using an adapted version of the Kenya Demographic and Health Survey (KDHS) SES measure (Central Bureau of Statistics 2004), which lists features, such as ownership of land, quality of housing and electric goods among others. Maternal education was operationalised as the number of years of formal schooling the mother attended. Developmental outcomes were assessed using a

Table 167.3 Key features of developmental and cognitive tests used in studies in East Africa

Name of the test	Purpose	Target age group	How it is administered
Raven's Progressive Matrices	Evaluate cognitive abilities by assessing abstract reasoning	Several versions appropriate for both children and adults	This is a multiple-choice test in which an individual is presented with a picture with a missing part and an option of four choices to complete the missing portions
Bayley Infant Development Scales	Evaluate mental, sensorimotor and behavioural development of children	0–42 months	This test involves the exposure of a child in a standardised manner to a series of tasks aimed at eliciting their developmental functioning in a several domains including motor, language, and memory
Kilifi Developmental Inventory	This is a locally developed and standardised measure of psychomotor functioning	6–35 months	This test involves the exposure of a child in a standardised manner to a series of tasks aimed at eliciting their developmental functioning in two main domains: gross-motor and fine-motor functioning

The key features of psychological measures used in the studies discussed here are presented. These include the purpose of the assessment, target age groups and how the measures are administered.

locally developed measure of psychomotor functioning, the Kilifi Developmental Inventory (KDI). We found that both SES indicators were positively associated with HAZ and WAZ, which, in turn, were associated with psychomotor development. Using path-analytic procedures, we fitted a model which indicated that the influence of SES on psychomotor outcomes in this population was fully mediated by the influences of anthropometric status on psychomotor development. We evaluated the influence of being underweight and being stunted separately and observed that being stunted was the stronger predictor of psychomotor outcome. In younger children ($N = 95$, age 2–10 months) from Kilifi, Kenya, we found similar patterns of results across different developmental domains including motor, language and personal–social development (see Fig. 167.2). The results from this younger population indicate that there is a robust relationship between SES, anthropometric status and developmental outcome.

Relatively few studies have examined the relationship between SES, anthropometric status and developmental outcomes. However, those studies that have addressed the issue have consistently found that anthropometric status is associated with developmental outcomes. Children with better physical growth show better developmental outcomes. These East-African findings are in agreement with those from other regions, as a similar pattern of results has been observed in two studies in Ethiopia. Among children aged 16–42 months, SES was found to be significantly associated with cognitive test score; moreover, anthropometric status predicted scores on the Bayley Scales of Infant Development (BSID) (Aboud and Alemu 1995). In this study, SES was not strongly related to the mental scale, but it was related to motor skills. Drewett et al. (2001) did not report correlations between SES and anthropometric status. However, they did find that anthropometric status influenced performance on the BSID and that SES influenced performance on the mental scales of the BSID but not on the psychomotor scales. Pollit and colleagues showed that among malnourished Indonesian children, SES was associated with anthropometric status which itself was associated with motor skills (Walka and Pollitt 2000). Results by Abubakar et al. (2008) indicate that the effects of SES on psychomotor outcome are fully mediated by anthropometric status. If this finding could be replicated across different studies, intervention efforts would focus on the mediating variables, anthropometric status, which is easier to influence than SES and the massive poverty burden.

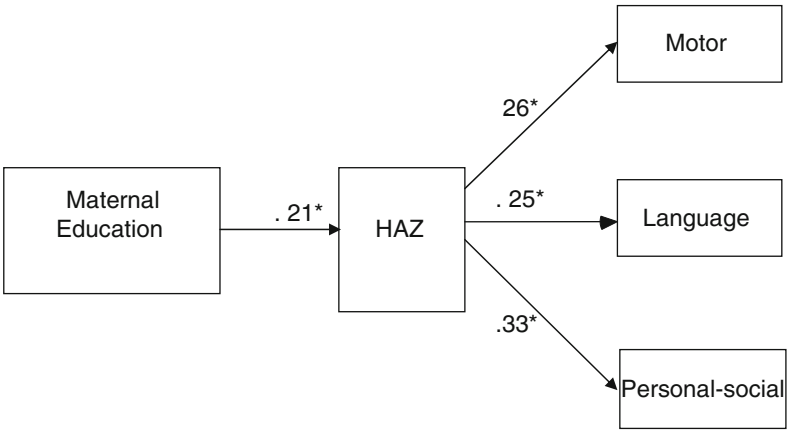

Fig. 167.2 Results of path analysis of the relationship between SES, anthropometry and developmental outcomes. The intervening role of anthropometric status on the relation between socioeconomic status (SES- maternal education) and developmental outcomes is shown in this figure. The results show that the model presented here fits properly with the data. The fit statistics: χ^2 (1, $N = 95$) = 3.43, $p = 0.32$, χ^2/df = 1.15, Tucker Lewis index = 0.97, root mean square error of approximation = 0.04, goodness-of-fit index = 0.98, and adjusted goodness-of-fit index = 0.92. The numbers presented are standardised path coefficients. Higher maternal education positively predicts height-for-age, which indicates that children from better educated mothers had a better anthropometric status. Height-for-age positively predicts all developmental outcomes. * $p < 0.05$

167.3 Potential Pathways of the Influences of SES on Anthropometric Status and Child Development

The statistical links that have been observed between SES, anthropometric status and developmental outcomes require a conceptual explanation. There are methodological problems in disentangling the interrelated causes of growth failure and impaired developmental outcomes; as a consequence, it is difficult to ascertain a causal link between poverty, growth and outcome. The aim of the present section is to present an overview of the existing evidence regarding the link between the three variables. The presentation and subsequent discussion are guided by the United Nations Children's Fund (UNICEF) extended framework (developed by UNICEF in 1990) on causes and consequences of malnutrition. The aim of this framework was to provide a set of guiding principles on how scientists and practitioners can conceptualise and approach intervention in the area of malnutrition. The main principle of the framework is that poor nutritional status is the manifestation of a complex, multilevel chain of causes. According to the framework, these causes can be placed under three strata:

1. Immediate causes: These causes manifest themselves at the individual level in the forms of ill health and inadequate nutrient intake.
2. Underlying causes: They manifest themselves at the household level. Three factors have been classified in this category: lack of finances, inadequate care for mothers and children (care here refers to provision of time, attention and support to meet the needs of both mother and child) and lack of access to health services.
3. Basic causes: These manifest themselves at the community and national level. Basic causes of malnutrition largely entail issues related to access to potential resources.

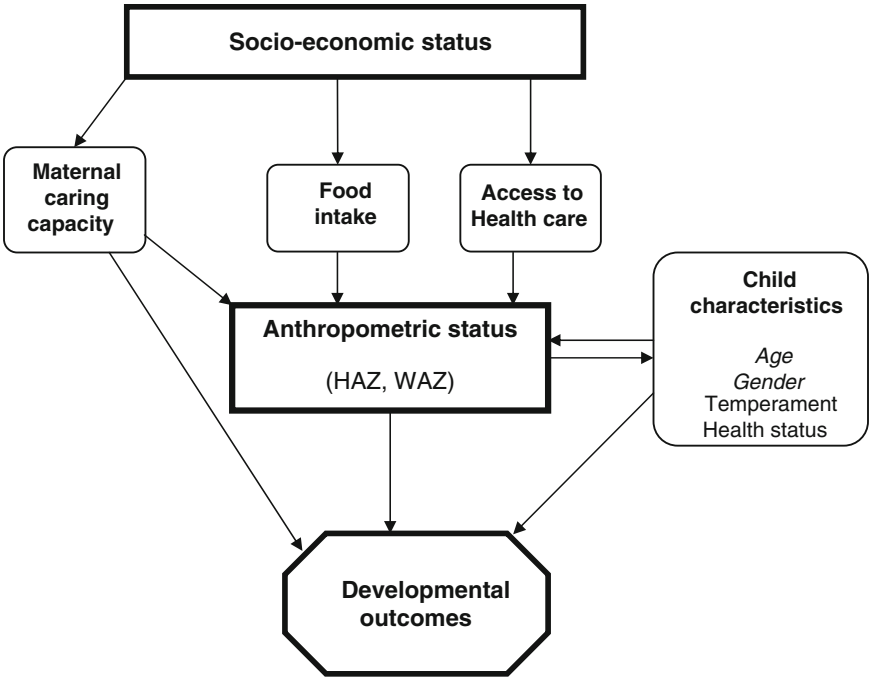

Fig. 167.3 Probable pathways regarding the relationship between SES, anthropometric status and developmental outcomes. The hypothesised potential pathways by which SES effects are transmitted to developmental outcomes through anthropometry are presented. As can be observed, this is a complex relationship that goes through several indirect pathways (maternal caring capacity, food intake and access to health). The relationships are further complicated by the fact that some of these factors, such as maternal caring capacity, may have a direct, independent influence on developmental outcomes. A bi-directional relationship is indicated for anthropometry and child characteristics. This bi-directionality is expected to hold true of all child characteristics, with the exception of gender and age; that is why they are italicised

Recently, Wachs (2008) proposed an extension of the UNICEF model with a view to providing a more detailed picture of the mechanisms by which underlying factors may contribute to poor anthropometric status. Specifically, the presentation aimed at highlighting the role of maternal contributions and child characteristics, such as temperament, age and gender, in the discussion about causes of malnutrition. The UNICEF framework and the proposed extension by Wachs guide the presentation here. The next section reviews studies which provide evidence or suggestions on pathways that link the observed relationship between anthropometric status, SES and developmental outcomes.

The numerous studies discussed in the subsection on SES and anthropometric status all underscore the fact that poverty is a major underlying cause in the high rates of malnutrition observed across East-African countries. Inadequate social, economic and human resources all seem to contribute to growth restriction. There is ample research evidence to show that SES indicators are pathways to poor anthropometric status. In Fig. 167.3, we present a simplified model of our hypothesised potential pathways from poverty to impaired developmental outcomes via anthropometric status. In the following subsections, we evaluate evidence for our model.

Limited material resources limit a family's capability to acquire food, which, in turn, limits a child's dietary intake. Studies in Kenya by Sigman et al. (1991, 1989a, b) indicate that families with limited economic resources have inadequate dietary intake, especially of animal proteins. This deficiency in intake of animal protein, which is not compensated for by intake of similar nutrients from

other sources, has been observed to contribute to both poor anthropometric and developmental outcomes, because of the absence of vital micro- and macronutrients for physical and cognitive development. Moreover, the lack of material resources contributes to inadequate access to health services and a healthy environment, which may also contribute to poor growth and development due to a lack of timely preventive and interventional health measures.

The contribution of maternal caring behaviour to a child's anthropometric status and cognitive abilities has been addressed in studies in East Africa. In a study among toddlers aged 18–30 months, it was observed that children who experienced a less supportive home environment were more frequently ill, which, in turn, led to poorer anthropometric and developmental outcomes. Follow-up data indicated that, at 5 years of age, children with relatively poor outcomes during their toddler days still had relatively poor cognitive outcomes (Sigman et al. 1991; Whaley et al. 1998). The negative effects reported in this study seemed to be moderated by gender, with girls showing worse outcomes. Girls who were lighter and shorter were more likely to experience more days of morbidity, to show poorer cognitive outcomes and to come from homes with mothers who did not provide enough stimulation. Results on the contribution of maternal care-giving behaviour on cognitive and anthropometric outcomes are consistent with what has been observed in Kilifi, Kenya (Abubakar 2008). Scores on a measure of quality and quantity of stimulation received at home (Bradley and Corwyn 1996) correlated positively with HAZ, WAZ and cognitive outcomes. Additionally, there was also a significant, positive relationship between SES and stimulation provided at home. Bhargava and Fox-Kean (2003) evaluated how different maternal characteristics may influence food and calorie intake. Although maternal education did not predict calorie intake, maternal scores on an IQ test had a positive influence on intake (and hence, nutritional and anthropometric status). These findings are in line with Wachs' hypothesis on the saliency of maternal characteristics as a pathway to poor outcome.

Wachs proposes the inclusion of four child characteristics in the conceptual model on undernutrition: health, age, gender and temperament. Children's *health status* has been associated with compromised anthropometric status across different studies in East Africa. Illnesses, such as HIV, malaria, parasitic infections and diarrhoeal disease, have all been associated with poor anthropometric status (Stoltzfus et al. 1997; Nyakeriga et al. 2004; Abubakar et al. 2009; Olney et al. 2009). The relationship between ill health and poor anthropometric status is complex. Existing evidence points to the increased risk for growth failure in most of the common childhood illnesses (e.g., malaria, HIV and parasitic infections); however, it is difficult to ascertain a causal link (see section on disease for further elaboration). Several studies have observed that a *child's age is* a significant, positive predictor of both stunting and being underweight. The prevalence of underweight and stunted children starts to dramatically increase at the age of 3–6 months (which coincides with the inception of weaning) (Stoltzfus et al. 1997; Kwena et al. 2003; Bloss et al. 2004) and seems to peak at between 12 and 24 months (see Fig. 167.4). The role of *gender* as a potential risk factor for poor anthropometric status has been highlighted. Based on data from the global database on malnutrition, we present a summary of rates of prevalence of underweight among boys and girls aged 0–60 months (see Fig. 167.5). The data indicates that boys had higher prevalence rates of underweight than girls in all East-African countries, with the exception of Burundi where the rates for both genders were similar.

Of the four proposed child characteristics likely to impact on nutritional status, the least studied is *temperament*, though there have already been early studies on the role of temperament in growth and development of East-African children. Among the Maasai of Kenya (De Vries 1994, 1999), it was observed that fussy children had better growth outcomes and survived longer compared to those who were mostly quiet. It was hypothesised that in conditions of extreme poverty and need, fussy children forced caregivers to pay more attention to their needs, which increased and improved their chances for survival. The opposite effect was observed among the Digos of Kenya, where children with 'difficult temperaments' were less likely to thrive. These differential effects were attributed to

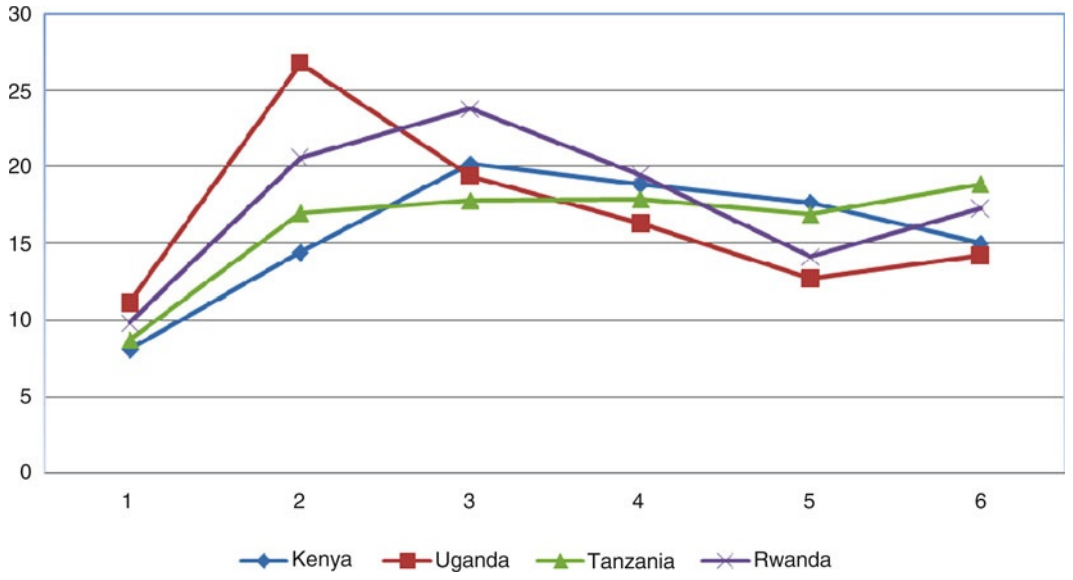

Fig. 167.4 Rates of underweight children by age group in different countries of East Africa. Children aged 0–5 months have the lowest rates of underweight, and then a drastic increase is seen in the next age group before stabilisation although not a return to the low rates observed in the first months of life. Key to different age groups: (*1*) 0–5 months of age, (*2*) 6–12 months, (*3*) 12–24 months, (*4*) 24–36 months, (*5*) 36–48 months and (*6*) 48–60 months. The figure was generated based on data extracted from the WHO database on child growth and malnutrition

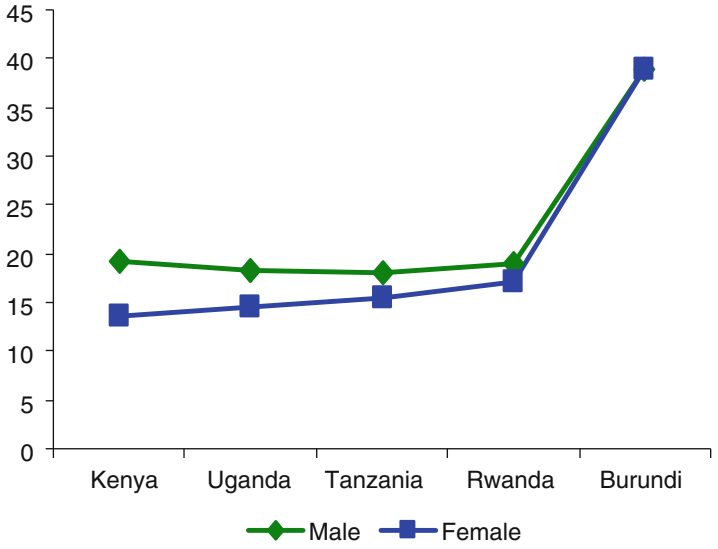

Fig. 167.5 Rates of malnutrition by gender in the five East-African countries**.** Other than in Burundi, boys are at an elevated risk of being underweight in all East-African countries. In the case of Burundi, the prevalence of underweight is similar for boys and girls. The figure was generated based on data extracted from the WHO database on child growth and malnutrition

the fact that how a child thrived could be related to the 'goodness of fit' between the child's characteristics and the environment.

Our review has produced consistent evidence for the existence of statistical associations between poverty/SES, anthropometric status and developmental outcomes. It is less clear, though, which developmental pathways underlie the statistical associations. We were not able to identify any East-African study, which aimed to identify pathways by which SES affects anthropometric status or anthropometric status influences cognition. However, using the UNICEF extended care model and Wachs' recent extension, we were able to collate existing evidence and illustrate some potential pathways to poor outcome in the undernourished East-African population. Our summary of potential pathways in the East-African data is consistent with existing literature from elsewhere, which shows that poverty (low SES) influences anthropometric status by limiting food intake, lowering maternal caring capacity and lowering child's general health. As a consequence, children are more susceptible to infections, and the negative influence of these infections on developmental outcomes is more likely, given the unfortunate accompanying lack of access to vital services (e.g., healthcare and clean water). How does anthropometric status influence cognitive outcomes? There are two potential pathways. The first is through damage to brain structure. Data from other regions of the world indicate that malnutrition is associated with structural and functional abnormalities in the brain. Malnutrition has been associated with reduced brain cells, damage to the hippocampus, delayed myelination and alteration in neurotransmitter systems, among others (Levitsky and Strupp 1995). The resulting brain damage may contribute to poor developmental or cognitive outcomes. Second, ill health may limit the degree to which children are able to get and attract stimulation and experience new things that contribute to their cognitive development.

167.4 SES, Common Diseases, Anthropometric Status and Developmental Outcome

Risk factors tend to cluster together. Children living in poverty are more likely to experience poor health compared to those from high socioeconomic backgrounds. Sub-Saharan Africa (SSA) is the poorest region of the world and many children tend to be exposed to multiple health risks. Not surprisingly, this part of the world carries a disproportionate portion of the global disease burden.

HIV has been associated with both poor anthropometric status and cognitive impairments. In a study carried out in Kilifi, Kenya, it was observed that HIV-infected children who had poor anthropometric status (i.e. underweight) performed significantly more poorly on measures of psychomotor development compared to HIV-exposed but uninfected peers without growth failure (Abubakar et al. 2009). In this rural population, anthropometric status provided an indicator to identify which HIV-positive children needed psychomotor monitoring and rehabilitation that are relatively cheap and easy to administer.

Various studies have shown that malaria, especially in its severe form, is detrimental to developmental and cognitive outcomes. Additionally, malaria has been associated with poor anthropometric status. In a sample of more than 1,862 children, it was observed that a higher proportion of stunted children had more malaria parasetemia (odds ratio = 1.98, $p < 0.001$), indicating that being stunted puts children at an elevated risk of malaria-related morbidity. SES and poor anthropometric status have been suggested as potential pathways explaining the poor neurocognitive outcomes of children surviving severe malaria; however, these have yet to be investigated (Kihara et al. 2006). Children with a heavy helminth infection load are at a higher risk of both poor anthropometric status and cognitive impairment. Jukes et al. (2002) reported that children with heavy worm infestation and

poor nutritional status suffered cognitive impairments. Olney et al. (2009) studied more than 800 children in Zanzibar to investigate the effects of malaria, anthropometric status and anaemia on developmental outcomes. Using structural equation modelling (SEM), Olney and colleagues examined the relationships between malaria, stunting, anaemia and child developmental outcome. It was found that children with higher malaria parasite densities had significantly lower Hb and HAZ. Moreover, HAZ was a significant, positive predictor of developmental outcome (motor activity and motor and language development). Additionally, children with higher Hb had higher motor development and activity scores. Malaria was directly and indirectly related to motor activity in the 10–14-month-old group [standardised total effects: -0.14; direct: -0.10 ($p = 0.015$) and indirect: -0.04]. It can be concluded that major health risks, such as HIV, malaria and anaemia, can contribute significantly to impaired developmental outcomes. The available evidence tentatively suggests that the influence of the disease on developmental outcomes can be both direct and indirect through the influence of the disease on anthropometric status.

167.5 Implication for Practice and Policy

Our review suggests that frequent anthropometric measurements and surveillance of children living in poverty can be used to identify children at risk of developmental or cognitive delay or impairments. The implementation of such a programme in resource-constrained countries would be feasible, given that those anthropometric measures are relatively cheap and easy to administer.

The relationship systematically found between anthropometric status and cognition implies that the implementation of combined nutritional and psychosocial intervention measures is likely to give the best results in terms of improving childhood cognitive outcomes. The value of combined programmes has been evaluated and confirmed in a series of studies in Jamaica (Grantham-Mcgregor et al. 1991; Walker et al. 2005). Although interventions aimed at reducing poverty levels are underway (and badly needed), implementing combined nutritional and psychosocial interventions could be a cheaper way of reducing developmental delays among children living in poverty.

167.6 Application to Other Areas of Health and Disease

Among children living in poverty, improved anthropometric status through combined nutritional and psychosocial intervention has been observed to lead to enhanced performance on developmental and cognitive tasks. Therefore, in diseases where anthropometry is negatively affected, similar intervention measures should be put in place to enhance both anthropometric and developmental status.

167.7 Practical Methods and Techniques

Issues in developmental assessments in East Africa

(a) There are numerous measures of cognitive, language and social–emotional functioning that are commercially available for children of all ages.
(b) Most of the available measures have been developed for and standardised for use in Europe and North America. However, the transfer of tests developed for Western populations to a non-Western

context is frequently accompanied by test bias (Greenfield 1997; Vijver 2002). This bias may arise from a lack of familiarity with the demands of taking formal psychological tests in non-Western children (Mulenga et al. 2001), poor translation of test items (Vijver 2002) and unfamiliarity with test material (Sigman et al. 1988; Sonke et al. 1999) among many other difficulties.

(c) Two approaches, adaptation and assembly, seem to provide an adequate solution to the shortage of assessment measures in East Africa and other developing regions of the world (Malda and Van De Vijver 2005). Adaptation involves retaining some and changing other features of a Western instrument to increase the suitability of the instrument for the new context; assembly involves the construction of a new assessment measure. Recent efforts in East Africa and surrounding regions indicate that such efforts can lead to the development of culturally appropriate and valid assessment procedures.

(d) Systematic approaches and guidelines for adequate test adaptation that can be used in East Africa and other developing regions of the world have been developed.

Summary Points

- Children from families with low SES in East Africa are at an elevated risk of poor anthropometric status (i.e. being underweight or stunted).
- Poor anthropometric status (i.e. being underweight or stunted) is significantly associated with poor developmental outcomes.
- Several factors in the day-to-day life of children in low SES families may contribute to their poor anthropometric status. These factors include suboptimal maternal caring behaviour, inadequate access to food and a lack of access to adequate health services.
- Anthropometric status is linked to poor developmental outcomes through several mechanisms including potential brain damage and inability to attract and receive adequate stimulation and learning opportunities from the environment.
- Anthropometric measurements are an important target of intervention among children living in poverty. Intervention efforts aimed at improving the anthropometric status of children living in poverty are likely to lead to improved developmental and cognitive outcomes.

Chapter 168
Body Mass Index and Mortality in India

Catherine Sauvaget

Abstract The paper reviews the current nutritional situation of India. The country is still facing childhood and adult under-nutrition, 28% of adult men and 33% of adult women have a body mass index (BMI) lower than 18.5 kg/m^2. Recently, due to demographic, epidemiological and nutritional transitions, going along with economic changes, the country is also facing a dramatic increase in the prevalence of overweight and obesity. Consequently, India is currently suffering from the coexistence of both chronic energy deficiency and obesity. Disparities in terms of nutritional status are observed: populations from East and Central states suffering more frequently from malnutrition, while people living in urban areas, highly educated, or from a high socio-economic level suffering more often from overweight and obesity. Although the association between mortality and body mass index in India has been scarcely addressed, studies on morbidity related to overweight and obesity report a growing prevalence of type 2 diabetes mellitus (31 million patients in 2005) and cardiovascular diseases (36 million patients in 2004). It is estimated that within a decade, the number of cases of these two diseases will double. The body composition of Indians has specific features such as excess body fat and great abdominal fat. Persons may be classified as "normal" by BMI criteria are actually "metabolically-obese" when body fat or abdominal obesity are considered. Attempts have been made for lowering BMI cut-off points for Asian ethnic groups; increased risk of diabetes and cardiovascular diseases is likely to start from a BMI of 23 kg/m^2, and high risk of these diseases at 25 kg/m^2.

168.1 Introduction

India is the second most populous country in the world with 1.2 billion inhabitants, representing 17% of the world's population (Fig. 168.1, drawn with Statistical Analysis Software, GMAP procedure) (SAS Institute Inc. 2002).

Based on the World Health Organization (WHO), in 2005, the mean body mass index (BMI) values in India were low (men: 21.1 kg/m^2, women: 21.6) as compared to values from Western countries such as UK (men: 26.8 kg/m^2, women: 26.7) or USA (men: 28.4 kg/m^2, women: 28.8) (World Health Organization 2008b). Consequently, the BMI distribution tends traditionally to shift toward the low level, with a high proportion of underweight and a small proportion of overweight and obese persons.

Over the past two decades, however, there has been a clear rightward shift in the distribution, thereby suggesting an improvement in the adults' rates of underweight over this period. This has been accompanied with a concomitant increase in the obesity rates in certain urban areas (Pednekar et al. 2008). India is currently facing the double burden of undernutrition as well as overnutrition (Table 168.1).

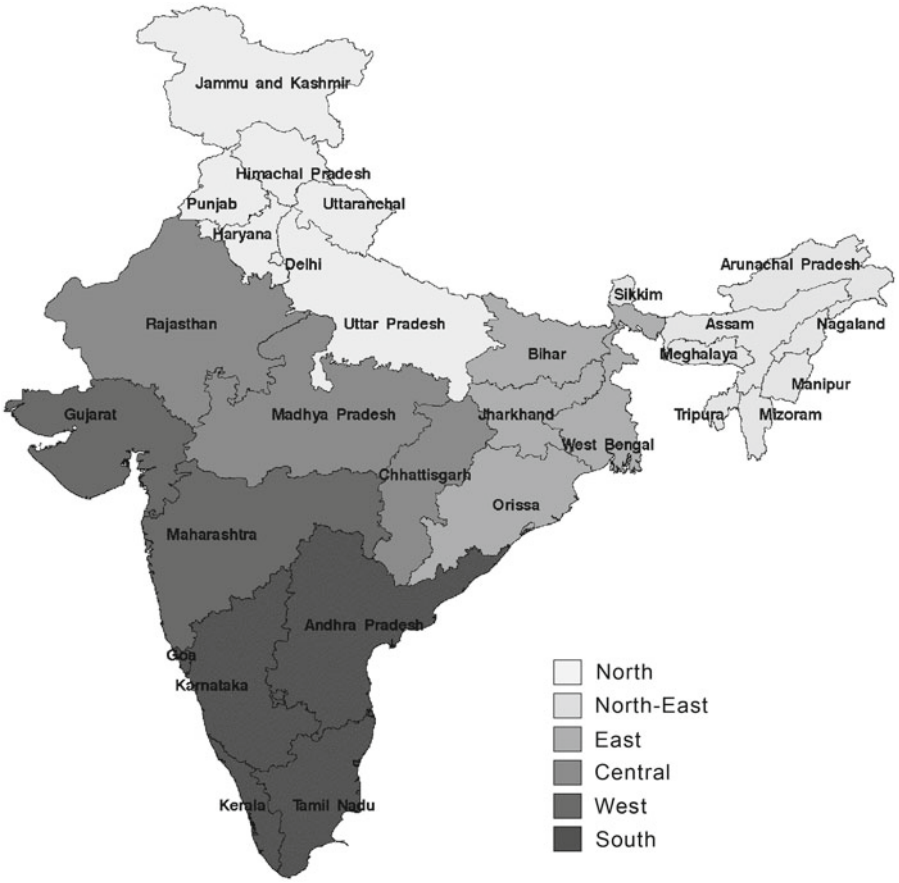

Fig. 168.1 Map of India with states and regions. This map shows the states and main regions of India

Table 168.1 Key features of the twin burden of under- and overweight in India

1. India is still suffering from undernutrition with half of the children aged less than 3 years old and one-third of adults being underweight.
2. At the same time, prevalence of overweight is increasing, especially in urban areas, among those educated and those from high socioeconomic status.
3. Overweight and obesity are known risk factors of diabetes and cardiovascular disease.
4. It is likely that the prevalence and the mortality from cardiovascular disease is becoming a major public health problem in the country.

The table shows the current nutritional situation in India with the double burden of under- and overweight. Short-term consequences of overweight and obesity are an increase in the prevalence and mortality from cardiovascular disease

168.2 Predictors of Body Mass Index

Within the country, large differences in nutritional status are observed between the regions, the living area, the gender, the education level, and the socioeconomic status. Certain regions show extremely high rates of childhood undernutrition (ranging from 20% to 80%), others have a high prevalence of adult undernutrition (more than 50%), while some have both (Pednekar et al. 2008). As shown in Table 168.2, those living in East and Central India had a low mean BMI as compared to those from North and South India. Persons living in urban areas had a greater BMI than those living in rural areas, and women presented a higher BMI than men. The average value of BMI in Asian Indians appears to increase with urbanization and migration (Misra and Vikram 2004).

It has been hypothesized that the causes of rural–urban differences may include the effects of urbanization, processed and fast food, and dependence on TV and radio, leading to less physical activity and the consumption of a diet rich in calories and poor in nutrients (Bharati et al. 2007). In many urban areas of India, increased consumption of energy and fat in conjunction with reduced levels of physical activity was found to be associated with escalation of adolescent and adult obesity (Bharati et al. 2007). Similarly, when people living in rural areas migrate to metropolitan cities and settle in urban slums, they tend to become obese, glucose intolerant, and dyslipidemic, as a result of changes in their activity pattern and dietary profile (Misra 2003).

Education is one of the most important regulatory factors; it enhances awareness of health and hygiene in the society. Higher educational level has been associated with healthier dietary patterns and decreased prevalence of obesity in Western countries (Sundquist and Johansson 1998). The standard of living is another important factor. A strong association between BMI and socioeconomic status, particularly income and standard of living, has been found in developing countries (Nube et al. 1998). However, in contrast to high-resource countries where poverty is associated with greater obesity, in India increasing education level and socioeconomic status are associated with increasing prevalence of obesity. Figure 168.2 shows the relationship between income and overweight in each Indian state: the higher the per-capita income, the higher the prevalence of overweight.

Indeed, overweight is becoming a serious problem in urban India, particularly in the upper-middle class, while rural-based populations in India have a low prevalence (nearly half or less compared to urban ones) of obesity, hypertension, diabetes, dyslipidemia, and coronary heart diseases. One of the important reasons could be that the latter have a physically vigorous lifestyle and consume low-calorie, low-saturated-fat diets (Misra 2003).

The comparison of data between two major nation-wide surveys performed in 1998 and 2005 (Table 168.3) shows that, for the whole country and in a majority of states, the prevalence of underweight in women (BMI <18.5 kg/m^2) has hopefully declined (in 1998: 35.8%, in 2005: 33%). However, the prevalence of overweight and obesity in women has also increased (in 1998: 10.6%,

Table 168.2 National and state-wise mean body mass index and prevalence of underweight and obesity in the National Family Health Survey 2 (NFSH-2 1998–1999), women only (Source: Ministry of Health and Family Welfare 2000)

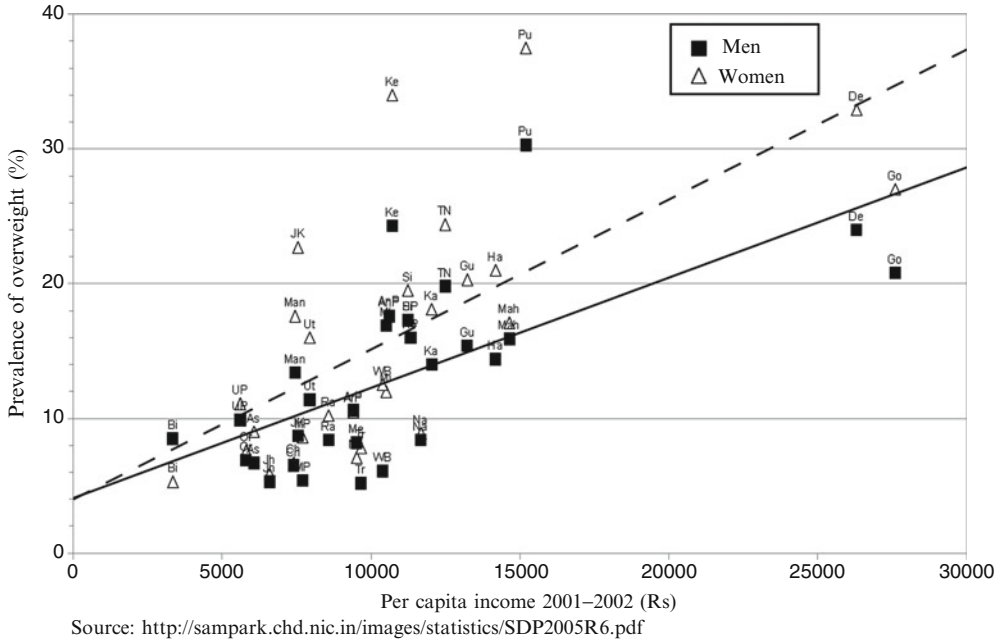
Women living in the East and Central parts have a lower mean BMI than those living in the North and South parts. Those from urban areas have a higher BMI than those from rural areas

in 2005: 14.8%). Again, in the 2005 survey, the prevalence of overweight as well as the prevalence of underweight in women was higher than in men (Ministry of Health and Family Welfare Government of India 2000; 2008).

In Table 168.4, the results being based on several large-scale cross-sectional studies, the prevalence of overweight in rural areas shows an increase with time, in both men and women. However, no specific trend is observed in those living in urban areas.

According to WHO, in 2015, one-third of the Indian adult population will be overweight and the prevalence of obesity will double in 10 years, from 2005 to 2015 (World Health Organization 2008b).



Source: http://sampark.chd.nic.in/images/statistics/SDP2005R6.pdf

Fig. 168.2 State-wise income and prevalence of overweight. Per-capita income and prevalence of overweight (BMI ≥25 kg/m^2) for each state are plotted and the correlation line is drawn. It shows the higher per-capita income and the higher prevalence of overweight, in both men and women (Source: http://sampark.chd.nic.in/images/statistics/SDP2005R6.pdf)

According to another prediction, 20% of Indian females and 16% of males will be overweight by the year 2020 and therefore the incidence of chronic diseases is expected to increase (Dasgupta et al. 2008). What are the chronic diseases associated with overweight and obesity in India?

168.3 Obesity-Related Morbidity

The increasing prevalence of overweight and obesity in India is concomitant to the growing prevalence of obesity-related comorbidities, such as hypertension, metabolic syndrome, dyslipidemia, type 2 diabetes mellitus, and cardiovascular diseases. India is now facing an epidemic of diabetes and coronary heart diseases (Gupta et al. 2007). It has been predicted that, within the coming 15 years, these diseases will increase rapidly and the country will be host to more than half the cases of heart diseases in the world. So far, prevalence of coronary heart disease and stroke are increasing in both urban and rural areas, at all age groups (Fig. 168.3) (Ministry of Health and Family Welfare National Commission on Macroeconomics and Health 2005).

This fact is explained by the substantial rise, over the past decades, of their risk factors: tobacco use, obesity with high waist/hip ratio, high blood pressure, high LDL cholesterol, low HDL cholesterol, diabetes, low consumption of fruits and vegetables, high fat intake, and sedentary lifestyles (Gupta 2008).

Cardiovascular disease is the leading cause of death in India, representing 26% of all causes with 2.7 million deaths in 2004 (among them: 1.5 million deaths from ischemic heart diseases and

Table 168.3 National and state-wise prevalence of underweight (BMI <18.5 kg/m^2) and overweight/obesity (BMI ≥25 kg/m^2) in the National Family Health Surveys 2 and 3 (NFHS-2, NFHS-3) (Sources: Ministry of Health and Family Welfare Government of India 2000; Ministry of Health and Family Welfare National Commission on Macroeconomics and Health 2005)

This table shows the time trend of prevalence of under- and overweight, by states. In majority of states, the prevalence of underweight in women is decreasing; however, the prevalence of overweight is increasing. Women present a higher prevalence of both underweight and overweight, as compared to men

0.7 million deaths from stroke) and an age-standardized death rates of 382/100,000 (World Health Organization 2008a). In 2005, 36 million patients were diagnosed with coronary heart diseases, the number is expected to double in 2015 (Ministry of Health and Family Welfare National Commission on Macroeconomics and Health 2005; Ministry of Health and Family Welfare Government of India 2006).

Table 168.4 Prevalence of overweight in large studies according to gender, area (urban or rural), and year (Source: WHO, WHO Global InfoBase 2008)

		Men		Women	
	Study level	Sample size	% BMI ≥25 kg/m^2	Sample size	% BMI ≥25 kg/m^2
Urban					
1985	Subnational	6,143	21.3	7,271	33.4
1998	National	14,236	5.8	21,385	6.1
2000	National	5,275	25.4	5,904	35.8
2005	National	23,304	15.9	36,366	23.5
Rural					
1975	Subnational	19,157	2.3	19,986	3.4
1988	Subnational	9,447	2.6	11,914	4.1
1996	Subnational	12,751	4.1	18,022	6.0
1998	National	60,993	4.0	81,227	4.1
2005	National	42,438	5.6	75,416	7.4

This table lists the results of large national and subnational surveys on nutritional status. In rural areas, prevalence of overweight is increasing with time. Specific time trend is not observed in urban settings

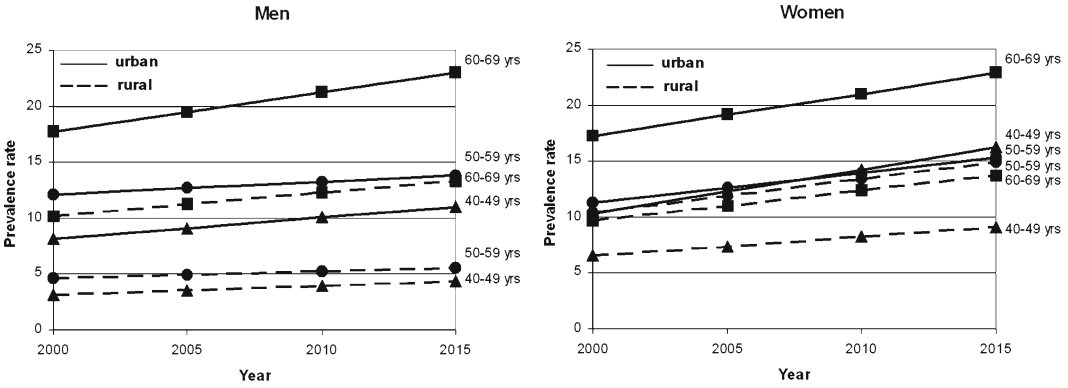

Fig. 168.3 Estimation and prediction of prevalence rate of coronary heart disease according to age group and place of living, in men and women. In men and women, at all age groups, the prevalence of coronary heart disease is increasing with time. This is observed in both urban and rural areas (Source: Ministry of Health and Family Welfare National Commission on Macroeconomics and Health 2005)

In 2004, 160,000 persons died from diabetes (age-standardized death rate: 22.4/100,000) (World Health Organization 2008a), and in 2005, 31 million Indians were suffering from diabetes – there are expected to be more than 79 million persons in 2030 suffering from diabetes (World Health Organization 2004; Ministry of Health and Family Welfare Government of India 2006).

Moreover, low birth weight followed by increased obesity could lead to the insulin resistance syndrome during adulthood (Pradeepa and Mohan 2002). A large proportion of children is still born undernourished; they represented 46% in the last national nutritional survey (Ministry of Health and Family Welfare Government of India 2008). If these children are later exposed to high-fat diets and sedentary lifestyles and develop into obese adults, then it is likely that they will suffer severe consequences in the form of early heart disease, hypertension, and diabetes (Gill 2001).

168.4 Body Mass Index and Mortality

The association between BMI and overall mortality in India has been scarcely addressed. A previous study reported that, in 800 men, with 40% being categorized as normal BMI (BMI ≥18.5 kg/m^2) and 60% being undernourished, the mortality rates increased with decreased BMI (Satyanarayana et al. 1991). More recently, two large-scale studies performed in adults aged 35 years and over, one in the main city of Mumbai (former Bombay) and the other in a rural area of Trivandrum (Kerala State), reported very similar results (Pednekar et al. 2008; Sauvaget et al. 2008). Both studies had a prospective design, and they had a similar methodology: vital status information and cause of death actively assessed: exclusion of the first years of follow-up to eliminate existing medical conditions at baseline with potential effects on both BMI and mortality, and adjustment for tobacco use and other potential confounding factors in the statistical analyses. The two studies reported that the thin and very thin persons were at increased risk of death, while those overweight or obese were not. A similar inverse-J-shaped association was observed in men and women (Fig. 168.4). The detrimental consequence of overweight and obesity observed in high-resource countries was not supported by these two studies. However, the Mumbai study reported that obese subjects had a 40% increased risk of dying from diseases of the circulatory system (especially cardiovascular diseases), while overweight and obesity had no effect on mortality from cardiovascular diseases in the Trivandrum study. Unfortunately, the

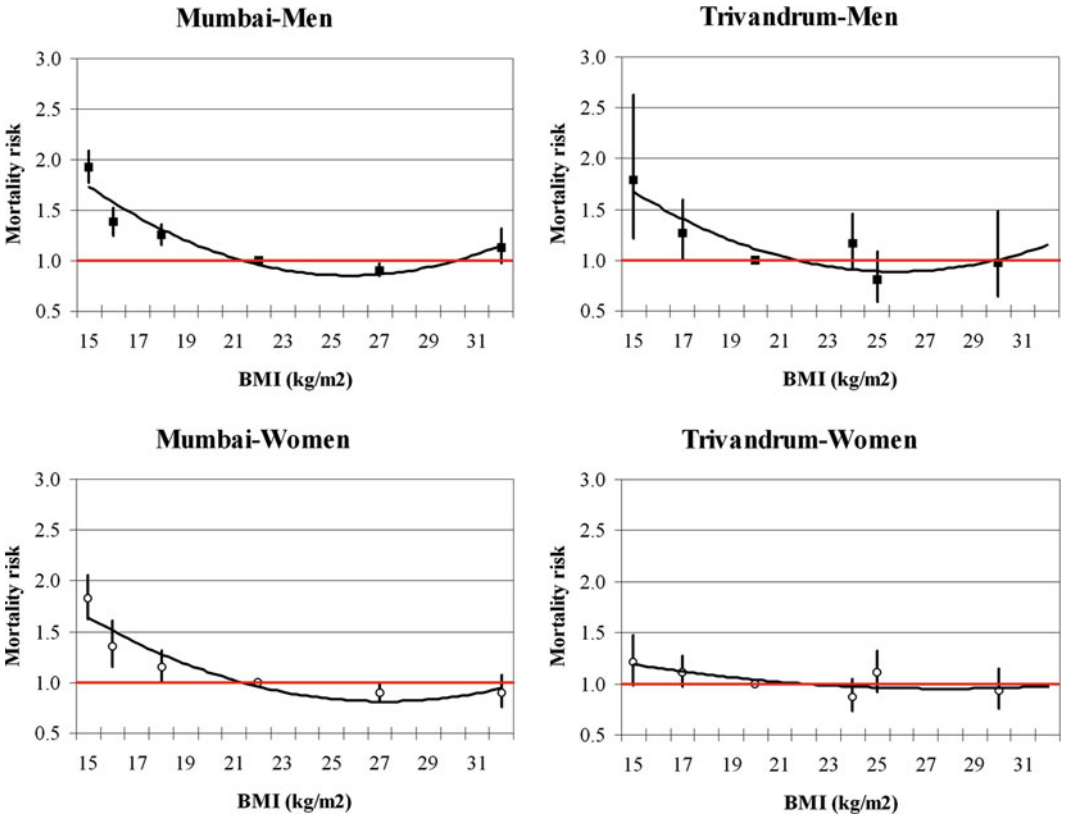

Fig. 168.4 BMI and mortality risks in the Mumbai and Trivandrum studies. An inverse-J-shaped relationship is observed between BMI and all-cause mortality risk; subjects with low or very low BMI are at increased risk of death, while those with BMI greater than 25 kg/m^2 do not show any increase in risk. The two studies report similar results (Sources: Pednekar et al. 2008; Sauvaget et al. 2008. With permission)

two studies addressed solely the effect of BMI and did not consider body fat and excess body weight. However, body composition needs to be considered when studying the Indian ethnic group.

168.5 Body Composition

The body composition of Asian Indians presents several specificities: (1) an excess body fat in relation to body mass index, (2) a lesser lean body mass, and (3) a greater abdominal adiposity with (i) high waist/hip ratio, (ii) normal waist circumference, and (iii) high intra-abdominal fat, as compared to other Asian ethnic groups or Caucasians (Deurenberg-Yap et al. 2000; Misra and Vikram 2004). Indeed, some Indians classified as 'non-obese' by the WHO criteria are actually obese when *body fat* is used to define obesity. Moreover, the prevalence of *abdominal adiposity* is high even in people who are otherwise considered non-obese, these normal-weight persons being described as 'metabolically obese' (Ruderman et al. 1998; Misra 2003). Even among relatively thin urban men with a mean BMI of 22.4 kg/m^2, body fat content was found to be as high as 28% (Misra and Vikram 2004). Also, among overweight subjects (BMI ≥ 25 kg/m^2) from the metropolitan area of New Delhi, abdominal fat – measured with the waist/hip ratio – was found in 68% of men and 58% of women (Gill 2001) (Fig. 168.5).

The relevance of the definition of normal range of BMI (18.5–25 kg/m^2), because it is associated with a high proportion of body fat in Asian ethnic groups, is questioned. The concern that the current BMI cutoff points actually in use – which were originally based on data from European Caucasian populations – were not applicable to Asian populations, has motivated a group of experts to propose a specific classification for Asian ethnic groups (World Health Organization 1995; WHO Expert Consultation 2004). Alternative trigger points for public health action were identified as 23 kg/m^2 or higher, representing increased risk of cardiovascular diseases and diabetes, and 25 kg/m^2 or higher as representing high risk of these diseases (Table 168.5) (WHO Expert Consultation 2004).

Lowering the BMI cutoff points, especially in Asian populations, may be beneficial in identifying individuals at risk for developing overweight-associated comorbidities and their complications (Raji et al. 2001). However, as explained earlier, although BMI is the most commonly used anthropometric indicator of nutritional status, it is not a perfect marker because it does not take into account the proportion of body fat as well as abdominal adiposity. Increased central or visceral fat independent of relative body weight is known to be associated with a variety of metabolic disorders and increased cardiovascular mortality (Gupta et al. 2007).

168.6 Conclusion

Transition is defined in terms of *demographic* transition through its increased longevity and change in the age structure, *epidemiological* transition by way of its decreasing prevalence of infectious diseases and increasing rate of chronic diseases, and *nutritional* transition with the receding famine and malnutrition and rising prevalence of diet-associated non-communicable diseases (Popkin 2002). India is experiencing the three transitions due to economic changes, although this is mostly observed in urban areas. Some of the major consequences of these transitions are the twin burden of under- and overnutrition, where chronic energy deficiency is still a major problem for large parts of the population, associated with an epidemic of cardiovascular diseases and other diet-associated non-communicable diseases, making some experts warn that India is sitting on a diabetes time bomb (Unknown 2009).

Fig. 168.5 Men enjoying a shower under a waterfall in Tamil Nadu state

Table 168.5 International classification and BMI cutoffs for Asian population (Sources: World Health Organization 1995, 2008a)

	BMI cutoffs		Risk of comorbidity	
	International classification	Asian populations	International classification	Asian populations
Severe thinness	<16.00	<16.00	Low	Low
Mild and moderate thinness	16.00–18.49	16.00–18.49		
Normal range	**18.50–24.99**	**18.50–22.99**	**Average**	**Average**
Mild overweight		23.00–24.99		Increased
Pre-obese class I	25.00–29.99	25.00–27.49	Increased	
Pre-obese class II		27.50–29.99		Moderate
Obese class Ia	30.00–34.99	30.00–32.49	Moderate	Severe
Obese class Ib		32.50–34.99		
Obese class II	35.00–39.99	≥35.00	Severe	
Obese class III	≥40.00		Very severe	

International classification refers to the current WHO classification in use. The classification for Asian populations was established by a group of experts for populations specifically from Asia. Risk of comorbidity appears at a lower level in Asia (from BMI 25 kg/m^2 in Asia and 30 kg/m^2 in other populations)

168.7 Practical Methods and Techniques

- WHO BMI cutoff points for Asian populations should be used.
- Besides height and weight, hip:waist ratio and markers of abdominal fat should be measured.
- Training of field workers is necessary.
- Two measurements per subjects are needed.

Summary Points

- Burden of underweight is high in India (46% of children aged <3 years old, 28% of adult men, and 33% of adult women).
- Burden of overweight and obesity is increasing (12% in men, and 15% in women).
- Obesity is more often reported in urban areas, among highly educated subjects and among wealthy populations.
- Prevalence of hypertension, metabolic syndrome, dyslipidemia, type 2 diabetes mellitus, and cardiovascular diseases is dramatically increasing.
- Cardiovascular disease is the leading cause of death (26% of all causes) with 2.7 million deaths and an age-standardized death rate of 382/100,000.
- The body composition of Indians differs from other ethnic groups, with excess body fat and great abdominal fat leading to 'metabolically obese' subjects with 'normal' body mass index (18.50–24.99 kg/m^2).
- Alternative cutoff points of body mass index for Indian populations were identified as ≥23 kg/m^2 for overweight, and ≥25 kg/m^2 for obesity.

Key Points – Twin Burden of Under- and Overweight in India

- India is facing a twin burden of under- and overweight.
- Large discrepancies in nutritional status are observed between regions, living areas, education level, and socioeconomic status. Those living in urban areas, highly educated, or from a high socioeconomic level are suffering more often from overweight and obesity.
- Obesity is associated with metabolic disorders, such as diabetes mellitus, and increased risk of cardiovascular diseases. Prevalence and mortality rates of diabetes and cardiovascular diseases are expected to double within the next decade.
- The body composition of Asian Indians presents specificities: an excess body fat, a low muscle mass, and a high abdominal adiposity. These specificities should be taken into consideration in classifying subjects at risk of diabetes or cardiovascular diseases.

Part XXIV
Anthropometry and Nutrition: General Aspects

Chapter 169
Anthropometric Measurements and Nutritional Status in the Healthy Elderly Population

Lilia Castillo-Martínez, Carmen García-Peña, Teresa Juárez-Cedillo, Óscar Rosas-Carrasco, Claudia Rabay-Gánem, and Sergio Sánchez-García

Abstract Anthropometric evaluation is an essential part of the nutritional assessment in geriatrics to determine conditions of malnutrition, overweight and obesity, as well as the loss of muscle mass, gain of fat mass and redistribution of adipose tissue. These anthropometric indicators have been used to evaluate the prognosis of acute and chronic diseases, and to guide medical intervention in the elderly.

It has been demonstrated that anthropometric measurements are highly reliable in determining nutritional status in comparison with other, more sophisticated methods (hydrodensitometry, dilution techniques, radio-labeled potassium and electronic bioimpedance), the use of which is restricted by their complexity and cost.

Changes in body composition at different stages of life differ in men and women, and are reflected in anthropometric measurements. There is a certain consensus in which the values of the body mass index (BMI) currently in use in the elderly underestimate deficit and overestimate the condition of being overweight, and that the critical points of waist circumference probably underestimate metabolic risk.

The nutritional needs of older adults with a good level of health vary little in relation to the needs of adults in general. Nevertheless, some special recommendations are indicated for groups at special risk; their application to all the population is still a motive for discussion.

Nutritional evaluation in the elderly is especially difficult because many of the signs related to malnutrition are also related to the ageing process itself. Currently, a series of rapid application scales have been developed for nutritional evaluation in geriatrics. The selection of instruments for said evaluation should consider the intended objective (screening of the population at risk or care and follow-up), the profile of the population and the available resources, including the trained personnel and time required.

169.1 Introduction

Anthropometry and nutrition are interrelated and include genetic and environmental characteristics, sociocultural conditions, lifestyle, functional status, and health. Anthropometric evaluation is an essential part of nutritional assessment in geriatrics, to determine conditions, such as malnutrition, overweight, and obesity, as well as loss of muscle and gain of fat mass and the redistribution of adipose tissue. These anthropometric indicators have been used to evaluate the prognosis of acute and chronic diseases and also to guide medical intervention in the elderly.

The changes in body composition at the different stages of life differ in men and women, as is reflected in anthropometric measurements. Consequently, different anthropometric indicators are used to evaluate nutritional status. However, there are few studies in a population over 60 years of age directed toward understanding the changes in anthropometric measurements and nutritional status in a healthy elderly population.

169.2 Aging and Body Composition: Physiological and Nutritional Changes

169.2.1 Molecular Changes Involved in Nutrition

Human aging is a progressively deleterious process, which inevitably occurs over time through the interaction of multiple factors. These include multiple molecular changes that have recently been reported, which we will describe later.

One of these factors is oxidative stress, which has been shown to play a fundamental role in harming DNA, promoting apoptosis and inducing cellular death (Guarente 2007).

The sirtuins (disacetylases of histones) are enzymes that, upon being activated, regulate metabolic processes that retard aging and contribute to preventing diseases, such as obesity, diabetes, and cardiovascular disease. To date, seven types of sirtuins have been established in humans (SIRT 1–7), formed by a domain of approximately 237 amino acids. Alterations in these proteins through acetylation have the important functions of activating transcription, stabilizing proteins, and modulating the affinity of histone proteins for DNA, the transport of proteins between the nucleus and cytoplasm, and the activity of chaperone proteins (Wenzel 2006).

A relationship between the sirtuins and nutrition (Fernandez et al. 1976) was indicated when the authors showed that a reduction of food intake (caloric restriction) prolonged life expectancy in various animal models. In recent years, the effect of a hypocaloric diet upon the specific activation of sirtuins has been demonstrated. One of these studies (Civitarese et al. 2007) was performed to determine the response of muscle cell mitochondria to caloric restriction alone or in combination with exercise in 36 overweight young people. Two groups were included: one with 25% caloric restriction and the other with 12.5% restriction but with an increase in energetic spending of 12.5% through exercise. Both groups exhibited an increase in the genetic expression of sirtuin 1 (SIRT1); after 6 months, the cellular consumption of oxygen was diminished and damage to DNA had occurred via free radicals.

In another clinical study, it was demonstrated that caloric restriction of 48 overweight men and women reduced two markers of longevity (fasting insulin levels and core body temperature) at 6 months (Heilbronn et al. 2006). In obese subjects, it was also demonstrated that, after 8 weeks, caloric restriction provoked the direct activation of sirtuins and resulted in both weight loss and a reduction of oxidative stress in the patients (Crujeiras et al. 2008).

Before these findings, questions had arisen with regard to possible interventions that could be used to prolong life, as well as to retard the appearance and/or modify the clinical of different diseases that include oxidative stress in their physiopathology. Among these treatments are antioxidants; one of the most studied recently is resveratrol, a polyphenol found in the skin of red grapes, raspberries, blueberries, peanuts, and pine nuts. In different studies, the positive effects of these treatments have been shown, such as antiaggretory, antineoplastic, and anti-inflammatory effects as well as a stimulating effect on SIRT-2. Therefore, there is a possible benefit for aging, longevity, and neurodegenerative diseases, such Parkinson's disease and the dementias (Milne and Denu 2008).

169.2.2 Changes in Body Composition

Weight: Over a lifetime, weight is constantly modified. In adults, in general some amount of weight increase is seen until 60 years, after which, in certain studies a gradual reduction has been reported of up to 0.5% of the body per year.

Height: Height diminishes proportionately with age. On average, there is the loss of 1 cm per decade of age. This could be due to a shortening of the height of the vertebral bodies through a reduction in calcium in the bone tissue and a reduction in the hydration of the intervertebral disks. In addition, there is also a modification of the axis, and dorsal kyphosis often develops. These abnormal mechanical loads deform the vertebral diameter and osteophytes frequently appear (Gutiérrez et al. 2006).

Changes in body composition: Associated with age, there is an increase in fat tissue. The distribution of this tissue is presented both peripherally and centrally (perivisceral), as well as the intrahepatic and intramuscular accumulation of fat that accompanies disorders, such as insulin resistance. The muscle tissue (lean tissue) is reduced up to 30% due to replacement with fat tissue because of physical and molecular metabolic factors (Chapman 2006).

A reduction of the water compartment of the organism has been described as being associated with difficulties in maintaining fluid balance. This reduction predominates in the intracellular space and is one of the causes of loss of weight in older people.

169.2.3 Changes Due to Progressive Aging in Different Organs Related with Nutrition

Oral changes: Multiple changes in the stomatognathic apparatus are related with aging, such as anatomic modification of the temporomandibular joint through variations in weight and increase in fibrous muscle tissue, which can cause pain associated with movement, limitation of the oral opening and crepitation of articulation. There can also be weakness of the chewing muscles. There is a reduction of the tongue epithelium, atrophy of the taste buds, and especially phyloforms, with fissures and presence of sublingual varices.

With regard to the teeth, these acquire a yellowish color, become fragile, and undergo a reduction in water content and organic matter in the enamel; and there are phenomena of attrition and abrasion. Caries become more frequent; the radicular type brings a series of consequences including dental extraction (D'Hyver de las Deses and Gutiérrez Robledo 2006).

Periodontal disease is characterized by inflammation and destruction of the supporting tissues of the tooth. Gingivitis and periodontitis come to present dental mobility along with the loss of teeth. Frequently, a reduction of salival production is encountered (less than 500 cc a day or salival flow less than 0.2 ml/min and a sensation of dry mouth [xerostomy]). Swallowing is often characterized

by a longer duration. When related to neurodegenerative diseases, cancer, etc., there can be upper and/or lower dysphagia (D'Hyver de las Deses and Gutiérrez Robledo 2006).

Sense organs: Reduction of visual acuity can bring about changes in nutritional intake patterns and is caused by such diseases, such as cataracts, glaucoma, macular degeneration, and retinopathy, which hamper the person physically from engaging in a pattern of good nutrition (D'Hyver de las Deses and Gutiérrez Robledo 2006).

Digestive system: Presbyesophagus is sometimes evident. Often, reduction is found in the secretion of gastric juices compensated for by a retardation in gastric emptying. At the level of the small intestine, a retardation in digestion is brought about by atrophy of the intestinal cilia, reduction in the cellular renovation of the intestinal epithelium, proliferation of conjunctive tissue, and vascular arteriosclerosis, which carries with it a consequent deficiency in the absorption of various nutrients and vitamins.

At the level of the colon, smooth muscle weakness and replacement of the original cells with collagen results in major weakness and the appearance of diverticula. Alteration in the motility associated with immobility can contribute to constipation (D'Hyver de las Deses and Gutiérrez Robledo 2006).

Respiratory system: Kyphosis promotes restrictive respiratory insufficiency due to reduction of the alveolar surface, pulmonary distension, and eventually diminution of vital capacity, which, in turn, negatively influences tolerance of exercise.

Cardiovascular system: Systolic dysfunction both limits the tolerance of exercise and reduces appetite (D'Hyver de las Deses and Gutiérrez Robledo 2006).

169.3 Anthropometric Evaluation in the Elderly

169.3.1 Nutritional Assessment of the Elderly

Anthropometric evaluation is an essential part of nutritional assessment in geriatrics because it allows the determination of conditions of malnutrition, overweight and obesity, loss of muscle mass, gain or loss of fat mass, and the redistribution of adipose tissue. It can be performed by trained health personnel, is low in cost, noninvasive, and very sensitive to the different components of body structure, such as muscular and fat components.

In addition to height and weight, which were mentioned previously, the anthropometric measurements most commonly used in the elderly are as follows.

Circumference of body segments, abdominal and hip circumference, and cutaneous folds. The circumference of certain body segments (arm, thigh, and calf), the abdominal and hip circumference, as well as the cutaneous folds (tricipital and subscapular) are all used to indicate the respective fat and muscle levels.

Given the reduction of muscle mass and the accumulation of fat (at the intra-abdominal level), the measurement of cutaneous folds is not an accurate reflection of total fat. Therefore, the reliability of these anthropometric parameters for detecting malnutrition and predicting morbimortality is relatively limited, but they can be used, together with weight and a physical examination, as complementary measurements.

Longitude or body segments: heel–knee length. In the elderly population, there are typically a great many confounding pathologies; hence, serious difficulties are often encountered in determining height. For this reason, other means have been developed to estimate as exactly as possible the height of elderly individuals with these confounding elements. Measurement of the heel–knee length is therefore the optimal procedure to determine the height of the elderly.

Due to the fact that the large bones maintain the adult length at maturity, simple formulas have been developed that allow a fairly accurate estimation of height (Chumlea et al. 1985).

Body mass index (BMI). BMI is most frequently used in nutritional and epidemiological studies as an indicator of body composition and to evaluate patterns of nutritional status. It is a less reliable indicator to evaluate changes in adiposity in older adults because it is affected by both reduction in height and increase in fat, even in subjects with otherwise stable weight.

Waist–hip index (WHI). Aging is associated with a redistribution of adipose tissue with an increase in visceral fat. Measurement of these circumferences (waist and hip) and their combination in the waist–hip index allows a simple approximation of the distribution of body fat. The use of the waist circumference can have limitations in older adults due to the fact that, with age, said circumference could reflect a shortening of the trunk; therefore, the diameter of the abdomen increases accordingly as the trunk is reduced. This is supported by the inverse as well, that is, there is a significant association between abdominal circumference in the elderly and height taken in a sitting position.

169.3.2 Anthropometric Measurements and Nutritional Status in Healthy Elderly Population by Age and Sex

In the study reported by Sánchez-García et al. (2007), an analysis was performed to determine the sex and age differences in anthropometric values (Table 169.1).

Differences were observed among the measurements of the anthropometric values obtained from the elderly in weight, height, BMI, mid-brachial circumference, waist–hip ratio, waist circumference, hip circumference, and elbow amplitude (ANOVA, $p < 0.05$). Among the men, differences were found in weight, height, CMI, mid-brachial circumference, and elbow amplitude (ANOVA, $p < 0.05$).

Measurements of weight, height, waist–hip ratio, waist circumference, elbow amplitude, and knee–heel length were superior in men ($p < 0.05$), while the measurements of BMI and hip circumference were superior in women ($p < 0.05$). For the body mass index, a difference was observed in the group of 70–74 years of age; the mean was greater for women in comparison with men ($p < 0.05$). For calf circumference, a difference was found in the group of over 80, with the greater mean value being in men ($p < 0.05$).

Regarding hip circumference, it was observed that in the groups of 60–64, 65–69, and 70–74 years, the mean values are greater for women ($p < 0.05$). No differences were observed in the mean of the mid-brachial circumference, waist circumference, or elbow amplitude between men and women in any of the age groups.

169.3.3 Distribution of BMI in Healthy Elderly Population Using Different Criteria as Cutoff Points to Determine Nutritional Status

Evaluation of nutritional status is essential to determine the health of the elderly, both at the individual and collective levels. There is a consensus that the BMI values currently in use underestimate deficits and overestimate the condition of being overweight, and, perhaps, the critical point of waist circumference underestimates metabolic risk in the elderly.

If one considers the high prevalence of obesity, especially the abdominal type, in this age group, it is indispensable to have cutoff points to identify groups at risk that would allow putting into practice

Table 169.1 Anthropometric values according to age and gender in participating subjects (Source: Sánchez-García et al. 2007)

Changes in body composition at different stages of life differ in men and women and are reflected in anthropometric measurements

[a] Significant differences between age range in women ($p < 0.05$)

[b] Significant differences between age range in men ($p < 0.05$)

[c] Significant differences between age range ($p < 0.05$)

[d] Significant differences between women and men ($p < 0.05$)

Table 169.2 Body weight classification by BMI (kg/m^2) according to different criteria

Weight classification	WHO (1995)	Reidpath et al. (2002)	Perissinotto et al. (2002)	Douketis et al. (2005)
Malnourished	<18.5	<20	<20	<21.9
Normal	18.5–24.9	20–25	20.0–29.9	22.0–29.9
Overweight	≥25	> 25	≥30	≥30

There are disagreements among the different cutoff points used to classify the health status based on body mass index

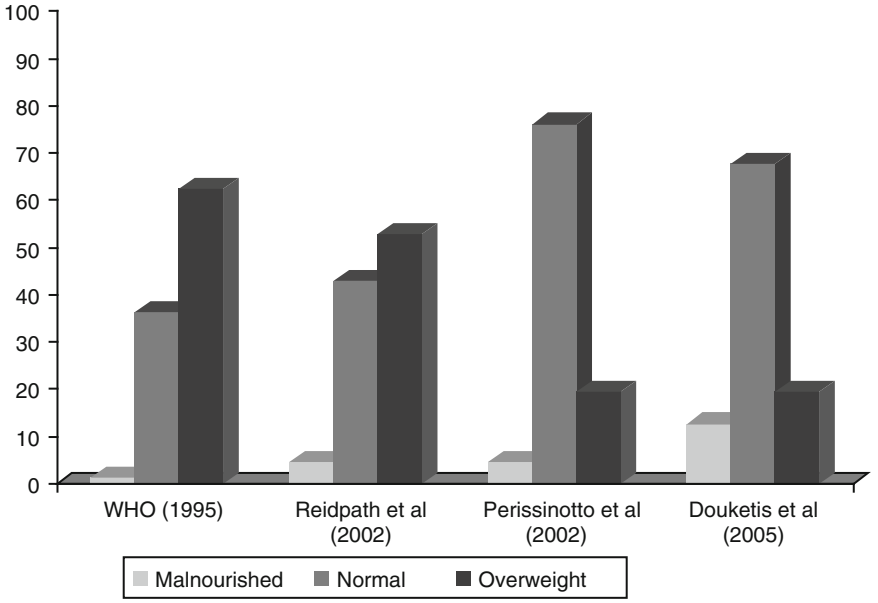

Fig. 169.1 The distribution of the BMI using various criteria proposed in the literature for the elderly population. WHO cutoff points underestimate the deficit and overestimate the degree of being overweight; therefore, it is necessary to validate these measures in a more extensive way with different cutoff points

programs with a sharp focus. It has been suggested that if the same BMI cutoff points are used for adults and the elderly, it would lead to a misclassification of nutritional risk in the latter and that the waist circumference is a better predictor of metabolic risk than BMI in older adults. Furthermore, the critical points are different from those proposed in the literature to determine the response required.

Table 169.2 and Fig. 169.1 depict the distribution of the BMI using different criteria proposed in the literature for the elderly population.

The ratio of waist circumference and hip circumference, or WHR, is used more and more frequently in estimating a possible increase regarding abdominal fat, with the purpose of identifying those individuals at risk of incurring non-insulin-dependent diabetes mellitus, dyslipidemias, arterial hypertension, and/or coronary problems. WHR values of <1.00 for men and <0.85 for women are considered desirable (World Health Organization 1997); values above these points identify individuals at risk for morbidity and mortality of cardiovascular disease.

The joint use of BMI and waist circumference could better orient health professionals toward making the proper decisions regarding the nutritional status of the elderly to control those with problems of weight and distribution of adipose tissue (Fig. 169.2).

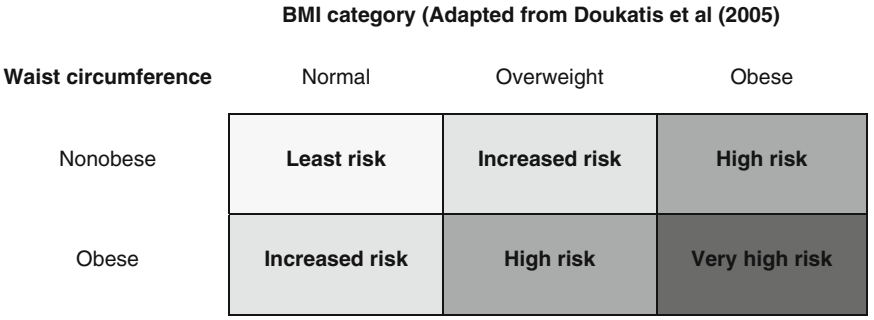

Fig. 169.2 Applying BMI and waist circumference measurements to assess a patient's risk of health problems. The BMI and waist circumference reflect a person's risk status at a single time point. The pattern of BMI and waist circumference over the long term may provide additional information. The need for weight-loss interventions should be determined not only on the basis of a person's BMI and waist circumference, but also on the presence or absence of concomitant disease and other patient characteristics

It must be stressed that the reference ranges for evaluating the nutritional status of elderly adults either have been extrapolated from younger adults, or are based on statistical cutoff points, more than on the actual results of morbidity, mortality, and quality of life from population studies in older adults.

169.4 Anthropometry and Evaluation of Body Composition in the Elderly

169.4.1 Prediction of Total Body Fat and Skeletal Muscle

The three most commonly used methods to obtain criteria for estimating body composition are: hydrodensitometry, total body water, and count of the d ^{40}K level. They may not be valid in the elderly who might have total body water, bone mineralization, or concentrations of potassium in the fat-free mass (FFM) other than the normal values. Specifically, hydrodensitometry or underwater weight, which uses a model with two compartments (2C), divides the body into fat mass (FM) and fat-free mass (FFM). It considers constant densities (FM = 0.0900 kg/l and FFM = 1.100 kg/l at 37°C), the fixed hydration for the FFM (72–74%), and the relative quantities of the three components of FFM (aqueous, mineral and proteins), which are known, additive, and progressive in all ages, genders, and ethnic groups (Huerta et al. 2007).

The reliability of the equations used to estimate body composition depends on the precision of the method in question and the ethnicity. Precision also depends on changes in elasticity, hydration, and the compressibility of the tissues. Studies that utilize anthropometry need to take into consideration a variety of possible measurements that are not confounded by changes related with age. Furthermore, the equations have to be designed and validated for specific groups, using as a reference the four-compartment model (4C) (Huerta et al. 2007).

The 4C model combines the measurement of the total body water (TBW) with diluted isotopes; total bone mineral mass obtained by DEXA and total body density by underwater weight. The advantage of this method is that it uses minimum suppositions and is based on direct measurements of the main compartments of body composition. In addition, the measurement of bone mineral mass and TBW is independent, allowing a more exact, accurate estimate of body composition in older adults by considering the effect of age on these components (Huerta et al. 2007).

Differences between the 2C and 4C models in the estimation of percentage of fat in elderly people have been associated with either variation in the aqueous fraction or hydration in FFM, mainly in men. Equations have been developed based on cutaneous folds to estimate body fat in older adults using the multiple-compartment method as the method of reference (Huerta et al. 2007).

In one study, an equation was generated that included only anthropometric data in 202 Mexican individuals from 60 to 89 years old. A cross-validation with a 4C model was performed, with body density determined by plethysmography by displacement of air (BOD-POD), total body water by the dilution with deuterium oxide method, and total body bone ash through bone densitometry. The equation selected to estimate fat mass in kilograms was

$$\mathrm{FM(kg)} = (0.165 \cdot \mathrm{CS}) + (0.355 \cdot \mathrm{BS}) + (0.521 \cdot \mathrm{BW}) - (6.054 \cdot \mathrm{S}) - 13.171,$$

where FM = fat mass expressed in kg, CS = calf skin fold in mm, BS = bicipital skinfold in mm, BW = body weight in kg, and S = sex (women = 0 and men = 1).

In the cross-validation application, an equivalency was observed between the methods. It is worth remembering that, by subtracting the fat mass already obtained from the total body weight, the FFM can be obtained (Huerta et al. 2007).

There are a few studies that have evaluated muscle mass by anthropometry in the elderly population. One is derived from the Brussels Cadaver Study, where prediction formulas were developed through anthropometry for total skeletal muscle mass. Anthropometric dimensions were quantified and 12 elderly male cadavers were dissected to obtain the following equation:

$$\mathrm{SM(g)} = \mathrm{Ht} \cdot (0.0553 \cdot \mathrm{CTG}^2 + 0.0987 \cdot \mathrm{FG}^2 + 0.0331 \cdot \mathrm{CCG}^2) - 2445,$$

where Ht = height (cm); CTG = corrected circumference of the muscle according to the thickness of the cutaneous skinfold of the anterior thigh (cm); FG = uncorrected forearm circumference; and CCG = corrected calf circumference by the thickness of cutaneous skinfold. This model had a random error of approximately ±2 kg in comparison with other models which have been shown to consistently underestimate muscle mass by 5–10 kg (Lee et al. 2000).

Therefore, the equations to predict the body composition of the elderly from anthropometric measurements should have access to estimation criteria obtained through a multicompartment model. A representative sample should be taken with internal and external cross-validation and with the measurement of an independent sample using the same techniques.

169.4.2 Distribution of Adipose Tissue

The accumulation of visceral fat without the corresponding changes in weight in the elderly can cause the waist circumference and sagittal diameter parameters to be less sensitive to the identification of health risks attributable to being overweight or the distribution of abdominal fat in comparison with young people. Indeed, data obtained in two studies that compared visceral adipose tissue valued through computerized axial tomography with anthropometric indices (waist circumference, sagittal diameter, waist–thigh ratio, and cutaneous skinfolds) demonstrate that these are not good prognostic factors of visceral adipose tissue in men and women of advanced age and that they are related with total body fat (Sardinha and Texeira 2007).

169.4.3 Estimation of Changes in Body Composition

Anthropometric measurements do not detect any level of intramuscular adiposity; therefore, this method only gives an estimate of muscle mass. In addition, reduction in muscle volume only explains half of the reduction in muscular strength that is produced with aging; this could be due to a modification of muscle composition, since data based on magnetic resonance have shown that, in the sedentary elderly, there is progressive replacement of muscle tissue with intramuscular fat (Arroyo et al. 2007). This change is not reflected in subcutaneous fat and, therefore, anthropometry fails to record this change.

169.5 Anthropometric Indicators for Prognosis and Intervention in Older Adults

169.5.1 Association Between the Indicators of the Percentage of Fat and Muscle Mass and Health Risks

Functional limitations, defined as the restriction of the physical or mental capacities required to carry out the tasks of an independent life, are important predictors of mortality, morbidity, and incapacity in the older adult. Sarcopenia (progressive reduction of muscle mass) contributes to the presence of functional limitations and incapacity in aging. The reduction of muscle mass negatively impacts physical output and limits mobility (Arroyo et al. 2007).

Various epidemiological studies have demonstrated a direct association between BMI and functional limitations and report that overweight subjects have a loss of movement and functional limitations. Nevertheless, Arroyo et al. (2007), in 377 subjects of 65 years or more, found that neither BMI, nor waist circumference, nor percentage of fat is associated with functional limitation, but muscle mass measured through dynamometry is (women <15 kg; men <27 kg); only on multivariate analysis was it found that a greater BMI in women means a greater risk of limitation.

By contrast, Houston et al. (2009) found that, in subjects aged 70–79 years for whom BMI was calculated, with self-reported weight at 25 and 50 years along with current weight, those with overweight and obesity had a greater risk of limited mobility on follow-up (4.2 years on average) compared those with normal weight.

On the other hand, there is evidence in elderly populations that, being obese or overweight (BMI = 24.6–29.8), does not increase the risk of mortality and might even be protective (Arnold et al. 2010). However, if only weight in old age is taken into account, this association might be distorted by the preexistence of chronic degenerative diseases and/or smoking, which are related to reduced BMI and increased risk of death. More studies are needed that evaluate the effects on health of weight-loss therapies in the elderly who are obese or overweight that minimize the loss of muscle and bone mass.

169.5.2 Changes in Weight and Mortality

Weight fluctuations in older adults can indicate difficulties in maintaining homeostasis and, therefore, might be an early indicator of deterioration in health and physical function (Arnold et al. 2010).

In a 6-year follow-up of participants in the Cardiovascular Health Study of 3,278 individuals over 65 years, there was an evaluation performed between the average weight change per year and evidence

of functional difficulty, including physical incapacity and deterioration in mobility and mortality. The participants were classified into groups of weight loss (≥5%), stable weight, weight gain (≥5%), or 'weight cycling' (gain and loss of ≥5% in the same year). It was found that more men remained stable in comparison with women, and of the latter, Afro-Americans were those who least frequently lost weight or experienced fluctuations. On the other hand, the participants who experienced weight loss or fluctuations in weight were older and had the more deteriorated health, smoked more, and had either diabetes or cardiovascular disease, compared with those who remained stable or gained weight, including after adjustment for age, sex, race, height, education, diabetes, cancer, and self-reported health. The categories of weight gain, variability in weight, and weight cycling are associated with deterioration in the activities of daily life. Those with weight cycling had a 20% greater risk of mortality. In addition, when using patterns of weight change (loss–gain, stable–loss, gain–loss, and loss–loss), it was found that the greater the variability in weight, the greater the relative risk of physical incapacity and mortality in the following 7 years.

A higher average weight was associated with a greater incidence of events indicating physical limitation. Weight loss, low weight, and very high weights increased the risk of mortality (Arnold et al. 2010).

Part of the relationship between the weight dynamic and such events might reflect the presence of simultaneous diseases in these participants. It should be remembered that the elderly form a group in which there are commonly multiple pathologies, handicaps and poor nutritional status, as well as persistent edema. For example, patterns of weight gain–loss could be explained by the presence of chronic heart failure, which produces weight gain through edema and volume overload as well as weight loss due to treatment with diuretics. In the pattern of weight loss, one could suspect cachexia, which is a complication of many diseases, such as the arthritis, cancer, heart failure, and chronic pulmonary obstruction disease, which are frequently present in elderly people.

Also, it is recommended not to evaluate only on current weight, but rather history (weight in early adulthood) and the weight dynamic in recent months and years, and to consider any history of smoking and/or simultaneous diseases.

169.5.3 Relationship Between Nutrition and Anthropometric Measurements in a Healthy Elderly Population

Loss of weight is related to an inadequate nutriment intake and digestive system changes (Villarino-Rodríguez et al. 2002). Several authors have reported that increases in body fat can be caused by a decreased capacity for free fat acids, to a lower tissue capacity to oxidize free fat acids, or a combination of both. These conditions would contribute to higher level of accumulation (Toth and Tchernof 2000).

The role of diet in age-related changes in body composition remains unclear. Although research indicates that age-related changes in body composition may be modifiable by environmental variables, particularly physical activity, the role of diet remains unclear. Despite experimental evidence in support of a direct relationship between energy and/or protein intakes and muscle mass, many observational studies of diet and sarcopenia report null effects. The role of nutrition in age-related increases in body fat has so far been limited to decreases in energy expenditure. Age-related increases in body fat are primarily attributed to declines in physical activity and basal metabolic rate, rather than to dietary intake.

The relationship between diet and age-related changes in lean and fat mass may become clearer if concurrent changes were studied together. Considerable evidence indicates that patterns of change in body composition over the short term are explained by particular profiles of energy and protein intake.

Clinical studies of obesity (overfeeding studies), starvation, and the treatment of obesity-controlled feeding studies, as well as the treatment of malnourished individuals (refeeding studies), demonstrate that energy and protein intakes, relative to dietary requirements, predict simultaneous change in both the lean and fat compartments. Longer-term, age-related changes in body composition may thus be associated with long-term dietary intake profiles (Stookey et al. 2001).

In a study that used longitudinal data on 608 healthy, non-obese Chinese (aged 50–70 years) from the 1993 and 1997 China Health and Nutrition Surveys, the subjects were described in terms of the changes in the mid-arm muscle area and body fat (waist circumference). Patterns of change involving gains in arm muscle and lost of fat were associated with increased protein intake, urban residence, and moderate or heavy levels of physical activity at baseline. Variation in protein intake, physical activity, and urban residence were also differentiated between the groups that gained fat and those that gained muscle mass. They also found that taller subjects appeared more likely to lose muscle, and this may be accounted for by the fact that any given level of energy or protein intake is more likely to fall short of requirements among larger individuals than among smaller individuals. In conclusion, the patterns of age-related change in body composition appear to be associated with modifiable variables, including income, urban residence, activity level and protein, and energy intake (Stookey et al. 2001).

Data from Castaneda et al. (1995) show that feeding healthy elderly women 0.4 g/k of protein (half the recommended dietary allowances), compared to 0.8 g/k for 9 weeks produces a marked reduction in cell mass, muscle mass, and nitrogen balance, as well a weakness by electrical stimulation testing. Thus, in just a few months, nutrition can make a dramatic difference in muscle function and mass.

Bernstein et al. (2002) hypothesized that consumption of a more diverse diet would predict better nutritional status in frail elderly persons. In a study that included elderly people (72–98 years), they found that, in women, high dietary variety score was associated with higher BMI ($p < 0.001$) and higher total body potassium ($p = 0.02$); high fruit and vegetable variety score was associated with higher BMI, mid-arm circumference, and mid-arm muscle area.

By contrast, in a cross-sectional study, Roberts et al. (2005) found that healthy older adults (≥61 years) with low BMI (<22 kg/m^2) consumed a lower variety of energy-dense foods compared with older adults with higher BMIs ($p < 0.05$). Another result of this study was that the percentages of the participants who consumed the recommended dietary allowances for protein and the estimated average requirements for micronutrients were particularly low among older persons who had a low BMI and low micronutrient-dense variety: only 65.4% for protein (compared with 97.6% for older adults who consumed a wide variety of micronutrient-dense foods and had a BMI <22 kg/m^2) and 0.0% for the estimated average requirements for all 14 micronutrients (compared with 9.2% for older adults who consumed a wide variety of micronutrient-dense foods and had a BMI <22 kg/m^2). These results may help to explain both unintentional weight loss and the maintenance of undesirably low body weight in old age. Taken together, these findings suggest that consuming a wide variety of micronutrient-rich foods tended to counterbalance the reduced micronutrient intakes associated with old age, with positive associations of micronutrient-dense variety with the intake of vitamins A, E, C, folate, B12, magnesium, and zinc.

169.6 Nutritional Recommendations for Healthy Aging

Aging can and should be a healthy, pleasant, productive life process if the risks are diminished and the protective factors increased. It is important to know how changes in dietary behavior over the course of time can provide aging people the knowledge to select, preserve, and prepare their foods so as to consume balanced, healthy diets.

Table 169.3 Daily needs of vitamins for older adults

Riboflavin	Men 1.3 mg/day Women 1,1 mg/day
Vitamin B12	2.5 μg/day
Vitamin A	600–700 μg/day
Vitamin C	60–100 μg/day
Vitamin D	10–15 μg/day
Vitamin E	100–400 UI/day
Vitamin K	60–90 mg/day

Nutritional needs for older adults in good health vary little in terms of basic needs. Essential nutrients for which there are reliable data for older adults include proteins, carbohydrates, lipids, vitamins, minerals, phytochemicals, and water.

Source: Organización Panamericana de la Salud. Universidad Tufts. Facultad de Ciencias y Políticas de Nutrición. Mantenerse en forma para la vida. Necesidades nutricionales de los Adultos Mayores. Publicación Científica y Técnica no. 595. Washington: PANO; 2004. p 2.

Healthy eating offers all the essential nutrients and energy each person needs to remain robust. Nevertheless, there are a large number of different gastronomic cultures and cuisines; hence, WHO and FAO (1985) established a culturally acceptable method that considers the relationships between dietary regimen and health.

169.6.1 Recommendations for the Intake of Nutrients in Older Adults

The nutritional needs of older adults in good health vary little in terms of the basic necessities. However, special recommendations are indicated for groups at special risk, although this is still a subject of controversy as regards the general population. The essential nutrients about which there are reliable data for older adults are: proteins, carbohydrates, lipids, vitamins, minerals, phytochemicals, and water (Table 169.3).

Energy: Research from various countries indicates that energy consumption in older adults commonly diminishes due to a reduction in physical activity, and that is an important factor in efforts to prevent weight gain and/or obesity. As a general guideline, various authors point out that the intake level should be equivalent to 1.5 times the basal metabolism (Kritchevsky 2001).The intake of foods necessary to balance higher energy expense should be increased so as to ensure an adequate intake of essential nutrients.

It is important that older adults with low energy intake consume foods abundant in nutrients, instead of those with low nutrient density such as are afforded by sugars, fats, and alcohol. The recommended dietary intake (RDI) is 2.100 and 2.500 kcal for women and men, respectively, although the quantity can be lower in accord with co-morbidities, physical activity, and height.

Calcium: It has been demonstrated that a lower absorption of calcium is related with age, due to changes in the metabolism of vitamin D. Intervention studies have been performed on an extensive scale for the purpose of calculating the requisite calcium requirement of older people, based on the level of intake of this substance to protect against bone mineral loss, mainly in older women. One study performed by Lundberg (2008) demonstrated that although vitamin D consumption was not adequate to meet the requirements of 800–1,200 mg/day of calcium, there was a beneficial effect on bone mineral density in the femur, spinal column and lumbar, and a reduction in the rate of fractures, besides maintaining arterial pressure and lowering the risk of colon cancer.

Iron: Aging does not affect the absorption of heminic iron, nor have changes been observed in the elderly compared with healthy young people. Some studies have demonstrated an increase in non-heminic iron in ferritin in older men, but the ferritin serum concentration is difficult to interpret in the elderly because inflammation can increase it. Due to the fact that iron is a pro-oxidant nutrient, it is necessary to investigate if there is a progressive accumulation in the body during aging and whether there is a relationship between the status of iron and chronic disease due to the increase in oxidative stress (Vaquero 2002). Therefore, it is recommended that 10 mg/day be construed as an adequate intake level for both older men and women.

Magnesium: Magnesium plays an important role in the prevention of cardiovascular diseases, hypertension, osteoporosis and diabetes. The greatest losses of magnesium are found in alcoholics, diabetics, and in patients undergoing treatment with certain diuretics (Vaquero 2002). In addition, hypocalcemia and hypopotasemia are associated with hypomagnesemia. It is estimated that the intake of magnesium should be 225–280 mg in older adults.

Copper: Copper participates in the formation of hemoglobin and is fundamental for the development and maintenance of bones, tendons, connective tissue, and the vascular system. The recommended copper intake, according to WHO, for persons over 60 years of age is 1.3 mg/day (Bunker et al. 1984).

Chromium: Chromium acts as a co-factor for insulin and is necessary for normal metabolism of lipids and glucose; for persons over 60, a dosage of ~50 μg/day is recommended (Vaquero 2002).

Selenium: A micromineral which protects against cardiovascular disease, selenium stimulates the immunological system and is associated with the prevention of cancer. Beck et al. (2007), in a study performed in Baltimore, Maryland, in a community of handicapped women, demonstrated that selenium participates in muscular function, mainly in grip strength, since selenoenzymes protect the muscle against oxidative effects. Selenium is reduced in older adults; hence, the daily recommendation for this age group is 50–70 μg/day.

Zinc: Zinc is extremely important in older adults, because it helps to maintain optimal immunocompetence. Prasad et al. (2007) administered zinc supplements to older adults in a controlled, randomized clinical trial. They had observed that a deficiency of zinc caused immune dysfunction, susceptibility to infections and increased oxidative stress. After administering zinc supplements, the incidence of infections was significantly lower. Therefore, zinc is an effective antioxidant and anti-inflammatory agent. The daily intake recommended for healthy elderly is 5.8–12.8 mg/day. As a supplement, 45 mg/day is recommended.

Proteins: Older people are less efficient in metabolizing proteins. They commonly exhibit a reduction in lean mass. With a good level of caloric intake, most of the elderly do not exhibit a deficit in protein intake. Some authors consider it reasonable to increase the recommended intake to 0.9–1 g/kg/day (RI = 0,8 g/kg/day) (World Health Organization 1985). All this suggests the need for an adequate intake of proteins, which is recommended to not be less than 12% of the total caloric intake, although the renal function of the patient must also be taken into account.

Carbohydrates: Recommendations for carbohydrates are estimated as being between 50% and 60% of the total value of the diet, and it should be stressed that an inadequate intake results in the appearance of alterations in protein metabolism as well as in the loss of sodium and in dehydration.

Lipids: It is recommended that the proportion of lipids in the diet not surpass 30% of the total energetic intake or 35% if olive oil is consumed habitually without frying. Less than 10% should be saturated fatty acids and less than 10% should be polyunsaturated fatty acids. It is important to ensure the administration of essential fatty acids and to avoid the consumption of trans-fatty acids, such as hydrogenated vegetable oil in foods.

Table 169.4 Key facts on anthropometric measurements and aging

There are a variety of molecular changes that indicate a close relationship between aging and nutrition.
The changes which come with aging may directly impact the nutritional status of older adults.
The joint use of BMI and waist circumference better orients the decision-making process regarding nutritional status of the elderly.
The greater the variability in weight, the greater the physical incapacity and mortality.
Changes in body composition in the elderly differ between men and women and are reflected in anthropometric measurements.
Nutritional needs for older adults in good health vary little in relation to the needs of other adults.
Adequate intake of antioxidants, fiber, and water has a positive effect on nutrition and health in the elderly.
The choice of instruments to evaluate nutritional status should consider the intended objective.

This table summarizes the most important points discussed in this chapter regarding nutrition in healthy elderly

Table 169.5 Key antioxidant facts

Antioxidants have the critically important function of eliminating (the) free radicals from the organism.
Free radicals are produced as a result of cellular oxidation and are related to degenerative diseases, such as cancer, cardiovascular disease, premature aging, and diseases of the nervous system.
Selenium, zinc, copper, magnesium, vitamin E (alfa-tocoferol), vitamin C (ascorbic acid, and beta-carotene (provitamin A) are some of the antioxidants that help protect cells against the toxic effect of free radicals.
Antioxidants are found in almost all fruits and vegetables.
Some of the fruits and vegetables with a high antioxidant value are: carrots, spinach, potatoes, tomatoes, garlic, squashes, cabbages, peppers, oranges, lemons, apples, apricots, almonds, pecans, green tea, and soya.
Foods with antioxidant value must be consumed daily for an effect on healthy aging.

This table presents the importance of the consumption of fruits and vegetables with antioxidants in order to maintain healthy nutrition

Fiber: The RDI suggests a consumption of 20–30 g/day, in equal parts of soluble and insoluble fiber. A greater amount can result in flatulence and digestive discomfort, in addition to deleteriously affecting the absorption of some micronutrients.

Vitamins: Vitamins are of special importance because of the effects their lack provokes. The most important vitamins include the following.

Vitamin D: Due to the fact that older persons have less capacity to synthesize this micronutrient from exposure to solar light, in many cases a supplement is necessary.

Vitamins E and C: These are antioxidant vitamins par excellence. They should be present in the diet because they maintain proper functioning of the immune system as well as the antioxidant pathways which have been associated with a slowed process of aging. Their immunomodulating effect has been demonstrated in older persons (75–80 years).

Vitamins B6, B12, and folic acid: A deficit in these vitamins provokes alterations in the levels of highly toxic homocysteine in the blood, which can eventually lead to the appearance of cerebrovascular disease and dementia.

Tables 169.4 and 169.5 indicate the daily requirements for vitamins in older adults, whether based on diet or supplements and the key facts on antioxidants.

Water: The necessary amount of water in older adults is 30 ml/kg day, but this amount is insufficient in older adults of lower weight, who should consume 1,500 ml/kg a day if they afflicted with renal disease (Table 169.6).

Table 169.6 Key hydration facts

After 60 years of age, it is recommended that water consumption per day should be approximately one and a half liters for a person with 70 kg.
In old people, a lack of proper hydration produces bone frailty, constipation, kidney problems, and even behavior problems.
The sensation of thirst may diminish as a person ages. Therefore, there is a risk of not drinking enough liquids in older people.
A balanced diet provides 700 ml of fluid intake per day, but it may be necessary for older people to consume an additional liter.
It is known that alcohol consumption increases the dehydration risk because of the increment in urinary loss and interferes with an adequate of liquids at the intravascular level

This table presents the daily recommendations of liquids for persons older than 60 years. It also includes the risks and benefits of the intake of liquids

169.7 Practical Methods and Techniques for Assessing Nutritional Status

The elderly are vulnerable to a number of nutritional risks because of associated multiple pathologies and the frequent changes in body composition and nutritional needs which they undergo. Furthermore, nutritional assessment in the elderly is especially difficult because many of the signs of malnutrition are also associated with the aging process.

Recently, rapid-application scales have appeared for the purpose of allowing nutritional assessment in geriatrics; these instruments can be classified according to their objective and scope of application.

Nutritional Screening Initiative, Level I and II Screening (NSI). This is a set of instruments well suited to community screening. It incorporates a simple nomogram to determine body mass index and a questionnaire of laboratory data (albumin and serum cholesterol), clinical characteristics, eating habits, living environment, and mental and cognitive states. Level II adds skinfold measurements and biochemical indicators. The objective of these instruments is to estimate the magnitude and causes of malnutrition (Montorio and Lázaro 1996). The questionnaire, applied separately, can be used as an indicator of high, medium, or low risk of malnutrition.

Mini Nutritional Assessment (MNA). This is a questionnaire created for the elderly population and can be applied in cases of ambulatory or hospitalized care. It qualifies the condition of the malnourished patient, the risk of malnutrition, and the general nutritional status. It can be performed in approximately 10 min, consists of 18 questions which comprise an anthropometric evaluation (weight, height, and magnitude of weight loss over time), general assessment (lifestyle, medication and mobility), dietary assessment (number of meals, self-directed food, and liquid intake), and a brief questionnaire for a subjective evaluation (self-perception of health and of nutritional status).

One of its advantages is that there is the possibility of studying each section separately. The total score possible is 30 points. A score above 23.5 classifies the individual as well-fed; scores between 17 and 23.5 indicate a situation of risk, in spite of no evidence of loss or biochemical alteration; and scores below 17 express a situation of malnutrition (Guigoz et al. 1996).

Mini Nutritional Assessment-Short Form (MNA-SF). This abbreviated form was created to reduce the time of administration to 10 min without losing diagnostic power and thus simplifying and generalizing implementation in clinical practice. Among its characteristics, the followings stand out: good correlation with the MNA, adequate sensitivity and specificity, and good internal consistence. This form presents false positives when compared with customary dietary assessment due to the fact that it detects not only malnourished individuals but also those at risk of malnutrition. This version consists of six questions that

can be effectively asked in approximately 3 min. The questionnaire should be used in two phases: the first consists of filling out the short form; if a risk of malnutrition is detected (score lower than or equal to 11 points), the entire questionnaire is then administered (Rubenstein et al. 2001).

Malnutrition Universal Screening Tool (MUST). Initially, this tool was developed for non-institutionalized individuals, but currently its use has been validated in various contexts including the hospital environment, external consultation, and home residences (Stratton et al 2004). Its fundamental objective is to identify individuals at risk for malnutrition, including an assessment of BMI, changes in weight and any disease that affects food intake for more than five days. With regard to BMI, the cutoff points are based on clinical and physiological observations that indicate minor functional deterioration with a BMI of 20. This is the cutoff for which modifications are made for the elderly population. In terms of prognostic value, in hospitalized individuals the results can predict length of stay and the likelihood of mortality. In non-institutionalized individuals, it is related to the likelihood of future hospitalization. It allows the establishment of three risk categories: low, medium, and high, which enable making a series of recommendations. Its limitations include not incorporating any measure of functionality and a focus on acute disease.

Subjective Global Assessment (SGA). This method was designed by Detsky et al. (1987) to estimate nutritional status through clinical history and physical exploration. It has greater sensitivity and specificity than assessment with measurements of albumin, transferrin, cutaneous sensitivity, anthropometry, height-creatinine, or the prognostic nutritional index. The SGA can be used to determine which patients require nutritional intervention and which would benefit from intensive nutritional support.

The data obtained from the clinical history include the evolution of weight, current dietary intake in relation with customary dietary intake, digestive symptoms present in the last 2 weeks, functional capacity, and metabolic requirements. Within the scope of the physical examination are evaluations of: loss of subcutaneous fat, musculature and the presence of edema or ascitis. Each of the elements is evaluated as light, moderate, or severe and patients are classified into three groups: (a) adequate nutritional status; (b) suspicion of malnutrition or moderate malnutrition; and (c) severe malnutrition. One of the limitations is that it depends on an assessment by the professional who administers it. It has been used in both hospitalized and non-hospitalized patients. It has also demonstrated to have utility in patients with severe disease. Given the simplicity of its use, it is frequently used for multicenter studies (Detsky et al. 1987).

The selection of these instruments should be considered from the perspective of the objective that is desired (sifting of the population at risk or in follow-up), the profile of the population or individual, and the available resources, especially personnel and time.

There are other instruments, such as *indices of nutritional prognosis*, designed to improve the sensitivity and specificity to detect risk or morbidity and mortality associated with malnutrition, combining various assessment parameters in formulas derived from regression analysis. These are often used in surgery patients, but currently the results suggest certain variations in their prognostic value in other groups.

169.8 Conclusions

It is important to note that, although there are different patterns of reference, tests, or anthropometric measurements that can be useful for determining the nutritional status of the older adult, considerably more research is needed in this field. This population is heterogeneous and presents with physiological and pathological changes that affects their nutritional status and needs. The objective is to be able to determine from the nutritional status insights into the prognosis of both and chronic diseases, as well as to guide appropriate medical intervention in the elderly, both individually and collectively.

Summary Points

- There are molecular changes that reflect a close relationship between aging and nutrition. One of them is the activation of sirtuins (histone desacetylases) that delay aging, promote longevity, and contribute to the prevention and/or amelioration of chronic diseases.
- The changes that occur with aging at the level of the oral cavity and the cardiovascular, respiratory, sensory, and gastrointestinal systems can directly impact the nutritional status of older adults.
- Evaluation of body composition should consider changes in FFM related with age, whether they occur either as the result of an increase in TBW or as a reduction of mineral mass.
- It is recommended that, in addition to current weight, the history and dynamic of weight in recent months and years be considered, in addition to any history of smoking and simultaneous diseases.
- Anthropometric values by sex are higher in men. Upon comparing groups by age, in both sexes there is a tendency toward reduction of the average values with greater age.
- The joint use of BMI and waist circumference can help to orient health professionals in making decisions regarding nutritional status of the elderly in order to properly manage those with excess weight and/or distribution of adipose tissue.
- There is a certain consensus that the values of BMI currently in use in the elderly tend to underestimate weight deficits and to overestimate the condition of being overweight and, that, probably the critical point of waist circumference underestimates metabolic risk in the elderly.
- Nutritional needs for older adults in good health vary little in basic needs. Essential nutrients for which there are reliable data for older adults include proteins, carbohydrates, lipids, vitamins, minerals, phytochemicals, and water.
- The selection of instruments to assess nutritional status should consider the objective which needs to be met (e.g., sifting the population at risk or care and follow-up), the profile of a given population or individual, and the available resources, especially personnel and time.

Chapter 170
Anthropometry of Leg Lean Volume: Application to Nutrition in Systemic Disorders

Débora Villaça and J. Alberto Neder

Abstract Depletion of leg lean mass has been progressively recognised as an important clinical outcome in disease populations, being related to early disability, impaired health-related quality of life, and even mortality. Estimation of leg lean volumes (LLV) from circumferences and skinfold thicknesses, in particular, have long been used as these techniques are inexpensive and widely-available in clinical settings. The truncated cones method proposed by Jones and Pearson (1967) might be particularly useful for clinical populations in which loss of leg lean mass is common, usually as part of the cachexia syndrome (e.g., chronic heart failure, chronic obstructive pulmonary disease (COPD), chronic renal failure, liver failure, sepsis, rheumatoid arthritis, AIDS and cancer). The method divides the leg into six segments which are assumed to represent truncated cones. Summation of the volume of each cone, determined from the circumferences and the height of each individual cone, gives an estimate of total LV. By subtracting the skinfold thicknesses from the circumferences, a lean volume of each cone can be derived, thereby providing an estimate of LLV. Despite its obvious advantages compared to more sophisticated and costier approaches, the method is time-consuming, needs careful standardization and a trained observer. Moreover, it is technically difficult to be performed in bed-bound patients, being influenced by oedema and obesity. More importantly, however, skinfold thickness measurements are obtained only at few selected locations and it is assumed that they are invariant across the lower limbs and not influenced by gender-specific patterns of fat tissue deposition. Notwithstanding these limitations, there is limited evidence that the method might be highly sensitive to indicate depletion of metabolic active tissue and its functional consequences in specific clinical populations, such as those with chronic obstructive pulmonary disease (COPD). Additional studies are warranted to extrapolate these findings for other disease populations with different levels of nutritional impairment.

170.1 Introduction

Sarcopenia (from the Greek *sarx* (flesh) and *penia* (poverty)) refers to the progressive decline in muscle mass, force-generating capacity and quality that frequently accompanies the aging process (Cruz-Jentoft et al. 2010). By contrast, cachexia (*kakòs* (bad) and *héxis* (condition)) is as a multifactorial syndrome characterized by severe loss of body weight, fat, and muscle associated with increasing protein catabolism due to underlying disease(s), such as chronic heart failure (CHF), chronic obstructive pulmonary disease (COPD), chronic renal failure, liver failure, sepsis, rheumatoid arthritis, AIDS, and cancer (Table 170.1) (Anker et al. 2006). The *Cachexia Society* (Evans et al. 2008) proposed the following definition of the syndrome which was recently (Muscaritoli et al. 2010) endorsed by the 'cachexia-wasting syndromes' and 'nutrition in geriatrics' Special Interest Groups of the *European Society for Clinical Nutrition and Metabolism*: "*cachexia, is a complex metabolic syndrome associated with underlying illness and characterized by loss of muscle with or without loss of fat mass. The prominent clinical feature of cachexia is weight loss in adults (corrected for fluid retention) or growth failure in children (excluding endocrine disorders). Anorexia, inflammation, insulin resistance and increased muscle protein breakdown are frequently associated with cachexia.*

Table 170.1 Objective criteria for cachexia diagnosis. Diagnostic criteria for wasting disease (cachexia) in adults according to the European Society for Clinical Nutrition and Metabolism (2010) (Based on Muscaritoli et al. 2008)

Weight loss of at least 5% (edema free) in 12 months or less in the presence of underlying illness,[a] plus three of the following criteria:

- Decreased muscle strength (lowest tertile)
- Fatigue (defined as physical and/or mental weariness resulting from exertion; an inability to continue exercise at the same intensity)
- Anorexia [Limited food intake (i.e., total caloric intake less than 20 kcal/kg body weight/day; <70% of usual food intake) or poor appetite]
- Low fat-free mass index[b]
- Abnormal biochemistry
  - increased inflammatory markers CRP (>5.0 mg/l)
  - IL-6 >4.0 pg/ml
  - Anemia (<12 g/dl)
  - Low serum albumin (<3.2 g/dl)

[a]In cases where weight loss cannot be documented, a BMI <20.0 kg/m^2 is sufficient

[b]Lean tissue depletion (i.e., mid-upper-arm muscle circumference <10th percentile for age and gender; appendicular skeletal muscle index by DEXA (kg/m^2) <5.45 in females and <7.25 in males

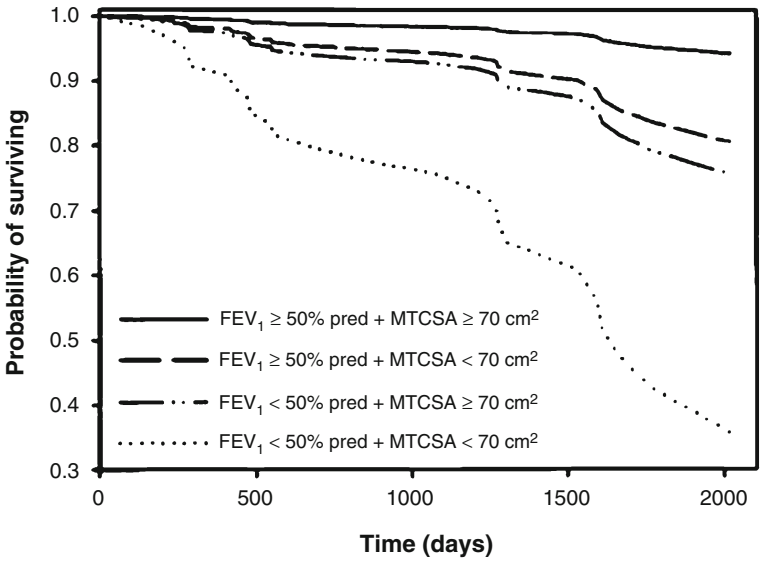

Fig. 170.1 Survival as a function of leg muscle depletion and lung function in patients with COPD. Marked reduction in survival in COPD patients with decreased leg muscle mass (mid-thigh muscle cross-sectional area by computed tomography (*MTCSA*) <70 cm^2) and worse airflow obstruction (forced expiratory volume in one second (FEV_1) <50% predicted). Note the better survival rates of patients with similar degrees of airflow obstruction but with preserved MTCSA values (Extracted from Marquis et al. (2002). With permission)

Cachexia is distinct from starvation, age-related loss of muscle mass, primary depression, malabsorption and hyperthyroidism and is associated with increased morbidity."

In this context, it has been well established that depletion of lean body mass (LBM) has important deleterious consequences to different clinical populations (Schols et al. 1993; Fiori et al. 1999; Mafra et al. 2008). Loss of appendicular LBM is particularly relevant to decrease patients' mobility and health-related quality of life. In addition, fat-free tissue depletion increases the likelihood of negative clinical outcomes, such as osteoporosis and frequency of falls (Fiori et al. 1999; Evans et al. 2008; Muscaritoli et al. 2010). There is also evidence that LBM depletion and its functional consequences tend to be more pronounced in the lower compared to upper limbs, suggesting that at least part of the wasting process might be ascribed to physical inactivity (see also *Pathophysiology of lean tissue depletion in clinical populations*) (Fransen et al. 2002). In fact, exercise tolerance, especially in patient populations, is strongly influenced by the amount of metabolic active tissue and vice versa (Baarends et al. 1997; Anker et al. 1997).

Interestingly, recent data demonstrated a significant association between decreases in appendicular LBM and long-term survival in patients with COPD (Fig. 170.1) (Marquis et al. 2002) and subjects at risk of dying from cardiovascular disease (Heitmann et al. 2009) suggesting a prognostic role for segmental body composition estimates in these patients. Unfortunately, however, simple indices of whole-body LBM depletion, such as the body mass index (BMI), are poorly sensitive to indicate abnormalities in appendicular composition, making its direct measurement clinically relevant.

It is not surprising, therefore, that there is a renewed interest in measuring appendicular LBM in patients with chronic diseases. For this purpose, several methods have been used, ranging from expensive and sophisticated laboratory techniques, such as magnetic resonance imaging (MRI), computed tomography (CT), and dual energy X-ray absorptiometry (DEXA) to simpler and widely available methods, such as anthropometry. Anthropometric segmental measurements, in particular,

have long been used to estimate leg lean volume (LLV) from circumferences and skinfold thickness in children (Davies et al. 1972) and adults (Jones and Pearson 1969). Although such techniques would be expected to be particularly useful in clinical settings due to their simplicity and low cost, most of the extant literature on this topic is based upon measurements performed in young and healthy subjects, frequently in the sports science arena (Winter et al. 1991; Doré et al. 2001; Howden et al. 2002; Temfemo et al. 2007).

This chapter, therefore, will present some key technical aspects of the more relevant anthropometric methods of segmental body composition assessment with special attention to LLV and its role in the evaluation of nutritional status in clinical populations.

170.2 Pathophysiology of Lean Tissue Depletion in Clinical Populations

It has been recognized that the 'fat-free' (i.e., muscle and bone) compartment is frequently reduced as disease progress in systemic disorders. In the context of lean tissue assessment by anthropometric techniques, much more attention has been paid to loss of appendicular muscle mass compared to decrease in bone mass, as the latter contributes to only a fraction of the whole limb volume. Nevertheless, decrease in bone mineral density is an important correlate of LBM depletion and both share similar etiological and pathophysiological mechanisms in clinical populations.

170.2.1 Mechanisms of Impaired Protein Balance in Chronic Diseases

The prevailing view is that nutritional depletion in chronic, systemic, non-malignant disorders results from a disturbed energy balance, which mainly affects body fat mass, and an impaired protein balance, resulting in predominant loss of metabolic active lean tissue (Fransen et al. 2002; Evans et al. 2008; Muscaritoli et al. 2010).

Although most of the available literature pertains to chronic cardiopulmonary and inflammatory diseases, it is likely that similar mechanisms are operant in other systemic, non-malignant disorders. For instance, cardiac cachexia affects 12–15% of CHF patients being diagnosed if, over 6 months or more, there is weight loss of more than 6% (in the absence of edema) compared to previous weight (Anker et al. 2006). Patients with cardiac cachexia have increased resting energy expenditure and a chronic state of neuroendocrine and immunological disturbances, which predisposes to an imbalance between anabolism and catabolism. More specifically, muscle atrophy is the final result of sympathetic overactivation associated with increased cortisol, aldosterone, and rennin levels under the influence of a pro-inflammatory status. Loss of appetite (anorexia) plays a significant role in only 10–20% of all cases of cardiac cachexia (Anker et al. 2006).

Similar alterations have been described in 25–40% of the patients with advanced COPD (Schols et al. 1993). Clinically relevant weight loss (5% of actual weight within 3 months or 10% within 6 months) is linked to tissue hypoxia, aging, physical exercise, increased resting metabolic rate, low-grade chronic inflammatory activity, and certain drugs, such as corticosteroids. Different from CHF, however, a pronounced loss of appetite (anorexia) and decreased food intake are common. Disease exacerbations worsen the nutritional status and intake is further reduced due to difficulties in chewing and swallowing secondary to the altered mechanics of breathing. Moreover, severe hypoxia might reduce the appetite via the neurohormonal actions of leptin and additional pro-inflammatory cytokines' burden (Anker et al. 2006). Regardless of the precise mechanism(s), disease exacerbations are associated with further decreases in LBM and deterioration of the health-related quality of life.

170.2.2 Muscle Morphological and Functional Abnormalities

In addition to decreases in the muscle mass bulk, there is a relative shift in fiber-type distribution in patients with COPD and CHF. The percentage of type I oxidative muscle fibers is decreased, and the proportion of type II (mainly type IIX) glycolytic fibers is increased. In addition, muscle fibers seem to be smaller in patients compared to healthy controls (Fransen et al. 2002). There are also striking similarities in terms of alterations in activities of metabolic enzymes, as well as bioenergetic abnormalities indicative of impaired oxidative metabolism in these diseases. Such alterations are associated with variable decreases in muscle strength and endurance which seem to affect primarily the lower limbs in COPD but might be more generalized in CHF. In patients with chronic renal failure, the muscle weakness is also more pronounced in the lower than in the upper limbs and is particularly present in the proximal muscles (Mafra et al. 2008).

A controversial issue on this topic is the putative structure–function relationship, as both mass and performance are concomitantly reduced. Using an allometric approach, Malaguti and co-workers (2006) found that the coefficients for correction of isokinetic strength and endurance by leg muscle mass (DEXA) were significant higher in COPD patients than in controls. In other words, more muscle mass was needed to generate a given functional output in patients than in normal subjects. These data seem to indicate that factors other than simple atrophy (i.e., mass-independent mechanisms) might play a role in explaining the COPD-related skeletal muscle dysfunction.

170.2.3 The Role of Deconditioning and Aging in Muscle Atrophy

Reduced physical activity is a ubiquitous finding in clinical populations. In fact, skeletal muscle alterations in patients with CHF, COPD, and renal failure do resemble those occurring during disuse. However, there is a trend for disease-related atrophy to affect type II fibers, while disuse-induced atrophy disproportionately involves type I fibers (Fransen et al. 2002). Moreover, muscle atrophy and qualitative alterations remain present long after organ transplantation, especially in patients with COPD. Therefore, despite deconditioning seeming to constitute an important contributing factor for the observed loss of lean tissue in systemic disorders, it is clear that this is not the main mechanism behind muscle atrophy in patients with more advanced disease.

Aging per se is also associated with decrease in appendicular muscle mass and impaired oxidative capacity. However, there is a relative increase in proportion of type I muscle fibers, that is, a pattern not identical to that observed in disease (Cruz-Jentoft et al. 2010). More importantly, however, most studies investigating disturbances in peripheral skeletal muscle in patients involved age-matched control groups that did not depict the same extensive abnormalities found in patient populations.

170.3 Practical Methods to Determine LLV

170.3.1 The Truncated Cones Method of Jones and Pearson (1969)

The method consists in dividing the non-dominant leg into six segments (Fig. 170.2), which are assumed to represent truncated cones. Summation of the volume of each cone, determined from the circumferences and the height of each individual cone, gives an estimate of total LV. By subtracting

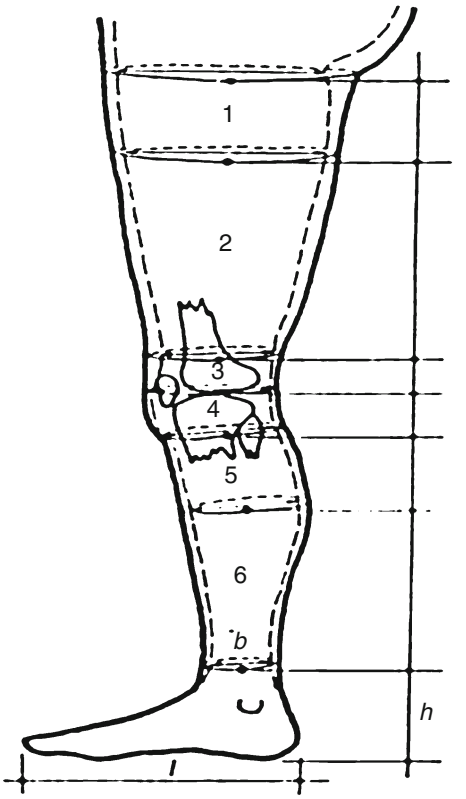

Fig. 170.2 Reference markers for anthopometric measurements of leg lean volume. Schematic illustration of the sites from which the anthropometric measurements should be taken in order to obtain the six truncated cones for leg lean volume (*LLV*) estimation, according to the method proposed by Jones and Pearson (1969) (Extracted from Jones and Pearson (1969). With permission)

the skinfold thicknesses from the circumferences, a lean volume of each cone can be derived, thereby providing an estimate of LLV. The cross-correlation coefficients of total leg (thigh and calf) and total leg fat according to this method and those obtained by water displacement and soft-tissue roentgenogrammetric readings were highly significant ($r = 0.86$–0.99). Despite the method has been originally applied to a sample consisting of only 32 male and 15 female young adults, LV estimates demonstrate acceptable levels of accuracy for most practical uses in different healthy populations (Winter et al. 1991; Doré et al. 2001; Howden et al. 2002; Temfemo et al. 2007) and, more recently, in patients with COPD (Villaça et al. 2008).

In this method, seven circumferences are taken with a metric tape at predetermined sites (Fig. 170.2) with the patient standing erect and the feet slightly apart:

1. The gluteal furrow (C1),
2. One-third of the subischial height up from the tibial–femoral joint space (C2),
3. The minimum circumference above the knee (C3),
4. The maximum circumference around the knee (C4),
5. The minimum circumference below the knee (C5),
6. The maximum calf circumference (C6), and
7. The minimum ankle circumference (C7).

The heights (h) above the floor level for each circumference are obtained by using a stadiometer. In addition, anterior and posterior skinfold thicknesses are measured at C2 (thigh) and medial

and lateral skinfold thicknesses are measured at C6 (calf) using a caliper following standard techniques.

In order to obtain the volume of a truncated cone (Vc), the following standard equation should be used:

$$\mathrm{Vc} = \frac{1}{3h}\left(a + \sqrt{(ab)} + b\right) \tag{170.1}$$

where a and b are the areas ($0.785 \times C^2$) of two parallel surfaces. The volume of the foot (Vf) is also calculated by assuming the foot to be wedge shaped:

$$\mathrm{Vf} = \frac{1}{2l \times b \times h} \tag{170.2}$$

where l is the foot's length and b is the diameter calculated from C7. LLV (L) is then calculated by summing up the volumes of the six lean cones (i.e., by subtracting the skinfold reading from their respective diameters) *plus* Vf. In addition, LLV might be expressed as a function of leg height (m) in order to further correct for interindividual differences in leg dimensions (Villaça et al. 2008). It is recommended that these equations be incorporated on a software for faster and more accurate results.

170.3.2 The Thigh Muscles' Cross-Sectional Area (CSA)

Although this method does not aim to estimate LVs, its practicality and similar rationale make it potentially useful for clinical populations. The method proposed by Housh et al. (1995) aims to estimate the area of specific muscle groups from mid-thigh circumference (MC) and anterior thigh skinfold (ATS) measurements. In this study, MRI was used to measure the CSA of the thigh muscles, which were separated into three groups: (1) the *quadriceps* (*vastus intermedius, vastus lateralis, vastus medialis*, and *rectus femoris*), (2) the hamstrings (*semimembranosus, semitendinosus*, and *biceps femoris*), and (3) *adductor* (*adductor longus, adductor magnus*, and *gracilis*). The CSA of the *sartorius* was measured individually and added to others to determine the total thigh muscle CSA. The following multiple linear regression equations were then derived to estimate individual muscle group CSA from the anthropometric measurements:

$$\text{Quadriceps CSA} = (2.52 \times \text{MC in cm}) - (1.25 \times \text{ATS in mm}) - 45.13. \tag{170.3}$$
$$R = 0.86; \quad \text{SEE} = 5.2\ \text{cm}^2$$

$$\text{Hamstrings CSA} = (1.08 \times \text{MC in cm}) - (0.64 \times \text{ATS in mm}) - 22.69. \tag{170.4}$$
$$R = 0.75; \quad \text{SEE} = 3.5\ \text{cm}^2$$

$$\text{Total thigh muscle CSA} = (4.68 \times \text{MC in cm}) - (2.09 \times \text{ATS in mm}) - 80{,}99 \tag{170.5}$$
$$R = 0.86; \quad \text{SEE} = 9.5\ \text{cm}^2$$

Data obtained on a derivation group ($N = 30$) indicated better results for the *quadriceps* CSA ($r = 0.85$) though there was a substantial intra-subject disagreement between predicted and criterion CSA.

170.4 Advantages and Shortcomings of LLV Estimation in Patients

Anthropometric-based methods for the estimation of LLV (and mass) are particularly attractive in clinical settings, as they are inexpensive and widely available, being therefore suitable for bedside applications. However, there are some inherent limitations that should be carefully considered (Table 170.2):

1. These methods are time consuming and need careful standardization and a trained observer.
2. They are technically difficult to be performed in bed-bound patients, being clearly influenced by edema and obesity.
3. The bulk of the evidence demonstrates that leg muscle mass tends to be overestimated (12–48%) and subcutaneous adipose tissue underestimated (25–47%) (Buckley et al. 1989; Fuller et al. 1999; Elia et al. 2000) though better results have been described in younger and leaner subjects (Holmes et al. 2005; Burkhart et al. 2008).
4. LLV might be a particularly weak estimate of 'fat-free' volume, as intermuscular adipose tissue infiltration (Ruan et al. 2007), a finding associated with impaired functional performance and metabolic consequences, is more prevalent in older and diseased populations (Hilton et al. 2008).
5. Skinfold thickness measurements are obtained at few selected locations and it is assumed that they are invariant across the lower limbs and not influenced by gender-specific patterns of fat tissue deposition. In fact, Tothill and Stewart (2002) found that this source of error was the central mechanism to explain the substantial underestimation of adipose tissue by the truncated cones method (Jones and Pearson 1969), as the central anterior measurement was poorly representative of the non-uniform thickness distribution around the limb (Fig. 170.3).

170.5 LLV and Nutritional Status in Chronic Diseases

Decline in muscle mass commonly occurs with the aging process and it is closely related to physical disability. Loss of lean body mass per year in elderly persons has been estimated to reach 0.1–0.3 kg (Cruz-Jentoft et al. 2010). As mentioned, however, a number of chronic conditions which are more

Table 170.2 Anthopometry of leg lean volume in practice. Recommendations for using leg lean volume measurements according to the Jones and Pearson method (1969) in clinical populations

Factor	Recommendations
Subject	Extra caution in interpretation of data from obese subjects due to low accuracy and reproducibility
	Eedema as a potential confounding factor
Body position	Subjects should stand on a platform with a stadiometer 150 cm high parallel to the non-dominant leg
	Members slightly apart.
	Limited experience with bed-bound patients
Skinfold thickness	Posterior skinfold thickness at C2 particularly difficult to be obtained in women and overweight subjects
	Record in triplicate and use the average.
Circumferences	Variations in C2 and C6 are the main source of variability for the calculation of the volume of the cones
	A plastic metric tape should be used.
	Record in triplicate and use the average.
Data calculation	Computer calculation is advisable.

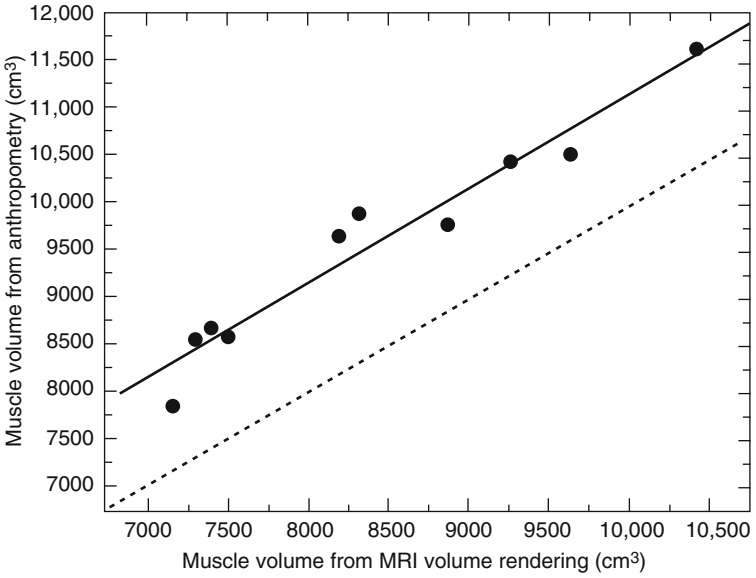

Fig. 170.3 Anthropometry versus magnetic resonance imaging for the estimation of leg muscle volume. Muscle volume derived from anthropometry (Jones and Pearson 1969) as a function of magnetic resonance imaging in healthy adults. The *dashed line* is the line of identity. Note the consistent, and apparently linear, overestimation of the readings by anthropometry (Extracted from Tothill and Stewart (2002). With permission)

prevalent in this age group further contribute to accelerate muscle wasting and weakness, including cancer, chronic kidney, liver and heart failure, and COPD (Evans et al. 2008; Muscaritoli et al. 2010).

The truncated cones method (Jones and Pearson 1969) has been recently used by Villaça and co-workers (2008) to investigate the usefulness of LLV estimates in identifying nutritionally depleted (BMI ≤ 21 kg/m^2 and/or fat-free mass index by DEXA ≤15 kg/m^2 in females and ≤16 kg/m^2 in males) (Schols et al. 1993) from non-depleted (N = 21) patients with moderate to severe COPD. The authors found that anthropometric and DEXA-based estimates of LLV agreed within 0.4 L (95% CI: 0.59, 1.39) and 0.5 L (95% CI: 1.08, 2.08) in depleted and non-depleted patients, respectively (Fig. 170.4). Leg-height-corrected LLV values also showed acceptable sensitivity and specificity to identify systemic depletion (area under a receiver operating characteristics curve = 0.93 (range 0.86–1.00); P < 0.001) (Fig. 170.5). In fact, the 'best cutoff' value of 9.2 L/m was 95% sensitive and 80% specific to indicate depletion of metabolic active muscle. Also important, patients with LLV ≤9.2 L/m had significantly lower exercise capacity and muscle function than their counterparts. These data provided novel evidence that the truncated cones method can be clinically useful in predicting the presence of nutritional depletion and its functional consequences in COPD.

Mathur et al. (2008) tested the performance of the thigh muscles CSA method developed by Housh et al. (1995) in establishing lean leg tissue depletion in 19 patients (10 females) with COPD. In contrast with the results of Villaça and co-workers (2008), they found that anthropometrically determined *quadriceps* and hamstrings CSAs (170.3 and 170.4) overestimated those determined by MRI to an extent that there were no significant between-group differences in these measurements. However, the sample presented with a forced-expiratory volume in one second (FEV_1, an index of airflow obstruction) and BMI values quite similar to the 'non-depleted' group of Villaça´s study (1.38 ± 0.48 L *vs.* 1.34 ± 0.41 L and 26.6 ± 4.7 kg/m^2*vs*. 25.6 ± 2.6 kg/m^2, respectively). These numbers contrast sharply with those found in the 'depleted' group of the latter study (0.99 ± 0.39 L and 19.3 ± 2.1 kg/m^2). Consequently, Marthur et al. (2005) seemed to have evaluated a group of COPD

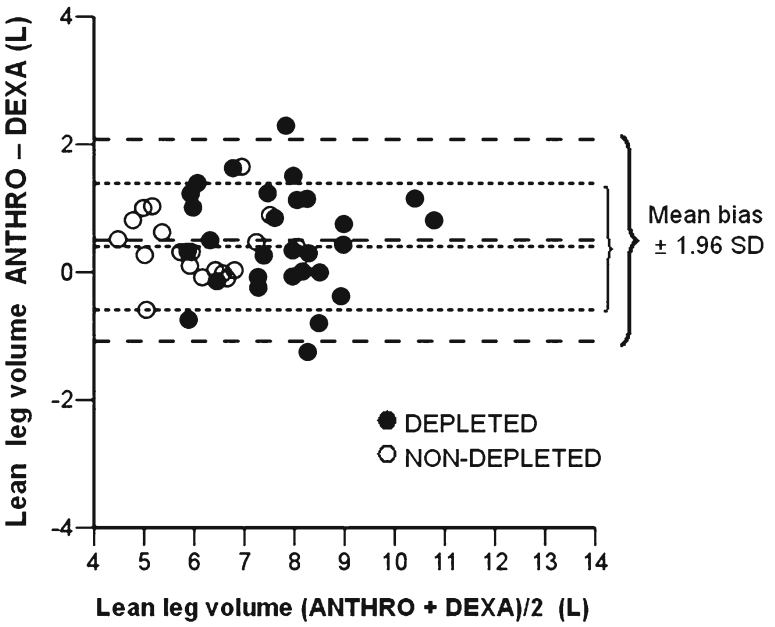

Fig. 170.4 Leg lean volume according to anthopometry and DEXA in patients with COPD. The limits of agreement between anthropometry and DEXA in estimating leg lean volume (*LLV*) in nutritionally depleted and non-depleted patients with COPD (Villaça et al. 2008). Note the homocedastic overestimation of LLV by anthropometry in both groups (Extracted from Villaça et al. (2008). With permission)

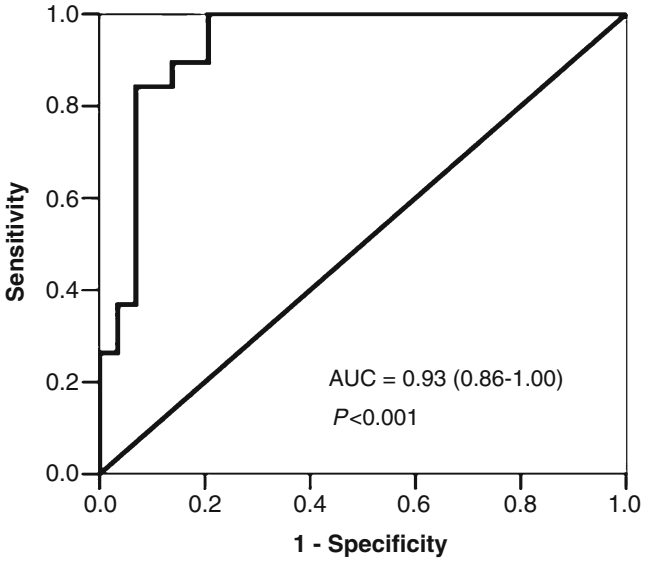

Fig. 170.5 Leg lean volume to establish nutritional depletion in patients with COPD. A ROC curve analysis of the diagnostic performance of anthropometric estimates (leg lean volume/leg height, L/m) in identifying patients with nutritional depletion. Notice that a threshold of 9.2 L/m presented with the best combination of sensitivity and specificity (95% and 80%, respectively). Depletion was defined according to the following criteria: body mass index ≤21 kg/m^2 and/or fat-free mass index ≤15 kg/m^2 in females and ≤16 kg/m^2 in males (Schols et al. 1993). AUC is the area under the curve (Extracted from Villaça et al. (2008). With permission)

patients with low prevalence of nutritional depletion, making difficult the assessment of the actual performance of anthropometry in this specific setting.

Unfortunately, despite the widespread recognition of the relevance of segmental body composition abnormalities in systemic diseases, there is a lack of information regarding the usefulness of anthropometric estimates of LLV in determining nutritional depletion in other clinical populations.

170.5.1 Future Research

There are several important gaps in the current knowledge on the sources of variability of anthropometric estimates of LVs in clinical populations. There is an urgent need to validate the Jones and Pearson method (1969) in the elderly and develop more comprehensive technical approaches, probably by using additional sites of skinfold thickness and circumference measurements. Moreover, little is known about the sensitivity of anthropometry to early detect subtle reductions in leg lean volumes before the development of cachexia and its negative metabolic and functional consequences. There is also a lack of data on accuracy, reliability, and external validity of these measurements in specific patient population groups, such as those with cancer and AIDS. Finally, it is likely that there are important ethnical and racial variations in the relationship between LLV and leg height (Villaça et al. 2008), an issue which remains largely unexplored.

170.5.2 Application to Other Areas of Health and Disease

Measurements of LLV have been previously used in applied research in sports sciences (Winter et al. 1991; Doré et al. 2001; Howden et al. 2002; Temfemo et al. 2007). However, there is a large potential for these estimates to be used as a screening and follow-up tools in selected sport modalities in which the muscle mass of the lower limbs is particularly relevant for performance. LLV could be useful to estimate the risk of negative clinical outcomes in the general population, such as the risk of cardiovascular and metabolic disease. Large-scale, longitudinal evaluations of LLV might also prove to be relevant for screening sarcopenia in the aged population. These potential developments, however, depend on multinational studies to establish reliable reference values for LLV across age groups in both males and females.

170.6 Conclusions

Contemporary methods for body composition assessment rely on highly sophisticated and expensive equipment despite the progressive curtailment of healthcare resources. By contrast, inexpensive and widely available anthropometric methods to estimate segmental body composition, especially the Jones and Pearson's (1969) approach to measure LLV, are potentially useful to identify nutritionally depleted subjects with systemic diseases. In the specific context of COPD, there is limited evidence that leg-height-corrected LLV (≤9.2 L/m) is highly sensitive to indicate depletion of metabolic active tissue. There is, however, no published experience in other disease groups which calls for additional validation studies in wider clinical settings.

Summary Points

- Patients suffering from chronic diseases which affect the major organs (e.g., heart, lungs, liver, and kidney) frequently present with loss of fat-free ('lean') tissue, a finding that impairs quality of life and leads to disablement and early death.
- These abnormalities seem to disproportionately affect the lower limbs, making clinically important the measurement of leg lean mass.
- The methods available to measure leg lean mass are cumbersome and expensive. Anthropometric techniques to estimate leg lean volume, however, are easily performed with a minimum of equipment.
- The techniques are based on a series of measurements of circumferences, girths, and the thickness of subcutaneous ('fat') tissue, which allows the estimation of the leg volumes.
- There are some research findings indicating that a particular method of measuring leg lean volume developed in 1967 by Jones and Pearson is useful to establish if patients with a chronic lung disease (COPD) are nutritionally depleted and functionally impaired.
- Despite these encouraging results, very few studies have looked at these aspects in other disease populations and there is large room for future investigations before these techniques actually reach the clinical practice on a larger scale.

Key Features

Table 170.3 Key points on leg lean volume to indicate nutritional depletion in patients. Key points on clinical value of leg lean volume in estimating nutritional status in disease populations

Depletion of lean body mass is a relevant clinical outcome in several disease populations, being related to increase disability and mortality.
The lower limbs are particularly affected in this process, thereby making the anthropometry of the legs of special interest.
Although there have been several attempts to develop techniques to measure leg lean volumes, the truncated cones method of Jones and Pearson still provides a more comprehensive evaluation of the whole limb.
Preliminary evidence suggests that this method might be highly sensitive and specific to indicate fat-free tissue depletion in selected groups, such as those suffering from chronic obstructive pulmonary disease.
There is a need for further research on different clinical populations presenting with varied degrees of nutritional impairment.

Chapter 171
Nutritional Anthropometry for Amputees: Challenges for Clinicians

Elaine Bannerman, Jolene Thomas, and Michelle Miller

Abstract Anthropometric measurements pose interesting challenges for clinicians when attempting to perform and interpet these in individuals with a lower extremity amputation. With little evidence to guide best practice, when clinicians do incorporate anthropometry into their practice they tend to apply measures with demonstrated validity in other populations. Following a comprehensive literature review, very few studies challenging the application of anthropometric measurements in those with a lower extremity amputation were identified. Largely the literature makes recommendations to continue to utilise body mass index, with complex equations developed to enable estimation of weight for the amputated limb. Alternatively the literature advocates for adopting measurements of the upper body while acknowledging that while these have correlation with measures such as body mass index, there is yet no information on whether these measures have any predictive ability in terms of health outcomes. The ideal approach is thus still controversial and research should focus on evaluating the ease and validity of various anthropometic measurements amongst those with a lower extremity amputation with a view to establish best practice recommendations for this group.

171.1 Introduction

171.1.1 Statistics

In 2005, the prevalence of individuals with amputations in USA was approximately 1.6 million individuals. Nearly all (97%) amputations were of a lower limb, of which approximately one-quarter were above the knee. Incidence rates of amputations due to trauma have shown a decline in recent years; however, the risk remains high in those over 85 years (National Limb Loss Information Centre 2008). The main cause was vascular complications associated with chronic diseases, such as diabetes mellitus (38%), these being more common in males and also in African-Americans (Zeigler-Graham et al. 2008). With the growing prevalence of diabetes, it is projected that the number of those individuals with vascular complications and thus need for amputation will also increase.

The National Amputee Statistical Database for the UK (NHS NSS 2009) reported approximately 5,000 new referrals to prosthetic services for the period 2006/2007. Of these, 28% were over the age of 75 years and less than 3% were under 16 years. The gender ratio of new referrals remained relatively constant over the 10 years (1997–2007), with approximately two-thirds being male (2006/2007, 3506 males: 1,451 females). Over 90% of referrals were for lower-limb amputations.

The National Hospital Morbidity Database Procedure Data cubes as classified by the ICD-10-AM Australian Classification of Health Interventions (ACHI), 5th Edition allows identification of the number of lower-limb-amputation procedures that were performed in Australian hospitals for the period 2006–2007 to 2007–2008 (Australian Institute of Health & Welfare 2009). In terms of procedures on the musculoskeletal system, amputations below the knee (1505 – 44367-02) reported 2,589 cases, of which 71% were male and 61% were >65 years. Amputation above the knee (1484 – 44367-00) reported 1,950 cases, of which 63% were male and 79% were >65 years. Neither specific details of diagnoses for related procedures nor prevalence data are available. Differences in statistics reported may, in part, be related to different definitions for procedures.

Key features of lower-limb amputees are outlined in Table 171.1.

Table 171.1 Key features of lower-limb amputees

1. Amputation is the removal (often by surgical operation) of a limb, or part of a limb, of the body.
2. Individuals who are most likely to need to undergo an amputation are individuals who have developed significant problems with their blood circulation as a result of chronic diseases, such as diabetes mellitus. The other key group of individuals who have an amputation are individuals who have injured a limb through a traumatic event.
3. The most common part of the body where amputations are performed is on the lower limbs (legs). This may be surgical removal of a foot or of the lower leg (below the knee) or the full leg.
4. Many individuals who undergo a lower-limb amputation will have an artificial limb (prosthesis) made to improve their everyday functioning.
5. Being overweight or obese can add complications for individuals with lower-limb amputations, including affecting their mobility and can increase wear and tear of their prosthetic device meaning it may need to be replaced more frequently.
6. Being able to accurately monitor weight status and nutritional status of individuals with lower-limb amputations has important implications for the management and health outcomes for the individual.
7. However, many of the tools used for nutritional screening and assessment purposes include weight and height, which can be difficult to measure or interpret in individuals with an amputation.

This table lists the key features of individuals who undergo amputations, how this is generally managed and how this can impact on an individual's quality of life and their health

171.1.2 Health-Related Quality of Life and the Importance of Nutritional Well-Being

Assessment of individuals after a lower-extremity amputation has shown varying factors that predict health-related quality of life (HRQoL), including depression, the use of prosthetic devices, presence of other comorbidities and social functioning (Asano et al. 2008). Research has shown significant reductions in health-related quality of life in individuals with diabetic neuropathy who undergo amputation (Happich et al. 2008).

The importance of nutritional well-being post-amputation has been a largely neglected area of research as much focus has been on diet as a causative factor. Neuropathy and vascular complications of the lower limbs of individuals with diabetes is one of the leading causes of amputation, particularly of the lower limb. Overweight and obesity increase the risk of individuals developing type 2 diabetes and other metabolic complications, including hypertension and abnormal blood lipid profiles. This is especially evident in those with poorly managed blood glucose levels, increasing the risk of diabetic neuropathy, and therefore the risk of amputation as well as increasing the risk of cardiovascular disease.

Post-amputation, obesity has been noted as a complication for some individuals with lower-extremity amputation (Kurdibaylo 1996). While it is well known that obesity increases the risk of chronic disease as highlighted earlier, obesity can also pose practical problems for use of the prosthetic device. An audit of repairs to lower-extremity prosthetic devices of amputees ($n = 113$) in the UK showed that even after controlling for length of use of device, increasing body weight was significantly related to increased need for prosthetic repairs (Haboubi et al. 2001). Thus, in addition to the metabolic complications, the weight status of individuals with lower-limb amputations requiring prosthetic limbs brings economic implications, considerations of maximum body weight for use of specific devices as well as negative effects on an individual's psychological, physical and social quality of life. Being able to accurately monitor weight status and nutritional status of individuals with lower-limb amputations has important implications for their management and the health outcomes for the individual.

171.1.3 Measurement of Nutritional Well-Being

It is well recognised that nutritional screening to identify individuals with nutritional risk should be routinely performed in acute, primary and rehabilitation settings (Council of Europe 2003; NHS QIS 2003; Watterson et al. 2009) and is considered to be a cost-effective method in low-mortality-risk individuals (NICE CG32 2006). While most prominently recognised for its ability to assess risk of undernutrition, nutrition screening is also capable of identifying those individuals who are at increased risk of overweight and obesity (NICE CG 43 2006). A key challenge for clinicians working with individuals post-amputation, however, is that many of the tools used for nutritional screening purposes contain measures of anthropometry, including weight and height. Nutritional assessment poses an even greater challenge for clinicians as all methods of assessment will require some measurement of body size and/or composition.

Measurements of body size and composition (anthropometry) are recognised as a core part of the nutritional assessment of an individual, which are then interpreted in conjunction with medical and diet history, physical examination and various laboratory data. These assessments contribute to determining individuals' nutritional health status and can be used to indicate appropriate care pathways,

clinical management of an individual as well as monitoring the impact of therapeutic interventions and changes in nutritional status. Measurements need to be valid and reliable and have prognostic value in terms of health outcomes; however, they need to be simple to perform to ensure that they are administered when necessary. However, the assessment of either the weight or the nutritional status of an individual with an amputation brings with it a number of complications. The aim of this review is to present a summary of the literature reporting recommendations for measuring nutritional anthropometry in amputees and to provide some practical guidelines for clinicians.

171.2 Search for Relevant Studies

The studies in this review were obtained through electronic databases. The electronic databases MEDLINE, PubMed, CINAHL, Cochrane Library and SportDiscus were searched using the following terms: amputation, artificial limbs, above knee amputation, below knee amputation, transfemoral amputation, transtibial amputation, amputee, limb, anthropometry, measurement, circumference, girth, skinfold, weight, body mass index, body weight or body mass, overweight, underweight, nutritional assessment, diet, assessment and nutritional status. The databases were searched for the period up until September 2009. Titles and abstracts were examined by the authors and if the abstracts met the inclusion criteria, the full text of the article was retrieved. A total of 45 abstracts was screened as worthwhile for retrieval and, of these, ten resulted in being appropriate for the purpose of this review.

171.3 Summary of the Evidence

One of the key points that this review has uncovered is the lack of research performed regarding the use of nutritional anthropometry amongst amputees and the resultant lack of suitable data for contributing to a review of this kind. While ten studies were located that were deemed suitable for inclusion, the samples across this scant literature are extremely heterogeneous, making overall recommendations difficult.

The literature is global, covering such diverse populations as those in India (Monzumdar and Roy 2004), Australia (Miller et al. 2008) and Brazil (Innocencio da Silva Gomes et al. 2006). Baseline nutritional health and healthcare following amputation are likely to be very different; hence, pooling of this data would be inappropriate. Likewise, pooling of data is questionable when the samples surveyed in the literature span from elite athletes (Innocencio da Silva Gomes et al. 2006) (Table 171.2) to frail older people (Miller et al. 2008) (Table 171.3), where nutritional health, comorbidities and risk factors for further decline are vastly different. It is also important to consider the level of amputation undertaken, with many studies choosing to select transtibial (Eneroth et al. 1997) or transfemoral (Boonstra et al. 1995) but some choosing to pool data for both groups (Innocencio da Silva Gomes et al. 2006; Miller et al. 2008). With these issues in mind, the following discussion attempts to highlight where and what nutritional anthropometry has been reported for amputees and any implications or recommendations worthy of consideration for clinicians.

The most commonly performed anthropometric measurements are weight and height, which allow the determination of a relative body mass index (BMI: kg/m^2). Internationally accepted classification of weight categories has been developed by the WHO (1995). The BMI and this classification system have been shown to have a strong relationship with body fat and significant prognostic

Table 171.2 Anthropometric parameters of the Brazilian Amputee Soccer Team players, with respect to the positional role on the team (Reprinted by permission from Elsevier Innocencio da Silva et al. 2006)

	Positions				
Variables as mean (SD)	Goalkeepers ($n = 2$)	Fullbacks ($n = 4$)	Midfielders ($n = 3$)	Forwards ($n = 6$)	All groups ($n = 15$)
Stature (cm)	177.1 (5.9)	177.0 (2.1)	172.5 (3.9)	172.9 (5.2)	174.5 (4.5)
Body mass (kg)	76.5 (5.0)	64.5 (3.6)	73.9 (7.6)	62.5 (7.5)	67.2 (8.1)
Corrected body mass (kg)	78.3 (5.1)	76.4 (8.6)	90.6 (9.4)	74.9 (9.4)	78.9 (10.0)
Skinfold thickness (mm)

Calf circumference (cm)	33.3 (3.4)	36.8 (6.8)

Comparison of selected anthropometric measurements between above and below knee amputees

value in terms of morbidity and mortality at both extremes of weight status (underweight and obesity) in a variety of patient groups. Use of the BMI in the assessment of individuals with amputations is complicated not only regarding how to compensate for the missing limb in the weight measurement but also regarding difficulties in being able to get an accurate measurement of height or estimate of stature.

Body weight is a routine measure conducted in the general population to assess and monitor nutritional health. In the general population, this measure is relatively simple to obtain and has considerable predictive ability in terms of poor health outcomes. However, the same cannot be said for the amputee population. There is a great deal of debate in the clinical setting surrounding the issue of which body weight to utilise. Pre-amputation weight is difficult to determine without weighing either the individual pre-surgery or the amputated limb. As a pragmatic approach to this challenge, for many years clinicians have been recommended to determine body weight in amputees using results from cadaver studies (Osterkamp 1995) in which body segments were weighed to determine the % body

weight attributable to particular segments. However, it is important to note that these data were derived from old studies with small samples, and there was no consideration of differences between gender, age or ethnic background. Also, since these data were collected, there have been changes in body size and body composition; hence, the data may no longer be applicable to the population of today. Given these issues, it is not unreasonable to suggest that tracking post-amputation weight alone might in fact be a sufficient marker of change in nutritional health. However, practical considerations include the need for a calibrated chair, bed or hoist scales to make weight measurements.

Giving support to this suggestion is the complexity of measurements and calculations proposed for estimation of pre-amputation weight by Mozumdar and Roy (2004) (Fig. 171.1). In this study, 102 male unilateral lower-limb amputees from India were enrolled, and data from the unaffected lower limb used to predict the proportion of weight loss from the amputated limb. While the formulae were well developed, the measurements and calculations required result in this method being difficult to implement in clinical practice. Furthermore, there does not appear to be any evidence to suggest that prediction of pre-amputation weight and the ability to calculate BMI is any more meaningful in terms of health outcomes than simply monitoring change in post-amputation weight. This is an area that requires further research

While BMI, obtained through measurement of standing height and body weight, is a common index of nutritional health used in the general population, there are considerable complexities involved in obtaining these measures in the amputee population. The complexities of body weight measurement have, while briefly, been acknowledged in the literature and are described above, there has not yet been acknowledgement in the literature that ability to accurately measure height in the amputee population may be compromised. Certainly, for bilateral amputees measurement of standing height is not possible. For unilateral amputees, however, it may be possible to measure standing height, but the contribution that the prosthesis might make would need to be considered. An alternative for standing height in unilateral amputees may be knee height (or, a more consistent approach for all lower-limb amputees might be to recommend a measure such as demispan (Bassey 1986) or arm span). Furthermore, the reference ranges available are based on the non-amputee population (Lehmann et al. 1991); clinicians should therefore question the feasibility and reliability of this index in this population.

A small number of studies have attempted to establish methods for assessing BMI in the amputee population (Mozumdar and Roy 2004; Tzamaloukas et al. 1994; Tzamaloukas et al. 1996). Both studies clearly demonstrate that using actual post-amputation weight significantly underestimates BMI and consequently leads to inaccurate assessment of nutritional health. To overcome this issue, it is suggested that an adjusted weight would be more appropriate for use in the standard BMI equation. The methods employed in these studies were based on mathematical determination of body weight based on pre- and post-amputation weights and the proportion of weight attributable to the amputated body segment, which could then be used in the standard BMI equation. Comparisons could then be made to the standard BMI reference ranges to determine BMI status in the amputee. Again, the formulae were well developed, but the method would be difficult to implement in the clinical setting. Also, no evidence was provided to support the use of BMI in these health settings over the use of monitoring changes in body weight in terms of subsequent health outcomes.

Other indices used in the evaluation of nutritional health are calculated based on upper-limb anthropometric measures or indices, common ones being mid-arm muscle circumference (MAMC) and corrected arm muscle area (CAMA) (Friedman et al. 1986). Miller et al. (2008) evaluated the use of BMI and CAMA as measures of nutritional health in 58 unilateral amputees. Comparisons were made between BMI (corrected and uncorrected) and CAMA with the conclusion that there was a moderate–high correlation between them. CAMA was also predictive of quality of life.

$$W_E = W_O / (1 - \Delta W / W_E)$$

where,

$\Delta W/W_E = W_S/W_E + W_T/W_E\ (1 - L_{Stp}/L_{Kn})$ (for individuals with below-knee amputation)

$\Delta W/W_E = W_S/W_E + W_T/W_E + W_F/W_E\ (1 - L_{Stp}/L_{BtK})$ (for individuals with above-knee amputation)

where, W_E is the body weight to be estimated, W_O is the observed body weight, $\Delta W = (W_E - W_O)$, L_{Stp} is the length of the stump (remaining portion of the limb from its nearest distal bone-joint) and W_S, W_T and W_F are weight of sole/foot, knee and thigh, respectively.

Based on Osterkamp (1995), $W_S/W_E = 1.5\%$, $W_T/W_E = 4.4\%$, $W_F/W_E = 10.1\%$, L_{Kn} = knee height and L_{BtK} = buttock knee length.

Measurements

Knee height: The subject sits erect, with foot resting on a surface so that the knee is bent at right angle. The vertical distance from the floor to the top of the patella is measured.

Buttock knee length: The subject sits erect, with foot resting on a surface so that the knee is bent at about right angle. The horizontal distance from the rear-most point of the buttock to the front of the kneecap is measured.

Therefore,

$\Delta W/W_E = 0.015 + 0.044\ (1 - L_{Stp}/L_{Kn})$ (for individuals with below-knee amputation)

$\Delta W/W_E = 0.015 + 0.044 + 0.101\ (1 - L_{Stp}/L_{BtK})$ (for individuals with above-knee amputation).

Here are two examples:

Patient 1 (with below-knee amputation):

$W_O = 67.5$ kg

$L_{Stp} = 26.5$ cm

$L_{Kn} = 50.8$ cm

$\Delta W/W_E = 0.015 + 0.044\ (1 - 50.8\ \text{cm}/24.0\ \text{cm}) = 0.015 + 0.044\ (1 - 0.472) = 0.038$

Patient 2 (with above-knee amputation)

$W_O = 67.5$ kg

$L_{BtK} = 58.5$ cm

$L_{Stp} = 26.5$ cm

$\Delta W/W_E = 0.015 + 0.044 + 0.101\ (1 - 58.5\ \text{cm}/26.5\ \text{cm}) = 0.015 + 0.044 + 0.101\ (1 - 0.453) = 0.114$

Therefore, $W_E = 79.5\ \text{kg}/(1 - 0.114) = 89.75$ kg

Fig. 171.1 Formulae for estimating weight for adults with above- or below-knee amputation. Formulae for estimating body weight from anthropometry in lower-limb amputees

Table 171.4 Descriptive statistics of anthropometric measurements in individuals with lower-extremity amputation (Reprinted by permission from Macmillan Publishers Ltd Mozumdar and Roy 2006)

	Above-knee amputees (n = 32)		Below-knee amputees (n = 70)	
	Mean	SD	Mean	SD
Stature (cm)	164.47	6.16	161.22	7.41
Body weight (kg)	66.79	13.58	57.54	12.30
Body mass index (kg/m^2)	24.51	3.89	22.02	3.74
Upper arm circumference (cm)	29.34	3.14	26.63	3.15
Waist circumference (cm)	90.04	10.72	83.07	12.76

Selected anthropometric data for 103 lower-limb amputees in India

Skinfolds are also commonly used anthropometric measures. Innocencio da Silva Gomes et al. (2006) investigated the nutritional profile of Brazilian amputee soccer players. The sum of three skinfolds (abdominal, thoracic and thigh) was calculated in 15 subjects on the non-amputated side of the body. They found that subjects had a higher level of subcutaneous fat compared to non-amputee athletes, particularly around the abdomen; however, as prediction equations were developed in non-disabled individuals, the results should be treated with caution. Innocencio da Silva Gomes et al. (2006) cited another study (Kurdibaylo 1996) that found higher rates of obesity, particularly relating to increased subcutaneous fat, in amputees when compared to non-amputees.

Triceps skinfold thickness has been used by Eneroth et al. (1997) to describe the nutritional status of postoperative amputees. It was reported that 37% of subjects had a triceps skinfold thickness below the 10th percentile, hence indicating nutritional depletion in the population. While commendable, the studies described above made no or limited comparisons between their results and results in non-amputees, and where Innocencio da Silva Gomes et al. (2006) did, comparisons were made to athletes and not to the general population.

Girths or circumferences of body parts are also commonly used anthropometric measures, and there have been some attempts to use these to describe and monitor nutritional well-being amongst amputees. Innocencio da Silva Gomes et al. (2006) measured brachial and thigh circumference on the non-amputated side of 15 Brazilian amputee soccer players. The main findings related to the differences in measurements according to position played, rather than to any key recommendations for use of these measures for assessment of nutritional well-being amongst amputees. By contrast, Miller et al. (2008) evaluated the use of upper-arm anthropometric measures and BMI as measures of nutritional health in 58 lower-limb amputees. Mid-upper arm circumference (MUAC) was compared to uBMI and cBMI, resulting in a moderate–high positive correlation between the two measures. The correlation between BMI and upper-limb anthropometric measures was also found by Mozumdar and Roy (2004) in 102 unilateral, male amputees in India (Table 171.4). They found that MUAC was significantly positively correlated with both observed BMI (r = 0.846, P = 0.01) and estimated BMI (r = 0.872, P = 0.01). It is important to recognise that changes in upper-body strength, as a result of lower-limb amputation, can lead to problems in the interpretation of upper-arm anthropometric measurements as these may not reflect whole body status.

As noted, individuals who require lower-limb amputations are often those with advanced diabetic neuropathy. It is clearly documented that individuals with diabetes are at increased risk of morbidity and mortality from cardiovascular disease and metabolic complications (Wilson et al. 2002). It is well recognised that waist circumference measurement provides prognostic value in terms of central obesity and associated metabolic health risks (NICE 2006). Although there is no specific evidence for its use in individuals with lower-limb amputations, support for its use comes from the practicalities for its measurements compared with limiting factors for using body mass index in this patient group, as outlined above. Further research in this area is needed.

171.4 Conclusion

Assessment of the weight and nutritional status of individuals with lower-limb amputations should be a standard component of the health management of this group of individuals. Upper-arm anthropometrics appear to be a useful and reliable measure in determining nutritional health in the amputee population and also enable simple, repeated measuring for monitoring purposes. While using body weight as a monitoring tool, actual body weight is probably adequate to monitor change over time. The current classification system for BMI has limited use in this population group. While using BMI to assess nutritional health, an adjusted/corrected BMI should be employed to allow comparison to available reference ranges, as unadjusted BMI underestimates BMI due to the weight associated with the absent limb. It is recommended that future research is carried out to determine the prognostic value of various nutritional indices that can be performed relatively easily within amputee populations.

171.5 Applications to Other Areas of Health and Disease

Inability to accurately measure nutritional anthropometry is not limited to the area of amputees. Elderly, those with skeletal deformity or individuals who are bed or chair bound are other groups where anthropometric assessment is difficult and fraught with inaccuracies. Precise and reliable measures of nutritional anthropometry that are meaningful have use outside the amputee population. Upper-arm anthropometry therefore has broad applicability and potential.

171.6 Practical Methods and Techniques

Performing anthropometric measurements takes significant skill. Anatomical landmarks require accurate identification and proficient use, and understanding of measurement error is mandatory. Training programmes are available at many universities and it is highly recommended that either these or equivalent training programs are undertaken prior to undertaking these measurements in clinical practice (see http://www.isakonline.com/). Standard protocols should be adhered to, including regular calibration of any necessary equipment.

Summary Points

- Obesity or increasing weight following amputation poses challenges for the clinician with increasing risk of metabolic disturbances and also the physical complications for prosthetic fit and longevity.
- Nutrition screening and assessment for identification of nutritional risk (over- and undernutrition) mostly require accurate measurement of body size, commonly stature and/or weight; however, these measures are complex in those with a lower-extremity amputation.
- There is little data available to guide recommendations for measurement of body size in those with a lower-extremity amputation. Weight, BMI, skinfold thickness and upper-arm girths have all been reported.
- Weight monitoring post-amputation is feasible and informative.

- BMI is underestimated if weight is not corrected to account for the amputated limb. Equations to estimate the weight of the amputated limb are complex and rely heavily on either old data or difficult-to-obtain anthropometric measurements.
- Girths and skinfolds have not been measured widely, but there is some preliminary evidence to suggest that upper-arm anthropometry could be a suitable alternative for BMI in those with a lower-extremity amputation.

Chapter 172
Anthropometry of Malnutrition in End Stage Liver Disease

E.T. Tsiaousi and A.I. Hatzitolios

Abstract One of the most common encountered clinical complications in end stage liver disease (ESLD) is macro- and micronutrient deficiency. Clinically evident malnutrition is strongly correlated with the degree of the disease progression reflected in the Child Pugh classification. The pathogenesis of malnutrition in ESLD is multifactorial. The use of anthropometry has provided us with an efficient but simple method for the assessment of malnutrition in cirrhosis. Most common anthropometric indices are triceps skinfold thickness (TST) and mid arm muscle circumference (MAMC). Both parameters are of great prognostic value and are recommended, along with subjective global assessment (SGA), by the European Society for Clinical Nutrition and Metabolism (ESPEN) for the evaluation of malnutrition in cirrhotic patients and patients awaiting liver transplantation.

Abbreviations

BCM	Body Cell Mass
BMI	Body Mass Index
CP CLASSIFICATION	Child Pugh classification
ESLD	End Stage Liver Disease
ESPEN	European Society for Clinical Nutrition and Metabolism
FFM	Free Fat Mass
MAA	Mid Arm Area
MAC	Mid Arm Circumference
MAFA	Mid Arm Fat Area
MAMA	Mid Arm Muscle Area
MAMC	Mid Arm Muscle Circumference
PEM	Protein Energy Malnutrition
REE	Resting Energy Expenditure
SGA	Subjective Global Assessment
TST	Triceps Skinfold Thickness

172.1 Introduction

Protein–energy malnutrition is a common feature of end-stage liver disease (ESLD) and is by far regarded as one of the most important prognostic factors regarding the final course of the disease. Collective evidence points to the fact that malnutrition is considered a severe complication of ESLD and merits the same attention as the presence of hepatic encephalopathy, esophageal varices, or ascites. It may adversely affect quality of life and most importantly the outcome of liver transplantation (Kondrup 2006).

The prevalence of malnutrition in cirrhosis is considered universal although not always evident. Deficits in micro- and macronutrients are present from the very early stages of the disease. The severity of malnutrition ranges from subclinical micronutrient deficiencies to protein–calorie malnutrition with obvious muscle wasting and depletion of fat tissue (Figueiredo 2005).

Screening the majority of patients with ESLD for nutritional abnormalities has therefore emerged as a necessity in order to identify those at greater risk for complications that could emerge as a direct effect of protein–fat depletion. The modified Child–Pugh classification that has substituted the original Child–Turcotte classification after 1973 has replaced nutritional status with prothrombin time. Nevertheless, the specific guidelines on enteral nutrition that were issued in January 2006 (updated 2009) by the European Society for Clinical Nutrition and Metabolism (ESPEN) emphasize the importance of the correction of the nutrient deficit in patients with ESLD, stressing that it reduces complications and prolongs survival. The original ESPEN guidelines propose the use of simple anthropometric parameters in the evaluation of malnutrition in cirrhotic patients and patients awaiting liver transplantation. In particular, the measurement of mid-arm muscle circumference (MAMC) or mid-arm circumference (MAC), and triceps skinfold thickness (TST) which are not affected by the presence of ascites or peripheral edema provide sufficient information regarding the loss of protein and fat tissue, respectively (Plauth 2006, 2009).

172.2 Most Common Causes of End-Stage Liver Disease

The most frequent causes of ESLD are reflected in the major indications for liver transplantation. Alcoholic liver disease and chronic hepatitis C represent more than 40% of all cases reported. Other less common liver diseases with an ominous prognosis are chronic hepatitis B, cryptogenic cirrhosis (a majority of which may represent non-alcoholic steatohepatitis-related cirrhosis), primary biliary cirrhosis, primary sclerosing cholangitis, autoimmune hepatitis, hepatic malignancy, acute liver failure, and metabolic diseases. In the pediatric populations, α1-antitrypsin deficiency and metabolic disorders are more common (Table 172.1) (Martin 2006).

172.3 Pathophysiology of Malnutrition in ESLD

Hypermetabolic state. The contribution of hypermetabolism, which is often present in liver cirrhosis, to the extent of malnutrition is still debated. Systematic vasodilation, which leads to an expanded intravascular blood volume, is a direct effect of the hyperdynamic circulation of cirrhosis (Guglielmi 2005). An increase in the resting energy expenditure (REE) of 120% of the expected value is observed in 34% of patients with cirrhosis of any degree (Kondrup 2006). Hypermetabolic patients exhibit

Table 172.1 Most common liver diseases in patients with ESLD

Chronic hepatitis C
Alcoholic liver disease
Chronic hepatitis B

Primary biliary cirrhosis
Primary sclerosing cholangitis
Autoimmune hepatitis
Acute liver failure
Hepatic malignancy
Metabolic diseases

Chronic hepatitis C and alcoholic cirrhosis represent more than 40% of all cases
ESLD End-Stage Liver Disease; *NASH* Non-Alcoholic Steatohepatitis

greater losses in muscle mass, free-fat mass (FFM), and body cell mass (BCM) and have a better chance to be transplanted than normometabolic patients (Matos 2002). In the post-transplant era, hypermetabolism is corrected. Apart from these, the frequent infections observed in cirrhotic patients due to the compromised gut-barrier function raise the REE. Elevated pro-inflammatory and anti-flammatory cytokines, such as tumor necrosis factor (TNF), point to a cytokine-driven hypermetabolic state (Plauth 2002).

Poor nutrient intake. Although hepatic synthetic function may be preserved even in the late stages of the disease, a low caloric diet that the majority of the cirrhotic patients follow may compromise their nutritional status. Patients often complain about loss of appetite, which has been attributed to the elevated levels of TNF (cytokine-mediated anorexia), presence of ascites, altered taste, and early satiety (Plauth 2002). Patients may experience gastrointestinal symptoms, such as abdominal pain, nausea, and bloating, which are associated with diminished food intake and subsequent weight loss. Diet restrictions regarding sodium, fluids, and protein in the circumstance of ascites, peripheral edema, and hepatic encephalopathy make the diet unpalatable and may reduce even more the ingested calories and micro- and macronutrients. Nevertheless, unjustified diet restrictions of protein for the fear of hepatic encephalopathy are still imposed, despite the strict guidelines issued by ESPEN (Plauth 2002; Tsiaousi 2008).

Malabsorption and maldigestion. Utilization of the ingested nutrients is often hindered by the presence of portal hypertension and its effects on gut function. Mucosal congestion and villus atrophy, bacterial overgrowth, pancreatic insufficiency, and diminished digestive enzyme production and secretion impair the absorption of nutrients. Apart from these, reduced intraluminal bile salt concentrations, especially in cholestatic diseases, inhibit the absorption of fat and fat-soluble vitamins. The toxic effect of alcohol on the gut mucosa is another cause of malabsorption (Matos 2002).

Inadequate hepatic synthesis. The diminished synthetic ability and storage capacity of the cirrhotic liver in combination with the accelerated loss of body protein, due to infections and episodes of gastrointestinal bleeding, often lead to protein depletion. In the late stages of the disease process, the liver has lost most of its capacity to synthesize protein, glycogen, and very low density lipoproteins. Owen et al. made evident that, after an overnight fasting, patients exhibit a metabolic state similar to that of healthy individuals after a three days' fast (Owen 1981, 1983) (Table 172.2).

Table 172.2 Main causes of malnutrition in end-stage liver disease

Hypermetabolic state	Poor nutrient intake	Malabsorption and maldigestion
Systematic vasodilation	Loss of appetite (TNF driven?)	Portal hypertension
Expanded intravascular blood volume	Abdominal pain, nausea, and bloating	Mucosal congestion and villus atrophy
Increase in the resting energy expenditure (REE)	Diet restrictions (sodium, protein, and those for diabetes mellitus)	Pancreatic insufficiency and diminished digestive enzyme production and secretion
Infections	Altered taste	Bacterial overgrowth
Elevated pro-inflammatory and anti-inflammatory cytokines	Unjustified diet restrictions	Reduced intraluminal bile salt concentrations
Decreased hepatic synthetic ability	Ascites (early satiety and discomfort)	Alcohol

The pathogenesis of malnutrition is multifactorial. Diminished hepatic synthetic ability, portal hypertension, and overexpression of cytokines are the principal causative factors
TNF Tumor necrosis factor

172.4 Body Composition and Redistribution of Somatic Fluids in Liver Cirrhosis

Proper understanding of the alterations in body composition in liver cirrhosis could help healthcare physicians to assess and manage malnutrition in patients with ESLD. Protein–calorie malnutrition is ideally measured by body cell mass (BCM) depletion. BCM is the metabolically active compartment of lean tissue.

Protein depletion. Peng et al. have found significant protein depletion in 51% of their patients measured by in vivo neutron activation analysis (INVAA), which is the gold standard for the measurement of protein loss. The degree of protein depletion correlated with the Child–Pugh (CP) grade, with increased protein loss in grades B and C. It is noteworthy to mention that >40% of patients with CP grade A presented with increased protein losses and malnutrition (Peng 2007). An interesting observation that was made is that hydration of the free-fat mass (FFM) was higher in protein-depleted patients, a fact which was also observed by Heymsfield et al. in postmortem examinations. Increased hydration of wet muscle tissue can mask the losses of muscle functional protein (Heymsfield 1982). Clear evidence of the increased catabolism of protein are plasma amino-acid accumulation, skeletal-muscle wasting, and increased urinary excretion of nitrogen and 3-methylhistidine (a byproduct of myofibrillar protein) (Matos 2002).

Fat metabolism. The greater dependence on lipids as a fuel source, because of the impaired synthetic ability and storage capacity of glycogen, results in marked lipolysis and reduction of fat tissue. Figueiredo et al. quantified body-composition changes and found that BCM and body fat were significantly reduced mainly in patients with moderate and severe disease. In CP grade A, body-fat loss predominated (Figueiredo 2005).

Somatic fluids. Fluid retention is a common feature of liver cirrhosis. The presentation of ascites and peripheral edema are hallmarks of decompensated cirrhosis and a major therapeutic burden. Fluid shifts to the extracellular compartment as a result of portal hypertension and the hyperdynamic circulation. Total body water (TBW) and extracellular water are measured using dilution techniques (tritium dilution). Up to 64% of patients are over-hydrated even in the absence of clinically evident ascites. Greater hydration correlates with the severity of liver disease (Peng 2007).

Bone metabolism. In cholestatic and non-cholestatic liver diseases, bone density is affected with lower levels as the disease progresses and malnutrition is established.

172.5 Assessment of Malnutrition with the Use of Anthropometric Measurements

172.5.1 Common Anthropometric Indices Used in ESLD

Among the anthropometric parameters best studied and evaluated for the recognition of the presence of malnutrition among patients suffering from liver decompensation, triceps skinfold thickness (TST) and mid-arm muscle circumference (MAMC) correlate better with the actual loss of lean body tissue. The extreme catabolic effects of liver decompensation are attributed to the poor nutritional intake and to the hypermetabolism which characterizes liver cirrhosis. Since fluid tends to accumulate in the lower extremities as peripheral edema, measurement of the mid-arm circumference (MAC), mid-arm muscle circumference (MAMC), triceps skinfold thickness (TST), mid-arm area (MAA), mid-arm muscle area (MAMA), and mid-arm fat area (MAFA) is not affected by fluid retention. Fluid tends to accumulate to a lesser extent in the upper extremities, even in the late stages of the disease process. The presence of ascites precludes other anthropometric indices most commonly used in different states of malnutrition. In the setting of generalized edema, careful correction of fluid retention is required in order to deduct correct conclusions using anthropometry. Body mass index (BMI) has also been extensively used for the assessment of malnutrition but in combination with the previously mentioned anthropometric measurements, since the accumulation of fluid cannot ensure proper results using only this parameter.

BMI is calculated from the estimated weight or dry weight and height. MAC and TST are measured in the dominant side of the body using skinfold calipers and a steel tape measure. MAC is measured to the nearest centimeter with the arm hanging relaxed midway between the tip of the acromion and olecranon. TST is measured to the nearest millimeter at the back of the arm at the same height as the mid-arm circumference, using a skinfold caliper, having a pressure of 10g/mm^2 of contact surface area. The mean of three calculations is enough to provide accurate results. MAMC, MAA, MAMA, and MAFA are then calculated using the previous parameters. MAMC and TSF measurements are compared with published standards and expressed both in relation to the 5th percentile and as a percentage of the 50th percentile (relative MAMC) with correlation to age and gender (Table 172.3) (Frisancho 1981; Heymsfield 1982; Morgan 2006).

Table 172.3 Anthropometric measurements used for the identification of malnutrition in ESLD

Weight (kg)	BMI (kg/m^2) = weight (or estimated dry weight)/[height]^2
Height (cm)	MAMC (cm) = MAC – [TSF × π]
MAC (cm)	MAA (mm^2) = (π/4) × (MAC/π)
TST (mm)	MAMA (mm^2) = [MAC – (π × TST)]^2/4π
	MAFA (mm^2) = MAA – MAMA

TST and MAMC are of great prognostic value regarding the evaluation of malnutrition in cirrhosis. MAMC, MAA, MAMA, and MAFA are derived from the measurements of TST and MAC (MAC converted to millimeters)

BMI Body mass index; *MAMC* mid-arm muscle circumference; *MAC* mid-arm circumference; *TST* Triceps skinfold thickness; π 3.142; *MAA* Mid-arm area; *MAMA* mid-arm muscle area; *MAFA* Mid-arm fat area

Table 172.4 Anthropometric parameters in cirrhotic patients according to the degree of nutrition

		Well nourished	Moderately nourished	Moderately malnourished
Campillo et al. (2005)	BMI (kg/m^2)	27.2 ± 5.0	23.5 ± 3.7	20.3 ± 3.2
	TST (mm)	12.5 ± 6.4	8.0 ± 4.2	4.2 ± 2.0
	MAMC (cm)	24.3 ± 2.6	21.2 ± 2.1	18.5 ± 2.1
Guglielmi et al. (2005)	BMI (kg/m^2)	22 ± 3	NA	17 ± 2
Gunsar et al. (2006)	BMI (kg/m^2)	26	22	19
	TST (mm)	15	14	6
	MAMC (cm)	25	22	20
Riggio et al. (2003)	BMI (kg/m^2)	27.5 ± 0.4	NA	23.3 ± 0.6

The level of malnutrition is reflected in simple anthropometric measurements
NA not applicable

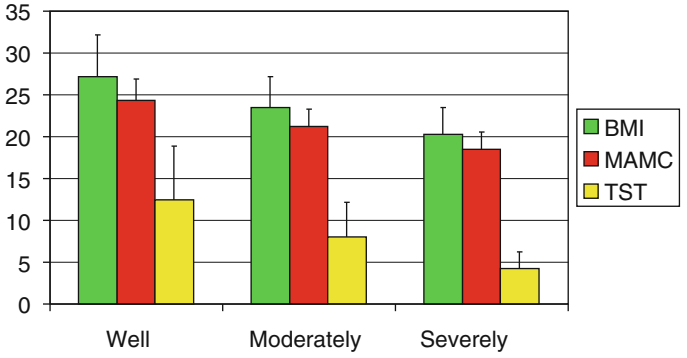
172.5.2 Evaluation of Anthropometry as a Significant Diagnostic Tool for the Detection of Malnutrition in Cirrhosis

The methods which are used universally for the evaluation of the nutritional status are subjective global assessment (SGA) and anthropometric parameters. Assessment of protein–energy malnutrition (PEM) severity and evaluation of the outcome of nutritional therapeutic intervention are crucial in order to differentiate patients with good or bad prognosis. Proper therapeutic intervention should be given to the ones who actually need it in order to improve their clinical status (Table 172.4).

PEM is best measured by body cell mass (BCM) depletion. BCM is the heat producing or metabolically active cell mass representing the compartment of the body which utilizes and produces energy. It has been identified as an important parameter of nutritional status with strong correlation with the clinical outcome. Figuiredo et al. have attempted to investigate which nutritional parameter best correlates with BCM depletion (Figueiredo 2000). They conducted a thorough nutritional assessment of 69 patients awaiting liver transplantation. The parameters that were assessed, apart from BCM analysis, using isotope dilution (bromide) with correction for extracellular water were SGA, handgrip dynamometry, laboratory tests, body composition measured by dual-energy X-ray absorptiometry (DEXA) and anthropometric measurements. In multivariate analysis, the most interesting finding was that anthropometry and handgrip strength were the best predictors of BCM depletion. The anthropometric data that were collected were weight, height, triceps skinfold thickness (TST), mid-arm circumference (MAC) and mid-arm muscle circumference (MAMC). MAC correlated better with BCM. It is astonishing that more sophisticated and time-consuming methods for the evaluation of PEM and BCM are not superior to simple, inexpensive, bedside methods, such as anthropometry and handgrip dynamometry.

Anthropometric parameters that are more often used in the evaluation of nutritional deficit in patients with terminal liver diseases or in patients awaiting liver transplantation are TST and MAMC (Table 172.5). Malnutrition seems to be an independent risk factor and predictor of survival, according to Alberino et al. (Alberino 2001). In fact, it was shown that the inclusion of MAMC and TST improved the prognostic accuracy of the CP score. This evidence confirmed the findings of a previous study, which showed that the inclusion of MAMC improved the predictive outcome of the CP classification (Abad-Lakruz 1993). On the other hand, Chang et al. found that only triceps skinfold fat thickness correlated with the etiology and the severity of liver disease (Chang 2003). Similar results were deduced in a cross-sectional study among 42 cirrhotic children aged three months to 18 years in Brazil. The index with the highest prognostic value was TST. The parameters that were measured

Table 172.5 Malnutrition and changes in anthropometric measurements (Data taken from Campillo et al. 2006)



The degree of malnutrition is reflected by anthropometric parameters. Gradual loss of soft tissue is typical as the disease progresses

were weight/age, height/age, BMI, TST, and MAMC, and they were compared with the CP classification score that was given for each child (Schneider 2007). Perhaps the addition of anthropometric parameters to the CP classification could improve its prognostic value (Abbott 2001). The diminished muscle status and loss of functional tissue among liver disease patients with differences in etiology and pathogenetic mechanism or liver disease are associated with advanced CP classification and early postoperative morbidity (Abbott 2001).

Taking into account the accumulating evidence regarding the importance of the nutritional status with the use of simple and subjective anthropometric measurements, Gunsar et al. evaluated a modified SGA. The Royal Free Hospital (RFH)-SGA index combines subjective assessment of nutritional status with BMI, TST, MAMC, and a subjective override. The RFH-SGA index adds body mass index (BMI), TST, and MAMC to the standard SGA. According to this index, patients are easily classified into three groups: well nourished, mild or moderately malnourished, and severely malnourished. The RFH-SGA index may provide additional information to CP or model for end-stage liver disease scores regarding nutritional indices (Gunsar 2006) (Fig. 172.1).

Anthropometric parameters have been associated with survival. Merli et al. showed that patients with a MAMC below the 5th percentile, which reflects marked muscle tissue depletion, were expected to have poorer survival rates since malnutrition is considered a bad prognostic value (Merli 1996).

Therefore, the inclusion of anthropometry in the guidelines issued by the European Society for Clinical Nutrition and Metabolism (ESPEN) on January 2006, regarding the evaluation and therapeutic intervention of the nutritional deficit in end-stage liver diseases along with SGA, was not a surprise. *The use of simple bedside methods, such as SGA and anthropometry, to identify patients at risk of undernutrition* makes the evaluation of malnutrition fast and easy to perform. The ESPEN guidelines recommend the use of MAMC or mid-arm circumference (MAC) and TST (Plauth 2006). Diagnosis of undernutrition is established on values of MAMC and/or TST below the 5th percentile in ages 18–74 years or the 10th percentile in patients over 74 years (Campillo 2005).

It is very interesting to mention that the measurement of BMI can prove to be sufficient enough for the evaluation of the nutritional deficit. Campillo et al. used a simple method for the evaluation of the nutritional status of cirrhotic patients. The use of different BMI cutoff values according to the presence or not of ascites and its severity can prove reliable enough for the detection of malnutrition. Malnourishment was confirmed when patients had a BMI below 22 without the presence of acsites, below 23 with the presence of mild ascites, and below 25 with tense ascites (Campillo 2005).

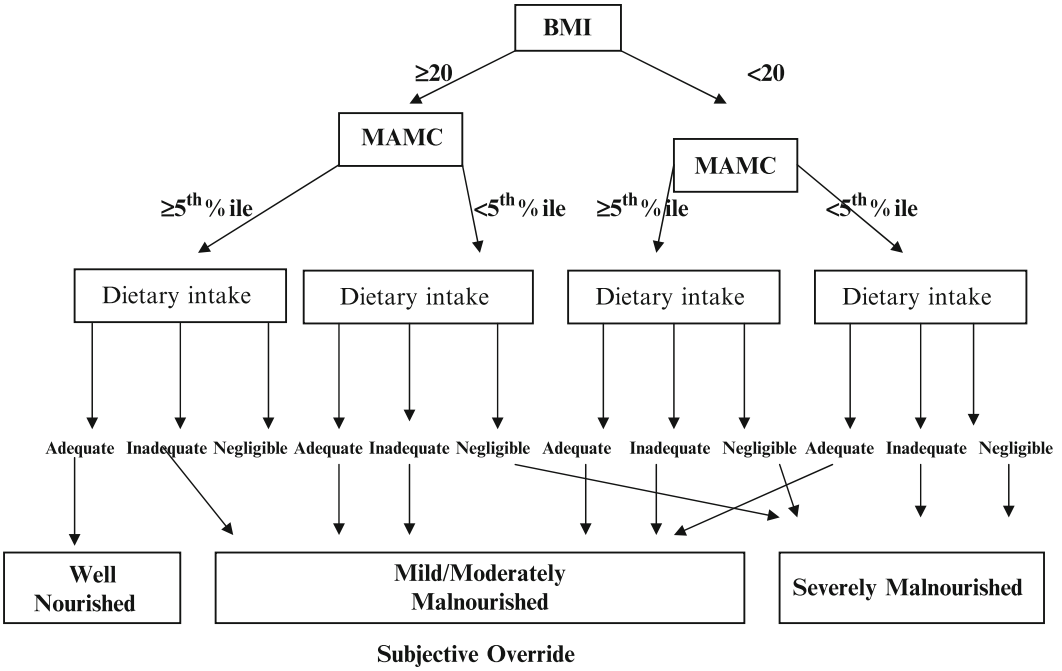


Fig. 172.1 Royal Free Hospital-Subjective Global Assessment (RFH-SGA) scheme for the assessment of the nutritional status in patients with ESLD as proposed by Gunsar F et al. Patients are divided in three categories: adequately nourished, moderately nourished (or suspected to be), and severely malnourished, with the use of simple anthropometric measurements

For long, BMI was not and perhaps is still not considered a reliable anthropometric parameter for the evaluation of malnutrition in the setting of liver cirrhosis since it can be falsely affected by the extreme accumulation of fluids in cirrhotic patients. Fluid retention, which is quite often encountered in liver decompensation, may inhibit the use of body weight and BMI for the identification of malnutrition since false negative results will be deduced. Since almost two-thirds of all cirrhotic patients exhibit overhydration, even in the absence of ascites, due to the shift of fluids to the extracellular compartment, the measurement of body weight and BMI certainly calculates much of all these fluids instead of the actual lean body mass (Tsiaousi 2008).

172.5.3 Limitations of Anthropometric Measurements

Despite the fact that anthropometric measurements are considered simple and reliable tools in the evaluation of the nutritional deficit in patients with liver cirrhosis, there are several factors that affect the precision of the measurements in this special group. In several cases, it seems extremely difficult to assess subjectively the nutritional state because of the gross maldistribution of bodily fluids among the various compartments. Marked fluid retention and overhydration of the peripheral tissues including the muscle tissue are the major factors that could interfere with the accuracy of the results taken from anthropometric measurements (Peng 2007).

Weight and BMI, which are widely used for the identification of malnutrition in several diseases, are not a reliable indicator of malnutrition in decompensated cirrhosis since the surplus body water will increase body weight but the actual lean body tissue might be significantly reduced. The presence of ascites and peripheral edema prohibit the use of common anthropometric parameters apart from body weight and BMI. For instance, subscapular skinfold thickness, suprailiac skinfold thickness, and waist circumference cannot be used in cirrhotic patients even without the obvious presence of fluid retention because more than two-thirds of this special population exhibit overhydration of body tissues.

Another potential limitation of anthropometry is the poor inter-observer reproducibility and intra-observer variability, especially among physicians inexperienced with this method. Possible means of receiving more accurate measurements are the repeated measurements on different occasions in the same hospital stay or visit and by more than one experienced physicians.

172.5.4 Diagnostic Accuracy of Anthropometry in Comparison with Other Applied Techniques

One of the parameters that should be estimated in the effort to assess the nutritional status is the degree of depletion of BCM. Morbidity and mortality among patients with markedly depleted lean tissue are significantly higher before and after liver transplantation (Muller 1992; Selberg 1997). BCM, which represents the active metabolic compartment of the body, can be quantified by various techniques. Whole-body potassium, in vivo neutron activation analysis, and isotope dilution are considered the most precise methods in the evaluation of the body compartments. These techniques are not available in the routine clinical assessment of malnutrition because they are costly and labor intensive. Perhaps, they should be limited to specialized units with sufficient clinical experience. Bioelectrical impendance analysis is a more readily available technique. Unfortunately, its diagnostic accuracy is affected by the retention of fluids.

Evaluation of resting energy expenditure (REE) with indirect calorimetry is also a practical method in the evaluation of malnutrition. Since hypermetabolism in cirrhosis drives many cirrhotic patients to protein and fat depletion due to the increased energy consumption, the evaluation of the status of energy metabolism is considered important (Henkel 2006).

Handgrip examination dynamometry has emerged to be a simple method in the detection of malnutrition. Alvares-da-Silva and Reverbel da Silveira have shown that handgrip examination is a reliable and easy-to-perform method with comparable results (Alvares-da-Silva 2005). Handgrip strength and MAMC have proved to be important nutritional assessment parameters for the detection of depleted BCM, which has been associated with adverse outcomes in patients with ESLD (Figueiredo 2000).

Anthropometric measurements may be the most practical objective indices of nutritional deficiency. They are simple, easy to perform, costless, and easily reproducible. They should be used routinely for the assessment of malnutrition in cirrhotic patients, along with SGA. The combination of a subjective assessment of nutritional status with BMI, TST, MAMC, and a subjective override (The Royal Free Hospital (RFH)-SGA index) can identify those malnourished patients in need of therapeutic intervention. The use of these two simple methods (anthropometry and SGA) in routine hospital visits is adequate in the screening for malnutrition (Gloro 2006; Gunsar 2006). The original guidelines of ESPEN propose the use of anthropometry and SGA since liver decompensation is an ongoing process with multiple complications, which require repeated evaluations of the liver function and the nutritional state (Tables 172.6 and 172.7).

Table 172.6 Methods of evaluation of the nutritional status in ESLD

Table 172.7 Key features of anthropometry in malnutrition in ESLD

1. Malnutrition is an independent predictor of survival in ESLD.
2. Anthropometry and SGA should be preferred to more sophisticated techniques in the routine examination of the nutritional state.
3. Common anthropometric indices used in ESLD: mid-arm circumference, triceps skinfold thickness, and mid-arm muscle circumference.

The table lists the key features of anthropometry in ESLD and emphasizes its prognostic value regarding the levels of malnutrition

172.6 Applications to Other Areas of Health and Disease

The evaluation of malnutrition in ESLD, in particular among patients awaiting liver transplantation, is of foremost importance. The outcome of liver transplantation in the early and late post-transplantation period depends, among others, on the nutritional state of the patient. The use of an inexpensive and practical method for the assessment of malnutrition in these patients is preferred to other more sophisticated but labor-intensive techniques. Apart from this, since anthropometry, along with SGA, provides sufficient information to categorize patients into the various degrees of malnutrition, it could be incorporated into the classifications used for the staging of the severity of end-stage liver disease.

172.7 Practical Methods and Techniques

- Assessment of the nutritional state should be performed in every hospital visit or stay in patients with end-stage liver disease since malnutrition is an independent predictor of survival.
- Measurement of anthropometric parameters and SGA should be preferred to more sophisticated techniques in the routine examination of the nutritional state.
- Measurement of mid-arm circumference (MAC) with the use of a simple or steel tape measure and the triceps skinfold thickness (TST) with skinfold calipers of the dominant arm will provide sufficient information regarding nutritional deficit.
- The mean of three measurements should be taken into account.
- Diagnosis of undernutrition is established on values of MAMC and/or TST below the 5th percentile in ages 18–74 years or the 10th percentile in patients over 74 years.
- Body mass index (BMI) will not provide sufficient data because of the fluid retention in cirrhosis and should not be used without the measurement of TST and MAMC for the evaluation of malnutrition.

Summary Points

- Malnutrition is almost universal in patients with decompensated liver cirrhosis and is an independent predictor of survival.
- Malnutrition is considered a severe complication of ESLD with adverse effects on the outcome of the disease before and after liver transplantation.
- The methods which are used universally for the evaluation of the nutritional status are subjective global assessment (SGA) and anthropometric parameters.
- Most common anthropometric parameters that are measured in cirrhotic patients are mid-arm circumference (MAC) and triceps skinfold thickness (TST).
- The anthropometric parameters with the greatest diagnostic and prognostic value are TST and mid-arm muscle circumference (MAMC).
- Possible limitations of anthropometry in ESLD are the fluid retention and the overhydration of tissues observed in liver cirrhosis, which may lead to false negative results and the intra- and inter-observer variability.
- Diagnosis of undernutrition is established on values of MAMC and/or TST below the 5th percentile or the 10th percentile.

Chapter 173
Anthropometry in Anorexia Nervosa

Antonella Diamanti and Fabio Panetta

Abstract Anorexia Nervosa (AN) is a disorder characterized by a refusal to maintain body weight at or above a minimally normal level for age and height. Two subtypes of the disorder have been identified by the American Psychiatric Association: restricting and binge-eating/purging types. In the former, weight control is attained by a marked reduction in food intake only; in the latter, the occasional food consumption is followed by some forms of compensatory behaviours, such as self-induced vomiting, laxative or diuretic misuse, or strenuous physical exercise. This psychiatric disease mainly involves adolescent girls and young women. Their incidence is increasing in adolescent girls, but first symptoms sometimes appear in childhood. Malnutrition is the prominent feature of AN, requiring a careful and complete medical surveillance, based on anthropometry and body composition assessment.

Anthropometric evaluation in AN patients includes the direct determination of some anthropometric parameters (height, weight, skin fold thickness and mid-upper arm circumference) and the calculation of nutritional indices derived from these (BMI and Weight-for-Height). Most single anthropometric measurements, indeed, in themselves may partially assess the nutritional status. Nutritional indices are derived either by combining two or more anthropometric measurements, or by comparing the anthropometric measurements with reference to values of healthy, well-fed populations.

The evaluation of body composition completes the anthropometric evaluation and is relevant in these patients, because it gives an objective measure of their malnutrition. These patients, indeed, overevaluate their shape and weight and then have limited motivation to change, which results in unreliable self-evaluation and anamnestic assessment. A wide variety of methods are available to measure body composition. Anthropometry, based on the evaluation of skin fold thickness and mid-upper arm circumference, represents the simplest method of estimating body composition and, as such, are often used. More sophisticated techniques to study body composition are represented by bioelectric impedance analysis and dual-energy X-ray absorptiometry, both employed in clinical practice as well as in research settings. Other methods, employed only in research settings, are represented by total body imaging techniques (magnetic resonance imaging and computed tomography), underwater weighing, isotope dilution techniques and neutron activation analysis.

173.1 Introduction

Anorexia nervosa (AN) is the visible eating disorder, universally associated with emaciation and usually accompanied by marked increase of physical activity. AN typically arises in adolescence but often persists into adulthood. Patients with AN lose weight by restricting their food intake and by exercising a lot; several AN patients also self-induce vomiting after meals and take laxatives, diuretics, or diet pills. Individuals with AN are unable to maintain a normal healthy body weight, often dropping well below 85% of their ideal weight. Despite increasing cachexia, individuals with AN have an obsession about gaining weight, feel frustrated about the perceived largeness of their bodies, and engage in an array of behaviors designed to perpetuate weight loss. Table 173.1 shows the key features of AN.

Table 173.1 Key features of Anorexia Nervosa

- Eating disorder, universally associated with emaciation and usually accompanied by marked increase of physical activity.
- Typically arises in adolescence but often persists into adulthood.
- Patients with AN lose weight by restricting their food intake and by making high exercise
- Patients self-induce vomiting after meals and take laxatives, diuretics, or diet pills.
- Individuals with AN are unable to maintain a normal healthy body weight, often dropping well below 85% of their ideal weight.
- Despite increasing cachexia, individuals with AN have an obsession about gaining weight, feel frustrated about the perceived largeness of their bodies, and engage in an array of behaviors designed to perpetuate weight loss.

This table lists the key facts of AN including clinical and psychological features of this disease
An annorexia nervosa

Table 173.2 DSM IV-TR criteria for anorexia nervosa

(a) Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected, or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
(b) Intense fear of gaining weight or becoming fat, even if underweight.
(c) Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
(d) In postmenarcheal females, amenorrhea, that is, the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen administration.)
Restricting type: During the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or misuse of laxatives, diuretics, or enemas).
Binge-eating/purging type: During the current episode of anorexia nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or misuse of laxatives, diuretics, or enemas).

This table lists the diagnostic criteria of anorexia nervosa by DSM-IV, a manual published by the American Psychiatric Association that provides diagnostic criteria for mental disorders
DSM-IV Diagnostic and Statistical Manual for Mental Disorders-IV

Table 173.3 ICD-10 criteria for anorexia nervosa (F50.0)

(a) The patient's body mass index (BMI) is 17.5 or less, or body weight is maintained at least 15% below the expected or average body weight for the patient's age and sex. If the patient is prepubertal, then the expected weight gain does not occur during the growth period.
(b) Weight loss is self-induced and/or sustained through the avoidance of 'fattening' foods and through the utilization of other weight-loss tactics.
(c) Body-image distortion and a morbid dread of fatness, such that the patient imposes an unhealthy and unreasonably low weight threshold on themselves.
(d) There is evidence of endocrine disorder in the form of amenorrhea among women and loss of sexual desire and potency among men. There may also be elevated levels of growth hormone and cortisol, alterations to the metabolism of thyroid hormone, and abnormal insulin secretion.
(e) In prepubertal patients, puberty is delayed but is often completely normal after recovery.

This table lists the diagnostic criteria of anorexia nervosa by ICD-10: a coding of diseases and signs, symptoms, abnormal findings, complaints, social circumstances, and external causes of injury or diseases, as classified by the World Health Organization (WHO)
ICD-10: International Classification of Diseases and Related Health Problems 10th Revision

173.1.1 Diagnostic Criteria of AN

The clinical features of AN are easily recognized, and the diagnosis is usually made by highly reliable clinicians. The diagnostic criteria of the two major classification systems currently used, Diagnostic and Statistical Manual for Mental Disorders-IV (DSM-IV) and World Health Organization's (WHO) ICD 10th edition (ICD-10), are very similar (Tables 173.2 and 173.3). Both diagnostic criteria currently use a % ideal body weight equivalent to 85% of expected body weight or a failure to achieve expected growth during a growing period. The ICD provides an additional index utilizing body mass index (BMI) of <17.5 kg/m^2, which is below the WHO and CDC (Centers for Disease Control and Prevention) definitions of underweight (BMI < 18.5 kg/m^2). DSM-IV, however, distinguishes between two subtypes of AN, restricting and binge-eating/purging, based on the presence or absence of bulimic symptoms. It happens more often that individuals with the binge-eating/purging type present comorbidity, impulsivity, as well as substance use disorders, mood lability, and suicidality, compared to those with the restricting type. Tables 173.2 and 173.3 report diagnostic criteria for AN by DSM-IV and ICD-10.

173.1.2 Epidemiology

In the large-scale population, prevalence of AN is estimated at 1%.

About 90–95% of patients with anorexia are females. Data gathered from two recent, large population-based studies, one in USA and one in Scandinavia, found lifetime prevalence rates of 0.9% and 1.20%, respectively, for women and 0.3% and 0.29%, respectively, for men (Bulik et al. 2007). Researches suggest that prevalence of AN has increased in recent years. AN typically first manifests in adolescence; midlife onset is rare. Age at onset for AN ranges from preteen to adult, with bimodal peaks at ages 13–14 and 17–18 years. Prepubertal AN may be associated with a more severe profile, and onset at adolescence is associated with a better prognosis than are prepubertal and adult ones. AN is no longer predominantly a disorder of the middle class, as it may have been 50 or 100 years ago. In developed societies today, it is distributed fairly equally between the social classes; it is also found in developing countries. Some evidence indicates that women immigrating to more industrialized countries from countries in which the prevalence of AN is low may be at greater risk of assimilating thin body ideals.

173.1.3 Clinical Features

Adolescent patients often appear physically younger than their chronological age, whereas those with chronic AN may look considerably older than they actually are. Cachexia and breast atrophy are apparent. Often, the skin is dry and yellow tinged due to carotenemia. Physical signs commonly include bradycardia, hypotension, lanugo, alopecia, and edema. Patients who self-induce vomiting present dental erosion and dorsal-surface hand lesions.

AN patients may complain of cold intolerance, dizziness, constipation, and abdominal discomfort. Despite malnutrition, these patients are often hyperactive; lethargy may indicate fluid and electrolyte imbalance, dehydration, cardiovascular compromise, or severe depression.

Table 173.4 reports clinical complications of AN.

173.1.4 Differential Diagnosis of Eating Disorders

In the absence of behavioral or cognitive indicators of AN, the clinician may suspect a somatic cause of weight loss. However, it is not advisable to encourage extensive and invasive clinical investigations if the patient's symptoms can be explained adequately by making a diagnosis of either AN or another eating disorder. Main diseases that can mimic eating disorders and that, therefore, should be ruled out during the diagnostic work-up of AN are: Addison's disease, hyperthyroidism, inflammatory bowel disease, and celiac disease.

173.1.5 Course of Illness

Although the course of the disorder varies, it is often marked by chronicity and relapse. A comprehensive meta-analysis of 119 studies including 5,590 patients with anorexia indicated that over long-term follow-up (up to 29 years; mode = 5–10 years), less than one-half of the surviving patients

Table 173.4 Clinical features of anorexia nervosa

Metabolic	Electrolyte disturbances (hypoglycemia, hypophosphoremia, hypocalcemia, and hypomagnesemia)
Cardiovascular	Orthostatic hypotension
	Bradycardia
	Arrhythmia
	Attenuated response to exercise
	Atrial Fibrillation and Flutter
	A-V Blocks
Neurological	Pseudoatrophy of the brain
	Abnormal electroencephalogram and seizures
	Peripheral neuropathy
	Psychomotor slowing
Hematological	Anemia
	Leukopenia
	Thrombocytopenia
	Hypocellular bone marrow
	Infectious complications
Renal	Partial diabetes insipidus
	Acute and chronic renal failure
Endocrine	Amenorrhea
	Pubertal delay
	Low T3 syndrome
	Growth delay
	Raised growth hormone
Musculoskeletal	Cramps, tetany, and muscle weakness
	Osteopenia, osteoporosis, and stress fractures
Gastroenterological	Dental caries and erosion of enamel (with vomiting)
	Superior mesenteric artery syndrome
	Delayed gastric emptying, severe constipation, and bowel obstruction
	Irritable bowel syndrome and melanosis coli (from laxative misuse)
Skin	Acrocyanosis
	Lanugo
	Hypertrichosis
	Brittle nails
	Sparse and brittle hair

This table lists main clinical features of AN according to the different body organs involved

achieved full recovery (Steinhausen 2002). Even among those who achieve full recovery, up to one-third are likely to experience relapse. The majority of individuals with AN engage in bingeing and purging behaviors during the course of the disorder; thus, diagnostic migration from the restricting type of AN to the binge/purge type or to bulimia nervosa is common, particularly within the first 5 years of illness (Eddy et al. 2002). In spite of diagnostic and treatment advances, the prognosis of AN does not seem to have improved during the twentieth century (Steinhausen 2002). The mortality rate for women with AN, at 0.56% per year, is more than 12 times higher than that for age-matched women in the general population (Sullivan 1995). The rate of suicide is also high, with one study reporting a 57-fold increase in death by suicide among individuals with AN (Keel et al 2003). In a survey of 14 outcome studies, Herzog et al. (1988), found that 24% of the deaths reported were due to suicide. Although death is commonly due to suicide, it is also frequently ascribed to inanition and cardiac failure. Table 173.5 summarizes the main prognostic, reported factors in AN outcome.

Table 173.5 Prognostic factors of Anorexia nervosa

Favorable factors	Unfavorable factors	Predicting death factors
• Absence of severe emaciation (i.e., body mass index >17)	• Presence of vomiting in very malnourished patients, particularly vomiting that has become so frequent as to be almost automatic	• Abnormally low serum albumin levels and low weight at intake
• Absence of serious clinical complications	• Later age of onset	• Poor social functioning,
• Motivation to change present behavior	• History of neurotic and personality disturbances	• Longer duration of illness
• Presence of supportive family and friends	• Disturbed family relationships	• Bingeing and purging
	• Longer duration of illness	• Comorbid substance abuse • Comorbid affective disorders

This table lists the prognostic factors in AN that were subdivided into favorable, unfavorable, and predicting death

With recovery from AN, physical health can be regained. Patients can live a long and normal life. Fertility is not impaired, and pregnancy and normal childbirth can be achieved. There is no evidence of permanent brain, heart, or kidney injury in recovered patients who did not present a too serious form of the disorder. Possible permanent physical complications are loss or erosion of teeth, Korsakoff's syndrome (the permanent clinical syndrome of impaired short-term memory that results if Wernicke's encephalopathy is not treated), and, perhaps, osteopenia. Whether bone density can return to 'normal' is not known, but recovery to 'within normal limits' is possible.

The most common long-term symptoms after recovery from AN are those related to the bowel. Constipation, bloating, and abdominal pain may last for decades or may even be permanent. The most common complaint that endangers health is osteoporosis. Recurrent bone fractures can cause chronic pain and lead to chronic disability. Those patients who do not recover suffer from progressive weakness, decreased exercise tolerance, bone pains and fractures, episodes of faintness, tiredness, stress incontinence of the bladder, bowel pain, cramping, and bloating, and decreased ability to recover from bacterial infections or for wounds to heal following surgery.

With regard also to the psychiatric outcome, the recovered AN patients can live a normal life. They can return to work and have families; however, they will always have a greater concern than others about their body weight and shape and might respond to a life trauma with recurrent anorexia behavior. Patients who are chronically anorexic become reclusive, have low self-esteem, and remain obsessional and depressed (Bulik et al. 2005).

173.2 Malnutrition in AN

Malnutrition is the prominent feature of AN, requiring a careful and complete anthropometrical evaluation. AN is different from other forms of malnutrition because it is voluntary, resistant to nutritional treatments, accompanied by increased physical activity, without an initial organic cause (such as malignancy or surgery) and without associated infections. Due to the fact that AN is a state of mere malnutrition without associated increase of energy expenditure due to fever, immune response, or tissue reconstruction, these patients have a lowered metabolic rate and do not tend to develop opportunistic infections. In AN, a very low weight is achieved through weight loss as the result of a

severe and selective restriction of food intake. In most instances, there is no true anorexia as such. Many patients engage in a driven type of overexercising, which can contribute to their weight loss. Self-induced vomiting and misuse of laxatives or diuretics are practiced by a few individuals (restrictive vs. purgative patterns). AN is a self-imposed starvation. The term 'anorexia' is a misnomer since (at least initially) these patients are hungry. The exact mechanism by which these patients are able to control their hunger is unknown. Disturbed brain neurotransmitter activity may be implicated primarily or secondarily.

The psychiatric illness of AN, which occurs mainly in adolescent girls and young women, is characterized by strict dieting, a morbid fear of fatness, maintenance of an abnormally low weight, and amenorrhea. The obsession of losing weight leads AN patients to adopt some distorted attitudes toward food and an altered pattern of food consumption which, in some cases, produce in the patients such a serious state of malnutrition as to require their hospitalization. It seems extremely difficult to correct the psychic aspect of the illness without first improving the nutritional status.

173.3 Anthropometry and Body Composition

Anthropometric evaluation in AN patients includes the direct determination of some anthropometric parameters and the calculation of nutritional indices derived from these. Most single anthropometric measurements, indeed, in themselves may partially assess the nutritional status. Nutritional indices are derived either by combining two or more anthropometric measurements, or by comparing the anthropometric measurements with reference to values of healthy, well-fed populations.

The main anthropometric measurements employed in AN patients are height, weight, skinfold thickness (SFT), and mid-upper arm circumference (MUAC). Among all the nutritional indices available, a relevant role in diagnosing and monitoring the nutritional status of these patients is attributed to BMI and to weight-for-height ratio.

Regarding the reference values of all these parameters, many countries have developed their own reference standards for weight and height of children and adolescents. In USA, the CDC published, in the year 2000, growth charts for people 0–20 years of age. UK, France, and several other countries have developed reference growth curves based on national data sets. Although growth rates differ across countries, there is, in general, a consensus that, in a healthy population, these differences are encompassed within the boundaries of acceptable percentile ranges, usually the 5th and 95th. A new reference data set, derived from mostly cross-sectional studies undertaken between 1978 and 1990 of 23,000 British people aged 0–20 years, has been developed by the Human Measurements Anthropometry and Growth Research Group. Growth charts from these data have been produced by sex for weight-for-age, height-for-age, length-for-age, head circumference-for-age, and BMI-for-age (http://www.cdc.gov/growthcharts/).

In the clinical management of AN, some anthropometric measurements are also employed to estimate body composition. The evaluation of body composition completes the anthropometric evaluation and is relevant in these patients, because it gives an objective measure of their malnutrition. These patients, indeed, overevaluate their shape and weight and then have limited motivation to change, which results in unreliable self-evaluation and anamnestic assessment. A wide variety of methods are available to measure body composition. Anthropometry represents the simplest method of estimating body composition and as such is often used.More sophisticated techniques to study body composition are represented by bioelectric impedance analysis (BIA) and dual-energy X-ray absorptiometry (DXA), both employed in clinical practice as well as in research settings.

Other methods, employed only in research settings, are represented by total body imaging techniques such as magnetic resonance imaging (MRI) and computed tomography (CT), underwater weighing (UWW), isotope dilution techniques, and neutron activation analysis.

173.4 Anthropometry

173.4.1 Anthropometric Measurements

173.4.1.1 Height

Height indicates attained size or growth of adults and children. Long periods of inadequate food intake, as in AN patients, result in a slowing of skeletal growth and individuals being short for their age, or stunted. Consecutive measurements of height every three to six months should be adopted to assess growth velocity in prepubertal AN subjects. Growth velocities are useful to monitor growth and assess the response to therapy including nutritional supplementation. In AN patients, the duration of hospitalization, a marker of disease severity and chronicity, seems to strongly influence growth velocity, with negative influence on the target height at adulthood for a given individual (Rozé et al. 2007).

173.4.1.2 Weight

The initial assessment of weight is a good time to inquire about the greatest weight the patient has ever attained, the lowest weight (at the current height), the weight trajectory over the past few years, the patient's desired weight, and the weight the patient would settle upon to achieve good health. Along with obtaining a careful history, a treatment team member should measure weight and height and, during the course of treatment, should continue to measure weight in a consistent manner, under similar conditions, for example, at the same time of the day, postvoiding, and with the patient in similar garb. Occasionally, some patients with AN may try to make themselves appear heavier than they really are either by strapping weights close to their body, or by carrying heavy objects in their pockets, or by drinking excessive amounts of water and avoiding urinating before weighing. If possible, for purposes of accurately comparing repeated weights, the weight should be obtained at the same time each day, preferably in the morning, immediately after voiding. Excess clothing, such as coats, scarves, shoes, belts, and watches, should be removed.

Consecutive measurements of weight can be used to monitor the effects of treatment, such as either weight loss on reduction diets or weight gain with nutritional interventions and supplementation.

This anthropometric marker is important in diagnosing, monitoring, and predicting the outcome of AN. Both the diagnostic criteria employed for the diagnosis of eating disorders include the weight. Both schema currently use either a % ideal body weight equivalent to 85% of expected body weight or a failure to achieve expected growth during a growing period, as diagnostic criteria of AN.

Indications to hospitalization take also into account the weight. In-patient brief hospitalization (7–14 days) is sometimes possible for patients with the following: weight loss of either 10–15% from normal weight if relapsed or 16–20% if first episode. Extended hospital treatment (14–60 days)

is often necessary for patients who have weight loss >20% of normal for age, height, and bone structure (Yage and Powers 2007).

As a prognostic factor, in a well-documented sample of 84 female patients with anorexia, who had been followed up after an average of 21.3 years following first in-patient treatment, it was shown that an inadequate weight gain during the first hospitalization was an additional risk factor for a poor outcome (Zipfel et al. 2000).

173.4.1.3 SFT

Precision SFT calipers are used to measure the double fold of skin and subcutaneous fat to the nearest millimeter. SFT is not useful for monitoring short-term change in fat stores but can have great importance in chronic situations, such as AN. The study of body fat distribution can have important implications for the treatment of AN because of the patients' intense fear of gaining weight and becoming fat, which is enhanced by the belief that this would be accompanied by fat distribution in the abdominal region. Hence, the amount of body fat at discharge may influence the further evolution of the disease (Krahn et al. 1993). In addition, plicometry seems to have a prognostic value in the clinical assessment of AN: a trend to revert to the restricting habits once the patients leave the hospital seems to exist; therefore, there is a critical time with a high risk of relapse around the end of the first year of follow-up. The decrease in the intake of energy and macronutrients at this time of treatment seems to be related to fat replenishment (Nova et al. 2001).

There are various measures of skinfold thickness:

- *Triceps*: at a point equidistant from the tip of the acromion and the olecranon process;
- *Subscapular*: just below the tip of the inferior angle of the scapular;
- *Biceps*: at the midpoint of the muscle with the arm hanging vertically; and
- *Suprailiac*: over the iliac crest in the midaxillary line.

In AN, triceps SFT seems to be the most significantly correlated with percentage of body fat (Kerruish et al. 2002).

173.4.1.4 MUAC

MUAC is assessed on the non-dominant arm, midway between the tip of the acromion process and the olecranon, and it measures upper-arm fat and muscle in adults and children. It is a useful surrogate of weight when weighing is impossible. This parameter represents a simple, objective, and reproducible marker of nutritional status that correlates with BMI in adolescents with AN. Lack of consistency between longitudinal measurements of BMI and MUAC in individuals with AN should be viewed suspiciously and prompt a more detailed nutritional assessment. Since the rate of change of arm circumference is slow, it cannot be used to assess short-term changes in nutritional status as response to therapy. Longitudinal measurements of MUAC, instead, provide an unbiased and truly objective picture of the trend in nutritional status over time.

This measure seems to have an important role not only in monitoring the nutritional status of these patients but also in indicating the hospitalization due to malnutrition. Indeed, it is suggested that adolescents with AN who have a MUAC $\geq$ 20 cm rarely require hospitalization for malnutrition (Martin et al. 2009).

173.4.2 Nutritional Indices

173.4.2.1 BMI

In addition to determination of the patient's weight and height, calculation of BMI has gained increasing attention in both research and clinical settings. The use of the simple measure of body weight as an indicator of body protein and triceps skinfold thickness as an indicator of percentage of body fat obviates the need for more sophisticated, expensive, and hazardous techniques.

This index has high value in the diagnosis of eating disorders (ICD-10) and in the assessment of protein malnutrition in these patients: a BMI >16.5, indeed, is likely to be indicative of a normal protein status. In addition to diagnosis, BMI of 13 seems to have great importance as a prognosis factor in these patients. BMI of less than 13 entails a strongly elevated mortality risk (Hebebrand et al. 1997).

Furthermore, in a well-documented sample of 84 female patients with anorexia, followed up for about 21 years, low BMI, inadequate weight gain during first hospitalization, and severe psychological or social problems resulted risk factors for a poor outcome (Zipfel et al. 2000). It is also shown that a BMI percentile range of 14th–39th is generally associated with the resumption of menses and, therefore, can be used to assign a treatment goal weight (Hebebrand et al. 1997), while a persistently low BMI predicts for delayed menarche (Rozé et al. 2007). A low BMI is also considered the most important predictor for a disturbed bone turnover (Weinbrenner et al. 2003).

173.4.2.2 Weight-for-Height

In children aged 1–10 years, this index seems to be more reliable than BMI. The BMI criterion based on a BMI less than 17.5 is indeed only applicable to adults; for example, in 10-year-old girls, this BMI is above the 50th centile, thus clearly documenting its inapplicability in children and young adolescents.

Children with weight-for-height less than 85% of the median reference are considered wasted.

173.5 Body Composition

173.5.1 Changes in AN

In the underweight state, although patients may feel 'huge', studies have documented that all components of body are severely diminished (Krahn et al. 1993; Kerruish et al. 2002).

Therefore, AN patients, adults, and adolescents have less FM and LBM. However, in the starvation that accompanies AN, although both FM and LBM decrease, FM is preferentially depleted (Soh et al. 2009).

With weight recovery, AN subjects had increases in FM and LBM (Vaisman et al. 1988).

However, reduced % of FM is maintained also in recovered AN patients, probably due to the fact that former AN patients are more physically active than control ones (Frey et al. 2000).

Regarding the fat distribution, in contrast to adults with AN, percentage extremity fat is not significantly different in AN subjects compared with control subjects. In addition, adolescent girls with

AN had lower percentage trunk fat than did control subjects. Weight recovery led to an increase in trunk fat relative to extremity fat and thus led to central fat accumulation, as in adult patients (Misra et al. 2003).

Boys with AN had lower fat and lean mass than did control subjects. However, in addition and in contrast with findings in girls with AN, percentage trunk fat was higher than in control subjects, particularly after adjustment for weight and fat mass. LBM in boys with AN also resulted lower in control subjects than reported in girls with AN. These findings are consistent with a sex-specific dichotomy and are likely mediated by low concentrations of testosterone. To summarize, boys with AN have preferentially lower FM and LBM in the extremities and higher FM in the trunk than do control subjects. In contrast, girls with AN have much lower FM in the trunk than in the extremities than do control girls (Misra et al. 2008).

The changes in body composition may have a clinical significance for the prognosis. The amount of FM may indeed affect the clinical outcome. Menses return with refeeding when patients reach higher percentages of body fat (18%); however, the changes in FM and the return of menses may also enhance the psychological stress in patients, increasing the likelihood of relapse (Probst et al. 2001).

Additionally, in weight-restored women, lower percent of FM is associated with poor long-term outcome (Mayer et al. 2007).

173.5.2 Assessment of Body Composition

Various direct and indirect methods for estimation of body composition have been developed, all of which are imperfect and require several assumptions and age- and gender-specific considerations. For research purposes, body composition has been determined using techniques, such as total body water, DXA, total body imaging techniques, UWW, neutron activation analysis, and isotope dilution techniques. In clinical studies, bioelectrical resistance and skinfold measurements are most frequently employed. Table 173.6 summarizes the potential application of all anthropometry and body composition measurements in the diagnostic work-up of AN patients.

173.5.3 Assessment of Body Composition Direct Methods

173.5.3.1 Anthropometry

Body composition by anthropometry is potentially a very accurate, reliable, and inexpensive way of estimating total body fat. Anthropometry is based on the evaluation of SFT and MUAC. SFT measures subcutaneous body fat. Durnin and Womersley made measurements of SFT and body density using UWW and produced tables to enable calculation of the percentage of body-fat weight from skinfold measurements (Durnin and Womersley 1974). MUAC measures the totality of mid-upper arm tissues (bone, muscle, fluid, and fat).

Mid-upper arm muscle circumference (MUAMC) and upper-arm muscle area (AMA) are estimates of upper-arm muscle and, therefore, body composition. They can be used as indicators of muscle mass and protein stores. Both MUAMC and AMA can be compared with reference values by age and sex (Caballero et al. 2005).

173.5.3.2 MRI/CT

The use of CT has had limited application in body-composition research primarily due to radiation exposure. Its use has mainly been limited to single-slice acquisitions in the abdomen and mid-thigh, whereby information on adipose-tissue distribution and muscle cross-sectional area has been derived. The use of MRI has resulted in important advances in body-composition phenotyping. MRI studies are safe, and instruments are available in most hospitals or related facilities. Expense is a limiting factor. The importance of both CT and MRI is that both methods acquire cross-sectional images of the body at pre-defined anatomic locations. These methods are used for research purposes, to evaluate the regional body-fat distribution in AN patients and in controls.

173.5.3.3 Isotope Dilution Techniques

Examples of commonly used tracers for these studies include deuterium oxide for total body water, sodium bromide for extracellular water, and total body potassium for body cell mass. These studies, reported only in research settings, showed that stable female patients with AN have more body water and more body potassium per kilogram body weight than age-matched healthy female controls (Dempsey et al. 1984).

173.5.4 Assessment of Body Composition by Indirect Methods

173.5.4.1 BIA

BIA is a simple, inexpensive, noninvasive body-composition measurement method. It is based on the electrical conductive properties of the human body. Measures of bioelectrical conductivity are proportional to the total body water and to the body compartments with high water concentration, such as fat-free and skeletal muscle mass. BIA assumes that the body consists of two compartments, FM and fat-free mass (FFM).

This method seems to be a promising tool for the assessment of changes in nutritional status and of body composition in AN patients during refeeding. This is of particular clinical importance in the planning of adequate energy and nutrient intake to support restoration of weight and proportionate body composition to normal nutritional status in the patients (Mika et al. 2004).

Both anthropometry and BIA are tools to estimate FFM and FM. Although there was a good linear correlation between the two methods, when BMI declines below 15, a progressive disagreement between methods is documented, being a (threshold) function of BMI in the estimation of FM and FFM. Below BMI 15 kg/m^2, BIA equations progressively underestimated FM (overestimated FFM) compared with skinfold. Hence, BIA equations should not be used in anorexic patients with a BMI of 10–15 (Piccoli et al. 2005).

173.5.4.2 DXA

DXA represents the most commonly used technique today, with good reproducibility in children and adults. There are no known factors, including hydration effects, which significantly influence the validity of DXA body-composition estimates, unlike BIA. The radiation exposure is minimal, and the technique can be used in children and adults of all ages. Significant correlations between BMI and percentage of body fat evaluated by DXA are found (Kerruish et al. 2002).

Assessment of bone density represents the main goal of this procedure. The studies performed with DXA in this field showed that girls with AN had reduced bone mineral accrual and progressive spinal osteopenia over the years, compared with their healthy counterparts. Change in FFM was the most significant determinant of change in lumbar BMD in both AN and healthy girls (Soyka et al. 2002).

However, AN patients at the early stage do not show significant differences in bone mineral status when compared to healthy controls (Diamanti et al. 2007).

173.5.4.3 UWW

UWW is considered to be the method of reference for body-composition assessment and is estimated to have excellent reliability and validity. The correlation between UWW and SFT measures ranges from 0.65 to 0.93 (Zipfel et al. 2000). Because there was sufficient agreement among the results obtained by UWW and SFT measurement, for AN patients with relatively little body fat, simple SFT measurements are as useful as this more sophisticated measure for the estimation of body composition (Mayer et al. 2007).

173.6 Neutron Activation Analysis

The advantage of using this method over other techniques for estimating protein nutritional status is that it measures body protein directly and is not affected by other factors, such as hydration status, renal function, and catabolism. Neutron activation analysis has been shown to provide safe, accurate, and precise measurements of total body nitrogen in children and adolescents. It is employed, however, only in few research settings (Kerruish et al. 2002).

Summary Points

- Individuals with AN are unable to maintain a normal healthy body weight, often dropping well below 85% of their ideal weight.
- The American Psychiatric Association identified two subtypes of the disorder: restricting and binge-eating/purging.
- Prevalence of AN is estimated at 1%.
- Measurements of height every 3–6 months should be adopted to assess growth velocity in prepubertal AN subjects.
- Weight during the course of treatment should be measured in a consistent manner, under similar conditions, for example, at the same time of the day, postvoiding, and with the patient in similar garb.
- An inadequate weight gain during the first hospitalization is an additional risk factor for a poor outcome.
- SFT is useful for monitoring long-term change in fat stores.
- MUAC is a useful surrogate of weight when weighing is impossible.
- BMI >16.5 is likely to be indicative of a normal protein status.
- BMI <13 entails a strongly elevated mortality risk.
- Weight-for-height ratio seems to be more reliable than BMI <10 years.
- BIA seems to be a promising tool to assess changes in nutritional status and in body composition during re-feeding.
- BIA equations should not be used in anorexic patients with a BMI 10–15, because they underestimate FM.
- DXA is a good technique used to estimate the body composition in children and adults. However, the main goal of this procedure is the assessment of bone density.

Chapter 174
Clinical Practice of Body Composition Assessment in Female Subjects with Anorexia Nervosa

Michel Probst and Marina Goris

Abstract Anorexia Nervosa (AN) is characterised by a refusal to maintain a minimally normal body weight and by the distorted perception of one's own body (weight, size, shape) as a negative interpretation of their appearance as too fat, resulting in the intense fear of weight gain, even when severely underweight. Both from a physiological and psychological viewpoint, weight, weight restoration and body composition are crucial elements for the treatment of AN. AN patients have unrealistic ideas about body fat and the influence of food intake and dieting on body weight and shape.

Over the last ten years, body composition in female anorexia nervosa has become an important topic in treatment as well as in research. Increasingly, body composition is integrated into the assessment of the evolution of AN in patients.

A wide variety of methods have been used to measure body composition in anorexia nervosa. The skinfold measurements and the bio impedance analysis are most often used in clinical practices. However, clinicians have to be careful with the use of the bio impedance analysis BIA for the estimate of body fat in AN. Additionally, the body mass index (BMI) does not predict the body composition or reveal the change in body composition.

There are a number of available equations to estimate the percentage of body fat from the available body density. The Siri-Formula (In: Lawrence JH, Tobias CA, editors. Advances in biological and medical physics. New York: Academic Press, p. 239–280, 1956) is recommended, with some restrictions.

A weight gain program for patients with anorexia nervosa lead to a significant increase in body weight and body fat. More than half (55%) of the weight increase is attributed to the increase of fat mass. The body composition results had to be communicated and explained to the AN patients in psycho-education sessions.

Here, guidelines for a standard protocol of anthropometric assessments in the clinical practice are proposed. Despite an increase in knowledge about the body composition of patients with anorexia nervosa, more fundamental research is necessary in regard to the limitations of the techniques and equations for these specific group of underweight patients.

174.1 Introduction

Anorexia nervosa (AN) is characterised by a refusal to maintain a minimally normal body weight. A subgroup of AN is characterised by fasting, followed by inappropriate compensatory behaviours, such as self-induced vomiting, misuse of laxatives (or other medications), fasting or excessive exercise. A distorted attitude towards one's own body shape and weight is an essential feature of eating disorders. The disorder primarily affects female adolescents. Weight restoration is one of the important goals in the treatment of patients with anorexia nervosa. For the diagnostic criteria, see Diagnostic Statistical Manual (DSM-IV; American Psychiatric Association (APA) 1994).

These diagnostic features of AN could be accompanied by somatic, psychic, behavioural and social disturbances (APA 1994). For a more detailed description of the somatic features of AN, see chapter 174. Furthermore, in AN, many psychic symptoms are typically well developed, such as a distorted body experience, sexual problems, an attempt to prolong childhood and to escape the responsibilities of adulthood, perfectionism, feelings of ineffectiveness, inflexible thinking, limited social spontaneity, overly restrained initiative and emotional expression, a strong control over one's own environment, a denial of illness and mood changes with marked lability. Additionally, obsessive–compulsive features, both related and unrelated to food, are often prominent. The anorectic patient quickly develops a repertoire of behaviours in the pursuit of weight loss, including caloric restriction, refusal to eat food, adoption of special diets or vegetarianism, calorie obsession, hyperactivity, vomiting and laxative abuse. Moreover, unusual eating rituals are frequently described. These behaviours create a vicious cycle with behavioural and psychological sequelae that perpetuate the disorder. In a social context, patients become isolated and numerous conflicts arise with family members.

174.2 Clinical Manifestations of Body Experience in Eating Disorders

The distorted perception of one's own body (weight, size and shape) and the intense fear of weight gain, even when severely underweight, indicates how patients with anorexia nervosa experience their bodies. These characteristics are included in the current diagnostic criteria for AN (APA 1994).

Persons suffering from anorexia evaluate their body structure, their size or certain body parts in an unrealistic way. Even when clearly underweight, some patients experience their appearance as either normal, or even too fat. The discrepancy between the way they see themselves and the way they see others is striking; in most cases, AN patients can give a fairly accurate estimate of another patient's body size, while they do not realise that they themselves look the same or even worse. Furthermore, they have misconceptions about the consequences that eating will have on their body structure. After a meal, they feel their stomach is 'bulging' or that their belly is 'swelling'. In general, most patients with eating disorders maintain a very negative attitude towards their own bodies and their physical appearance. They are constantly watching their body, criticising it relentlessly or fighting it. Others avoid seeing themselves (naked) and often hide in loose clothing. Generally, they are dissatisfied with certain body parts (usually their belly, thighs or bottom). This dissatisfaction can also apply to body parts that are not related to weight (wide hips, short height, short legs and narrow shoulders). A minority of patients with anorexia seems to be proud of their emaciation (which they seem to show in an almost 'exhibitionistic' manner), but, for most of them, the weight loss does not increase their satisfaction at all. Along with frequent weighing or mirror inspections, some develop their own standards, such as 'my ribs must show' or 'the inner part of my thighs shouldn't touch when I am standing'.

Patients suffering from an eating disorder show a lack in confidence in their own bodies; they experience it as something annoying, and they do not feel "at home" in their bodies. The patients dislike being touched and have trouble with physical closeness, in general. The way that they think others regard them often plays an important role in their self-perception, and they generally anticipate a negative opinion. It is as if they looked at themselves through the eyes of someone very critical. This way, the opinion they have of themselves is constantly subject to conflicting points of view: 'how do I see myself' (the internal lens), 'how do others see me' (the external lens), 'how do I really look' (the unbiased or neutral lens) and 'how would I like to look' (the ideal lens). As the four lenses increasingly diverge, the self-perception becomes more problematic. The core problem resides in the absence of self-esteem and a negative self-perception, which is expressed in the negative body image.

174.3 The Importance of Body Composition Assessment in Anorexia Nervosa

This description of the disorder clearly illustrates why body-composition research is more and more important in the evaluation of subjects with AN.

1. The body composition of subjects with AN is influenced by the eating behaviour and is different from the body composition of a normal female population. In comparison to non-clinical subjects, patients with AN and athletes have a lower fat mass (FM). Athletes have a higher fat-free mass (FFM) than AN patients and non-clinical subjects.
2. The body composition in AN is important in regard to the female triad and fertility.
3. The body composition represents the state of (mal-) nutrition and the net results of metabolic processes and the structural contribution of ingested nutrients and is closely related to an organism's biochemical, metabolic and mechanical function (Heymsfield et al. 1995).
4. From both a physiological and psychological viewpoint, weight and body composition are crucial elements in the treatment of AN because the patients are dissatisfied with their body appearance and have unrealistic ideas about the influence that food intake and dieting have on body weight and shape. To educate the patients about their poor physical condition, information concerning body composition and consequence of weight gain/loss can help motivate the patients to change their way of thinking.

5. The study of body composition and body-fat distribution can have important implications for the treatment of AN; AN patients have an intense fear of weight gain and of becoming fat, and this is enhanced by the belief that this would be accompanied by fat distribution in the abdominal region. Hence, there is a possibility that the level of body fat upon discharge from clinic may influence the further progress of the patient.
6. The estimation of body composition over time is difficult. Therefore, body-composition studies that include an assessment of the changes after weight gain in large groups of patients are necessary.

174.4 Methods to Assess Body Composition in Anorexia Nervosa

A wide variety of methods have been used to measure body composition in anorexia nervosa. Table 174.1 reviews the most important studies in the field of body composition in anorexia nervosa. The mean search term, 'body composition (or related terms) in anorexia nervosa', was used. The studies had to mention percentage body fat (PBF).

The lowest value of PBF is 6.6% and the highest value is 18%. In 19 studies, PBF was found to be lower than 15%. In 11 studies, PBF was higher than 15%.

Body composition is primarily measured by anthropometry (skinfold thickness (SFT; Rusell et al. 1983; Charest-Lilly et al. 1987; Vaisman et al. 1988, 1991; Mayo Smith et al. 1990; Casper et al. 1991; Rusell et al. 1994; Probst et al. 1996, 2001; Orphanidou et al. 1997; Scalfi et al. 2002; Haas et al. 2009) and dual-energy X-ray absorptiometry (DXA; Mazess et al. 1990; Orphanidou et al. 1997; Pagliato et al. 2000; Grinspoon et al. 2001; Kerruish et al. 2002; Scalfi et al. 2002; Misra et al. 2003; Mayer et al. 2005; Haas et al. 2009; Yamashita et al. 2010).

The bioimpedance method (BIA) was used by Casper et al. (1991), Haas et al. (2005) and Probst et al. (2006). Casper et al. (1991) used the total body water method.

Probst et al. (1996, 2001, 2006) and Polito et al. (1998) applied the underwater weighing (UWW) method, which is considered as the method of reference of body-composition measurement.

The starting point for categorisation is based on how the body weight is divided. In the two-component model, body weight is simply partitioned into fat mass (triglycerides, FM) and fat-free mass (FFM), assuming that an individual only differs from the reference individual in terms of fat mass and has a constant composition of fat-free mass with a density of 1.1 g/cm³ (fat = 0.90 g/cm³) (Siri 1956). The assumptions of this traditional model may be sufficiently accurate for determining body composition in the general adult population, but this is not the case in deviations from the 'normal' body composition. Within this body-composition model, the SFT and the BIA methods are the mainly used. The difference between both methods is that, in the SFT method, PBF is estimated by density. Density is calculated by a regression formula using different SFTs.

BIA estimates the FFM, and percentage body fat is calculated from body weight minus FFM.

These methods are inexpensive, non-invasive, reasonably valid and easy to use in clinical practice for measuring body composition.

UWW is a gold standard but is related to a laboratory setting and difficult in clinical practice.

Other methods, such as DXA, total body water and neutron activation analysis, and other more invasive techniques, are based on a tissue-system component. In the three-component model, body weight is divided into three compartments (FFM, FM and bone). In the four-component model, body fat can be calculated from body weight, protein, water and body minerals. Although the methods are more valid, they are very expensive and more invasive. These methods are used as in-depth research, to overcome the limitations of simple techniques. Technical details of the different methods have been described elsewhere in this book.

Table 174.1 Chronological review of the percentage body fat (PBF) assessed by different methods in female subjects with anorexia nervosa

Authors	Method[a]	*N*	Age (years)	Duration (years)	Weight (kg)	Height (cm)	BMI (m/kg²)	PBF (%)	Equation[b] Density/PBF

174.5 Equations to Convert Density to Percentage Body Fat

A clinically useful formula is important for the estimation of body composition in specific age categories. Clinicians need a formula that can be used in the extreme conditions of severe underweight, as well as in the normalised conditions after weight restoration. There are different formulas available to convert the density (*D*) into percentage of body fat (Tables 174.2 and 174.3).

Probst et al. (2008) compared the Siri equation (1956), the age-specific Lohman's equation (1989), the Duerenberg-Westraete equation (1989) and the Heyward equation (1996) in 238 female adolescent AN patients. The relationship between the results of the four formulas in each different age category is higher than $r = 0.97$. Despite the high relationship, the authors found a significantly large difference in mean fat percentages within the different age categories. The differences between the mean fat percentages, when applying the four formulae, ranged from 0.021% to 6.33%; the average difference between the four formulae for all of the age categories was 2.6%. Negative fat percentages were found in the elder category with the Heyward and the Lohman formula. For that reason, Probst et al. (2008) recommended, with some restriction, to apply the Siri formula in AN patients. This formula might lead to an overestimation of the fat percentage in cases of underweight patients, but this overestimation will decrease when weight normalisation occurs.

Heyward and Stolarczyk (1996) stated that the use of the Siri equation for the estimation of per cent fat from density can be questionable in an anorectic population. Siri (1956) assumed that the density of the fat-free mass equals 1.10 g/cm³, that fat has a density of 0.90 g/cm³ and that FFM consists of 72% water ($D = 0.9937$ g/cm³), 21% protein ($D = 1.34$ g/cm³) and 7% mineral ($D = 3.00$ g/cm³). Heyward and Stolarczyk (1996) estimated that, in AN, the FFM components were 76% water ($D = 0.9937$ g/cm³), 6.3% mineral ($D = 2.73$ g/cm³) and 17.7 protein ($D = 1.34$ g/cm³). They proposed the following formula for calculating % fat from density: $\%\ \text{fat} = (5.26/D - 4.83) \times 100$. Compared to this formula, the average body fat of anorectic women will be systematically overestimated by 3–4% when the Siri equations are used to estimate % fat from density. Two problems arise when using the Heyward and Stolarczyk formula: (a) some patients with AN obtain a negative percentage fat and (b) when this formula is applied upon admission, it may not be still valid at discharge, when the test subjects more closely resemble the general population.

The Slaughter equation is also used in anorexia nervosa (Haas et al. 2009), but this equation has proved valid in the USA, but not in the UK (Nicholls et al. 2002).

174.6 Relation Between Different Body-Composition Methods

Seven studies compared two or more body-composition methods (Table 174.1). Body composition measured by skinfold thickness is compared with UWW, DXA and BIA.

174.6.1 Comparing UWW and SFT in AN

There is a sufficient agreement between and among the results obtained by UWW and SFT. UWW and SFT gave approximately the same values for PBF, FFM and FM. Indices from the two methods had good correlations, and there were no significant differences between the values (Probst et al. 1996). The relationship is $r = 0.76$ before and $r = 0.71$ after weight gain.

Table 174.2 Key features of the reference model of Siri to estimate the percentage of body fat from the body density

1. The starting point for the Siri formula is the two-component model where Siri (1956) assumed that body weight is simply partitioned into fat mass (triglycerides, FM) and fat-free mass (FFM).
2. Derived from the formula [body density (D) = mass/volume], the volume can be calculated as [volume= mass/density]. The volume of the body is measured by underwater weight or the water or air displacement of the body. More specifically, the volume is the sum of fat mass divided by the density of fat mass and the fat-free mass divided by the density of fat-free mass.
3. Siri assumed that an individual only differs from the reference individual in terms of fat mass and has a constant composition of fat-free mass with a density of 1.1 g/cm³ and fat with a density of 0.90 g/cm³.
4. Siri assumes that the density of the fat-free mass equals 1.10 g/cm³, that fat has a density of 0.90 g/cm³ and that FFM consists of 72% water (D = 0.9937 g/cm³), 21% protein (D = 1.34 g/cm³) and 7% mineral (D = 3.00 g/cm³).
5. The Siri formula to estimate body fat is the result of 4.95 divided by the density of the body minus 4.50. Percentage body fat is calculated by the same formula multiplied by 100.
6. The difference between methods could be supported by the reference body.

This table lists the key features of the Siri formula to estimate the percentage of body fat from body density

Table 174.3 Formulas to estimate the percentage of body fat from the body density

Author	Equation for percentage body fat
Siri (1956) adults	(4.95/body density) – 4.50
Lohman (1989) 13–15 years	(5.12/body density) – 4.69
Lohman (1989) 15–17 years	(5.07/body density) – 4.64
Lohman (1989) > 17 years	(5.05/body density) – 4.62
Deurenberg and Westraete (1989)	{[5.53–7.3 (age – 10)]/body density} – [5.14 – 8 (age – 10)]
Heyward and Stolararczyk (1996)	(5.26/body density) – 4.83
Specific equations for AN	
Slaughter et al. (1988)	1.33 × (Triceps + subscapular skinfold) - 0.013 (Triceps + Subscapular skinfold)² – 2.5

This table lists the different formulas to estimate percentage body fat from the density

The SFT percentage fat (density estimated from skinfolds by the formula of Durnin and Womersley 1974) was not significantly different from those obtained by UWW either before or after refeeding (Probst et al. 2001).

The findings suggest that, for an undernourished population, such as AN patients with relatively little body fat, simple skinfold measurements are, in clinical practice, as useful as more sophisticated measurements for the estimation of body composition. This is an important finding because SFT can be used more easily as a screening method. Moreover, the skinfold measurements have a lower cost and can reveal subcutaneous fat distribution.

174.6.2 Comparing SFT and BIA in AN

The results regarding the relationship between BIA and SFT are contradictory. Birmingham et al. (1996) found a low relationship (r = -.305), while Haas et al. (2005) and Probst and Goris (2006) found a relationship of 0.75. In the latter study, the PBF of five AN patients could not be determined by BIA. The inability of BIA to detect changes in body composition due to altered hydration and to accurately assess the distribution of water between intracellular and extracellular compartments limits its clinical usefulness in AN (Birmingham et al. 1996). In daily clinical treatment of AN, it appears that SFT measurement is preferable.

174.6.3 Comparing UWW and BIA in AN

Despite significant correlations between UWW and BIA (Maltron Model BF 907), significant differences in PBF were found in AN and in recovered AN patients (Probst 2006).

The same results were found between UWW and BIA (Tanita model TBF-300). Between the two BIA instruments, there was no significant difference. The correlation between both BIA methods was 0.84. Using Maltron and/or Tanita BIA, the body composition of five AN patients could not be determined, which shows the inability to measure the body composition in a certain group. Moreno et al. (2008) compared DXA with various impedance methods (a foot-to-foot impedance meter and Xitron 4200). In comparison with DXA, they found 7.8% (measured by the foot-to-foot impedance) and 4.5% (Xitron 4200) lower FFM. The results of the foot-to-foot impedance meter were significantly different from that of the Xitron 4200 in AN subjects, but not in control subjects.

This result suggests that the pre-programmed body-composition equations used in the BIA body-composition analyser have not been adjusted accurately by the company to provide accurate body-measuring instruments for different target groups.

174.6.4 Comparing SFT and DXA in AN

Orphanidou et al. (1997), Scalfi et al. (2002) and Haas et al. (2009) compared skinfold thickness and DXA. They found a significant difference in PBF between the skinfold methods and the DXA method. Contrary to the first study, both other studies found lower PBF with DXA.

174.7 Specific Topics in Body-Composition Assessment in Anorexia Nervosa Related to Clinical Practice

174.7.1 Percentage Body Fat and BMI

The relationship between BMI and PBF, estimated by SFT and UWW, was high (r = 0.75). Nevertheless, only 56.2% of the variance (r^2) in PBF could be predicted by BMI. The variation in PBF at any given BMI was great. For instance, with a BMI of 13, the PBF varied from 7% to 17% (Probst et al. 1996).

BMI reflects real changes in ratio of weight to height, but, despite the high correlation with PBF, it is not a direct indicator or predictor of relative body fatness. Changes in fat mass and fat-free mass are clinically important and may occur without a change in BMI or weight.

Hannan et al. (1993) stated that the target values for FFM may be more appropriate than BMI for assessing the severity of the disorder and its response to treatment.

In the light of these results, one may question some recent attempts to define AN in terms of BMI (APA 1994). Trocky and Shephard (2000) also questioned the use of weight gain alone for reinforcement in a behaviour therapy for anorexia nervosa.

Soh et al. (2009) assessed the relationship between skinfold and body mass index in North-European Caucasian and East-Asian young women with and without AN. For the same BMI, women

with AN had significantly smaller sums of skinfolds than did women without AN. East-Asian women both with and without AN had significantly smaller sums than their North-European Caucasian counterparts, after adjusting for BMI.

174.7.2 The Influence of a Refeeding Programme on Body Composition in Anorexia Nervosa

A refeeding programme led to a significant increase in body weight and body fat. More than half (55%) of the weight increase was attributed to the increase of fat mass (Probst et al. 2001). The low to very low PBF findings before refeeding are similar to other studies (Kerruish et al. 2002; Scalfi et al. 2002; Mayer et al. 2005). There is a general consensus in the literature about the 'normal percentage of body fat' for the general female population; the results of the refeeding program are in the normal range (BMI > 18; % fat > 22.5). Patients with a low PBF upon admission usually have a low PBF at discharge as well, and vice versa.

The length of treatment or the duration of illness has no effect on body composition after treatment and a rapid weight gain does not change the amount of fat.

The amount of body fat may also affect the clinical outcome. Menses returned with refeeding when patients reached higher levels of body fat (18%); however, the changes in body fat and the return of menses may also enhance psychological stress in the patients, increasing the likelihood of relapse.

The changes in body fat are also in contradiction with what patients want themselves, at least as long as they are anorectic. In the different studies, the mean percentage of body fat after refeeding was still lower than in normal-weight females, although most patients believe they are too fat and are afraid to become overweight. However, the results of body-fat percentage at discharge were still lower than in a normal female population (23–25%). Therefore, it could be important to include some sort of body-oriented therapy in the latter part of the treatment, in addition to a refeeding programme. The aim of this therapy is to educate the patients about their poor physical condition and to help them accept the physical and psychological changes as a result of increasing weight. A fitness-training programme (20 sessions; 2 times a week) during refeeding, supervised by a therapist who is familiar with the physical consequences of undernutrition, could increase the fat-free mass, redirect the patients' hyperactivity in a healthy way, allay the fears of weight gain and improve their sense of self-control. The possible influence of an adapted fitness-training programme on body composition and body experience of AN patients has not yet been assessed in detail and will be an interesting topic for future research.

174.7.3 Changes in Subcutaneous Fat

A skinfold analysis indicated that all of the skinfolds were significantly greater after weight gain. The greatest increase of skinfold thickness is not situated in the abdominal region, as many patients believe, but instead on the thighs, the waist and side (Probst et al. 2001). Orphanidou et al. (1997) found a larger increase of fat in the abdominal region and less in the arms and calves. Other studies (Orphanidou et al. 1997; Scalfi et al. 2002) have mentioned that relative increases in SFT during weight gain may not be the same at various sites. The lowest relative increase of subcutaneous thickness (less than 100%) was situated at the biceps, subscapula, chin and the lateral and medial calf. Changes

in SFT were highly correlated with weight gain. The highest correlation (Probst et al. 1996) was found for the chin ($r = 0.66$) and the sum of the 12 skinfolds ($r = 0.69$), and the lowest correlation was found for the medial calf ($r = 0.35$). SFT showed a small correlation with FFM ($r = 0.20$) but was moderately to highly correlated with PBF (before weight gain: $r = 0.51$, for abdomen to 0.74, for triceps; after weight gain: $r = 0.31$ for medial calf to 0.54 for the side). These correlations did not differ markedly among the common sites.

The relationship between PBF before and after treatment (Probst et al. 2001), measured by rank correlation, was $r = 0.44$ ($P < 0.0001$). This indicates that the ranking order before therapy was at least partially maintained after therapy.

174.7.4 Other Specific Elements in Body-Composition Research in Anorexia Nervosa

The level of physical activity, eating behaviour, stage of refeeding and maturity level influence body composition in anorexia nervosa.

Older and more chronic AN patients (>30 years) have a higher PBF than younger patients. This is not due to a difference in the duration of illness, which does not influence PBF. A detailed analysis did not reveal differences between adolescents (<19 years) and young adults (20–29 years) nor between the subgroup of ages (14–19).

The PBF of the mixed type of anorexia differed significantly from that of the restricting type using UWW. SFT differed significantly between the types, except for the abdomen SFT.

AN patients of the restrictive type had lower values and differed significantly from the binging–purging type for the variables, weight percentage body fat, fat mass and fat-free mass measured by UWWW. After treatment, no significant differences were found between the subtypes (Probst et al. 1996).

AN patients are sometimes compared to athletes. However, athletes have higher fat-free mass value when compared to AN patients and healthy controls (Iacopino et al. 2003).

174.8 Guidelines for a Standard Protocol of Anthropometric Assessments in Clinical Practice

1. The assessment of body composition has to be executed upon admission and at the end of treatment. If possible, it is recommended to repeat a regular body-composition assessment during the therapy.
2. For the standardisation of the assessment, it is advised that the assessment is done by the same highly experienced investigator and at the same time of the day.
3. Height is measured to the nearest completed 0.5 cm using a stadiometer. Body weight is measured, with the subject wearing only a swimsuit, on a beam balance to the nearest 100 g. The Quetelet or body mass index (BMI, kg/m²) is calculated. Although body mass index has been recommended as a measure for nutritional status in anorexia nervosa, BMI does not predict the body composition or the change in body composition. Body mass index has been shown to be an imprecise measurement of fat-free and fat mass.
4. At least three, but if possible 12, skinfolds should be measured: biceps, triceps, subscapular, suprailiac, chin, side, waist, abdomen, anterior and posterior thigh and lateral and medial calf on the left side of the body, using a well calibrated skinfold calliper (Probst et al. 1996).

5. The calculation of trunk fat and extremity fat percentages and the trunk/extremity ratio are useful. From skinfold measurements, the following formulae are proposed: percent trunk fat = sum of upper body skinfolds (subscapula, suprailiac, side, waist, abdomen and chin)/sum of 12 skinfolds; percent extremity fat = sum of extremity skinfolds (biceps, triceps, thigh anterior and posterior and calf lateral and medial)/sum of 12 skinfolds; trunk/extremity ratio = percent trunk fat/percent extremity fat (Probst et al. 2001).
6. From a clinical point of view, the two-component model using the skinfold technique is acceptable and is the most useful. This model proposes that the density of the fat and the fat-free mass is known and is constant, that the density and proportions of the components of the fat-free mass between individuals are relatively constant and that the individual only differs from the reference body in terms of the amount of fat mass.
7. Until now, and with some restrictions, the Siri formula is recommended to estimate PBF from body density.
8. If possible, the use of more than one method to measure body composition is advised in clinical practice. Clinicians should be careful with the use of BMI and the BIA. In fundamental research, more sophisticated models and methods are recommended.
9. In choosing their method, investigators must balance a host of issues including precision, bias, expense and safety. Body composition (research) in anorexia nervosa has to fulfil some conditions. The method and the equations used in anorexia nervosa can influence the results. Researchers have also taken into account age and maturation level, duration of illness and amenorrhea, level of physical activity and compensatory behaviour (purging behaviour and use of laxatives and other pills). In the anamnesis, a previous history of being overweight has to be checked.
10. The *therapeutic implications* of body-composition assessment are that patients with AN have to be informed about the physiological meaning of body fat. The therapist has to emphasise the importance of body fat for the return of menses and normalisation of the reproductive functions. Not only the implications of low body fat have to be addressed, but also the implications of low weight on maturation, growth and osteoporosis, certainly in young patients. On the other hand, therapists should be aware that a normalisation of body fat might also increase the patient's 'fat phobia', which has led to her pursuit of thinness.

174.9 Summary

Body composition has become an important topic in the treatment and research of anorexia nervosa. Table 174.4 lists clinical key points with regard to body-composition assessment in subjects with anorexia nervosa.

More fundamental research is necessary regarding the limitations of the techniques and equations for these underweight patients.

Table 174.4 Summary: Key points in clinical practice of body composition in subjects with anorexia nervosa

1. Body composition has become an important topic in the treatment and research of subjects with anorexia nervosa.
2. The results from different studies are difficult to compare because of the small groups, the different methods and the different equations for deriving percentage body fat (PBF).
3. Simple skinfold measurements are, in clinical practice, as useful as other instruments for the estimation of body composition.
4. The use of the bioimpedance analysis (BIA) in subjects with underweight has limitations.
5. Body mass index (BMI) is not a direct indicator or predictor of body fatness.

This table lists clinical key points with regard to body-composition assessment in subjects with anorexia nervosa

Chapter 175
Perceived Body Image and Actual Anthropometric Indices in Eating Disorders

Dieter Benninghoven

Abstract A disturbed body image is a main characteristic of patients with eating disorders and plays an important role in the development and maintenance of eating disorders. The construct of body image comprises two different components: an attitudinal and a perceptual component both of which need to be taken into consideration when body image distortions are addressed in research and in clinical settings. Attitudinal body image covers a global subjective, an affective, a cognitive, and a behavioral dimension. Mainly questionnaire instruments have been developed to assess body image attitudes. Distortions in body image perception are assessed by measuring discrepancies between actual, perceived and ideal body images. Again, a number of different methods are available in this context. Discrepancy calculations must be based on adequate anthropometric indices. They vary according to the body image assessment method. Traditional methods apply body calipers for measuring body width at specific body sites to compare these measurements with how subjects model their perceived body image. The same principle is applied when subjects are asked to morph their perceived and ideal body images on video or computer screens. Researchers or clinicians are then able to compare the results with actual images captured through video or digital photographs. These methods are basically unidimensional. In recent years more sophisticated multidimensional methods have been developed. They require more elaborate anthropometric techniques such as an assessment of body composition to depict distributions of body fat and muscularity. Both skinfold thickness and measurement of bioimpedance analysis have proven reliable methodologies in this context. An assessment of body movement patterns is needed to describe a dynamic body image.

Perceived body image and actual anthropometric indices in eating disorders.

175.1 Introduction

Two different types of risk factors are involved in the development and the maintenance of anorexia and bulimia nervosa, each of which are severe mental disorders with growing incidence rates during the past decades. Risk factors can be divided into general and specific factors. General factors are those risk factors relevant not only for the development of eating disorders but also for other psychiatric diseases. Specific factors, however, are risk factors specific for eating disorders. In a meta-analysis, Stice (2002) found that single risk factors have minimal predictive power for the pathogenesis of eating disorders except for one finding: the internalization of a very thin ideal body and the subsequent dissatisfaction with one's own body has been summarized under the term 'body image disturbance'. A negative body image seems indeed to be a single and relatively clear delimitable risk factor relevant for dieting, negative affect, and for distortions of eating behavior and food intake. The conviction that a more attractive, that is, a thinner body leads to more satisfying interpersonal relationships and to more positive feelings makes it likely to start with and to maintain a restrictive eating behavior. Restrictive eating behavior again is typical for each form of eating disorders at least at some point in the development of the disorder.

Body-image disturbances are relevant not only for the development of eating disorders, but they also became prominent parts of the definition of eating disorders in the two most commonly used classification systems: the International Classification of Diseases (ICD-10) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV). Both consider dysfunctional body image an important symptom of eating disorders (see Table 175.1).

The diagnostic criteria for anorexia nervosa in DSM-IV include "intense fear of gaining weight or becoming fat, even though underweight" and "disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight." Diagnostic criteria for bulimia require that "self-evaluation is unduly influenced by body shape and weight."

Table 175.1 Key features of dysfunctional body image in eating disorders according to ICD-10 and DSM-IV

	Anorexia nervosa	Bulimia nervosa
DSM-IV	– Intense fear of gaining weight or becoming fat, even though underweight – Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight	– Self-evaluation is unduly influenced by body shape and weight.
ICD-10	– Body-image distortion in the form of a specific psychopathology, whereby a dread of fatness persists as an intrusive, overvalued idea and the patient imposes a low weight threshold on him- or herself.	– Morbid dread of fatness; – Sharply defined weight threshold, well below the pre-morbid weight that constitutes the optimum of healthy weight in the opinion of the physician.

This table lists key features of dysfunctional body image as they are included in the diagnostic criteria for anorexia and bulimia nervosa according to DSM-IV and ICD-10

The diagnostic criteria in ICD-10 list a "body-image distortion in the form of a specific psychopathology whereby a dread of fatness persists as an intrusive, overvalued idea and the patient imposes a low weight threshold on him- or herself" for anorexia nervosa and "a morbid dread of fatness" and "a sharply defined weight threshold, well below the pre-morbid weight that constitutes the optimum of healthy weight in the opinion of the physician" for bulimia nervosa.

The importance of the body-image construct in eating disorders is reflected not only by its meaning for the development and by the fact that it is included in the diagnostic criteria but also by its clinical meaning. Hilde Bruch (Bruch 1962) is considered the first author who described body-image disturbance as a core feature of eating disorders. At least some form of body-image therapy is included in most treatment programs. Body-image disturbance also has prognostic value; persistence of severe body-image disturbance after treatment has negative prognostic value for long-term outcome.

175.2 Main Text

When defining body image, it is widely accepted that the construct of body image generally comprises two different components (Thompson and van den Berg 2002):an attitudinal component and a perceptual component (see Fig. 175.1).

The attitudinal component is generally divided into four dimensions:

- A global subjective satisfaction or dissatisfaction;
- An affective distress regarding appearance;
- A cognitive dimension of body image; and
- A behavioral dimension.

175.2.1 Attitudinal Body Image

The global subjective dissatisfaction refers to an overall satisfaction–dissatisfaction continuum as regards one's appearance. The easiest but necessarily most limited way of assessing body dissatisfaction is a single-item question such as "I am satisfied with the appearance of my body." The item can be adapted to weight, size, shape, or specific body features. More sophisticated are schematic figural methods. These methods use figures ranging in size from thin to overweight. Participants select figures representing their perceived current and their ideal body image. The discrepancy is a measure of dissatisfaction (see Fig. 175.2). An example of this technique is the Figure Rating Scale by Stunkard et al. (1983).

Subjective global satisfaction with body image can also be assessed through questionnaire measures. The most widely used instrument is the Body Dissatisfaction Subscale of the Eating Disorder

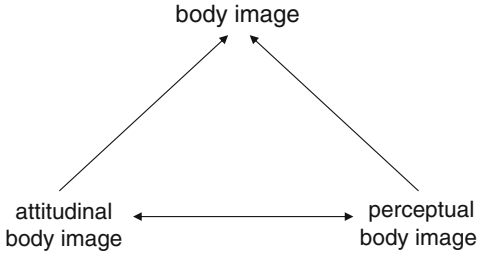

Fig. 175.1 The components of the body-image construct. The construct of body image comprises both an attitudinal and a perceptual component

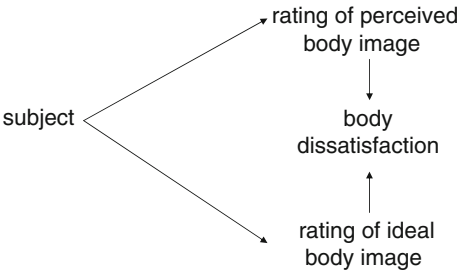

Fig. 175.2 Assessment of body dissatisfaction through figure rating scales. Body dissatisfaction is defined as the discrepancy between a subject's perceived and ideal body image

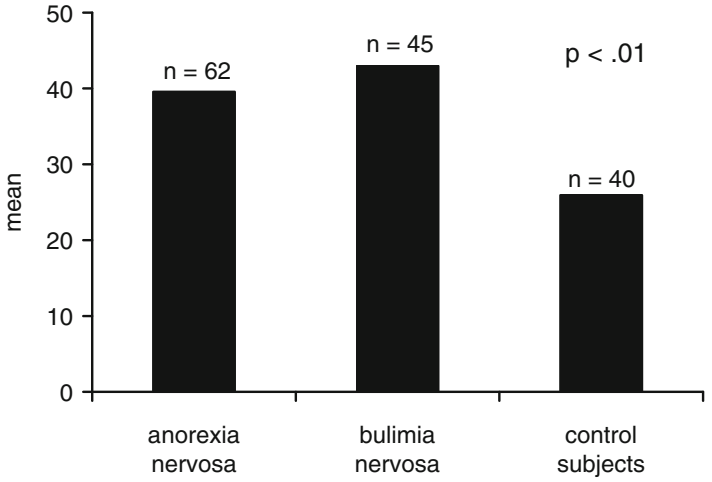

Fig. 175.3 Body dissatisfaction assessed through the Eating Disorder Inventory-2 – subscale Body Dissatisfaction within three female groups. Body dissatisfaction is significantly higher in patients with eating disorders than in healthy female control subjects

Table 175.2 Instruments for the assessment of attitudinal body image (examples)

Dimension	Assessment instrument	Author
Global subjective satisfaction or dissatisfaction	Figure Rating Scale	Stunkard et al. (1983)
	Body Dissatisfaction Subscale of the Eating Disorder Inventory (EDI-BD)	Garner et al. (1983)
Affective distress regarding appearance	Situational Inventory of Body-Image Dysphoria	Cash (1994)
Cognitive dimension	Appearance Schemas Inventory	Cash and Labarge (1996)
Behavioral dimension	Body Checking Questionnaire (BCQ)	Reas et al. (2002)

This table lists common instruments for the assessment of attitudinal body image

Inventory (EDI-BD; Garner et al. 1983). It discriminates reliably eating-disordered patients from female control subjects (e.g., Benninghoven et al. 2007, see Fig. 175.3).

Affective distress regarding appearance is often found in patients with eating disorders and can also be systematically assessed. The Situational Inventory of Body-Image Dysphoria (Cash 1994) measures how often a person experiences negative emotions about body image in different situations. Different questionnaires and subscales target cognitive aspects of body image, such as beliefs, thoughts, or attributions about or toward one's own body. For example, the Appearance Schemas Inventory (Cash and Labarge 1996) addresses dysfunctional appearance-related assumptions.

The behavioral dimension can be seen as the completing part in a picture of the attitudinal component of body image. It has received attention more recently in the field of eating-disorder research. The Body Checking Questionnaire (BCQ, Reas et al. 2002) is an example for this category of instruments. It assesses behavior aimed to control the appearance of one's own body, such as checking one's appearance in a mirror. Examples of scales for the assessment of the four dimensions of the attitudinal body image are given in Table 175.2.

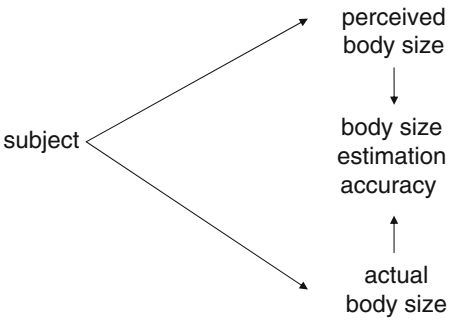

Fig. 175.4 Assessment of body-size estimation accuracy. Body-size estimation accuracy is defined as the discrepancy between a subject's perceived and actual body size

175.2.2 Perceptual Body Image

The perceptual component in body-image research focuses on the ability of individuals to accurately estimate their body dimensions (Thompson and Gardner 2002). This concept was attractive for numerous researchers because it targets so directly one of the main criteria for the diagnosis of eating disorders, that is, the disturbance in the way in which one's body weight or shape is experienced. Methodologies for the assessment of size-estimation accuracy have become more and more sophisticated since the beginning of this research in the 1970s. The basic method in this area is the 'movable caliper technique' (Slade and Russell 1973). Individuals are asked to adjust lights mounted on tracks to reflect their conceptions of their body dimensions at different body sites. Actual body size is assessed using body calipers. The difference between estimated and actual width indexes the estimation accuracy (see Fig. 175.4).

This method inspired a number of variations. A step beyond these body-part size-estimation procedures was the development of whole-body assessment techniques. These techniques enabled researchers to assess whole-image accuracy. Individuals have to modify the size of the entire body in an adjustable mirror, through an anamorphic lens, on a TV screen, on a life-size screen, or on a computer screen. A well-established example is the distorting video technique (DVT, Collins 1986; Freeman et al. 1984). The DVT alters a picture of an individual's body on a screen by distorting it along the horizontal or vertical axis. Again, body-image estimation accuracy is defined as the difference between perceived and actual images.

A more sophisticated methodology for the assessment of the perceptual component of body image is the application of the signal-detection theory on body-image research (Smeets et al. 1999). Subjects are presented with static video images of themselves with size distortion present or absent, with which they judge presence or absence of distortion. The dependent variables are an individual's sensitivity in detecting size distortions (sensory factor) and the response bias (non-sensory factor), that is, a tendency to overreport the body as too wide or too thin. It was found that patients with anorexia nervosa did not differ from control subjects in their ability to detect distorted images of themselves. However, anorexic subjects did show a tendency to report that their image was distorted in size. This result was interpreted as evidence for the theory that distorted size-estimation accuracy in eating disorders is caused rather by non-sensory attitudinal factors than by sensory deficits. Examples of unidimensional instruments for the assessment of perceptual body image are presented in Table 175.3.

175.2.2.1 Mirror-Sized Body-Image Assessment

Beyond what has been summarized so far, some promising new further developments have emerged in body-image research during the last years. Shafran and Fairburn (2002) and Farell et al. (2003)

Table 175.3 Unidimensional instruments for the assessment of perceptual body image (examples)

Assessment instrument	Author
Movable caliper technique	Slade & Russell (1973)
Distorting video technique (DVT)	Collins (1986) and Freeman et al. (1984)
Application of the signal detection theory on body-image research	Smeets et al. (1999)

This table lists common instruments for the assessment of perceptual body image

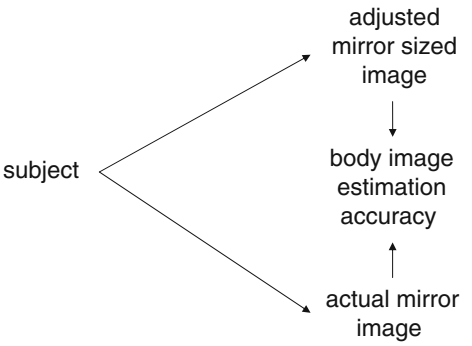

Fig. 175.5 Body-estimation accuracy as the difference between actual mirror image and adjusted mirror-sized image. Body-size estimation accuracy can also be defined as the discrepancy between a subject's actual mirror image and the adjusted mirror-sized image

presented a new ecologically valid method of body-size estimation. Ecologically valid, in this context, means that the authors presented subjects with a mirror-sized image of their own body, and let them compare and adjust this image against what subjects really see while looking in a mirror. A mirror-size image was used because the image with which we are most familiar is our reflection in the mirror and this is half our height, however far we stand from the mirror. The two aspects by which this new method differs from previous similar studies (e.g., Probst et al. 1998) are the size of the images used (mirror size) and the presence of an image for comparison. The latter is important because it ensures that the perception of the participant's body image rather than its memory is assessed (see Fig. 175.5).

175.2.2.2 Assessment of Multidimensional Body Image

Instruments that have so far been presented are limited by the fact that they are unidimensional. They allow subjects to choose among figures of varying sizes or to manipulate the size of a figure by using adequate software programs. The distorting video technique (DVT) has already been described as an example in this domain. However, distorting a body on a screen along the horizontal or vertical axis is not how the shape of a body changes as a person gains or loses weight. The shape changes produced by the DVT do not accurately mimic the pattern of shape change produced by changing body mass. It has been argued that this limitation in validity might be responsible for inconsistencies in the results obtained with this method. This dissatisfaction gave reason for the development of methods that assess body images multidimensionally.

Assessment of Body Size and Shape

To overcome the problem of unidimensional distortions, computer programs have been developed that allow individual body parts to be altered separately (e.g., Tovée et al. 2003). Subjects are photographed

using a digital camera in a standardized pose, wearing a close-fitting leotard. The photograph is entered in a computer program. Individual body parts in the image undergo shape transforms based on template shapes. Subjects are then presented with a distorted picture of their body on a VDU screen. The program allows altering body parts, such as arms, chest, abdomen, hips, thighs, and calf. Subjects are asked to alter their body to make it look like their real and their ideal body. The software then presents the researcher with the apparent body mass index (BMI) of the resulting images. The method used here is the perimeter–area ratio (PAR) (Tovée and Cornelissen 1999). To estimate the BMI of a morphed figure, the PAR needs to be calculated first. The PAR is defined as the area within the perimeter of a figure divided by the path length around the perimeter. The program then reads off the matching BMI value from its internal data bank. Discrepancy between the actual BMI and the estimated BMI of the morphed figure serves as an indicator of size- and shape-perception accuracy. In this context, it is important to mention that an accuracy of self-reported weight and height among women with eating disorders is low. Obtaining objective height and weight data is mandatory both within clinical and research settings (Meyer et al. 2009).

Assessment of Body Image Defined by Body Fat and Muscularity

Another shortcoming of traditional instruments is the fact that they do not allow emulating an apparently visible aspect of body composition, that is, the distribution of body fat versus muscularity. This was not a highly relevant issue in body-image research until colleagues became interested in assessing male body images. The most important body-image dimension for women is that of slimness versus fatness, which can be mapped by enlarging or narrowing body images. Conversely, men evaluate their body image mainly on two dimensions: body fat and muscularity. This gave reason to develop a new instrument for the simultaneous assessment of body fat and muscularity, the somatomorphic matrix (Gruber et al. 2000). Gruber and her colleagues became interested in this field as a result of their involvement with anabolic steroid use in bodybuilders. They found a phenomenon that they named as 'muscle dysmorphia' (Pope et al. 1997). It describes individuals who perceive themselves as less muscular and fatter than they actually are.

The somatomorphic matrix allows an assessment of muscularity and body fat of men's and women's body image. The instrument presents the user with a drawing of a male or a female body that the user can 'morph' through ten levels of muscularity (fat-free mass index, FFMI) and body fat (share of body fat in percent of total body mass). The images were drawn by a graphic artist, according to reference photographs of subjects with quantified levels of body fat and muscularity. Percentage body fat was calculated using skinfold measurements obtained with calipers, using equations developed by Jackson and Pollack (Jackson et al. 1980). Degree of muscularity was quantified by calculating the fat-free mass index with a formula originally developed by Kouri et al. (1995). Estimated body fat of the drawn images varied from 4 to 40 percent; FFMI varied, on the other axis, from 16.5 to 30.0 kg/m^2 for men and from 11.0 to 25.0 kg/m^2 for women (Gruber et al. 2000). Thus, both the male and the female matrices consist of a set of 100 images representing ten levels of body fat and ten levels of muscularity (FFMI). The 100 images for each matrix were then imported into a computer program that allows subjects to navigate among them by clicking buttons to increase or decrease the body fat and FFMI of the image that they are currently viewing. The user of the program is then asked to choose images representing (1) the best estimate of the own body (actual body), (2) the body the user would ideally like to have (ideal body), (3) the body that the user felt represents an average man/woman of her/his age (average body), and (4) the body that he/she felt was most preferred by the opposite sex (society's ideal). A number of studies have used the male version of the matrix (e.g., Mangweth et al. 2004). In applications of the female version, the body-fat dimension of

Table 175.4 Indices of body fat within three female groups assessed through the somatomorphic matrix

	Anorexia nervosa $n = 62$	Bulimia nervosa $n = 45$	Female control $n = 40$	
Body fat in %	M (SD)	M (SD)	M (SD)	p-value
Perceived	15.23 (8.72)	24.80 (9.67)	22.70 (6.92)	<.001
Desired	15.81 (6.08)	16.00 (5.97)	19.30 (4.87)	.007
Average	21.55 (6.12)	20.53 (5.76)	21.50 (5.49)	.636
Men's ideal	19.10 (6.85)	17.16 (5.37)	19.20 (5.14)	.184

Patients with eating disorders differ from female control subjects in terms of perceived and desired body fat
M mean; *SD* standard deviation

the somatomorphic matrix has been found to be most meaningful for defining body images (Benninghoven et al. 2006). As can be seen in Table 175.4, patients with eating disorders differ from female control subjects in terms of perceived and desired percentage of body fat. No differences are found when rating the image of an average woman or of the female body favored by men. This finding supports the theory that body-image disturbances are primarily found in those aspects of body image that directly apply to the patient's own body. Body-image disturbance in patients with eating disorders is not a problem of processing body-image-related information per se but rather a problem of processing self-referential information regarding body image.

For the assessment of dissatisfaction with body image, the somatomorphic matrix requires calculations similar to unidimensional rating scales: namely the difference between perceived and ideal body image, both on the body fat and on the muscularity dimension. A more complex procedure though is required for assessing estimation accuracy. When the accuracy of estimating body size only is the dependent variable, measuring body size is a sufficient methodology. Body size can be measured, for instance, with calipers. The result is then compared with how subjects adjust lights mounted on tracks to reflect their conceptions of their body dimensions. However, when it comes to assessing the accuracy of muscle and body-fat estimation, more sophisticated methods are needed. Skinfold-thickness measurements obtained with calipers for calculating an individual's percentage of body fat and fat-free mass index (FFMI) are appropriate. Estimation accuracy can then be computed as the difference between the objective measurements (actual body fat and FFMI) and the body fat and FFMI of the somatomorphic matrix image representing subject's best estimate of his or her own body (perceived body).

Skinfold-thickness measurement obtained with calipers is a practicable technique in many settings. In terms of reliability, it is comparable to more elaborate methods, such as underwater weighing (Probst et al. 2001). However, it is still invasive, compromising, and potentially traumatizing or retraumatizing, especially for victims of violence because subjects need to undress partly. Bioimpedance analysis (BIA) can be an alternative method in settings where a less invasive technique is required. This is a method for evaluating body composition. It measures the impedance of a small electrical signal as it travels through the body. Because fat has low impedance and muscle and water has high impedance, the impedance a certain body provides indicates what percentage of body mass is fat. Figure 175.6 displays body-estimation accuracy and perceived–ideal difference of patients with eating disorders and female control subjects. Body-estimation accuracy is assessed using BIA as the measure for actual body fat.

Patients with anorexia nervosa clearly overestimate their body fat. Overestimation of body fat can be found with the bulimia nervosa patients, too. Nevertheless, the implications are different for both groups. Overestimation in patients with anorexia nervosa may help patients keeping a subjectively non-pathological image of their body by negating their severe underweight. In women with bulimia though, overestimation contributes to a subjectively pathological image by negating the normality of the body. In anorexia patients, perceived and desired body images are hardly different.

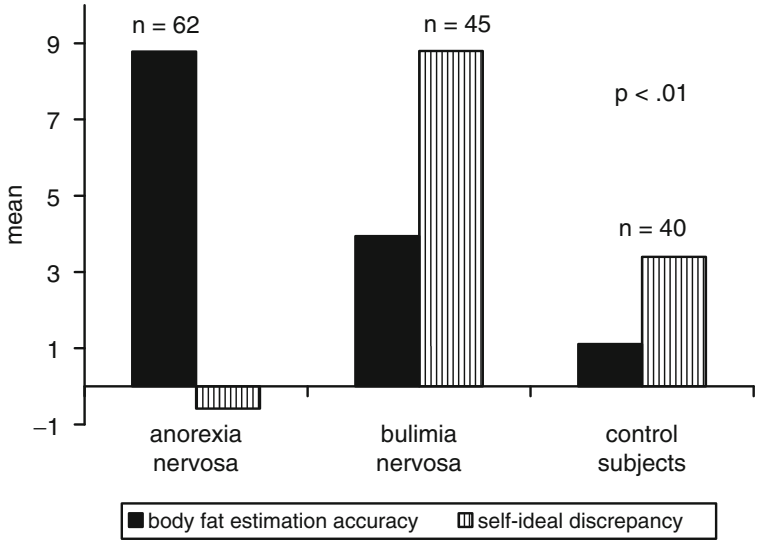

Fig. 175.6 Discrepancy scores within three female groups. Body-fat estimation accuracy and self-ideal discrepancy are significantly higher in patients with eating disorders than in healthy female control subjects. Body fat estimation accuracy: perceived minus actual body fat; perceived–ideal discrepancy: perceived minus desired body fat

Table 175.5 Changes in body-fat estimation accuracy and perceived–ideal discrepancy during a 6-week in-patient treatment

	Anorexia nervosa $n = 41$			Bulimia nervosa $n = 37$		
	adm	disc		adm	disc	
	M (SD)	M (SD)	ES	M (SD)	M (SD)	ES
Body-fat estimation accuracy	9.2 (10.8)	9.0 (7.9)	.03	4.5 (7.7)	1.5 (7.3)	.43
Perceived–ideal discrepancy	–.59 (9.9)	1.4 (9.3)	–.22	9.5 (9.3)	5.8 (9.1)	.40

Patients with bulimia nervosa benefit from in-patient treatment in terms of body-fat estimation accuracy and perceived-ideal discrepancy

M mean; *SD* standard deviation; *Body-fat estimation accuracy* perceived minus actual body fat; perceived–ideal discrepancy: perceived minus desired body fat; *adm* admission; *disc* discharge; *ES* effect size

Body satisfaction, in this respect, is nearly not impaired in spite of severe malnutrition. In patients with bulimia nervosa, body dissatisfaction is relevant in terms of a self-ideal discrepancy. Patients with bulimia nervosa perceive their bodies as too big and desire a thinner body. It seems to be a common feature of both eating disorders to favor a body image thinner than women without an eating disorder do. This results in much bigger self-ideal discrepancies for patients with bulimia than for women with no eating disorder. While perceptual inaccuracy is nearly irrelevant for the female control subjects, they do show a tendency toward a desired body thinner than the perceived body. However, self-ideal discrepancy is less distinct than in the bulimia group. Nevertheless, the desire for a thinner body is not limited to patients with eating disorders but is common also within the at-risk population of young women.

Table 175.5 shows changes in body-estimation accuracy and perceived–ideal difference obtained during a 6-week in-patient psychosomatic treatment for patients with anorexia and bulimia nervosa. Differences between actual and perceived and between perceived and desired body images in anorexia patients are difficult to change during treatment. No correction of the distorted

Table 175.6 New multidimensional instruments for the assessment of perceptual body image

Assessment instrument	Author
Separate alteration of individual body parts in a computer program	Tovée et al. (2003)
Somatomorphic matrix	Gruber et al. (2000)
Dynamic body-image assessment	Vocks et al. (2007)

This table lists three new multidimensional instruments for the assessment of perceptual body image

body-size perception takes place in spite of an increase in weight of 4.85 kg (707 g/week). A correction of body-size overestimation is easier to achieve for patients with bulimia nervosa. At the end of treatment, overestimation can still be found but is less pronounced than at the beginning of treatment. Also, perceived and desired body-image approximate during treatment because the perceived body image becomes more realistic toward the end of treatment. This process is possibly based on the experience of bulimic patients during treatment that their body is quite acceptable, so that there would be no necessity for any manipulation with the help of bulimic eating behavior (Benninghoven et al. 2006).

Assessment of Dynamic Body Image

Another new development is the extension of a traditional static body-image assessment toward an assessment of motion patterns (dynamic body image). Vocks et al. (2007) developed a technique that makes it possible to study biological gait patterns without interference from shape. The technique is based on point-light displays depicting a walking figure in a frontal-view perspective presented on a computer screen. This percept of their own body in motion can be altered by participants along a BMI axis. It was shown that patients with eating disorders not only overestimated their own body dimensions but also perceived their own motion patterns corresponding to a higher BMI than did control subjects. This new method might be an advance in the task of understanding the various dimensions of the complex body-image construct. Examples of methods for the assessment of multidimensional body image are presented in Table 175.6.

175.3 Practical Methods and Techniques

1. A number of different questionnaire methods are available for the assessment of the attitudinal component of body image.
2. Anthropometric techniques are relevant for the assessment of body-estimation accuracy indicating the perceptual component of body image.
3. The movable caliper technique is a basic method for the assessment of body-part estimation accuracy.
4. The distorting video technique is an example of assessing whole-body estimation accuracy.
5. Mirror-sized body-image assessment is an ecologically more valid method.
6. New software programs allow comparing actual and perceived body image in a multidimensional form. The shape of body parts, body fat, muscularity, or motion patterns can be simulated and compared with what has actually been measured.

175.4 Applications to Other Areas of Health and Disease

Most of the body-image methodologies applied in eating disorders can also be useful in other contexts. There are many examples where body-image issues have become of interest. Body dysmorphic disorder is an entity beyond eating disorders in mental health. Dermatology, dental medicine, oncology, and rehabilitation medicine are examples of medical contexts. Cosmetic and reconstructive surgery for acquired disfigurement are areas where changing the body is in the focus of attention. Body image also provides a perspective on developmental issues and cultural differences. A comprehensive overview can be found in Cash and Pruzinsky's (2002) body-image handbook.

Whenever body image is assessed in different areas, attention should be paid to both the attitudinal and the perceptual component. A discrepancy between actual and perceived or ideal body image can only be meaningful when actual body image is assessed by means of reliable anthropometric indices. Measuring body composition through skinfold thickness is an example of such a method.

Summary Points

- The construct of body image comprises an attitudinal component and a perceptual component.
- The four dimensions of the attitudinal component are:
- A global subjective satisfaction or dissatisfaction;
- An affective distress regarding appearance;
- A cognitive dimension of body image; and
- A behavioral dimension.
- The perceptual component focuses the ability of individuals to accurately estimate their body dimensions.
- Anthropometry is necessary to measure the accuracy of body-image estimations.
- Anthropometry in eating disorders should not rely on self-reported data.
- Unidimensional methods have traditionally been applied where body width was measured and compared with subjects' estimations of the same.
- Multidimensional methods that allow morphing of bodies in more than one direction have recently become more attractive.

Chapter 176
Anthropometry and Nutritional Rehabilitation in Underweight Eating Disorders

Giulio Marchesini, Laura Maria Ricciardi, Nicola Villanova, and Riccardo Dalle Grave

Abstract The restoration of a normal body weight is a key strategy in the treatment of eating disorders, in order to eliminate the adverse effects of starvation on health and on the eating disorder psychopathology. Unfortunately, weight regain is frequently hindered by changes in body shape, in particular a protrusion of the abdomen, which may lead underweight patients to stop their nutritional rehabilitation program. In adult patients with underweight eating disorders, studies using dual-energy X-ray absorptiometry, skinfold thickness, dual photon absorptiometry and circumference measurements found a preferential accumulation of body fat in the central regions rather than the extremities during the process of weight regain. These data, however, were not confirmed in adolescents and in young adults with eating disorders. To date, the mechanism(s) implicated in the preferential accumulation of abdominal fat (e.g., low level of estrogens, fast rate of weight regain) have not been settled by experimental research, nor is it settled whether the preferential accumulation is a transient phenomenon or it persists after complete and stable weight restoration. Available data indicate that weight regain produces an increase in bone mineral density, initially greater in the hip than in the spine, but in the long-term bone recovery is never complete, especially whenever the eating disorder starts during adolescence and peak bone mass has not been attained. As lack of exercising may contribute to decrease bone mass, to increase the risk for atherosclerosis and to decrease compliance with the program, clinicians tend to incorporate healthy and social exercising in the nutritional rehabilitation. Preliminary findings indicate that this procedure helps patients get out of the isolation of their disease, overcome the urge to exercise, accept weight gain and changes in shape, and increase lean body mass, while it does not reduce the short-term gain of body fat or BMI.

176.1 Introduction

Eating disorders are conditions characterized by a persistent disturbance of eating or eating-related behavior that result in an altered consumption or absorption of food and that significantly impair physical health or psychosocial functioning. The current DSM-IV classificatory system (American Psychiatry Association 2000) divides eating disorders into the three main diagnostic categories of anorexia nervosa (AN), bulimia nervosa (BN), and eating disorder not otherwise specified (EDNOS).

Almost 30% of individuals with eating disorders are severely underweight (i.e., body mass index (BMI) < 17.5 kg/m^2). This group includes all the individuals with AN and a subgroup of individuals with EDNOS (i.e., those with all the diagnostic criteria of AN without either amenorrhea or the overevaluation of shape and weight) (American Psychiatry Association 2000).

The active maintenance of an unhealthy low body weight is harmful and has numerous adverse effects on physical health and psychosocial functioning (Table 176.1). In addition, in individuals with eating disorder psychopathology (i.e., the overevaluation of shape and weight and their control), the symptoms of starvation seem to stimulate further dietary restriction by undermining the person's sense of being in control over his/her eating, shape, and weight, or themselves in general, while other symptoms exaggerate the tendency to use control over eating as an index of general self-control (Dalle Grave et al. 2007; see Table 176.2 for the proposed mechanisms). These observations indicate that the restoration of a normal body weight is a key strategy in the treatment of eating disorders for eliminating the adverse effects of starvation on health and on the eating-disorder psychopathology.

Weight restoration in eating-disorder patients is a complex and difficult task requiring the application of specialized procedures and strategies. The process is principally hindered by the eating-disorder psychopathology, a common difficulty being the change of body shape, in particular the sticking out of the stomach (abdomen) often observed in some patients during the first phase of weight regain, which may lead them to stop the nutritional rehabilitation. Therefore, the study of the changes in fat mass (FM) and body-fat distribution and accumulation during the process of weight regain not only is an interesting phenomenon for physiologists but also has important clinical implications for treatment.

Another important area of research regards the medical complications associated with weight loss, in particular the loss of bone mass. The reversibility of bone mass with the restoration of a normal body weight is a matter of concern, and we need to know whether a few procedures (e.g., associating healthy physical exercising to nutritional rehabilitation) may help improve the restoration of lean body mass (LBM or fat-free mass [FFM]) and the compliance of patients to treatment, without hindering FM gain.

The aims of this chapter are to review the data of the literature on the effect of nutritional rehabilitation on the relative proportion of FM and FFM, as well as on bone mass, and the role of healthy physical exercising in the treatment of underweight eating-disorder patients.

Table 176.1 Starvation effects reported by the Minnesota Study volunteers (Adapted from Keys et al. 1950)

Behavioral effects

- Eating rituals (eating very slowly, cutting the food in small pieces, mixing the food in a bizarre way, and ingesting hot food).
- Reading cookbooks and collecting recipes
- Increasing the coffee and tea consumption
- Increasing the use of salt, spices, gums, hot soup, and water
- Nail biting
- Increase smoking
- Bulimic episodes
- Increasing exercise to avoid the reduction of the caloric content of the diet
- Self-mutilation

Psychological effects

- Impairment of concentration capacity
- Poor insight and critical judgment
- Preoccupation about thought on food and eating
- Depression
- Unstable mood
- Irritation
- Hunger
- Anxiety
- Apathy
- Psychotic episodes
- Personality changes

Social effects

- Social withdrawal
- Loss of sexual appetite

Physical effects

- Abdominal pain
- Gastrointestinal discomfort
- Sleep disturbances and vertigo
- Headache
- Strength reduction
- Hypersensitivity to light and noises
- Edema
- Cold intolerance
- Paresthesia
- Reduction of basal metabolism
- Reduction of heart and respiratory frequency

Table 176.2 Proposed mechanisms through which starvation symptoms maintain the eating-disorder psychopathology

1. Being underweight and dietary restriction increase the need to control eating, shape, and weight, or all of the above in general.
2. Worries with food and eating maintain the eating-disorder mindset permanently in place.
3. Social withdrawal and loss of previous interests prevent the development of other domains of self-evaluation.
4. Maintaining underweight requires the adoption of a hypocaloric diet that favors the worries about food and eating;
5. Uncertainty makes it difficult for patients to decide whether to change or to delay changes (procrastination).
6. Strong need for routine and predictability interferes with change.
7. Sense of immediate fullness makes it difficult to increase the amount eaten.

176.2 Nutritional Rehabilitation and Body Fat in Underweight Adults with Eating Disorders

The effects of nutritional rehabilitation on the relative proportion of FM and FFM have attracted considerable attention. It was demonstrated that a reduction in both lean mass and body fat occurs in underweight eating-disorder individuals. Recovery might involve an increase in both components, but at different rates owing to the higher caloric cost of FM. Clinical observations have shown that the fear of weight gain by AN patients is enhanced by their belief that weight gain during nutritional rehabilitation is accompanied by preferential fat distribution in the abdominal area (Goldner and Birmingham 1994). As a consequence, they are reluctant to be compliant with nutritional treatment, even when it is medically important.

Forbes et al. showed that a satisfactory nutritional rehabilitation and weight regain did not require a high-protein diet (Forbes et al. 1984). Weight regain and changes in anthropometric measurements were similar in patients fed diets providing 20% or 10% energy from protein, but the high-protein diet resulted in higher blood urea nitrogen, suggesting that excess nitrogen may only harm.

The most recent publications on body-fat gain during nutritional rehabilitation are reported in Table 176.3. In female AN patients with a BMI of 16.5 ± 1.9, the accumulation of body fat was tested by dual-energy X-ray absorptiometry (DXA), skinfold thickness, and circumference measurements until they achieved maximum weight gain (Orphanidou et al. 1997). By the end of the observation period and a mean weight gain of 6.7 ± 5.3 kg, FM, LBM, and bone mineral content were all increased, with body fat being the component that increased the most. Fat gain measured by DXA was not significantly different in the three central regions: subscapular, waist, and thigh. In conclusion, 1. fat was the largest component of the weight gained; 2. there was no preferential fat accumulation in any one area of the female gynoid body; and 3. a significantly greater accumulation of body fat occurred in the central regions (i.e., chest, abdomen, hip, and thigh) than in the extremities (i.e., arm and calf), as also observed in studies based on skinfold-thickness measurement (Russell et al. 1983).

Preferential accumulation of body fat in the central regions rather than the extremities under conditions of weight regain seems to be a general phenomenon, being also the norm in individuals without AN (Lapidus et al. 1984), and it was demonstrated by skinfold-thickness measurements at five body sites in AN patients undergoing refeeding (Russell and Mezey 1962) and validated by underwater weighing (Probst et al. 2001) and bioelectric impedance analysis (BIA) (Moreno et al. 2008).

A study using multifrequency BIA (an appropriate tool for monitoring the nutritional status in AN, able to detect even subtle changes (Mika et al. 2004)) showed that, after an initial increase of FM, possibly related to previous depletion or individual variations in the control of energy partitioning, both LBM and FM increased in a parallel fashion until complete recovery (Mika et al. 2004).

176.2.1 Mechanisms Implicated in Fat Distribution During Weight Regain

One potential mechanism explaining the selective increase of FM in the trunk is that weight gain in the initial phase of weight gain in patients with underweight eating disorder occurs in the context of relative estrogen deficiency (Iketani et al. 1999) (Table 176.3). Support to this hypothesis comes from the observation that estrogen administration affects both regional and whole-body composition in estrogen-deficient women. In particular, it has been found that a combination of estrogen and progestin prevented abdominal-fat accumulation in early menopause (Haarbo et al. 1991) and led to significantly smaller overall weight gain in postmenopausal women (Espeland et al. 1997).

Table 176.3 Most recent studies on nutritional rehabilitation and body-fat gain in adults with underweight eating disorders

Study	Sample Size	Methods	Follow-up	Results and Comments
Orphanidou et al. (1997)	26 AN (in- and outpatients; age, 27.6 ± 6.6 y)	DXA and skinfold thickness	Max 6 months	↑↑ FM (78% of weight gain), ↑ LBM (21% of weight gain), and ↑ BMC (1% of weight gain). • Conflicting results between DXA and skinfold thickness
Iketani et al. (1999)	21 AN (both in-patients and outpatients)	DXA	Mean, 1.3 years (range 0.3–3.3)	↑ FM (central regions > extremities) Central adiposity tends to normalize with resumption of menses • Sex steroids might be involved in central adiposity
Probst et al. (2001)	130 AN in-patients	UW, skinfold thickness	113–215 days	↑ BW (55% as FM, LBM/FM = 1:3.4) • Body-fat estimation by skinfold-thickness as accurate as UW
Grinspoon et al. (2001)	27 AN outpatients (14 on estrogens)	DXA	9 months	FM = 68% BW gain; LBM = 32% BW gain Estrogen treatment not protective against ↑ FM in the trunk • The study challenges the estrogen theory of central adiposity
Scalfi et al. (2002)	Ten AN outpatients versus 18 controls	DXA, skinfold thicknesses, and anthropometry	Mean, 1.2 years	↑ FM = 56% BW gain; ↑ FM distributes in abdominal regions Abnormalities persist at follow-up • Nutritional rehabilitation does not restore normal anthropometry
Bertoli et al. (2004)	32 AN outpatients versus eight controls	DXA	3 years of stable recovery	At baseline, FM depletion more severe in limbs than in trunk At follow-up, FM normalized, but deficient LBM and trunk/limb FM ratio > controls • Nutritional rehabilitation does not restore normal anthropometry
Mayer et al. (2005)	29 AN patients versus 15 controls (age, 18–45 y)	DXA, MNR, and hormones	10 weeks	WHR, total trunk fat, and visceral adipose tissue remain > control ↑ cortisol, ↓ estradiol tend to normalize with refeeding (no return within control values) • Nutritional rehabilitation does not restore normal anthropometry
Moreno et al. (2008)	13 AN inpatients versus 17 controls	BIA, DXA	26 weeks	Changes in LBM/FM = 1:5 • BIA underestimates LBM in AN in comparison to DXA

AN Anorexia nervosa; *LBM* Lean body mass; *FM* Fat mass; *BMC* Bone mass content; *BW* Body weight; *DXA* Dual energy X-ray absorption; *UW* Densitometric technique of underwater weighing; *BIA* Bioelectric impedance analysis; *WHR* Waist-to-hip ratio

However, in amenorrheic women with AN randomly assigned to receive or not receive estrogens, treatment was not protective against the central fat accumulation associated with weight gain (Grinspoon et al. 2001).

Fat distribution during weight regain might also be influenced by the rate of accumulation. Most studies typically relied on cohorts predominantly recruited from in-patient populations, where the rate of weight regain is usually greater than that achieved in outpatient cohorts. However, this hypothesis was not confirmed in an outpatient study showing that the central accumulation of body fat was also present in these subjects, who had a slower rate of weight regain (Grinspoon et al. 2001).

176.2.2 Does the Prevalent Central Fat Accumulation Persist After Complete Weight Restoration?

Whether the lipodystrophy characterized by prevalent central-fat accumulation persists, or even worsens, after complete weight restoration is an important unresolved question (Table 176.3). Because healthy individuals tend to gain weight and abdominal fat with increasing age, future studies should control for the effect of time on body composition by serially assessing healthy subjects as well as eating-disorder patients.

In a study where an initial investigation was followed by a second assessment after a 15% weight gain and a third after a stable weight recovery, Bertoli et al. found that AN patients regained completely their FM, whereas LBM remained deficient (Bertoli et al. 2004).

After refeeding above a BMI threshold within the normal range (≥ 18.5 kg/m^2), FM represented on average 56% of the regained mass, being directly related to the extent of weight gain (Scalfi et al. 2002). Skinfolds at biceps and at abdominal sites and the waist-to-hip ratio remained significantly higher, whereas arm muscle circumference remained significantly lower compared to controls. In general, the selective accumulation of fat in the central depots is thus maintained. However, it is possible that a subgroup of these patients did not achieve their pre-morbid habitual body weight. In a large study, waist-to-hip ratio, total trunk fat, visceral adipose tissue, and intramuscular adipose tissue were shown to be significantly greater in patients after weight recovering than in control subjects, without differences in skeletal muscle mass (Mayer et al. 2005). The use of dual-photon absorptiometry has further confirmed the results; after restoring a normal weight, the soft mass of the pelvis and the trunk increased to the levels of controls, and the patients with AN maintained central obesity after weight restoration (Iketani et al. 1999).

176.3 Nutritional Rehabilitation and Body Fat in Adolescents and Young Adult Patients with Underweight Eating Disorders

A study carried out by computed tomography in young females with a short story of AN (on average 12 months) (Zamboni et al. 1997) found a preferential accumulation of fat in the subcutaneous tissue during nutritional rehabilitation (Table 176.4). None of the patients received estrogens during the entire course of the study. Regain of body weight was accompanied by a significant increase in total adipose tissue, but the increase observed in subcutaneous adipose tissue was significantly greater than that observed in visceral adipose tissue (212.6% vs 116.8%, respectively). Another study found that adolescent girls with AN, compared with control subjects matched for age and pubertal stage, had lower trunk fat, without differences in fat at the extremities. Weight restoration resulted in an increased percentage of trunk fat and an increased ratio of trunk to extremity fat; however, this ratio did not exceed that of control subjects (Misra et al. 2003). These results may be difficult to reconcile with the majority of studies on weight restoration in adults with eating disorders (Table 176.3). However, it should be considered that also fat loss in adolescents with underweight eating disorders mainly occurs in the trunk and spares the extremities (Kerruish et al. 2002). Fat accumulation during rehabilitation thus represents the return to normal of fat distribution rather than the development of truncal adiposity.

The pathophysiology underlying the age-related differences in fat accumulation during weight regain is unknown. The longer duration of AN in adults might result in higher cortisol concentrations and longer stimulation of truncal-fat accumulation, producing a different phenotype. These findings, which have important clinical implications for the possible cardiovascular events associated with trunk-fat accumulation, have not been confirmed in another cross-sectional analysis (de Alvaro et al. 2007).

Table 176.4 Nutritional rehabilitation and body fat in adolescents and young adults with underweight eating disorders

Study	Sample Size	Methods	Follow-Up	Results and Comments
Zamboni et al. (1997)	14 AN patients (age, 18–38 y)	TC	12 weeks	↑ total FM; ↑ subcutaneous FM > visceral FM • Normal fat redistribution with rehabilitation in adolescents
Misra et al. (2003)	21 AN adolescents outpatients versus 21 controls	DXA	12 months	At baseline, ↓ trunk fat, without differences in fat at the extremities At follow-up, ↑ trunk percentage FM; ↑ trunk/extremity FM; and trunk/extremity FM = controls • Normal fat redistribution with rehabilitation in adolescents
Mika et al. (2004)	21 young AN inpatients versus 19 controls (14 ± 1.5years)	BIA	15 weeks	Between week 3 and 7, ↑ FM, with only a minor gain in LBM ↑ LBM and ↑ FM increase to a similar extent by week 15 • Central adiposity in the early stages of nutritional rehabilitation
de Alvaro et al. (2007)	42 adolescent AN versus 23 controls	DXA	2 years	At baseline, ↓ trunk/extremity FM in patients with prolonged AN duration. No changes in regional FM in short-term malnutrition (amenhorrea < 1 year). • Fat redistribution during rehabilitation depends on AN duration and prolonged malnutrition

AN Anorexia nervosa; *DXA* Dual energy X-ray absorption; *FM* Fat mass; *LBM* Lean body mass; *TC* Computerized tomography

176.4 Nutritional Rehabilitation and Bone Mass in Patients with Underweight Eating Disorders

Body composition in underweight ED is also characterized by low bone mass and reduced bone mineral density (BMD) when assessed by DXA, with only 15% of AN patients with normal BMD (Compston et al. 2006; Valtuena et al. 2003; Viapiana et al. 2007). This translates into a high risk of fractures (cumulative risk, 57% at 40 years after diagnosis), which increases overall morbidity. In cases when the underweight eating disorder starts during adolescence, a normal peak bone mass is never reached, and the defect is maintained throughout life.

Decreased BMD and bone mineral content (BMC) result from both decreased bone formation and increased bone resorption (Dominguez et al. 2007); their pathogenic mechanism(s), as well as the changes in the homeostatic mechanism(s) during recovery, are largely unsettled. A first phase characterized by the increase of bone formation seems to reflect direct stimulation of nutrients on the osteoblastic activity. This is followed by decreased bone resorption, secondary to a slowing down of the osteoclastic activity, occurring 3–6 months after treatment starts. The initial increase in BMC does not produce an increase in BMD, because of a parallel increased bone area, particularly in adolescents (Tothill et al. 1999). In the long term, bone recovery is never complete in AN patients, even if weight recovery is held for several years (Tothill et al. 1999).

These problems constitute a major challenge during nutritional rehabilitation (Table 176.5). Weight regain produces an increase in BMD (Fig. 176.1), initially greater in the hip than in the spine, possibly due to the skeletal load produced by weight regain (Viapiana et al. 2007). Spine BMD is more affected by menstrual function, with a greater increase after menses restoration. This is confirmed in AN adolescents who restored menses, where the increase of bone mass progressed at higher speed than in AN adolescents with amenorrhea (Soyka et al. 1999). These data indicate a

Table 176.5 Changes in bone mineral parameters and biochemical indices of bone turnover during nutritional rehabilitation in underweight eating disorders

Study	Sample Size	Methods	Follow-up	Results and Comments
Soyka et al. (1999)	19 adolescent AN outpatients versus 19 controls (mean age, 15 years)	DXA, biochemistry, and hormones	12 months	↑ spine BMC and BMD, tBMC, and tBMD ↑ markers of bone turnover (osteocalcin, bone-specific alkaline phosphatase, Dpd, and NTX) • Despite recovery, poor bone mineral accrual persists in adolescent AN girls.
Compston et al. (2006)	26 adolescent AN in-patients (mean age, 16.5 years)	DXA and biochemistry	12 months	↑ tBMC but ↓ tBMD, ↓ NTX ↑ osteocalcin and bone-specific alkaline phosphatase • ↑ BW is associated with linear growth, but BMD does not increase because of a contemporaneous increased of bone area.
Miller et al. (2006)	65 AN outpatients	DXA	6 months	↑ spine BMD in AN who recovered menses ↑ hip BMD in AN who increased BW • Good reproductive function and increased BW, with ↑ LBM, are both necessary for skeletal recovery in AN
Viapiana et al. (2007)	71 AN inpatients	DXA, biochemistry	14 months	Hip BMD related to changes in BW and in bone AP; Spine BMD related to changes in serum osteocalcin • ↑ BW produces ↑ BMD, initially greater in the hip than in the spine possibly due to the skeletal load produced by weight regain
Dominguez et al. (2007)	28 AN inpatients (age, 18–35 y) versus 11 controls	DXA, biochemistry	2,2 months	↑ BMD, ↑ osteocalcin; and ↓ NTX only in subjects who regain menses • Nutritional rehabilitation induces a powerful anabolic effect on bone; full recovery involves a hormonal mechanism and requires a return of menses.

AN Anorexia nervosa; *DXA* Dual energy X-ray absorption; *NR*: Nutritional rehabilitation; *tBMD* total body mass density; *BMD* body mass density; *tBMC* total bone mineral content; *BMC* bone mineral content; *NTX* urinary N-telopeptide/creatinine excretion*; Dpd* deoxypyridinoline, *AP* Alkaline phosphates; *BW* Body weight; *LBM* Lean body mass

main role of the severity and the duration of the eating disorder, as well as of the hormonal status, on bone recovery (Compston et al. 2006). The changes in the bone homeostasis are confirmed by the circulating levels of biomarkers of osteoblastic and osteoclastic activity.

Increased LBM is associated with a more rapid and greater bone recovery than an increase of FM, both in adults and in adolescents (Compston et al. 2006).

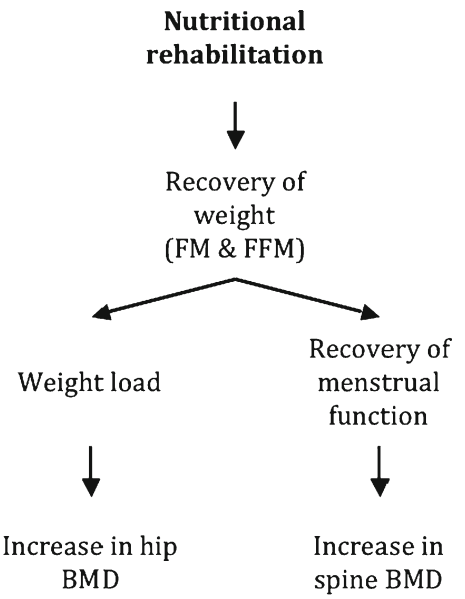

Fig. 176.1 Factors influencing the recovery of bone mineral density at different levels during the nutritional rehabilitation in underweight eating disorders. *Note*: The initial weight gain determines the recovery of bone mineral density in the hip, through the effect of weight load; the recovery in the spine occurs later, favored by the hormonal response

176.5 Physical Exercise and Nutritional Rehabilitation in Patients with Underweight Eating Disorders

Excessive and compulsive exercising in eating-disorder patients has three main general negative consequences. First, it is associated with an increased risk of over-use injuries, bone fractures, and cardiac complications. Second, it has a central role in the maintenance of the eating-disorder psychopathology through several mechanism(s): (1) by reducing the control over eating; (2) by increasing the over-evaluation of shape and weight and their control; (3) by favoring social isolation, which in turn intensifies the over-evaluation of shape and weight; and (4) by modulating mood in a dysfunctional way. Finally, compulsive exercising hinders weight restoration in underweight eating disorders and is a predictor of poor treatment outcome in patients with AN. It is also associated with longer in-patient treatment and a quicker relapse and is a negative predictor of improvement of the eating-disorder psychopathology (Dalle Grave et al. 2008b).

The incorporation of exercise in nutritional rehabilitation of underweight eating disorder patients is a matter of discussion (Table 176.6). In the past, clinicians prescribed AN patients a complete cessation of exercise (i.e., best rest), in order to reduce caloric expenditure and the compulsivity toward exercising. More recently, it has been observed that lack of exercising may contribute to decrease bone mass, to increase the risk for atherosclerosis and to decrease compliance with the program.

These clinical observations lead to incorporate social healthy exercising in the modern treatments of eating disorders (Dalle Grave et al. 2008a). Clinical experience suggests that helping eating-disorder patients, even when underweight, be physically and psychologically in good shape is an effective strategy to overcome excessive and compulsive exercise. Patients are educated to exercise moderately and with friends. In particular, social exercising (e.g., group tennis lessons, yoga classes, and so on) is useful to help patients get out from their isolation, a mechanism implicated in the maintenance of eating-disorder psychopathology. In addition, it may help practice body exposure, control the urge of exercising, and accept weight gain and changes in shape.

Table 176.6 Indication (pros and cons) of physical exercise during the nutritional rehabilitation in patients with underweight eating disorders

Pros	Cons
• Redirect patients' hyperactivity	• Risk of traumatic, over-use injuries
• Restore lean body mass and bone mineral density	• Maintenance of eating-disorder psychopathology
• Allay fears of weight gain	• Hinder weight restoration
• Increase self-control	• Longer in-patient treatment
• Favor compliance	• Risk of cardiac complications

Note that the pros are present with moderate exercise, whereas the cons are observed mainly with exaggerated or strenuous exercise

It has been demonstrated that a fitness-training program (20 sessions, 2 times per week) during refeeding of underweight eating-disorder patients, supervised by a therapist who is familiar with the physical consequences of undernutrition, may increase LBM and redirect the patients' hyperactivity in a healthy way, allay their fears of weight gain, and improve their sense of self-control (Probst et al. 1995). A supervised exercise program increased satisfaction of both staff and patients and was successfully implemented in hospitalized inpatients, with an average weight gain of 1 kg/week (Dalle Grave et al. 2008b). In a randomized, controlled study having change in percent body fat, BMI, and quality of life as outcome measures, Thien et al. tested the effects of a graded exercise program during nutritional rehabilitation in females with AN (Thien et al. 2000). The study showed that both the control and the exercise group increased from their BMI (by 0.8 and 1.0 kg/m^2, respectively) and percent body fat (by 0.5% and 0.9%). However, the exercise group showed an improvement, whereas the control group showed a significant deterioration, in all aspects of quality of life. In summary, although none of the above differences were statistically significant, the study supports the incorporation of a graded exercise program to increase compliance with treatment, without reducing the short-term rate of body fat or BMI increase.

176.6 Conclusions

The study of anthropometry during nutritional rehabilitation in underweight eating-disorder patients is an important research area with several clinical implications. The amount of body fat may indeed affect the clinical outcome. Menses return with nutritional rehabilitation, but both the changes in central body fat and the return of menses may enhance the worries about weight and shape, increasing the likelihood of relapse.

Modern cognitive behavior therapy for eating disorders suggests several strategies to help patients cope with the changes in body-fat distribution during the process of weight restoration (Fairburn 2008). First, eating-disorder patients should be informed that, at least in the initial phase of weight restoration, there is a natural preferential accumulation of body fat in the abdomen and, sometimes, a disproportionate sticking out of the stomach. The phenomenon becomes more prominent by the severe wasting of the abdominal and back muscles, by certain type of clothing (e.g., low-waisted jeans), and by the consumption of a diet rich in fiber and fizzy drinks, and finally by the common tendency of eating-disorder patients to observe their stomach, in particular after eating (Fairburn 2008). Second, they should be helped to disregard the sticking out of their stomach as a sign of overeating or being fat. Third, they should be encouraged to use some simple measures to

reduce this phenomenon (i.e., wearing clothes that do not exaggerate the stomach protrusions, interrupting the checking of their shape in particular after eating, and avoiding the consumption of a diet too rich in fiber and fizzy drinks). Fourth, they should be invited to practice a social healthy exercise that may help both accept weight gain and changes in shape and increase BMD, an important therapeutic target especially in adolescents with eating disorders, who failed to reach a normal peak bone mass.

Future studies should better clarify the physiological mechanisms of body-fat redistribution during weight regain, in particular if some factors (e.g., age, duration of the underweight condition, rate of weight regain, sex, and level of physical exercising) play a role in this process and if the prevalent accumulation of body fat in the abdomen is a transient phenomenon or persists after a complete weight restoration. If the relative increase in abdominal fat is an acute event and it redistributes with stable weight gain, patients should be informed that stomach protrusion is a transient phenomenon and the simple measures described above might be sufficient to help them accept the distorted fat accumulation until redistribution. Alternatively, if no return to normal distribution occurs with time, a targeted and more complex, cognitive approach might be needed to promote the self-acceptance of a different, but healthier, body shape.

176.7 Applications to Other Areas of Health and Disease

The dissemination of the knowledge about the effects of weight regain on body composition in underweight individuals might help improve the assessment and the treatment of the following conditions associated with underweight and low calorie intake (the list is not complete):

- AIDS
- Alcoholism
- Alzheimer's disease
- Anxiety
- Cancer
- Celiac disease
- Chronic heart disease
- Chronic liver disease
- Chronic lung disease
- Chronic renal disease
- Clinical depression
- Cystic fibrosis
- Dementia
- Denture difficulties
- Dysphagia
- Infections
- Inflammatory bowel disease
- Lactose intolerance
- Malabsorption
- Osteoporosis
- Starvation
- Stomach ulcer
- Stomatitis

- Systemic lupus erythematosus
- Schizophrenia
- Tuberculosis
- Uncontrolled diabetes mellitus

176.8 Guidelines

- The body composition of underweight eating-disorder patients should be assessed both at baseline and after weight restoration.
- Fat mass, fat-free mass or lean body mass, and body-fat distribution can be assessed with dual-energy X-ray absorptiometry (DXA), skinfold thickness, circumference measurements, and bioimpedance absorptiometry (BIA).
- Bone mineral density must be assessed by DXA.
- Social and healthy exercising should be incorporated in the nutritional rehabilitation programs of underweight eating-disorder patients.

Summary Points

- Underweight is a key diagnostic criterion for AN, but it is also present in a subgroup of patients with eating disorders not otherwise specified (EDNOS) (e.g., underweight patients who meet all DSM-IV criteria for anorexia nervosa except amenorrhea or the overevaluation of shape and weight).
- The restoration of a normal body weight is a key strategy in the treatment of eating disorders in order to eliminate the adverse effects of starvation on health and on the eating-disorder psychopathology.
- The process of weight regain may be hindered by changes in body shape, in particular a relative protrusion of the stomach (abdomen), which may lead to non-compliance with the treatment program and to stop weight regain.
- During weight regain, there is a preferential accumulation of body fat in the abdomen in adult eating-disorder patients. By contrast, there is a normal fat distribution rather than the development of truncal adiposity in adolescents and young adults with underweight eating disorders.
- The potential mechanism(s) implicated in the preferential abdominal fat accumulation (e.g., low level of estrogens and rate of weight regain) has/have not been definitely settled.
- It is not clear whether the preferential abdominal-fat accumulation is a transient phenomenon or it is maintained after a complete and persistent weight restoration.
- Weight regain is associated with an increase in bone mineral density, initially greater in the hip than in the spine; in the long term, bone recovery is never complete, especially whenever the eating disorder starts during adolescence.
- Social healthy exercising could help patients get out of their isolation, stop their urge to exercise, accept weight gain and changes in shape, and increase lean body mass, without reducing the short-term rate of BMI increase.
- Simple cognitive behavioral procedures and strategies may help compliance to treatment in underweight eating-disorder patients without intensifying the worries about body shape.

Key Points

- Weight regain is associated with a preferential accumulation of body fat in the abdomen, especially in adult eating-disorder patients. It is not yet clear if this is a transient phenomenon or will be maintained after a complete and stable weight restoration. The mechanism(s) proposed to explain this phenomenon have not been fully confirmed by experimental studies.
- Weigh regain is associated with an increased bone mineral density, but, in the long-term, bone recovery is never complete.
- Underweight eating-disorder patients should be educated that, at least in the initial phase of weight restoration, there is a natural preferential accumulation of body fat in the abdomen. Associating social healthy exercising to nutritional rehabilitation increases the compliance to treatment, without reducing the short-term rate of body fat or BMI gain.

Chapter 177
Anthropometric Nutritional Assessment in Children with Severe Neurological Impairment and Intellectual Disability

Corine Penning and Heleen M. Evenhuis

Abstract This chapter discusses the current evidence and best practices of anthropometric measurements in children with severe neurological impairment and intellectual disability, who both have a severe motor impairment and moderate to profound intellectual disability due to congenital or acquired neurological damage. First the target population is described in detail, with regard to the etiology of the disorder, frequent concomitant medical problems and life expectancy. The necessity of regularly measuring the nutritional state is underlined in the light of these children's nutrition-related problems, such as dysphagia and gastro-esophageal reflux, which are potential causes of malnutrition. In contrast, a subgroup of these children is at risk of developing obesity due to tube feeding.

An overview of the feasibility of commonly used anthropometric measurements in the target population, such as weight, height and skinfold measurements, is presented and where possible, alternative methods are described, such as the use of segmental measures when accurate measurement of standing height is not possible. Outcome of body composition measurement is interpreted by means of specific equations. An overview of frequently applied and, if available, group-specific norm values and equations for interpretation of the outcome is presented, followed by suggestions for future research needed for further improvement of the reliability and interpretation of anthropometric measurements in these children. Based on the current knowledge, practical recommendations are given for applying anthropometry in children with severe neurological impairment and ID.

Abbreviations

BIA	Bioelectric impedance analysis
BMI	Body mass index
CP	Cerebral Palsy
DLW	Doubly labeled water
DEXA	Dual-energy X-ray Absorptiometry
FFM	Fat-free mass
GER	Gastro-Esophageal Reflux
GMFCS	Gross motor function classification scale

177.1 Introduction

177.1.1 Children with Severe Neurological Impairment and Intellectual Disability (ID)

Many healthcare professionals will recognize children with severe neurological impairment and ID in their clinical practice as a typical subgroup of wheelchair bound, often spastic children with intellectual disability who have multiple health and nutrition-related problems. Since this is a heterogeneous population by nature, this introduction aims to give a clear description of these children and their health problems before discussing the group-specific methodology of anthropometric recordings.

Internationally, there is lack of consensus for the terminology and definition of this group of children and, as a result, various other descriptions of the disorder have been used in international literature, such as neurodevelopmental disorder, severe (generalized) cerebral palsy, spastic quadriplegic cerebral palsy, or profound intellectual and multiple disabilities. Typically, children with severe neurological impairment and ID are characterized by having both a moderate-to-profound intellectual disability (IQ below 55) and a severe motor handicap (either a hyper- or hypotonic generalized cerebral palsy or a severe motor developmental delay), corresponding with the functional levels of 4 or 5 on the Gross Motor Functional Classification Scale (GMFCS) (Palisano et al. 1997). The disorder is the result of damage to the developing brain that arises before, during, or after childbirth. The most common causes are congenital syndromes or metabolic disorders, prematurity, perinatal asphyxia or trauma, or meningitis, traffic accidents or near-drowning accidents when the disorder is acquired during childhood. Due to the severity of their disabilities, most of these children are wheelchair bound and rely on care from specialized day-care centers, specialized schools, or residential facilities for people with ID. As a result of the availability of multiple forms of specialized daycare in the Netherlands, the majority (approximately 95%) of children with severe neurological impairment and ID live with their parents and only those with severe comorbidity are admitted to residential facilities during childhood. Exact prevalence or incidence numbers are lacking, but, in the year 2000, in the Netherlands the prevalence rate was estimated at 0.6 per 1,000 live births.

177.1.2 Comorbidity

Most children with severe neurological impairment and ID are affected not only with the above-mentioned intellectual and motor disabilities but also with additional health problems that may result from neurological damage. A summary of frequently occurring health problems in these children is given in Table 177.1. As a result of these frequent comorbidities, many of these children use multiple medications, and they are often under treatment by several clinical specialists, such as pediatricians, neurologists, and orthopedic surgeons, and also by several paramedical professionals, such as dieticians,

Table 177.1 Comorbidity in children with severe neurological impairment and ID

General comorbidity	*Nutritional problems*
Epilepsy	Dysphagia
Visual impairment	Gastro-esophageal reflux and vomiting
Reduced pulmonary function	Delayed gastric emptying
(recurrent) Lower respiratory tract infections	Chronic constipation
Low bone mineral density and low-impact fractures	Nutritional status:
Scoliosis	• Malnutrition
Hip displacement	• Obesity
Contractures	Growth retardation

Frequently occurring general and nutrition-related concomitant disorders in children with severe neurological impairment and intellectual disability (ID)

physical therapists, and speech and language therapists. Furthermore, children are frequently admitted to the hospital for either elective surgical procedures or during acute (mostly respiratory) disease. As a result of these health problems, the life expectancy of these children is markedly reduced. Reported predictors of (early) mortality in children with cerebral palsy (CP) are intellectual disability, limited mobility, incontinence, and inability to eat without assistance (Eyman et al. 1990). In most children with severe neurological impairment and ID, typically all of the above are present and, in the early 1990s, presence of these risk factors was linked to a survival rate of 18% reaching the age of 25, with respiratory infections being the most common cause of death (Eyman et al. 1990). However, since then, medical care for this population has markedly improved: between 1983 and 2002, mortality among these children improved at an average rate of 3.4% per year (Strauss et al. 2007).

177.1.3 Nutritional Problems

Table 177.1 shows that many concomitant health problems in children with severe neurological impairment and ID are related to nutrition and food intake. Due to neurological damage, a large proportion of children suffers from severe dysphagia, clinically presenting as difficulties with the reception of food from the spoon or the cup, oral containment of foods, chewing, and oro-pharyngeal swallowing. As a result of dysphagia, feeding the child is often complex and may take a long period of time, while it may also put the child at risk for aspiration of oral contents. Swallowing difficulty may be further deteriorated by episodes of gastro-esophageal reflux (GER): the acidic gastric refluxate may irritate the mucosa of the oro-pharyngeal cavity, further hampering oro-pharyngeal swallowing. It has been suggested that these children may suffer from delayed gastric emptying, a condition that may enhance GER due to gastric stasis and may result in postprandial vomiting. Apart from theses disorders, food intake may also be limited by oro-pharyngeal hypersensitivity, which causes an unpleasant sensation in their mouths during the meals. It will therefore not be surprising that these children may develop negative associations with eating and mealtimes, and, in fact, food refusal is often observed. Since communication is often limited due to their intellectual disability, it may be hard for them to convey feelings of hunger or satiety to their caregivers. Due to all these potential difficulties, attaining a sufficient daily intake of calories is challenging. Indeed, the prevalence of malnutrition in these children is high: when comparing their results of nutritional-assessment tests to reference values for non-handicapped children, approximately 40% of them are undernourished (Sullivan et al. 2000). Since malnutrition increases the risk to develop infections, delays recovery

after surgery, may contribute to growth retardation, and has an overall profound negative effect on health and quality of life, early diagnosis of malnutrition in these children is desirable.

In order to prevent aspiration resulting from severe dysphagia or to assure sufficient daily caloric or medication intake, a considerable number of children are fed through a nasogastric tube or through a gastrostomy. Tube feeding may be administered as an adjuvant, or exclusively to those children with a high risk of aspiration who may receive nil per mouth. Although tube feeding may assure caloric intake, the potential risk of overfeeding should not be ignored. Due to immobility, muscle mass is often reduced, and it has been suggested that energy requirements in these children may be reduced as well; hence, the necessary daily amount of calories may be lower than the amount that is calculated through conventional equations, such as Schofield's pediatric formula. A recent study demonstrated that body-fat percentage was significantly higher in children receiving gastrostomy feeding versus those who were orally fed (Sullivan et al. 2006), while, from clinical practice, it has been reported that several tube-fed children become overweight. Thus, tube feeding may not only lead to a desirable weight gain, but as a result of administering too many calories, a proportion of the children with severe neurological impairment and ID may develop overweight or obesity.

Since nutritional problems leading to an undesired nutritional state are common in this frail population, regular screening and early diagnosis of malnutrition or overfeeding, and evaluation of the effects of surgical procedures, such as gastrostomy or anti-reflux surgery, are highly relevant.

177.1.4 Research in General

During the past decades, professionals have become aware of the multiple health problems in this frail population and of the lack of scientific evidence for specific diagnosis and treatment. Since then, the number of scientific studies, with topics varying from quality of life of their caregivers to the effectiveness of botulinum toxin injections, has gradually increased and, without a doubt, this has resulted in improved medical care and reduced mortality. However, the outcomes of published research projects are, in many cases, hard to interpret. As a consequence of the lack of an internationally accepted definition for the disorder and due to its varying etiology, different subgroups of the target population are being studied, thus hampering extrapolation of the research outcomes to the entire target population. Furthermore, since the prevalence of the disorder is low, most studies have included small groups of children or samples that are not representative, for example, children who are recruited through their pediatricians (many, but not all children with severe neurological impairment and ID are consulting a pediatrician). When interpreting the outcomes of published research, one should keep these potential limitations in mind.

177.2 Measuring Nutritional Status: Pitfalls and Status of Current Research

In clinical practice, growth and nutritional status are conventionally measured using nutritional assessment methods, such as height for age, weight for age, and weight for height. As an alternative measure, body composition (lean body mass or fat-free mass and fat mass) can be determined non-invasively by measuring percentage fat mass from skinfold measurements or from bioelectric impedance

Table 177.2 Equations for estimation of standing height from segmental measures

Segmental measure	*Equation for estimation of standing height (S; cm)*
Knee height (KH)	S = (2.69 * KH) + 24.2
Tibia length (TL)	S = (3.26 * TL) + 30.8
Upper-arm length (UAL)	S = (4.35 * UAL) + 21.8

Equations have been developed in a population of 172 children with severe cerebral palsy and are applicable for children up to the age of 12 years (Stevenson 1995)

assessment (BIA). Measurement of body composition is an accepted measure for the investigation of growth in children and adolescents, irrespective of their standing height and is a valid alternative for the use of growth charts (Sakate 1984). Skinfold measurements and BIA have been previously validated for application in schoolchildren and for several patient groups. Reference values, specified by age, gender, ethnicity, or disease, are available for many populations.

It is known that healthcare professionals involved in the medical care for children with severe neurological impairment and ID, such as pediatricians, intellectual disability physicians, or dieticians working in a hospital or in an ID-care organization, may experience several difficulties when applying these common nutritional assessment methods to the target population. These difficulties, subdivided by feasibility issues, applicability of available equations, and interpretation of the outcome, are discussed below.

177.2.1 Feasibility of Anthropometric Nutritional-Assessment Methods

177.2.1.1 Standing Height

For the determination of height for age or weight for height, an accurate measurement of standing height or stature is required. However, most children with severe neurological impairment and ID are unable to stand upright and, consequently, their height has to be measured while they are in a supine position. Unfortunately, supine measuring boards applicable to children older than infants are, in most cases, not available. The best method to measure their height is therefore with a flexible tapeline, although accurate measurement is hampered by physical deformities, such as the frequently occurring scoliosis or fixed contractures of the limbs. For those children in whom measuring standing height is complicated, the use of segmental measures is advocated. Group-specific equations have been developed for the estimation of standing height from knee height, tibia length, or upper-arm length (Table 177.2) (Stevenson 1995). However, these equations may not apply to all children within the target population, since they have been developed in a subset of children with severe cerebral palsy who were not all intellectually disabled, and, additionally, they can only be applied until the age of 12 years. The developed equation based on knee height showed the best correlation with measured stature and is therefore most accurate, but measuring knee height may not be feasible in children with fixed contractures of the knee and ankle, since these joints have to be flexed in a 90° angle during the recording and, besides that, a special caliper is required which is not available in most clinical offices. By contrast, measurements of tibia length or upper-arm length are not influenced by joint contractures since they do not encompass joints, can be measured with a tape line, and, for both reasons, may be more suitable for these children.

177.2.1.2 Body Weight

Measuring body weight can be challenging as well. In care organizations, the electrical hoists that are used for patient transfers in daily care can, in most cases, be used for measuring body weight. In addition, special wheelchair scales are available that weigh the child while it is sat in its wheelchair, but these specific scales are usually not present in general medical offices. In a clinical setting, smaller children are often lifted by their caregivers and then weighed together on a regular scale, after which the weight of the caregiver is subtracted from the total weight. However, this may be dangerous or even impossible when children are older and heavier and not very accurate.

177.2.1.3 Skinfold Measurements

Body composition can be calculated from indirect measurements, such as skinfold thickness measured at several locations of the body. Measurements are done with a standard caliper that is used for the general population or other patient groups. It is well known that, in general, intra-observer variability of skinfold measurements is considerably high, while it is even higher when comparing the outcome of two separate observers (McRae 2009). Regardless of this variability, regularly measuring skinfold thickness during the clinical follow-up, preferably by the same observer, offers valuable information on changes in the nutritional status of a child. For research purposes involving multiple observers, it is important though to establish acceptable inter-observer agreement by training before the measurements begin.

It is common practice to include either two skinfold measurements, or measurements from four sites, usually the biceps, triceps, suprailiac, and subscapular skinfolds. Measurements at seven or even more sites are mostly applied in research settings only. Since the target population is immobile and is often tube fed, it has been suggested previously that fat distribution may be altered in these children, with less subcutaneous fat on the limbs and a larger internal (abdominal) fat deposit (van den Berg-Emons et al. 1998; Spender et al. 1988). Hence, the use of equations that are based on biceps and triceps measurements only for calculation of fat percentage may lead to an underestimation of body-fat percentage in the target population. Unfortunately, additionally measuring the suprailiac and subscapular skinfolds may be time consuming in clinical practice since many children wear splints and corrective braces for maintaining an optimal body position. For correct measurement of the trunk skinfolds, children will have to be lifted onto an examination bench and have their clothing and braces removed. Since the available time for clinical consults is limited, measuring skinfold thickness at four sites may not always be feasible in clinical practice. Another aspect that limits feasibility is the finding that these children have reduced muscle mass and often also have an altered structure of the skin and subcutaneous tissue, the latter presumably being due to prolonged tube feeding, and, as a result, it may be hard or sometimes impossible to correctly pinch a skinfold for measurement. As a result, outcomes of skinfold measurements may be less reliable in the target population, and the need for an experienced observer is very high.

177.2.1.4 Bioelectric Impedance Analysis (BIA)

Where skinfold measurements aim to determine body composition from a number of local recordings, BIA aims to do so through a recording that involves the whole body or a major segment of it. During recordings, a weak electric current is transmitted through the body and the resistance to its flow through body tissues provides a measure of the amount of total body water, which can be converted into lean body mass, and, by subtraction from body weight, into fat mass. Multiple methods

Table 177.3 Factors influencing outcome of BIA recordings

Factor	*Recommendations for optimal BIA recording*
Fasting conditions	Prior to the test, subjects should have been fasted for at least 4 h
Physical activity	No moderate to heavy physical activity directly preceding the test
Time of the recording	Repeated or multiple tests should be performed on the same time of the day
Body temperature	Subjects should have normal body temperature during the recording (no fever)
Bladder voided	Prior to the test, subjects should have voided their bladder
Rest period	Prior to the test, subjects must have been supine at least 5 min or more
Body position	Subjects should be in a supine position with their arms and legs abducted at a 30–45° angle from the trunk

The optimal conditions for a standardized BIA recording

are available for BIA recordings. Available devices can be subdivided according to placement of the electrodes for transmission and reception, for example, hand-to-hand and foot-to-foot (segmental) recordings versus hand-to-foot (whole body) recordings, where the latter type of measurement is most indicative of lean body mass. Apart from that, BIA devices are available for impedance measurement at either a range of multiple frequencies or a fixed set of frequencies. BIA devices may be expensive and are usually not a part of the standard equipment of medical professionals. In addition, BIA recordings are most reliable when performed under standardized conditions. The most important factors that may influence the outcome of BIA recordings and the optimal recording conditions are listed in Table 177.3.

Since measuring body composition from skinfold measurements may be a challenge in children with severe neurological impairment and ID, a BIA recording may be a viable alternative for this purpose, since it is a quick and noninvasive procedure. In addition, it is hypothesized that the outcome of a BIA recording may be a more reliable estimator of body fat in these children when compared to skinfold measurements, since a BIA recording measures all fat deposits in the body and not only subcutaneous deposits. However, standardization of the recordings may be hard to accomplish, since it may be difficult to adhere to the requirements from Table 177.3. Being in a fasted state for at least 4 h prior to the recording may be complex with regard to medication intake or tube feeding. In addition, infections, such as middle-ear infections, urinary-tract infections, and pulmonary infections, occur often in this population and, as a result, fever is a common condition. BIA recordings in this group should therefore always be preceded by an accurate body temperature recording. Ideally, subjects should void their bladders prior to the recording. Since the majority of children within the target population cannot be toilet trained and wear diapers, varying contents of the bladder may affect the outcome of the recording as well. Finally, achieving and maintaining the prescribed supine position may be troublesome as well, due to lack of cooperation and frequent contractures of the limbs. In some cases, the observer may have to gently fixate the child's limbs using a flannel blanket. Regardless of these possible limitations, it was demonstrated that the influence on the outcome is limited and that BIA is a feasible recording in this population (Veugelers et al. 2006).

177.2.2 Applicability and Validity of Available Equations

When measuring body composition by either BIA or skinfold measurements, the raw outcome (usually the average of 3 recordings) has to be transformed into either fat-free mass or fat mass respectively, using a suitable equation. Most BIA devices have built-in equations and immediately produce

data on fat mass rather than raw outcome, but, in most cases, it may not be clear which equation is used and for which population it was originally developed. For both nutritional-assessment methods, several generic equations have been developed previously, based on outcome in large populations. However, the body compartments that are targeted by these nutritional-assessment recordings may be affected by several medical conditions, for example, altered hydration status and electrolyte balance in dialysis patients, affecting lean body mass and, thus, outcome of the BIA recording. According to the 2004 ESPEN guideline (Kyle et al. 2004), it is therefore important to use population-specific BIA equations for each individual patient group, in order to obtain reliable outcomes. As stated earlier, subcutaneous fat distribution is thought to be altered in children with severe neurological impairment and ID, with lower fat mass on the limbs and a supposed increased internal fat deposit (Spender et al. 1988; van den Berg-Emons et al. 1998), which may result in an underestimation of fat mass percentage when generic equations are applied. Several authors have studied the reliability of generic BIA and skinfold equations in the target population and some have developed population-specific equations. The current knowledge with regard to the available equations is summarized below, in order to help the clinician interpret the nutritional-assessment outcome.

177.2.2.1 Skinfold Measurements

Apart from comparing skinfold thickness or the sum of four skinfold thicknesses to age-related reference values, outcomes can also be converted to percentage body fat. For children, the most commonly applied generic equations for calculation of percentage body fat from skinfold measurements are the equations of Slaughter and Durnin. The equation developed by Slaughter (Slaughter et al. 1988) is based on measurement of the triceps and subscapular skinfolds and also includes gender, race, and pubertal stage. This equation was developed in a population consisting of children aged 8–18 years and, therefore, can only be reliably applied to children of those ages. By contrast, the equation developed by Durnin (Durnin and Rahaman 1967) is applicable to children of all ages, and it is based on the sum of four skinfold thicknesses (biceps, triceps, subscapular, and suprailiac). In addition, it includes gender and pubertal stage, and its outcome, body density, can be converted into percentage body fat by using the formula of Siri (Siri 1961). The above-mentioned equations are listed in Table 177.4.

Until recently, population-specific skinfold equations were not available for children with severe neurological impairment and ID. Several researchers have therefore applied the equations of Durnin and Slaughter to interpret their measurement outcome, but the outcomes raised questions about the applicability of these generic equations to the target population. As a consequence, some validation studies have been performed, in which the outcome of the equations, percentage body fat, was compared to body fat measured by means of a so-called gold standard: a reference method for the determination of body composition, for example, a dual-energy X-ray absorptiometry (DEXA) scan or the doubly labeled water (DLW) technique, which involves the ingestion of stable isotopes of water. Gold-standard methods are more complex measurement techniques that may be either invasive or very expensive and are therefore applied in research settings only. Although agreement with outcomes of a gold-standard method was considerable, it was observed that the generic equations underestimate percentage body fat in the target population (Rieken et al. 2009a; Gurka et al. 2009), which may be the result of the supposed altered2 fat distribution. Therefore, recently, a group-specific equation was developed for interpretation of skinfold measurements. This new equation by Gurka (Gurka et al. 2009) is displayed in Table 177.4 as well, is based on the generic equation by Slaughter,

Table 177.4 Population-specific and generic equations for interpretation of outcome of skinfold measurements in the target population

Generic equations			
1. Slaughter (sum[a] ≤35 mm)[b] (Slaughter et al. 1988)			
Males	Prepubescent[c]	White	% body fat = 1.21*(sum) – 0.008*(sum)^2 – 1.7
		Black	% body fat = 1.21*(sum) – 0.008*(sum)^2 – 3.2
	Pubescent[d]	White	% body fat = 1.21*(sum) – 0.008*(sum)^2 – 3.4
		Black	% body fat = 1.21*(sum) – 0.008*(sum)^2 – 5.2
	Postpubescent[e]	White	% body fat = 1.21*(sum) – 0.008*(sum)^2 – 5.5
		Black	% body fat = 1.21*(sum) – 0.008*(sum)^2 – 6.8
Females	All		% body fat = 1.33*(sum) – 0.013*(sum)^2 – 2.5
Slaughter (sum >35 mm)			
Males	All		% body fat = 0.783*(sum) + 1.6
Females	All		% body fat = 0.546*(sum) + 9.7
2. Durnin[f] (Durnin and Rahaman 1967)			
Males	Prepubescent		Density = 1.1690 – 0.0788*log(sum)[g]
	Postpubescent		Density = 1.1533 – 0.0643*log(sum)
Females	Prepubescent		Density = 1.2063 – 0.0999*log(sum)
	Postpubescent		Density = 1.1369 – 0.0598*log(sum)
Conversion to body fat (Siri 1961):			% body fat = ((4.95/density) – 4.5)*100
Population-specific equation			
3. Gurka[h] (Gurka et al. 2009), correction factors to Slaughter's equation:			
Overall			+12.2
Additional correction:			
	More severe GMFCS		+5.1
	Males		–5.0
	Black race		–3.1
	Pubescent		+2.0
	Postpubescent		–4.6
	Sum[a]>35 mm		–3.2

[a] Sum of triceps and subscapular skinfolds
[b] Applicable to children between eight and 18 years of age
[c] Prepubescent from the age of 8 years, Tanner stages 1 and 2
[d] Pubescent, Tanner stage 3
[e] Postpubescent, Tanner stages 4 and 5
[f] Applicable to children of all ages
[g] Sum of biceps, triceps, suprailiac, and subscapular skinfolds
[h] Applicable to children with CP between eight and 18 years of age, without genetic, metabolic, or neurodegenerative diseases

and adds correction factors for child-specific conditions. Gurka's equation has been developed for children aged 8–18 years with CP, excluding children with a history of metabolic, genetic, or neurodegenerative disorders. Agreement with the gold-standard method improved from 0.62 to 0.91 using Gurka's equation over Slaughter's equation. The development of this group-specific equation seems to be a promising improvement to the interpretation of skinfold measurements. Future research is needed, however, to cross-validate the developed equation, since it has been developed in a relatively small and narrow patient population, which may have affected its accuracy and limits its applicability to only part of the target population.

Table 177.5 Population-specific and generic equations for interpretation of outcome of BIA recordings in the target population

Equation for malnourished children	
1. Pencharz (Pencharz and Azcue 1996)	TBW = 2.99 + (0.649*H^2/R)
Population-specific equation	
2. Rieken (Rieken et al. 2009b)	TBW = 2.09 + (5.44*TL^2/R) + (0.19*weight)

TBW Total body water (kg), *H* Height (cm), *R* Resistance measured by BIA device, *TL* Tibia length, *W* Body weight in kilograms

177.2.2.2 BIA Recordings

Many medical disorders may affect aspects of body composition, as, for example, shifting of extra- to intracellular water or an altered electrolyte balance, and therewith may affect conductivity of the body and BIA outcome as well. The use of an interpretative equation that has been specifically developed for the target population is therefore an absolute requirement for a reliable BIA outcome. In 1996, a BIA equation was developed by Pencharz et al. for application in children with malnutrition (Pencharz and Azcue 1996) (Table 177.5), and since children with severe neurological impairment and ID are often undernourished, many researchers have applied this equation to the BIA outcome of the target population. Although malnutrition occurs frequently, clearly not all children are undernourished, and it is questionable whether such an equation may be applied to those children with normal nutritional status, since malnutrition largely affects body composition. Apart from that, detailed information on the population used for development of the equation, such as age range or medical conditions, is lacking. Standing height is a component of the equation; hence, the difficulty of an accurate height measurement in these children may be reflected by variable BIA outcome. Indeed, it was reported that the Pencharz equation largely overestimates fat-free mass in the target population, sometimes even resulting in values exceeding body weight and, thus, in negative values for fat mass (Liu et al. 2005; Veugelers et al. 2006). A few groups have validated the use of the Pencharz equation and found that fat-free mass values agreed reasonably well with those of a gold standard, while percentage body fat agreed poorly (Rieken et al. 2009a).

Recently, a population-specific equation was developed by Rieken et al. (Rieken et al. 2009b), in a population of 63 children of all ages and varying etiology (CP, syndromes, and unknown) with severe neurological impairment and ID (Table 177.5). Compared to the Pencharz equation, the new equation improved agreement with the outcome of the gold standard (DLW) from 0.94 to 0.96. However, the newly developed equation will be more applicable in clinical practice, since it includes measuring tibia length rather than standing height.

Both the newly developed population-specific skinfold (Gurka) and BIA equation (Rieken) may improve the reliability of nutritional assessment, although both equations should be cross-validated in a separate population prior to clinical use. Based on currently available information, it is not possible however to conclude which diagnostic method should be preferred, since the BIA and skinfold equation have comparable agreement with a gold standard. The major difference between both new equations is the population in which they have been developed, and one should keep in mind that the reliability of the skinfold equation when applied to children with etiologies other than CP is yet unknown. In clinical practice, the choice between both methods will depend on the clinician's preference and the availability of instruments.

177.2.3 Reference Values

After anthropometry or BIA, outcome is compared to reference or norm values in order to determine nutritional status and to estimate if the child is at risk for developing over- or undernutrition. Values for height for age, weight for age, and weight for height are compared to normative data from growth charts that are available for many nationalities and for specific patient populations. In addition, multiple reference charts are available for interpretation of body-composition outcomes, such as thickness of individual skinfolds for age and the sum of four skinfolds for age. It is questionable though whether these general pediatric reference values may apply to children with severe neurological impairment and ID as well, since they are generally shorter and lighter than the reference standards, indicating growth retardation. In addition, the shape of their bodies might be altered due to immobility and prolonged tube feeding, further limiting the use of general reference values.

In 1996, Krick et al. published population-specific growth charts (height and weight for age and weight for height) for boys and girls, based on measurements in 360 children with spastic quadriplegic CP (Krick et al. 1996). Although these reference values are based on a relatively large sample, they are only applicable until the age of 10 years. In addition, the reference curves were based on recordings in a clinical sample consisting of children visiting an orthopedic clinic, which increases the risk of selection bias. It could be suggested that these children have the most severe disabilities, which might have had additional effects on growth parameters. When obtaining a representative sample of children, as in the North American Growth in CP project (Stevenson et al. 2006), it may still remain unclear in how many of them growth is abnormal due to secondary disorders, such as growth-hormone deficiency and chronic or acute malnutrition, which limits the development of accurate predictive growth charts for clinical use.

In 2007, Day et al. published predictive growth charts for children with all subtypes of CP until the age of 20 years, including those with severe neurological impairment and ID, based on 141,961 measurements in 24,920 children (Day et al. 2007). Although the influence of secondary health problems on growth was not accounted for, the very large number of measurements may have eliminated some of this bias, although it still remains unknown if these charts represent how these children should grow rather than how they grew. The authors subdivided the children with CP into five subgroups, based on the level of motor disability, and children in groups 4 (do not walk, crawl, creep, or scoot; do not feed self; and are not fed by gastrostomy tube) and 5 (like group 4, but fed by gastrostomy tube) correspond with the target population. The authors compared their growth charts of group 4 and 5 children to those developed by Krick and found that centiles of weight for age of children in group 4 corresponded most to those of the Krick growth charts, while the children in group 5 had considerably higher centiles. Their gender-specific growth charts by subgroup (weight, height, and BMI for age) have been published online (http://www.lifeexpectancy.org/articles/GrowthCharts.shtml).

177.2.4 Results in Clinical Practice and Scientific Research

Due to the lack of clinical guidelines for performing and interpreting anthropometry in children with severe neurological impairment and ID, medical professionals are uncertain about their diagnosis. A recent investigation of currently applied nutritional assessment strategies by Dutch dietitians working in ID care, using a structured survey, showed that a variety of diagnostic measurements is applied, ranging from clinical judgment to anthropometry to blood nutrition panels. Only 2 of the 32

participating dietitians opined that the outcome of these methods is an accurate reflection of the child's nutritional status, while half of them said that current methods are indicative of their nutritional status only. Furthermore, several criteria for undernutrition were applied, for example, low body mass index (BMI), diminished food intake, stunted growth, or unwanted weight loss (Penning et al. 2010). During clinical follow-up by, for example, pediatricians, nutritional assessment is often incomplete or omitted, due to low feasibility of general nutritional-assessment methods and lack of group-specific norm values.

Apart from uncertainty in clinical practice, the lack of standardization of diagnostics has resulted in the use of a variety of nutritional assessment methods and equations in published research projects, which limits comparability of the outcome of different studies. When small sample sizes, the heterogeneity of the target population, and the lack of an internationally accepted definition for the disorder are added to that, it becomes clear that outcomes of many previously published reports on the epidemiology of nutritional problems should be interpreted with caution.

177.2.5 Future Research

In order to enhance the (international) generalizability of research outcomes, preferably consensus is attained first on the best terminology for these children. In the absence of consensus, it is essential that every research report clearly describes the characteristics of the population under study and provides detailed information on the severity of their disabilities.

In order to improve diagnostics and interpretation of nutritional assessment for clinical application in the target population, several additional research projects have to be performed: Newly developed equations for the interpretation of skinfold equations and BIA recordings have to be cross-validated in other groups within the target population. Due to the low incidence of the disorder, usually only small groups of children are available for participation in single-center research projects. When developing new predictive equations in small heterogeneous groups, the risk is high that the developed equations may only apply to the sample used for the developmental process and not to the entire target population. In order to reduce the error that is introduced this way, new equations should ideally be cross-validated. This means that the study population is subdivided into two subgroups: subgroup 1 is used for development of the equation, which is validated in subgroup 2. This process is repeated several times using different subgroups of the original study population, and the validation results of each round are averaged. However, proper cross-validation may be statistically impossible in small heterogeneous study populations, and development of valid predictive equations should ideally be done in an (international) multicenter setting, in order to include sufficient numbers of children.

Apart from the previously published population data for weight, height, and BMI for age, norm values for body composition, such as the thickness of individual skinfolds, the sum of four skinfolds, and body-fat percentage for age, should be developed for the target population in order to clinically monitor nutritional status of the child in more detail. For the development of norm values, data from a very large number of measurements, obtained in a large representative population, have to be gathered. The only viable method to achieve this will also be through (international) multicenter collaboration of expert clinical centers. The North American Growth in CP project is a good example of such collaboration, including six expert clinical centers in Canada and North America, and together these centers offer medical care to a large population of children with CP. Ideally, experts from several countries should collaborate in all applicable research projects that are done in this group of frail children, since performing research is complex in this group due to ethical and practical issues.

Studying relatively small patient groups hampers the extrapolation of results; hence, a long-term collaboration may enhance the clinical value of research outcomes in the target population.

After final development and reliability testing of group-specific interpretative equations and development of specific reference values for body composition, an evidence-based clinical guideline on nutritional assessment in children with severe neurological impairment and ID should be developed and implemented. This guideline should be targeted at pediatricians, intellectual disability physicians, and dietitians. The need for a guideline for nutritional assessment is high, and its implementation will be a step forward to improvement of care for the target population. In addition, standardization of anthropometric nutritional assessment in this population will enhance the comparability of international research outcomes.

177.3 Recommendations for Using Anthropometry and BIA Recordings in Clinical Practice Based on Current Knowledge

177.3.1 Linear Growth

- Instead of measuring standing height, measure upper-arm length or tibia length and predict the child's height using the equations by Stevenson (Stevenson 1995).
- Body weight should be measured with a wheelchair scales or by the electrical hoist used for patient transfers in the ID-care organization.
- Group-specific reference values for height, weight, and BMI for age are available (Day et al. 2007), although it remains unknown if these charts predict "healthy growth."

177.3.2 Body Composition – Skinfold Measurements

- It is recommended to measure triceps and subscapular skinfold thickness, to both include sites at the limbs and at the trunk. Percentage body fat can be estimated using a population-specific equation (Gurka et al. 2009).
- Specific reference values for triceps and subscapular skinfold thickness for age and for body-fat percentage are not available. Therefore, it is recommended not to use the outcome for diagnosing malnutrition or obesity, but for the child's clinical follow-up solely, for example, to monitor changes in body-fat percentage after PEG placement.

177.3.3 Body Composition – BIA Recording

- We recommend the use of a multifrequency hand-to-foot BIA device. Preferably, BIA recordings should be performed under standardized conditions (see Table 177.3).
- Percentage body fat can be calculated using a newly developed population-specific BIA equation that includes the measurement of tibia length rather than standing height, making it more applicable to clinical practice than previously published equations (Rieken et al. 2009b).
- In the absence of specific reference values, BIA outcome should not be used for diagnosis, but results are useful for individual follow-up.

177.4 Application to Other Areas of Health and Disease

This chapter describes the feasibility and interpretation of currently available anthropometric nutritional-assessment methods in children with severe neurological impairment and ID. It describes future research that is additionally needed for evidence-based guideline development, in order to improve the diagnostics of malnutrition or obesity and to identify children at risk. Summarizing, anthropometric methods that are commonly applied in the general pediatric population need to be adjusted for the target population to enhance feasibility and reliability. Therefore, the adapted methods described in this chapter cannot be applied to other pediatric patient groups. If nutritional assessment is currently inadequate in other patient groups as well, the following procedure should be used:

- Study feasibility and reliability of currently available instruments and methods.
- Adapt measurement procedures, if needed.
- Determine the predictive value of available (generic) equations for BIA and skinfold measurements, using outcome of a reference method that was applied at the same moment.
- If the predictive value is low, either develop a new population-specific equation or adapt an existing equation.
- Develop population-specific reference values using the adapted nutritional assessment methods, if generic reference values do not apply to the population.

Summary Points

- Children with severe neurological impairment and ID have a severe motor disability and a moderate-to-profound intellectual disability as a result of neurological damage. They are wheelchair bound and rely on specialized care for people with ID.
- These children may suffer from a variety of concomitant health problems, such as epilepsy and pulmonary or orthopedic problems. As a result, children are frequently admitted to the hospital and life expectancy is markedly reduced. In the past decade, medical care for this population has improved, resulting in lower mortality.
- Due to nutritional problems (dysphagia and gastro-esophageal reflux), daily caloric intake may be threatened and a large proportion of these children suffer from malnutrition. By contrast, others who receive tube feeding may develop obesity as a result of overfeeding. Therefore, regular nutritional assessment is essential in this frail population.
- In those children in whom measuring standing height accurately is not possible due to scoliosis or contractures, the use of segmental measures, such as upper-arm length or tibia length, is advocated.
- Skinfold measurements should include sites on the trunk and sites on the limbs, because of the proposed altered subcutaneous fat distribution. Previously, a generic equation (Slaughter) was applied to calculate percentage body fat using the outcome, but, recently, a population-specific equation has been developed (Gurka).
- Bioelectric impedance analysis is an alternative but feasible method for measuring body composition in the target population. It may be more reliable since it includes the measurement of internal fat mass. A population-specific equation has recently been developed by Rieken *et al.*, but needs to be cross-validated to establish its clinical value.
- Growth charts for the general pediatric population may not apply to the target population, because of growth retardation or an altered body shape due to immobility. Population values are available for weight, height, and BMI for age, but not for skinfold thickness or body-fat percentage.

- Due to the lack of evidence-based clinical guidelines for nutritional assessment in these children, medical professionals are uncertain about their diagnosis. In addition, a variety of anthropometric recordings has been applied in scientific research, which limits comparability of outcomes.
- Future research is needed to determine the predictive accuracy of the new skinfold and BIA equations and to develop specific reference values for body composition. With that information, a clinical guideline can be developed. Ideally, these studies should be performed in an international multicenter collaboration.
- In the absence of a clinical guideline, practical recommendations are given for anthropometric nutritional assessment in these children.

Key Points

See Table 177.6.

Table 177.6 Key points of anthropometric nutritional assessment in children with severe neurological impairment and intellectual disability

- As a result of nutritional problems, children with severe neurological impairment and ID are at risk of developing malnutrition. By contrast, the children who are tube-fed are at risk of developing obesity. Regular anthropometric nutritional assessment in this frail population is advocated
- Generic methods, equations, and reference methods for anthropometric nutritional assessment are not applicable to these children; either available methods should be adapted or new methods should be developed. In the absence of an evidence-based clinical guideline, clinicians should measure body weight and a segmental measure for predicting standing height
- Due to the low incidence of the disorder, development of applicable methods should preferably be done in an international multicenter setting

Chapter 178
Eating Frequency and Anthropometry

Karine Duval and Éric Doucet

Abstract There is a belief that eating between meals, or snacking, leads to increases in weight and obesity. Public health advice for body weight control often suggests avoiding snacks between meals in order to not increase total energy intake. However, available results from research on the influence of eating frequency on body weight status are equivocal. Studies in both adults and children have either failed to find a significant relationship between eating frequency and adiposity, or have found an inverse relationship. Several methodological discrepancies have been proposed to explain some differences observed between studies or the lack of such a relationship: various definitions of eating occasions, under-reporting of food intake, especially among the obese, various methods of assessing food intake and body composition, and the fact that many studies did not take into account factors related to energy expenditure, especially physical activity. Despite the inconclusive results, eating frequency seems to be related with leanness in men. In women, many studies found no association or negative correlation between eating frequency and adiposity, despite a higher energy intake. It was suggested that a higher eating frequency could very well be a marker of a physically active lifestyle, at least in leaner individuals. The impact of eating frequency on weight loss during energy restriction and on energy expenditure is more conclusive. No difference in total energy expenditure has been documented as a function of daily eating occasions and weight loss does not seem to be facilitated by high meal frequency. There is a need to examine the relationship between eating frequency and adiposity using longer-term studies with sufficiently large sample sizes and using adequate and standardized methodologies.

Abbreviations

BMI	Body mass index
BMR	Basal metabolic rate
DLW	Doubly labeled water
EE	Energy expenditure
EF	Eating frequency
EI	Energy intake

PAL	Physical activity level
REE	Resting energy expenditure
RMR	Resting metabolic rate
TEE	Total energy expenditure
TEF	Thermic effect of food
VO_{2peak}	Peak oxygen uptake

178.1 Introduction

Over the last few decades, the prevalence of obesity has rapidly increased in many countries around the world and reached now epidemic proportions (Hedley et al. 2004). The dietary pattern has changed substantially over the years (Briefel and Johnson 2004). The environment we live in has become 'obesogenic' (obesity-promoting). Food is constantly available and in practically unlimited amounts, which can lead to excessive energy intake (EI) and therefore positive energy balance (WHO 2002). Changes in dietary habits and physical activity have also been implicated as potential causes of obesity (WHO 2002).

Total EI has increased over the past 20–30 years (Nielsen et al. 2002). Using a nationally representative data from adults, Kant and Graubard looked at the change in eating frequency (EF) of American men and women over a 30-year period using data collected in the National Health and Nutrition Examination Surveys (NHANES) I (1971–1975), II (1976–1980), III (1988–1994), 1999–2000, and 2001–2002 (Kant and Graubard 2006). Over the time period, the reported number of eating occasions increased slightly in women from 4.90 in 1971–1975 to 5.04 in 1999–2002 (see Fig. 178.1). Cutler et al. have also shown an increasing in EF for both men and women between 1970 and 1990 (see Fig. 178.2a) (Cutler et al. 2003). During this time period, the increase in EI seems to be related with the increased EF and the energy consumed during snacks (see Fig. 178.2b, c). This change in eating pattern is probably a result of the increased availability of snack foods.

Studies have suggested that several eating behaviors, such as EF, the temporal distribution of eating events across the day, breakfast skipping, portion size, and the frequency of meals eaten away from home, may have an influence on body-weight control (Seagle et al. 2009). Research on the possible body weight and health benefits of EF started from observational and interventional studies in the 1960s, suggesting an inverse relationship between EF and adiposity (Fabry et al. 1964; Fabry et al. 1966).

When to eat and how often? Is it preferable to eat multiple small meals daily? These questions are frequently posed by persons who would like to lose or maintain their weight, and most health professionals would like to be able to answer it. However, they are not easy questions to answer. As will be discussed throughout this chapter, the impact of EF on body weight is not simple and implies more than one aspect. A great deal research has investigated the relationship between eating pattern and body-weight status (Bellisle et al. 1997). However, no clear consensus on the optimal number of daily eating occasions to facilitate weight management has emerged. This book chapter reviews the literature on EF with respect to energy balance and body-weight control.

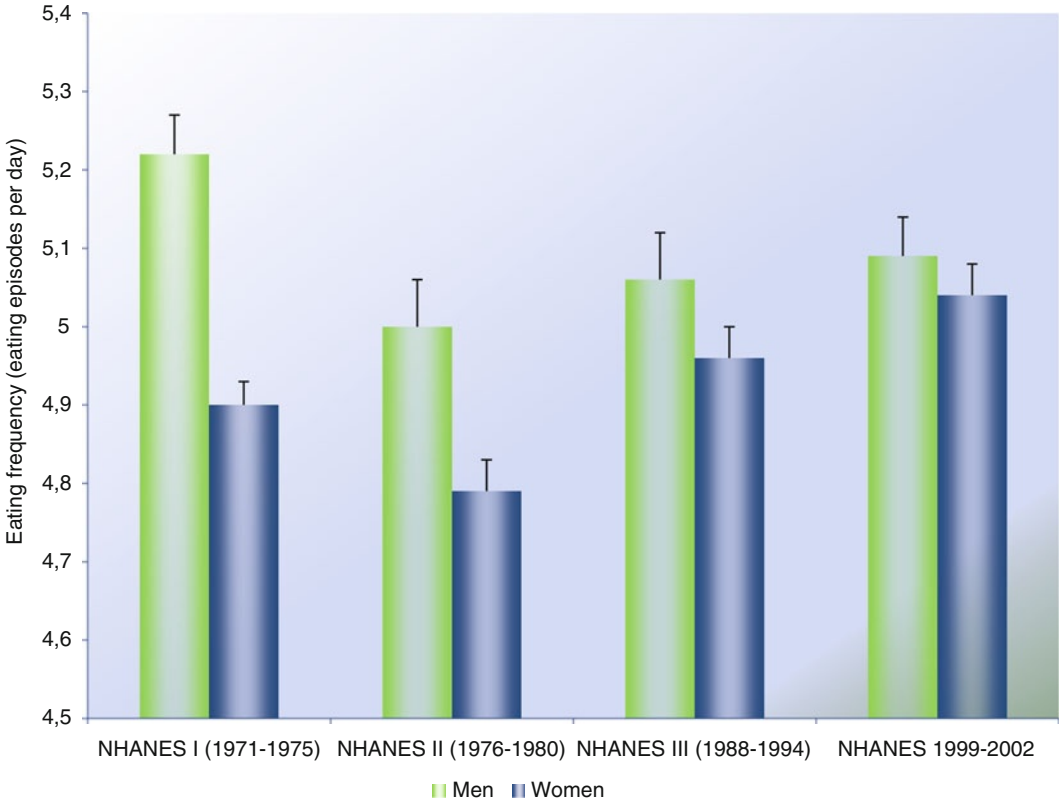

Fig. 178.1 Secular trends of eating frequency from National Health and Nutrition Examination Surveys (NHANES): NHANES 1971–1975 to NHANES 1999–2002. According to data collected in the National Health and Nutrition Examination Surveys from 1971–1975 to 1999–2002, this figure shows that EF of American adults, measured by 24-h recall, has increased significantly in women, but not in men during this time period. Results are presented as *mean* ± *SD*, *n* = NHANES I (men: 4,931; women: 5,060); NHANES II (men: 4,877; women: 5,241); NHANES III (men: 5,889; women 6,153); and NHANES 1999–2002 (men: 3,186; women: 3,211) (Data from Kant and Graubard 2006)

178.2 Part I: Methodological Aspects of Eating Frequency

178.2.1 Definitions of Key Eating-Frequency Terms

Part of the difficulty in identifying implications of eating more frequently is related to the lack of standardized definitions of key terms, such as eating occasions, meals and snacks (Drummond et al. 1996; Gatenby 1997; Gregori and Maffeis 2007). There have been several suggestions for these definitions, and each one was based on different cultural, biological, and empirical parameters of measurement (Drummond et al. 1996; Gibney and Wolever 1997). The type of definition used to describe key EF terms may significantly influence the outcomes and interpretation of results from different studies (Gatenby 1997; McBride et al. 1990). To date, no one definition has been universally accepted to categorize EF in the scientific literature. Comparisons among studies are even more difficult, as definitions of these terms were not always adequately reported in the literature.

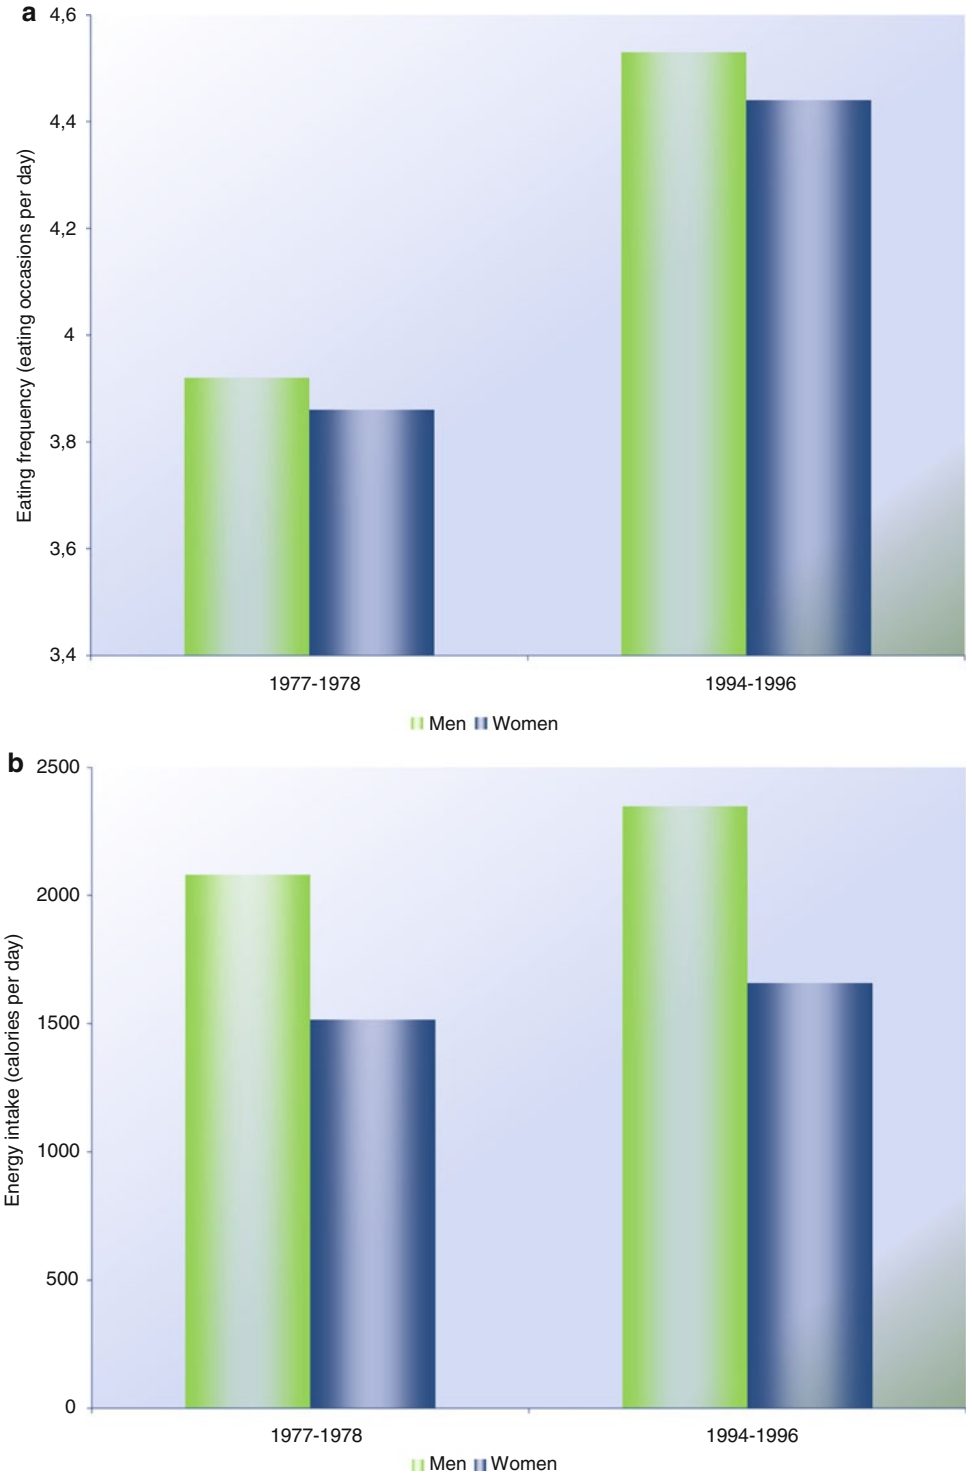

Fig. 178.2 (**a**) Secular trends of eating frequency among US adults from 1977–1978 and 1994–1996. According to cross-sectional data from the Continuing Surveys of Food Intake by Individuals (CSFII), this figure shows that EF has increased among American adults between 1977–1978 and 1994–1996 for both men and women. Results presented are means (Data from Cutler et al. 2003) (**b**) Secular trends of energy intake among US adults from 1977–1978 and 1994–1996. According to cross-sectional data from the Continuing Surveys of Food Intake by Individuals (CSFII), this figure shows that EI has increased among American adults between 1977–1978 and 1994–1996 for both men and women.

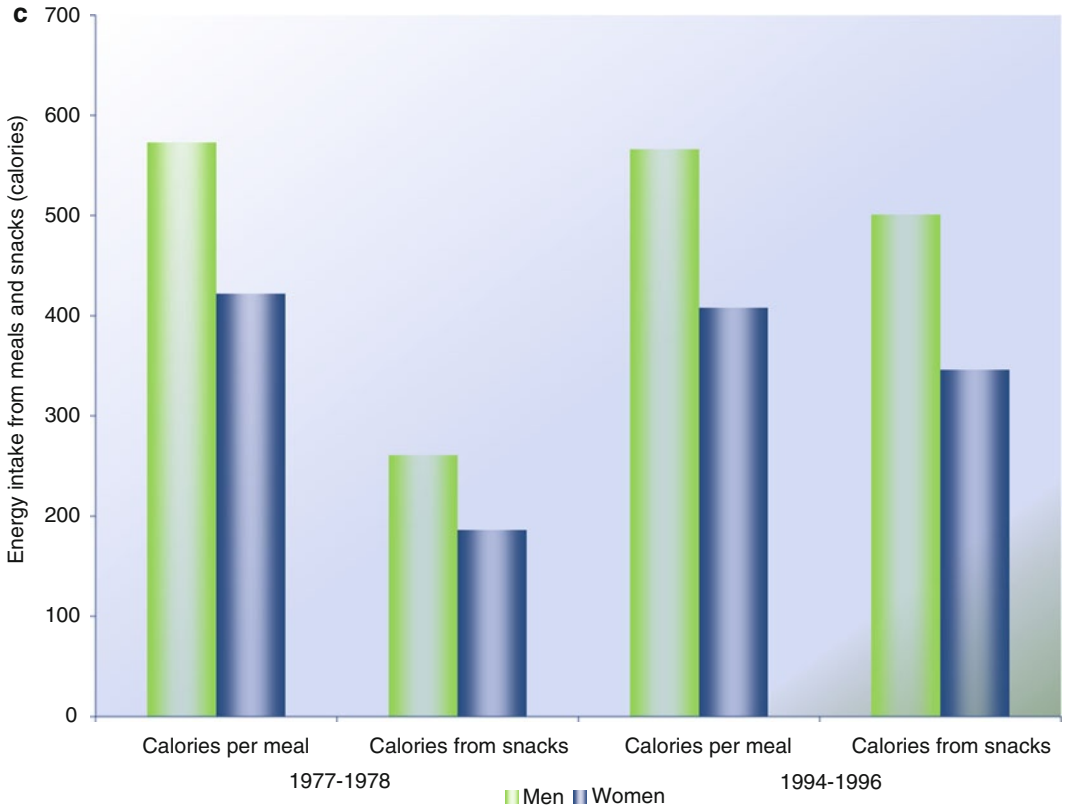

Fig. 178.2 (continued) Results presented are means (Data from Cutler et al. 2003) (**c**) Secular trends of energy intake from meals and snacks among U.S. adults from 1977–1978 and 1994–1996. According to cross-sectional data from the Continuing Surveys of Food Intake by Individuals (CSFII), this figure shows that most of the increase in EI is from calories consumed during snacks. Indeed, the energy consumed per meal has decreased (especially at dinnertime), while the energy consumed during snacks has increased by 90% among men and 112% among women between 1977–1978 and 1994–1996. Results presented are means (Data from Cutler et al. 2003)

178.2.1.1 Eating Frequency

Usually, low EF has been defined as "gorging" and high EF as "nibbling" (Berteus Forslund et al. 2002). However, there is no agreement about the number of meals required to be classified as frequent or non-frequent eater. In the literature, there is a wide range in the number of eating episodes used to describe "nibbling" (3–17 meals/snacks per day) and "gorging" (1–3 meals per day) (Berteus Forslund et al. 2002). Eating frequency is usually referred by a number of eating occasions, eating events or eating episodes per day. Two types of definition are normally reported to categorize EF: (1) predefined eating periods and (2) time interval between two eating occasions. Most studies that have been conducted until more recently used the predefined eating periods' definition to analyze EF (Summerbell et al. 1996; Dreon et al. 1988; Barba et al. 2006). In a study by Summerbell et al. (1996), daily food intake was divided into six eating periods (breakfast, mid-morning snacks, lunch, mid-afternoon snacks, evening meal, and evening snacks), which were defined as "meals" or "snacks." In this study, the maximum number of eating occasions was six. Such an approach may not permit an adequate analysis of EF due to inappropriate and insufficiently detailed information and may mask the actual EF (Gatenby 1997). The 'time interval' definition for calculating the total

number of eating occasions is now mostly used by the investigators (Drummond et al. 1998; Duval et al. 2008a; Yannakoulia et al. 2007; Ruidavets et al. 2002). The time interval between two eating occasions is normally ranged between 15 and 60 min. Drummond et al. (1998) defined an eating occasion as any occasion when food was consumed. If two eating occasions occurred in ≤15 min, both events were counted as a single occasion. Ruidavets et al. (2002) used a similar definition but with a longer time interval between two eating periods (60 min). Gibney and Wolever (1997) added energy content to this definition, which classifies an eating occasion as an event that provides at least 50 kcal (or 210 kJ) with a minimum time interval between occasions of at least 15 min. This type of definition allows to include all eating events in the calculation of EF and avoid the ambiguities of classifying eating events as either "meals" or "snacks," which, as mentioned earlier, can mask the number of actual eating occasions, especially when EF is high (Gatenby 1997).

178.2.1.2 Snack and Meal

The majority of investigators used quantitative definitions to describe what constitutes a "meal" and a "snack." These definitions were based mainly on the criteria of time of consumption and/or nutrient composition of the eating occasions (Gatenby 1997). Meals are generally described as one of the main eating occasions of the day, normally occurring in the morning (breakfast), mid-day (lunch), or evening (dinner) (Gatenby 1997; de Graaf 2006). Snacks refer to the other eating episodes consumed between meals, which are generally smaller and less structured than meals (de Graaf 2006; Gatenby 1997). However, it is difficult to obtain one specific universally accepted definition due to the problems inherent in individual perception of what constitutes a snack as opposed to a meal (Drummond et al. 1996).

Many criteria can be used to make a distinction between "meal" and "snack" (Gregori and Maffeis 2007; Vitapole 2003).

1. **Timing**
   Foods consumed at a specific period of time, for example, between 8:00 and 10:00 AM (breakfast), between 12:00 and 2:00 PM (lunch), and between 6:00 and 8:00 PM (dinner), are considered as meals. Anything else consumed between meals is thus considered as a snack (Gregori and Maffeis 2007). This criterion has to be used with caution because the time for a specific eating period may not always be the same for everyone depending on the work schedule, cultural aspects, or religious beliefs.
2. **Interval between adjacent eating episodes**
   It was observed that larger-size meals, as compared to snacks, are followed by longer periods of no eating (Bellisle et al. 2003).
3. **Social considerations**
   This criterion refers to the food consumed in the company of others or alone. Rotenberg used a social definition of eating occasions: the presence or absence of fellow diners (Rotenberg 1981). With this definition, a "meal" was defined as a planned social interaction centered on food, whereas a "snack" was identified as an eating event conducted individually.
4. **Nutrient composition**
   The nutrient-composition criterion of a meal or a snack includes the energy content and/or the type of food. Snacks are clearly different from meals. They differ in size (meals are about twice as large as snacks) and nutritional content (snack have a relatively high CHO content) (Drummond et al. 1996; Summerbell et al. 1996). Meals bring more energy and nutrient diversity than snacks.

Bernstein et al., studying the eating patterns of free-living subjects without time cues, defined "meal" as eating episodes of greater than 375 kJ (Bernstein et al. 1981).

5. **Hunger criterion**
   This criterion refers to the food consumed in either a hungry state or a non-hungry state. It was reported that a meal occurs usually when food is consumed in a state of hunger (Bellisle et al. 2003).

The definition of a meal or a snack should be based on more than one criterion in order to avoid ambiguities about what constitutes a meal and what constitutes a snack. As an example, a beverage with an apple consumed at 12:30 PM might be regarded as a snack or a meal depending on whether the definition refers to time of day or food type as a means of classification.

The problem with inconsistent definitions of eating occasion, meals, and snacks have been discussed earlier (Drummond et al. 1996; Gatenby 1997), and there is agreement on the need to clarify the terminology in order to be able to accurately investigate the role of EF on health (Gibney and Wolever 1997). A more consistent approach to the definition of eating occasions would facilitate appropriate interpretation of the available literature and future research. Even in the absence of a clear consensus, a clear description of what is considered to constitute an eating episode should always be provided in manuscripts investigating the topic of EF (Gregori and Maffeis 2007).

178.2.2 How to Measure Eating Frequency?

The methods used to assess food intake is worth taking into account when measuring EF. Various dietary-assessment methods have been developed for measuring food intake, and they have been extensively reviewed (Bingham 1987; Block 1982). Dietary methods most frequently used in research can be divided into three categories: (1) recall of actual food eaten, generally limited to the previous 24 h (24-h diet recall); (2) retrospective questionnaires or histories of the usual diet (food-frequency questionnaire or diet history); and (3) prospective diet records, usually for 3, 4, or 7 days, which are weighed or quantified by household measures, such as cups and spoons (Black et al. 1991; Barrett-Connor 1991; Block 1982; Livingstone 1995). Dietary recalls and food records are mostly used in EF studies. This can be explained by the fact that these two methods allow to determine more easily each eating occasion, as they provide information about the actual diet.

178.2.2.1 The 24-h Diet Recall

The 24-h diet-recall method is designed to quantitatively collect all foods consumed during the previous 24 h (Barrett-Connor 1991). This method typically involves face-to-face interview, although it may be conducted by telephone (Smith 1993; Block 1982). This technique demands high interviewing skills and can be affected by interaction between the interviewer and the interviewee and the subjective interpretation of questions and answers. Recall methods are prone to error of memory. However, the short-term memory required in the 24-h diet recall reduced the risk of errors. A 24-h diet recall obtained by a trained dietician takes normally around 30–60 min and can provide accurate quantitative information on recent intake. However, a single day of food intake may not be representative of habitual diet (Barrett-Connor 1991; Block 1982). Indeed, considering day-to-day variation in the food intake, multiple 24-h recalls are required to describe an individual's diet (Bingham 1987; Beaton et al. 1979; Basiotis et al. 1987).

178.2.2.2 Food Record or Diary

The food-record method provides a measure of current intake and involves a detailed record of all food consumed and measurements of portion size. Subjects have to record all food items consumed at the time of eating for a specified period, usually 3, 4, or 7 days. Subjects may estimate the portions eaten either by direct weighing (weighed food record) or by using household measures, such as cups or spoons (food diary). The accuracy of recording methods is based on the assumption that the usual dietary pattern is not changed because it is being recorded. Writing down everything they eat can be burdensome and time consuming for some subjects. Consequently, this method is often associated with poor compliance and an alteration of the diet and the dietary reporting during the recording period (Barrett-Connor 1991). In addition, recording intakes requires some literacy, which may limit the study to better-educated subjects. Nevertheless, the food record has often been considered the most accurate and precise method of dietary assessment (Barrett-Connor 1991). Whybrow et al. have shown that record of food intake for a period longer than 3 days and ideally 7 days is preferable (Whybrow et al. 2008). Seven-day food records are generally regarded as providing the best compromise between accurate data, investigator workload, and subject compliance (Black et al. 1991), although it is recognized that longer periods are needed to obtain precise measures of the habitual intakes of individuals (Basiotis et al. 1987; Beaton et al. 1979; Bingham 1987). However, for most studies in a free-living situation, it is unrealistic to collect dietary information for more than 3–7 days.

Data on the validity of recalls and records specifically for estimating EF are unavailable for the moment. Thus, the degree to which these methods accurately estimate the number of eating occasions is unclear. However, Longnecker et al. found that the day-to-day variation in a person's EF is larger than between-subject variation, which suggests that data from multiple days of a food diary are needed to measure a person's EF with precision (Longnecker et al. 1997). It has also been suggested that the use of a 7-day food diary provides a more accurate measurement of EI and is more representative of usual intake than is the use of food-frequency questionnaires or dietary recall (Block 1982).

The measurement of food intake is one of the hardest tasks in studies dealing with some forms of dietary assessments. None of the dietary-assessment methods is a priori better. The choice of the method will be based on the design and objectives of the study and the nature of the information required. Even when an appropriate method is selected, it remains difficult to acquire accurate data from food reporting (Livingstone 1995; Westerterp and Goris 2002).

178.2.2.3 Accuracy of Diet Reporting

During the past several years, there has been considerable discussion about the relevance of the dietary-survey methodologies, with much of this debate focused on their validity. A valid dietary report is one that measures the true intake, that is, all food consumed on specified days without exerting an influence on the choice of food and drinks consumed, during the period of study (Livingstone 1995). Accurate assessments of dietary intake are a prerequisite for assessing the relationship between diet and body-weight status (Gatenby 1997). Unfortunately, most of the methods for assessing dietary intakes have rarely been fully and independently validated because of the absence of accurate techniques to verify dietary-survey methodology.

Previous research in dietary assessment has indicated persistent errors in self-reported EI (Bailey et al. 2007; Livingstone 1995). The widespread occurrence of under-reporting of EI has been exposed by the introduction of the doubly labeled water (DLW) method for measuring total daily energy expenditure (TEE) (McCrory et al. 2002). The presence of error in self-reported dietary data may

attenuate or exaggerate associations between diet and weight status (Lissner et al. 1998). Most of the bias which appears when dietary intake is measured is mostly due to under-reporting (Livingstone 1995). When asked, people in general tend to underestimate the amount of food they eat. The only known method of gathering information on habitual diet intake is to ask subjects to supply this information themselves. Every self-report modality is prone to the problem of under-reporting. The problem of dietary under-reporting has been addressed in a number of articles as a major limitation in dietary assessments, and it is not easily overcome (Gatenby 1997; Garrow and Summerbell 1995; Bellisle et al. 1997). Under-reporting has been observed to vary from 10% to 50% (Livingstone 1995; Macdiarmid and Blundell 1997). Under-reporting of habitual intake can result from under-recording, under-eating, or a combination of both (McCrory et al. 2002; Bingham 1991). Under-recording refers to the failure to record all items and/or amounts of food consumed (McCrory et al. 2002). Under-eating corresponds rather to eating less than usual or than is required to maintain body weight (McCrory et al. 2002). A number of methodological and behavioral factors can generate these two biases. They include feeling embarrassed or guilty about recording specific foods or amounts, mostly foods perceived as "unhealthy," inability to estimate portion sizes accurately in non-weighed recording and recall methods, memory lapses, conscious or subconscious omissions to simplify the recording due to irritation and inconvenience in reporting, being more conscious of what they eat and, finally, using the study period as an opportunity to start dieting and to lose weight (Livingstone 1995). It has been documented that people admit that they would change their behavior when asked to complete dietary records (Mela and Aaron 1997)**.**

Reporting errors have been associated with a number of different subject characteristics, which was reviewed by Macdiarmid and Blundell (1997). Certain sub-populations are more likely to under-report their food intake than others, in particular the obese, the post-obese, the overweight, and the diet-restrained subjects (Livingstone and Black 2003; Heitmann and Lissner 1995). Westerterp and Goris (2002) have shown that percentage of under-reporting in normal-weight subjects varies from 0% to 25%, with an average of 16%. The range of under-reporting for obese subjects was twice as high as in normal-weight subjects, at 25–50%, with an average of 41% (Westerterp and Goris 2002). In a study conducted by Karelis et al., 57.5% of the overweight and obese postmenopausal women were identified as under-reporters (Karelis et al. 2010). In a context of EF measurement, it is also important to note that under-reporting affects not only EI, but also the daily number of eating occasions, and snacks are particularly prone to under-reporting (Bellisle 2004; Livingstone et al. 1990). Table 178.1 presents key features of under-reporting of EI.

To enhance the interpretation of studies examining food and nutrient intake in relation to EF, it is imperative that investigators validate EI data. Considerable caution needs to be employed when interpreting the self-reported energy intakes of weight-conscious subjects.

178.2.2.4 Evaluation of Under-Reporting in Dietary Surveys

There are a number of methods for validating reported EI. The reference methods include: (1) comparison between self-reported EI and the EI required to maintain body weight; (2) comparison between reported nitrogen (equal to protein intake) and 24-h urinary nitrogen excretion; (3) comparison between reported EI and TEE measured by the DLW; (4) comparison between reported EI and presumed energy requirements, both expressed as multiple of basal metabolic rate (BMR) (Goldberg cutoff) (Westerterp and Goris 2002; Livingstone and Black 2003); and (5) comparison of reported EI with predicted TEE using a combination of BMR and physical activity (Livingstone and Black 2003). In EF studies, the DLW technique, the Goldberg cutoff, and the predicted TEE are the most commonly used methods to evaluate dietary under-reporting.

Table 178.1 Key Features of under-reporting of energy intake (Source: Maurer et al. 2006; Livingstone 1995; Karelis et al. 2010; Macdiarmid and Blundell 1997)

1. Under-reporting of EI is a common problem. It can range from 10% to 50% depending on the population and the method and cut-point used to categorize under-reporters.
2. The use of invalid dietary data can biased the understanding of the association between diet and health or body weight.
3. Validity of dietary data can be verified by comparing self-reported EI with measured or estimated TEE.
4. Under-reporting of EI seems to be mainly a consequence of the omission of complete food items or meal/snack. Snacks are particularly prone to under-reporting.
5. Under-reporting of EI has been shown to be more prevalent in women, older adults, people with less education, overweight or obese subjects, and weight-conscious individuals.
6. Dietary patterns of under-reporters of EI include lower carbohydrate intake, lower fat intake, and eating on fewer occasions.
7. Behavioral characteristics of under-reporters of EI include frequent dieting attempts, lower level of physical activity, higher dietary restraint, and higher disinhibition.
8. Psychosocial characteristics of under-reporters of EI include higher social desirability, lower body image, depression, anxiety, and fear of negative evaluation.

This table presents key features of under-reporting food intake including the prevalence of under-reporting, the importance of using valid dietary data, methods to evaluate under-reporting in dietary survey, who under-report their food intake the most, what is most under-reported in general, the dietary patterns of under-reporters, and the psychosocial and behavioral characteristics of food intake under-reporters
EI energy intake, *TEE* total energy expenditure

Doubly Labeled Water

The DLW technique is the gold standard for measuring TEE (Livingstone and Black 2003). The comparison between reported EI and TEE measured by the DLW is also the most accurate method for the validation of reported EI by subjects under free-living situations (Bailey et al. 2007). However, for routine validation of EI data, this method is quite expensive and sophisticated (Bailey et al. 2007; McCrory et al. 2002; Livingstone and Black 2003).

Goldberg Cutoff

An alternative cost-effective technique for identifying inaccurate reports of EI was proposed by Goldberg et al. and Black et al. (Black et al. 1991; Goldberg et al. 1991). This method has been used by numerous investigators to identify under-reporters (Livingstone and Black 2003). In this method, the ratio of reported EI to BMR (EI:BMR) is used as a guide for the accuracy of food records. Reported EI is expressed as a multiple of the BMR estimated from equations and is compared with the presumed mean energy expenditure (EE) of the population, which is also expressed as a multiple of the BMR (EE:BMR). The ratio EE:BMR refers to the physical activity level (PAL). If there is no under-reporting, EE:BMR equals EI:BMR (Goris et al. 2001). A formula was elaborated by Goldberg et al. (1991) to calculate the lower 95% confidence limit of EI:BMR, assuming a given PAL requirement. Values of EI:BMR falling below the 95% confidence limit signify the presence of under-reporting. This formula considers errors associated with the number of subjects (n), the length of the dietary assessment (number of days), variation in both BMR and PAL, and daily variation in EI (Black 2000b).

The Goldberg cutoff has considerable limitations, which have been discussed (Black 2000a). It is best used for identifying the presence of bias in reported EI at the group level, but information on the habitual activity of the population is needed to choose an appropriate PAL for the calculation of

appropriate cutoffs. The ability of the Goldberg cutoff to identify under-reporting at the individual level is however limited (Black 2000a). At the individual level, the use of a single cutoff for EI:BMR applied to all subjects is inappropriate. Thus, for identifying under-reporters at the individual level, a short physical-activity questionnaire could be used to assign subjects to suitable PAL levels in large-scale studies. In small studies ($n < 100$), it would be desirable to obtain a measure of EE using detailed activities diaries, heart-rate monitors, or accelerometers. If these measurements are obtained, a comparison of reported EI and of a more objective measure of EE can be made, consequently reducing the limitations associated with the EI:BMR cutoff.

Predicted Total Energy Expenditure: Combination of Basal Metabolic Rate and Physical Activity Energy Expenditure

An easy and inexpensive method for validating reported EI of individuals is a combination of BMR (measured or calculated) and physical activity energy expenditure (PAEE), which can be assessed by physical-activity diaries, questionnaires, heart-rate monitors, or accelerometers. Accelerometers seem to be the most objective method that can be used to quantify PAEE at individual level in free-living situations (Goris et al. 2001). It was shown that the combination of measured resting metabolic rate (RMR) with PAEE was able to explain 85% of the variation in TEE measured with DLW (Westerterp and Goris 2002). Goris et al. (2001) found no significant difference between the percentages of under-reporting assessed with a tri-axial accelerometer as compared with DLW. The use of a combination of BMR (measured) and PAEE seems to be a good method for validating reported EI.

178.3 Part II: Eating Frequency and Body-Weight Status

Does snacking make you fat? There is a belief that eating between meals (snacking) leads to weight gain. Public-health advice for body weight control often suggests to avoid snacking between meals in order to not increase total EI (Kirk 2000). It has been suggested that snacking may be a cause of obesity, if, as assumed, the consumption of snack foods between meals increases total EI (Booth 1988; Basdevant et al. 1993). The work of Booth (1988) is frequently cited as evidence that snacking leads to over-consumption. Results reported by Booth suggest that snacks and/or high-energy drinks taken more than 1 h before meals fail to exert satiety and energy compensation (i.e., energy consumed at main meals is reduced) at subsequent meals, leading to overeating and ultimately to obesity. However, evidence supporting the implication of frequent eating in obesity is not that clear (Bellisle et al. 1997; Palmer et al. 2009).

178.3.1 Adult Studies

Many epidemiological and clinical studies have explored the association between EF and body weight in adults, but results have been inconsistent. Some studies observed an inverse relation between EF and body weight (Fabry et al. 1964; Metzner et al. 1977; Charzewska et al. 1981; Kant et al. 1995; Burley et al. 2002; Ruidavets et al. 2002; Drummond et al. 1998; Ma et al. 2003; Chapelot et al. 2006; Duval et al. 2008a), whereas others failed to detect any significant association (Dreon et al. 1988; Edelstein et al. 1992; Summerbell et al. 1996; Yannakoulia et al. 2007; Andersson and Rossner 1996) (see Table 178.2). One study observed a positive relationship between EF and

[c]Measured from underwater weighing

[d]Significant negative correlation for women only

[e]Significant negative correlation for men only

[f]Estimated using the method of Durnin and Womersley

[g]Self-reported measures

[h]Measured from dual-energy X-ray absorptiometry

[i]Significant only for the group who switch from a four- to a three-meal pattern by removing their usual afternoon meal

[j]The associations between adiposity and EF disappeared after correction for PAEE and VO_{2peak}

obesity (Howarth et al. 2007). Howarth et al. (2007) observed that eating more than three times a day was associated with being overweight or obese in both younger (20–59 years) and older (60–90 years) groups. Fabry et al. (1964) were the first investigators to show an inverse association between EF and body weight, suggesting that a "nibbling" pattern could help to prevent obesity. They found that, in a sample of 379 men aged 60–64 years, skinfold thickness and incidence of overweight were significantly greater in those who consumed three or less meals a day compared to those who ate five or more meals a day (see Fig. 178.3a, b). Metzner et al. (1977) also studied the relationship between EF and adiposity in 2,028 men and women aged 35–69 years. They found that subjects who ate six meals a day had a significantly lower adiposity index than those who ate two meals a day. In a cross-sectional study, EF and body mass index (BMI) were assessed in 220 free-living people in four age groups (adolescent, working age, middle-aged, and elderly) (Summerbell et al. 1996). Summerbell et al. (1996) found no significant relationship between eating pattern and BMI for each group after exclusion of under-reporters (see Fig. 178.4). More recently, Drummond et al. (1998) showed that eating more frequently was related to leanness in men but not in women. In women, although a positive correlation between EF and EI was observed, no relation was found between body weight and EF. A positive association between EF and PAEE at leisure time was found in women, suggesting that the higher EI associated with a high EF appears to have been balanced by greater EE from physical activity, sufficient to prevent an increase in body weight. Yannakoulia et al. (2007) found similar results in a cross-sectional study of 220 women. Indeed, they demonstrated that, in premenopausal women, frequent eating was not related to adiposity, but it was associated with high EI and high EE, especially PAEE spent at home. They also observed that EF was positively correlated with adiposity and EI in postmenopausal women. Possible explanations could be that frequent eating is not associated with a physically active lifestyle in postmenopausal women. In middle-aged women, decrease in RMR and physical activity could be accentuated (Evenson et al. 2002). This decline in EE, without a proportional reduction in EI, may explain a higher adiposity level in postmenopausal women who also display frequent eating patterns. Another study reinforces the findings of Drummond et al. (1998) and Yannakoulia et al. (2007). In a sample of 85 premenopausal women, Duval et al. (2008a) found that women who ate more frequently tended to have higher EI, but they were also leaner (see Fig. 178.5). Interestingly, they noted that the association between adiposity and EF disappeared after correction for PAEE and VO_{2peak}. These results indicated that a physically active lifestyle may be an important confounder of the relationship between adiposity and eating frequency. In a cross-sectional study where EF was collected at five equally spaced time points over a 1-year period in 499 participants, Ma et al. (2003) found that subjects who reported four or more eating episodes per day had a lower obesity risk, which is decreased by 45%.

178.3.2 Children Studies

Similar to results in adults, in children and adolescents, the association between EF and body weight is also inconclusive (see Table 178.3). Fabry et al. were again among the first investigators to show an inverse association between EF and body weight in children (Fabry et al. 1966). They performed a 1-year intervention study in which 226 children aged 6–16 years in three schools were selected for comparison. Children in one school were allowed to continue their habitual eating pattern of five meals a day. Children in the second school were switched to three meals a day and children in the third school to seven meals daily. After 1 year, the children who ate seven meals a day were charac-

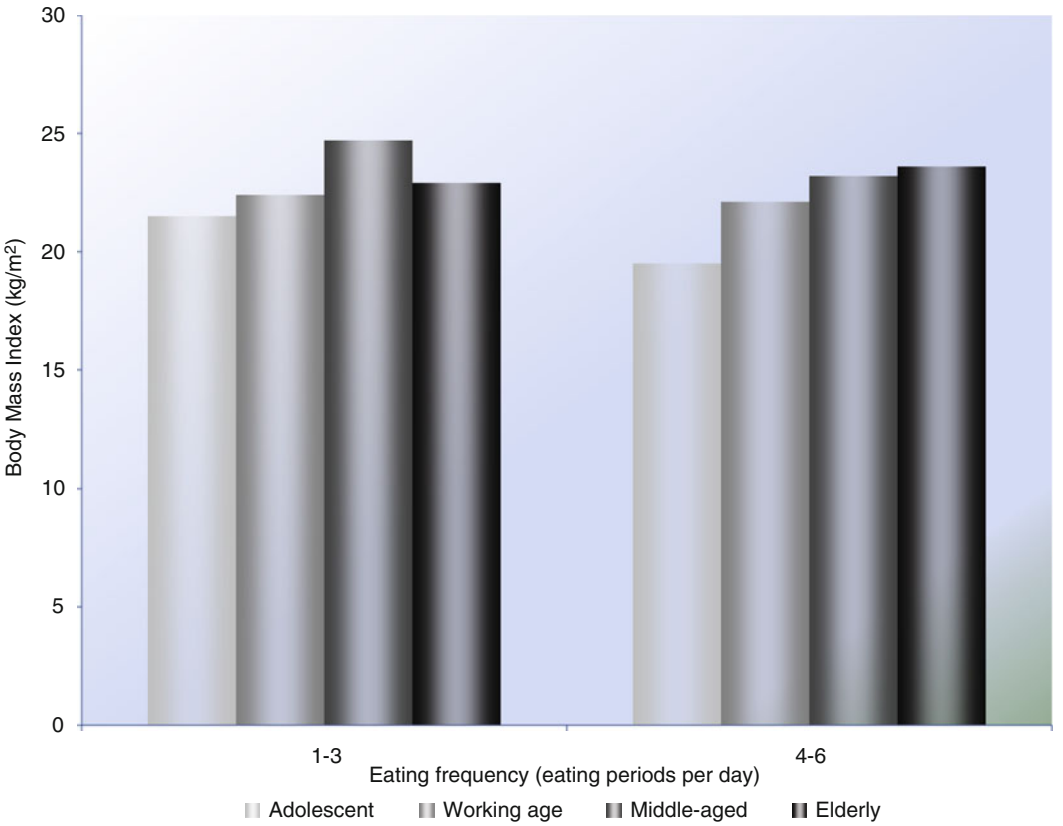

Fig. 178.4 Relationship between eating frequency and body mass index in 220 free-living people in four age groups. This figure shows that there was no relationship between BMI and EF for the four age groups after exclusion of invalid food records. Results presented are means, *n* = adolescent (33); working age (59); middle-aged (40); and elderly (88) (Data from Summerbell et al. 1996)

terized by significantly lower body weight and skinfold thickness. In another study conducted by Toschke et al., the prevalence of overweight and obesity decreased along with the number of meals per day in a sample of 4,370 German children aged 5–6 years (Toschke et al. 2005). The prevalence of obesity in children who ate three or fewer meals was 4.2%; four meals, 2.8%; and five or more meals, 1.7%. In this cohort, a higher EF was inversely related to the prevalence of childhood overweight and obesity, suggesting that a frequent eating pattern might exert protective effects against excess adiposity. In a large sample of schoolchildren aged 6–11 years participating in a cross-sectional survey of childhood obesity, Barba et al. (2006) found that daily EF was inversely associated with adiposity and central fat deposition (see Fig. 178.6 a, b). Also, in a 10-year longitudinal study, Franko et al. also found that girls who ate more than three meals per day had lower BMI *z*-scores for

Fig. 178.3 (**a**) Relationship between meal frequency and incidence of overweight in 379 men aged 60–64 years. This figure shows that the incidence of overweight tended to increase as the frequency of meals decreases in men aged 60–64 years. *Additional snacks between meals; †Additional snack at bedtime. Results presented are means (Data from Fabry et al. 1964) (**b**) Relationship between meal frequency and adiposity in 379 men aged 60–64 years. This figure shows that adiposity, measured by skinfold thickness, tended to decrease as the frequency of meals increases in men aged 60–64 years. TSF: Triceps skinfold thickness; SSF: Subscapular skinfold thickness; *Additional snacks between meals; †Additional snack at bedtime. Results presented are means (Data from Fabry et al. 1964)

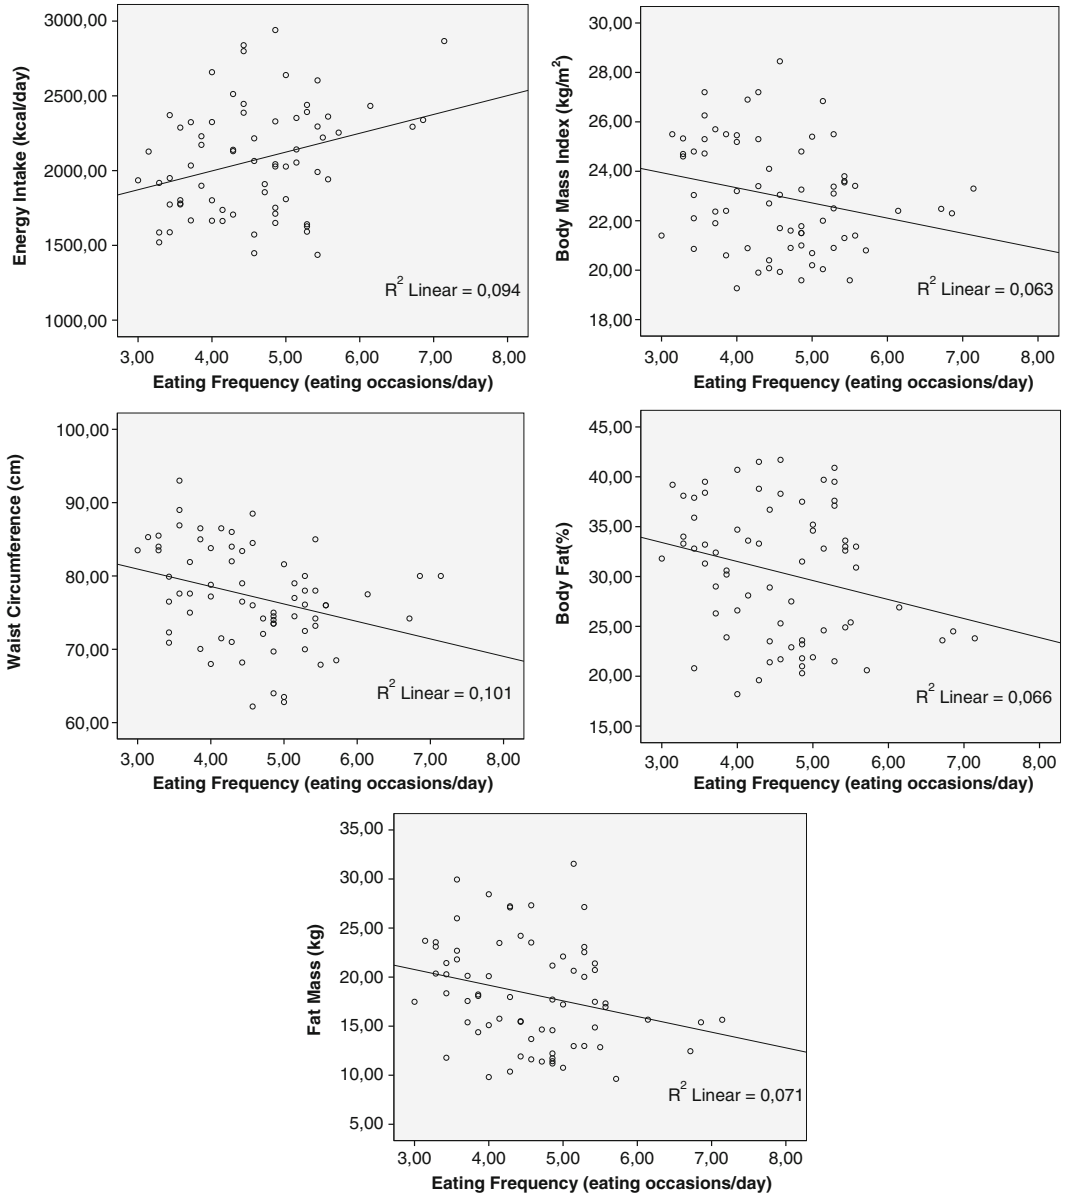

Fig. 178.5 Effects of eating frequency on energy intake and body composition in 85 premenopausal women. This figure illustrates correlations of EF with EI and body composition in a sample of 85 premenopausal women. These correlations show that EF was positively associated with EI and negatively associated with adiposity, measured by dual-energy X-ray absorptiometry. Women who ate more frequently tended to have higher EI, but they had also lower adiposity. However, these associations disappeared after correction for PAEE and VO_{2peak}. Values were obtained with the use of Pearson's correlation coefficient (Data from Duval et al. 2008a)

age (Franko et al. 2008). Zerva et al. conducted a study in a sample of 151 children aged 9–11 years (Zerva et al. 2007). Children were categorized in tertiles based on the daily number of eating occasions (≤4.1, 4.2–5.4, and ≥5.5). Physical activity was also assessed with 4-day accelerometry. The results of this study have shown that a higher EF was associated with a better body composition. This association occurred despite the higher EI of the frequent eaters compared with the non-frequent

This table presents a summary of studies that have investigated the relationship between EF and adiposity in children. This table gives some information about the study population, methods used to assess EF, definition choose to describe EF, categories of EF used to compare the results, information about the control of under-reporting, adiposity measures used to assess the relationship between EF and adiposity, and statistical significance of the results

EF eating frequency, *SFT* skinfold thickness, *BMI* body mass index, *WC* waist circumference, *%BF* percentage of body fat, *TER* trunk-to-extremity ratio, *NS* not significant, *S* significant, *M* male, *F* female

[a]The correlation coefficients are not provided

[b]Self-reported measures

[c]Percent of body fat was estimated from triceps and subscapular skinfolds from which fat mass and fat-free mass were calculated

[d]The trunk-to-extremity ratio (TER) is an index of body-fat distribution. It was calculated by dividing the sum of central (subscapular and suprailiac) by the sum of peripheral skinfolds (triceps and biceps)

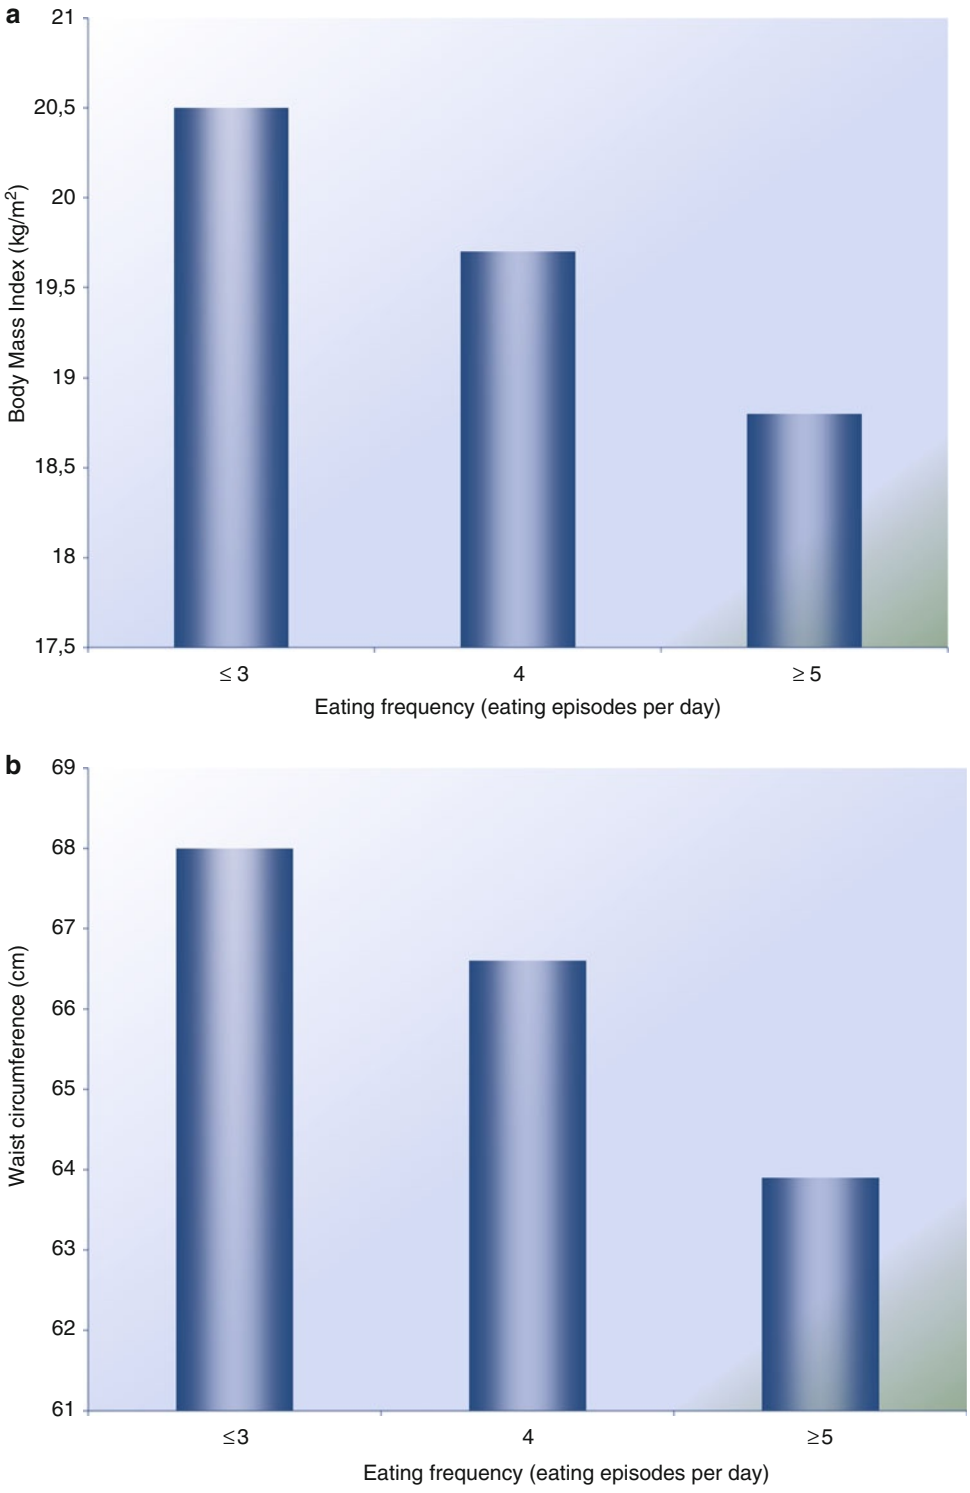

Fig. 178.6 (**a**) Relationship between eating frequency and body mass index in 3,668 school-children aged 6–11 years in the ARCA project. This figure shows that BMI was negatively associated with EF in schoolchildren aged 6–11 years. Results presented are means, $n = \leq 3$ (332); 4 (1334); and ≥5 (2002) (Data from Barba et al. 2006) (**b**) Relationship between eating frequency and waist circumference in 3,668 schoolchildren aged 6–11 years in the ARCA project. This figure shows that waist circumference was negatively associated with EF in schoolchildren aged 6–11 years. Results presented are means, $n = \leq 3$ (332); 4 (1334); and ≥5 (2002) (Data from Barba et al. 2006)

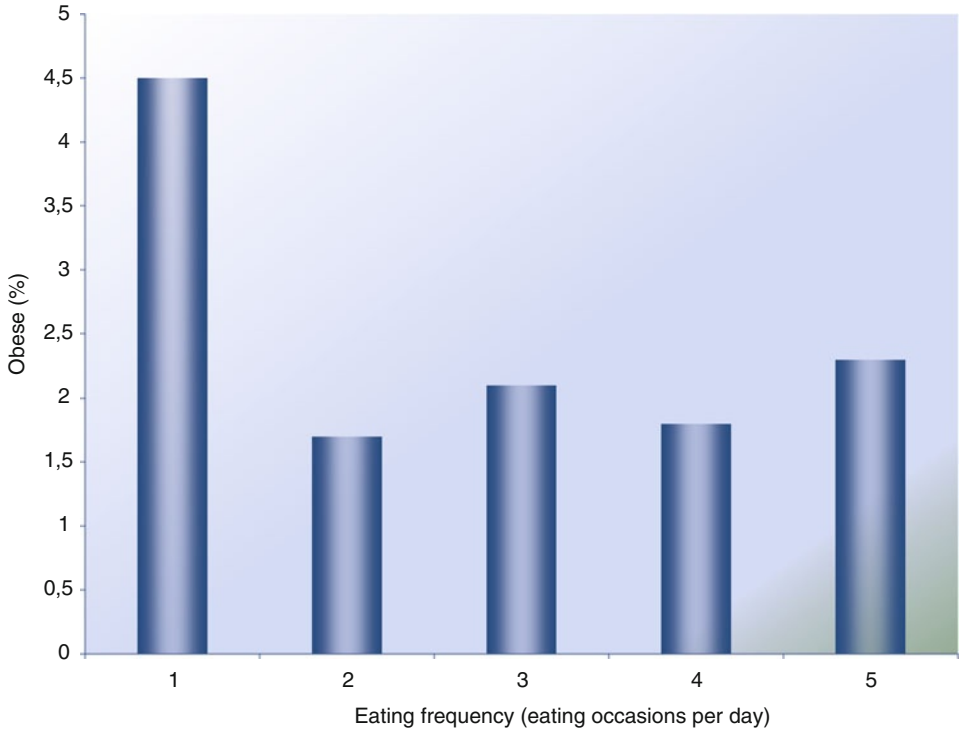

Fig. 178.7 Relationship between eating frequency and obesity in 972 children aged 5–18 years. This figure shows that there was no significant relationship between EF and occurrence of obesity in children aged 5–18 years. Results presented are means, n = 1 (267); 2 (129); 3 (129); 4 (162); and 5 (281) (Data from Morgan et al. 1983)

eaters. Higher physical activity was found in the frequent-eaters group, and it was suggested that this result may, at least partially, explain the findings of this study.

By contrast, findings from others' studies in children failed to identify a significant association between EF and childhood obesity (Morgan et al. 1983; Ruxton et al. 1996; Nicklas et al. 2003, 2004; Crawley and Summerbell 1997). In a group of schoolchildren, Ruxton et al. (1996) found no significant association between snacking frequency and weight, BMI, or skinfold thickness. These results confirm the findings of Morgan et al. (1983) reported 10 years earlier in a group of children aged 5–18 years. In this study, no relationship between eating patterns and obesity was observed (see Fig. 178.7). As well, they found no differences in snacking frequency between obese, heavy, average, and normal weight children. Similarly, results from Crawley et al. (1997) failed to produce results supporting a significant association between BMI and EF in a free-living sample of teenagers aged 16–17 years. Finally, in two different studies based on data from the Bogalusa Heart Study, Nicklas et al. (2003, 2004) found no significant relationship between overweight status and the number of eating episodes.

178.3.3 Weight-Loss Studies

The potential benefits of a nibbling versus a gorging meal pattern for body-weight loss were investigated in obese patients. With the exception of only one study, there is no evidence that EF can have a significant impact on weight loss in energy-restricted diets (see Table 178.4) (Bellisle et al. 1997;

Palmer et al. 2009). Indeed, most of the interventional studies failed to show any influence of EF on weight loss (Bortz et al. 1966; Young et al. 1971; Garrow et al. 1981; Finkelstein and Fryer 1971; Antoine et al. 1984; Schlundt et al. 1992; Verboeket-van de Venne and Westerterp 1993; Poston et al. 2005; Vander Wal et al. 2006; Berteus Forslund et al. 2008; Cyr et al. 2007; Duval et al. 2008b). In 1973, Debry et al. have shown a greater weight loss in dieting overweight subjects who were eating seven meals a day than in those who were eating only three meals a day (142 vs 78 g/day) (Debry et al. 1973). However, as shown in Table 178.4, other studies which have addressed the same issue found no significant effect of EF on weight loss. In a crossover study, Bortz et al. (1966) saw no difference in weight loss in a group of six obese women on an isoenergetic diet of 600 kcal daily in either one, three, or nine meals per day. Finkelstein and Fryer (1971) and Young et al. (1971) conducted weight-loss studies in students. The effects of different meal patterns (one, three, or six meals/day – Young et al.; three or six meals/day – Finkelstein and Fryer) were studied. Both studies failed to show any significant relationship between meal frequency and weight change. In a study conducted by Garrow et al. (1981), obese subjects were on an 800 kcal/d diet over 3 weeks. Weight loss was lower when subjects ate five times per day (0.22 kg/day) compared with one meal per day (0.26 kg/day), but this difference was not statistically significant. Verboeket-van de Venne et al. (1993) found that the intake of two or three to five meals per day has no significant effect on the rate and composition of weight loss in obese women on a 1,000 kcal/day diet. More recently, Duval et al. (2008b) found that eating more frequently does not seem to be related with a better body-weight status during weight loss in a sample of 79 obese postmenopausal women who participated in a 6-month weight-reduction program consisting of an 500–800 kcal daily energy deficit. In an 8-week study where subjects were prescribed a dietary energy restriction of 700 kcal/day, Cyr et al. (2007) shown that eating six versus three times per day does not promote greater weight loss. Also, in a ten-y prospective study, Burley et al. found that more-frequent eating and drinking was not associated with greater weight gain in middle-aged women (Burley et al. 2008). Finally, Berteus et al. (2008) observed that recommending snacks or not between meals does not influence 1-year weight loss. In summary, weight loss is not facilitated by high EF.

178.3.4 How Could High Eating Frequency Help Weight Management?

Kirk (2000) highlighted some of the possible advantages associated with a high EF that may help in the control of body weight. First, several studies have shown that snack foods are often higher in carbohydrates and lower in fat than meals (Basdevant et al. 1993; Summerbell et al. 1995; Drummond et al. 1996; Kirk 2000). Thus, a higher EF may be associated with an increased carbohydrate: fat ratio, which may be beneficial in body-weight control. Studies show that high-fat diets are positively associated with overweight and obesity, whereas high-carbohydrate diets are associated with leanness (Gazzaniga and Burns 1993; Miller et al. 1990; Tucker and Kano 1992). Second, eating more frequently may help to spread the EI over the day. It was suggested that obese individuals tend to eat little in the morning (skip breakfast) and much in the afternoon and the evening (Bellisle 2004; Fricker et al. 1990). Furthermore, it was shown that an individual who consumed fewer meals per day and who consumes more food in the evening may be more prone to weight gain (Fricker et al. 1990). Third, another argument for the potential beneficial effects of frequent eating on body-weight control relates to the reduction in hunger that has been postulated to occur with higher EF (Drummond et al. 1996). Burley et al. have shown that eating five times per day (three meals and two snacks) rather than three meals resulted in a flatter profile of hunger throughout the day (Burley et al. 1993). Eating more frequently may also have a beneficial effect in preventing subsequent overcompensation (Westerterp-Plantenga et al. 1994). In addition, spreading the energy load over the day by including

Table 178.4 Summary of weight-loss studies comparing different eating frequency patterns

several snacks may reduce appetite and as a consequence, decrease EI and body weight (Speechly et al. 1999). However, Cyr et al. (2007) shown that eating more frequently (three vs six times per day) does not have an impact on appetite. Fourth, higher levels of physical activity may promote a higher EF to meet increased energy requirements. As mentioned earlier, some studies on EF and body weight found that a higher EF could very well be a marker of a physically active lifestyle and may help in weight management (Duval et al. 2008a). However, as few EF studies have included a measure of physical activity, more studies are needed to confirm this finding.

178.3.5 Eating Frequency and Energy Expenditure

In the investigation of the association between EF and body weight and adiposity, both sides of the energy balance equation should be taken into account. TEE can be divided into three major components: thermic effect of food (TEF) (i.e., the increase in EE after ingestion of food), resting energy expenditure (REE), and PAEE. Most studies of EF and energy metabolism have failed to show any influence of EF on EE. Seven studies have investigated the effect of EF on TEE (see Table 178.5)

Table 178.6 Summary of studies that have investigated the effect of eating frequency on the thermic effect of food

Reference	Study population	Measure	EF pattern	TEF	Statistical significance
Belko and Barbieri (1987)	12 M; 18–34 years; Mean BMI 22 kg/m²	TEF for 10 h	2 4	43.3 ± 4.7 LO_2 43.4 ± 5.0 LO_2	NS[a]

(Taylor and Garrow 2001; Smeets and Westerterp-Plantenga 2008; Wolfram et al. 1987; Dallosso et al. 1982; Verboeket-van de Venne and Westerterp 1991, 1993; Verboeket-van de Venne et al. 1993). In these studies, rigorous measurements were made to compare subjects between a gorging (1–2 meals/day) or a nibbling (5–7 meals/day) eating pattern, including one study in which the 24-h whole-body calorimetry results were confirmed with DLW measurement of free-living EE (Verboeket-van de Venne et al. 1993). None of these studies reported any significant effect of EF on TEE. These studies provide evidence that there is no effect of meal pattern on TEE.

The results of the studies which specifically assessed TEF, as opposed to TEE, are inconsistent (see Table 178.6). While half of the studies found no significant differences between a gorging or a nibbling eating pattern (Belko and Barbieri 1987; Kinabo and Durnin 1990; Smeets and

Westerterp-Plantenga 2008; Verboeket-van de Venne et al. 1993), others reported either a higher TEF of food with lower EF (Tai et al. 1991; Molnar 1992) or the opposite (LeBlanc et al. 1993). Tai et al. (1991) found that the TEF of food was significantly higher in the low-EF group (one meal) than in the high-EF group (six meals) (7.68% vs 5.56%, respectively). Molnar et al. (1992) also found that the TEF (expressed as a percent of the energy ingested) was significantly higher with the single meal (11.9% ± 1.3%) than with the three small meals (8.5% ± 0.7%) in children. Inversely, LeBlanc et al. (1993) found an 8% lower TEF with one versus four meals a day. In light of the absence of effect of EF on TEE and the inconclusive evidence to support differences in TEF according to eating patterns, there is currently no reason to believe that changing EF would alter EE.

Concerning REE, it was found that higher EF has no effect on REE (Verboeket-van de Venne et al. 1993; Smeets and Westerterp-Plantenga 2008). Few of the published studies of EF and body weight have included a measure of the subjects' daily physical activity (Drummond et al. 1998; Duval et al. 2008a; Yannakoulia et al. 2007). As mentioned earlier in this chapter, it has been suggested that the inconsistent associations reported between EF, adiposity, and EI, especially in women, are due to differences in physical activity (Drummond et al. 1998; Duval et al. 2008a). Drummond et al. (1998) hypothesized that the absence of a relationship between EF and adiposity may be explained by the fact that frequent eaters may have higher EI due to higher physical activity levels. Duval et al. (2008a) found a positive correlation between EF and PAEE. Moreover, the results of this study showed that, after correction for PAEE and VO_{2peak}, the associations between adiposity and EF were no longer significant, which suggests that the relation between EF and body composition may be an artifact of higher PAEE and greater physical fitness. Therefore, higher EF resulting from higher physical activity and greater physical fitness could very well be a marker of a physically active lifestyle, at least in leaner persons. More studies will however be needed to confirm this finding.

178.3.6 Results' Discrepancies' Explanation

Methodological discrepancies have been proposed in order to explain some of the differences between studies in terms of the relationship between adiposity and EF: various definitions of eating occasions; under-reporting of food intake, especially among the obese; various methods of assessing food intake and body composition; and the fact that many studies did not take into account factors related to EE, especially physical activity. These methodological issues have been reviewed by Gatenby (1997).

As mentioned earlier in this chapter, the type of definition used to describe eating occasions may significantly influence the outcomes and interpretation of the studies. Inconsistencies in the definitions of EF used across studies, that is, time interval between two eating occasions versus predefined meal periods, make comparisons between studies hard to interpret and might have contributed to the heterogeneity of the findings.

Previous observations regarding eating patterns may also be affected by under-reporting of food intake. Since the Fabry et al. (1964) study, many studies have reported an inverse relationship between EF and body weight, suggesting that a "nibbling" pattern could help to prevent obesity. This notion has been put into question by the recognition of a high level of dietary under-reporting. In support of the latter idea, data from Summerbell et al. (1996) showed an inverse relationship between meal frequency and BMI in adolescents, which disappeared when dietary

Table 178.7 The associations between eating frequency and the variables related to energy balance

	EF correlates with…					
Population	Adiposity	TEE	REE	TEF	PAEE	Weight loss
Men	0 or –	0	0	0 or +	+	0
Women	0 or – (+ in postmenopausal women)	0	0	0 or – or +	+	0
Children	0 or –	No data	0	–	+	No data

This table presents a summary of the associations between EF and the variables related to energy balance. The associations are presented for three different populations (men, women, and children)
Plus (+) indicates significant relationship; negative (–) indicates significant inverse relationship; and zero (0) indicates non-significant relationship between EF and adiposity and EE and weight loss
EF eating frequency, *TEE* total energy expenditure, *REE* resting energy expenditure, *TEF* thermic effect of food, *PAEE* physical activity energy expenditure

records from under-reporters were excluded. Summerbell et al. (1996) has proposed that these findings may have repercussions for the interpretation of earlier studies, which did not screen for invalid dietary records. Research evidence indicates that under-reporting is particularly more frequent in overweight and obese persons (Livingstone and Black 2003; Heitmann and Lissner 1995), giving the impression that a low EF is positively related to adiposity. Even when under-reporters have been excluded, it was suggested that other factors, such as dietary restraint, have to be assessed. Indeed, in a study of a sample of 731 free-living teenagers, Crawley and Summerbell (1997) found an inverse relationship between meal and BMI, which was significant after exclusion of under-reporters. However, this relationship disappeared when dieting behavior and dietary restraint were taken into account. Under-reporting affects not only EI, but also the daily number of eating occasions, and snacks are particularly prone to under-reporting (Livingstone et al. 1990; Bellisle 2004).

The method used to assess food intake is another methodological issue which has been proposed to explain the contradictory results. However, while various methods have been used in EF studies, results do not differ consistently according to the method of assessment. Indeed, Metzner et al. (1977) (24-h diet recall) and Burley et al. (2002) (4-day food diary) found an inverse relation between EF and adiposity, whereas Drummond et al. (1998) (7-day food diary) and Yannakoulia et al. (2007) (3-day food diary) found no such relation in women. Most existing dietary-assessment methods are developed to analyze energy and nutrient intake but rarely eating patterns.

The techniques used to measure body fatness can have an effect on the relation between EF and body composition. Most studies of EF used BMI or included a measure of body composition using either skinfold-thickness measurements taken with calipers or underwater weighing to assess body fatness. Only two studies have used dual-energy X-ray absorptiometry for the measurement of body composition (Duval et al. 2008a; Yannakoulia et al. 2007). Duval et al. (2008a) found a negative relation between EF and adiposity, while Yannakoulia et al. (2007) did not find any relationship between EF and adiposity; conversely, Duval et al. (2008a) found a negative relation between EF, which was no longer significant after correction for PAEE and VO_{2peak}.

To obtain more accurate data, future studies need to identify under-reporters and individuals characterized by high levels of dietary restraint and exclude these from the analysis. They also need to use standardized criteria for defining EF in order to be able to compare results from different studies, and they should include an objective and valid measure of PAEE. The associations between EF and the variables related to energy balance are presented in Table 178.7.

178.4 Conclusion

Despite more than 40 years of research in this field, the influence of EF on body weight and adiposity is still not clear. The majority of the studies on EF and body weight status does not support the view that eating between meals, or snacking, leads to increases in weight and obesity. Indeed, some studies have reported a negative relation between EF and adiposity, whereas other studies found no association. The impact of EF on weight loss during energy restriction and on EE is more conclusive. Increasing EF does not promote greater weight loss. No difference in TEE has been documented as a function of daily eating occasions and weight loss is not facilitated by high EF. Several methodological discrepancies have been proposed to explain the differences observed between studies, especially the under-reporting of food intake and the lack of a standardized definition of key terms for EF.

Despite the inconclusive results, EF seems to be related with leanness in men (Drummond et al. 1998; Chapelot et al. 2006; Ruidavets et al. 2002). In women, many studies found no association or negative correlation between EF and adiposity, despite a higher EI (Burley et al. 2002; Drummond et al. 1998; Duval et al. 2008a; Yannakoulia et al. 2007). It was suggested that a higher EF could very well be a marker of a physically active lifestyle, at least in leaner persons. The combination of a high EF and increased physical activity may be an effective strategy for the control of body weight. In children, while some studies found no relationship between EF and body-weight status, the negative association between an increased EF and childhood overweight/obesity found by other investigators highlights the importance to assess eating pattern in childhood. Skipping meals might not be an appropriate approach for reducing the risk of obesity in children.

There is clearly a need to examine the relationship between EF and adiposity using both cross-sectional and longitudinal approaches. More long-term studies with sufficiently large sample sizes and using adequate and standardized methodologies are needed in order to provide accurate information on the association between eating occasions and body-weight control, which will be relevant for health-promotion strategies.

While the effects of EF on body-weight control are controversial, there is no evidence that dividing food intake in several daily eating episodes adversely affect body weight status. It was suggest that as long as EI is not greater than EE and that individuals eat only when they are hungry, splitting energy intake in several eating occasions over the day may be useful (Louis-Sylvestre et al. 2003). Louis-Sylvestre et al. (2003) also proposes that the EF pattern cannot be completely separated from the macronutrient composition of foods consumed. The composition of the food intake has also to be taken into account to be sure that low-energy, dense, high-carbohydrate foods are consumed. By itself, the currently available evidence does not support that increasing EF is associated to lesser adiposity, greater weight loss, or even the prevention of weight gain.

178.4.1 Applications to Other Areas of Health and Disease

There is some evidence that EF may be implicated in certain health parameters, notably diabetes, hypercholesterolemia, and colon cancer (Palmer et al. 2009). Studies investigating the metabolic effects of eating patterns have shown that, for a given EI, eating more frequently may lead to an improvement in blood lipid profile (decrease total and low-density lipoprotein (LDL) cholesterol), a better glucose tolerance, an improvement in insulin resistance, and a reduction of insulin concentration (Edelstein et al. 1992; Arnold et al. 1993; Jenkins et al. 1989, 1992, 1995; Gwinup et al. 1963a, b;

Carlson et al. 2007; Fabry et al. 1964). The lower levels of total and LDL cholesterol observed in more frequent eaters may help to reduce the risk of myocardial infarction (Fabry et al. 1968). However, more long-terms studies are needed to confirm these results. It should nonetheless be noted that results from at least one study suggest that the risk of colorectal cancer is proportional to EF (Gerhardsson de Verdier and Longnecker 1992).

Several physiological reasons have been proposed to explain the association between EF and diabetes risk indicators. It have been suggested that higher EF may lower insulin requirements and blood-glucose concentrations over the day (Jenkins et al. 1992). Indeed, Jenkins et al. (1992) have shown that spreading the nutrient intake throughout the day may promote glucose disposal resulting from a reduction of free-fatty acids' concentration. Another possible explanation is that more frequent eaters tend to produce less glucose-dependent insulinotropic polypeptide (GIP), which is an insulin stimulant and inhibits gastric emptying (Jenkins et al. 1990; Vitapole 2003). Thus, this decreased GIP production results in a decreased insulin secretion and a slowed rate of stomach emptying with consumption of smaller meals, which results in a slower rate of energy delivery to the intestine and less insulin required to control blood-glucose levels (Macdonald 1996; Doran et al. 1998).

Concerning the physiological mechanisms to explain the inverse associations between EF and total and LDL cholesterol, it was suggested that the reduction in insulin concentration observed in more frequent eaters may have an impact on the reduction of the enzyme hydroxymethylglutaryl-CoA (HMG-CoA) reductase, responsible for hepatic cholesterol synthesis (Jenkins et al. 1989). A decrease in cholesterol synthesis increases LDL receptors, resulting in lower concentrations of total and LDL cholesterol (Jenkins et al. 1989). A nibbling eating pattern may also give more opportunities to remove cholesterol, which is normally removed in the postprandial phase (Mann 1997).

Summary Points

- There is a lack of standardized definition of eating frequency. Two types of definition are normally reported to categorize eating frequency in the literature: predefined eating periods and time interval between two eating occasions.
- The 24-h dietary recall and the food record/diary are mostly used to assess eating frequency.
- Under-reporting has been recognized as an important methodological issue in the relation between eating frequency and body weight. Overweight, obese, and diet-restrained subjects are more likely to under-report their food intake.
- The association between eating frequency and body-weight status is not clear. Studies in both adults and children have either failed to find a significant relationship between eating frequency and adiposity or have found an inverse relationship.
- A high eating frequency may be associated with an increased carbohydrate: fat ratio and a reduction in hunger, which may help for body-weight control. A high eating frequency may also help to spread the energy intake over the day.
- The impact of eating frequency on weight loss during energy restriction and on energy expenditure is more conclusive. No difference in total energy expenditure has been documented as a function of daily eating occasions, and weight loss is not facilitated by high eating frequency.
- Physical activity seems to be related with a higher eating-frequency pattern. Subjects who eat more frequently tend to have a physically active lifestyle.
- Several methodological discrepancies have been proposed to explain some differences observed between studies: various definitions of eating occasions, under-reporting of food intake, various methods of assessing food intake and body composition, and the lack of physical-activity measurement.

Anthropometry and Nutrition: Micro- and Macro-Nutrients

Chapter 179
Relationship Between Calcium Intake and Anthropometric Indices

Herculina Salome Kruger

Abstract An emerging body of literature suggests that dietary calcium may play a role in the regulation of body weight and body fat. Literature has shown inverse relationships between calcium intake and body fat percentage and body mass index (BMI) of children and adults of different ethnic groups. In some studies, however, no association between dietary calcium intakes and body weight, BMI or fat mass was found. The aim of this study was to assess the association between dietary calcium intakes and anthropometric indices in different age groups and people from different ethnic groups worldwide. Results of cross-sectional studies of the relationship between calcium intake and anthropometric indices indicate inverse associations between calcium intakes and BMI among adolescents and adults. These associations were not found consistently, especially not in groups with a relatively low calcium intake. In most studies adjustment was made in statistical analyses for age, gender, total energy intake and smoking, but adjustment was seldom made for physical activity, which could have an important effect on the body mass index and skinfold thickness of the study participants and could be a confounder in the association between dietary calcium intakes and body composition. Longitudinal studies in children and young adults indicate an inverse association between dietary calcium intake over time and body fat or sum of skinfolds. Randomised controlled intervention trials showed inconsistent results and a meta-analysis of 13 randomised controlled trials showed no association between dietary calcium intake and body fat. In a cross-over clinical trial where the effects of low and high calcium diets were compared fecal fat excretion increased 2.5-fold when the participants took the 1,800 mg calcium diet with 15% of energy from protein compared to a 500 mg calcium diet. The authors proposed that increased fat and energy excretion over time may contribute to a decreased gain in fat mass, or a loss of body fat. Other plausible mechanisms include higher fat oxidation or protection against fat gain by creating a balance of lipolysis over lipogenesis in adipocytes. High calcium intake depresses 1,25-dihydroxy vitamin D leading to decreases in intracellular calcium, thereby inhibiting lipogenesis and stimulating lipolysis. Available data do not unequivocally support the hypothesis that a causal relationship exists between high dairy food intake and/or high dietary calcium intake and lower fat mass deposition. Daily calcium intake should, however, be encouraged to achieve optimal health.

179.1 Introduction

The prevalence of obesity is increasing in developed, as well as developing countries, and with that, the burden of chronic diseases associated with obesity, namely diabetes mellitus, coronary heart disease, and hypertension. Results from studies of coronary artery risk development have shown that people from different ethnic groups should avoid excess adiposity to improve their health (James 1998). There is little understanding of the optimal dietary composition necessary to promote weight loss and prevent weight gain, whereas it is of major importance to interpret dietary influences on body composition in order to develop practical guidelines for obesity treatment and prevention (Astrup et al. 2000). While much attention has been focused on macronutrient intake and body-weight regulation, particularly dietary fat, an emerging body of literature suggests that dietary calcium may play a role in the regulation of body weight and body fat (Barba and Russo 2006; Heaney et al. 2002; Heaney 2003; Zemel et al. 2000). Literature has shown inverse relationships between calcium intake and body fat percentage and body mass index (BMI) of children (Carruth and Skinner 2001; Skinner et al. 2003; Palacios et al. 2007) and adults in Western communities (Loos et al. 2004; Marques-Vidal et al. 2006), as well as in American Indians (Eilat-Adar et al. 2007) and African-Americans (Loos et al. 2004). Epidemiologic and limited experimental data from some studies suggest that differences in calcium intake may be associated with changes in body weight of 0.42 kg year (Heaney et al. 2002; Heaney 2003). In some studies, however, no association between dietary calcium intakes and body weight, BMI or fat mass were found (Brooks et al. 2006; Eilat-Adar et al. 2007) and, also, no difference in increase in body weight and BMI of fat mass between calcium supplemented and control groups (Lappe et al. 2004; Trowman et al. 2006; Yanovski et al. 2009).

Dietary calcium intakes vary, but generally African populations (Kruger et al. 2007) and American-Indians (Eilat-Adar et al. 2007) have usual calcium intakes much lower than the recommendations for health. In some studies, lower usual calcium intakes were reported for obese groups (dos Santos et al. 2008; Eilat-Adar et al. 2007; Marques-Vidal et al. 2006), and concern was expressed about the low calcium intakes of children and young adolescents (Barba and Russo 2006; Poddar et al. 2009). The aim of this study was to assess the association between dietary calcium intakes and anthropometric

indices in different age groups and in people from different ethnic groups worldwide. A large number of studies have been done in this field, and the author will include studies from a range of age groups, ethnic groups and countries in this review within the limits set for this textbook.

179.2 Cross-Sectional Studies

Results of cross-sectional studies of the relationship between calcium intake and anthropometric indices are summarized in Table 179.1. These results indicate inverse associations between calcium intakes and measures of adiposity among adolescent groups (Palacios et al. 2007; dos Santos et al. 2008). The association was clear in boys 13–15 years old, with a wide range of BMI values. In boys 16–18 years old and girls 13–18 years old, most children had BMI values within the normal range as well as high calcium intakes, and no significant association between calcium intakes and BMI was found (Palacios et al. 2007). A study, in adolescents, with more than 50% obese participants and a wide range of calcium intakes also indicated an inverse association between calcium intakes and body fat. Moreover, body trunk fat, fasting insulin, and homeostasis model assessment (HOMA) of insulin resistance were all inversely associated with calcium intakes, indicating increased risk of non-communicable diseases in the girls with low calcium intakes (dos Santos et al. 2008).

Table 179.1 also shows inverse associations between calcium intake and BMI, as well as body-fat percentage and skinfold thickness (Loos et al. 2004; Eilat-Adar et al. 2007; Garcia-Lorda et al. 2007; Kruger et al. 2007). These associations were not found in all groups studied. Two studies found no association between calcium intakes and BMI of black women (Loos et al. 2004; Kruger et al. 2007). In both studies, calcium intakes were adjusted for total energy intake, but black women had lower calcium intakes than white women. Kruger et al. (2007) suggested that a minimum calcium intake, combined with a relatively high fat intake, is necessary before calcium intake can have an effect on adiposity. No association was also found between the calcium intakes and BMI of whites in USA in the NHANES III Study (Eilat-Adar et al. 2007), young adults in USA (Brooks et al. 2006), and adults older than 55 years in Portugal (Marques-Vidal et al. 2006). For all these groups, relatively low calcium intakes ranging from around 300 to 800 mg per day were reported. The range between the lowest and the highest calcium intake quintiles in the study of American Indians was potentially large enough to produce an association, whereas this range in the NHANES III Study was not as large (Eilat-Adar et al. 2007). In most studies, adjustment was made in statistical analyses for age, total energy intake, and smoking, but adjustment was seldom made for physical activity, which could have an important effect on the body mass index and skinfold thickness of the study participants (Marques-Vidal et al. 2006; Varenna et al. 2007). The differing results across analyses may also have resulted from differences in age and gender distributions, as well as fewer adjustments for confounders in the NHANES III analysis (Eilat-Adar et al. 2007). A possible reason for a lack of association between number of dairy portions per day and BMI or percentage body fat could be that most of the dairy portions, for example, cheese, were also high in fat. The effect of fat intake on body composition was probably stronger than the effect of calcium intake (Kruger et al. 2007).

179.3 Longitudinal Studies

Generally, it is difficult to prove causality in cross-sectional studies, and many confounding variables may not be measured and adjusted for in statistical analyses. In longitudinal studies, a cohort of participants can be followed over time and outcomes of an exposure can be assessed. Table 179.2 summarizes

Adolescents				
Palacios et al. (2007)	100 adolescents, aged 13–18 y	Food-frequency questionnaire 1,076 mg/d	Correlation analysis	Significant negative correlation found between calcium intake and BMI in boys 13–15 y ($r = –0.39$, $p < 0.05$). This subgroup exhibited the widest range of BMI values among all groups evaluated. No correlation was seen in boys aged 16–18 y or girls, in whom BMI was in the normal range and with relatively high calcium intake
dos Santos et al. (2008)	96 postpubertal adolescents: 47 normal weight and 49 obese, mean age 16.6 +/– 1.3 y	3-day dietary record; Obese children: 585 mg/d Normal weight: 692 mg/d	Quartile analysis; Adjusted for energy intake	Calcium intake was inversely associated with body trunk fat, insulin, and HOMA-IR in the obese group. Girls in the highest quartile of Ca intake had decreased adiposity
Adults				
Brooks et al. (2006)	1,306 young adults 19–38 y	Semi-quantitative food frequency questionnaire; 799 ± 417 mg/d	Analysis of covariance; separately for gender and ethnic groups	No significant association was found between dairy product consumption, calcium intake, and body mass index or waist circumference. A significant inverse association was seen between calcium intake, low-fat dairy-product consumption, and waist-to-hip ratio in white males
Marques-Vidal et al. (2006)	17,771 men and 19,742 women aged > /= 18 y	Milk-intake frequency questionnaires Men: 187 ± 5–252 ± 3 ml milk/d Women: 222 ± 5–243 ± 3 ml milk/d	Correlation analysis adjusted for age, region, physical activity, smoking, number of meals, and educational level. Chi-square test, *t*-tests, and general linear model with post hoc Scheffe's test	In men, milk intake was inversely related to BMI (r = –0.10, $p < 0.001$); the relationship in women was weaker ($r = –0.06$, $p < 0.001$). In men, prevalence of milk consumers was lower in obese (62%) and in overweight (68%) than in normal-weight subjects (71%, $p < 0.001$). In women younger than 55 y, milk intake decreased with increased BMI categories (291 ± 9, 271 ± 10, and 269 ± 11 ml/d for normal, overweight, and obese subjects, respectively, $p < 0.001$); no relationship was found in the older group

Garcia-Lorda et al. (2007)	261 men and 313 women, 18–70 y	24-h dietary recall	Odds ratio analysis within quartiles of calcium intake adjusted for age, energy, total fat, and fiber intake	Odds ratio of being in the highest quartile of BMI was significantly reduced in the highest quartile of calcium intake [men: 0.63 (0.30–1.29); women: 0.36 (0.17–0.79)], compared to the lowest quartile.
Multiethnic groups				
Loos et al. (2004)	109 black and 253 white men, 201 black and 261 white women of the HERITAGE Family Study	Food-frequency questionnaires Black men: 766 ± 49 mg/d Black women: 825 ± 42 mg/d White men: 1,098 ± 38 mg/d White women: 1,060 ± 34 mg/d	ANOVA and regression against the energy-adjusted calcium intake to test for a linear trend	No significant associations were found in black women. Low Ca intake may be associated with higher adiposity, particularly in men and white women The percentage of fat of white men in the highest Ca-intake group was significantly lower than in the lowest calcium group ($p = 0.04$). The strongest inverse associations appeared in black men and white women. Black men in the high-Ca-intake group were leaner than those in the low-Ca-intake group: BMI 23.4 ± 0.9 versus 26.7 ± 1.1 kg/m^2 ($p = 0.01$); for all other adiposity measures, $p < 0.05$. In white women, regression analyses showed significant inverse associations between Ca intake and BMI ($p = 0.02$) and skinfold thicknesses ($p = 0.01$–0.006).
Eilat-Adar et al. (2007)	2,975 American Indians and 2,755 US whites aged 47–79 y	24-h dietary recall. Indian men: 680 ± 14 mg/d Women: 610 ± 10 mg/d White men 852 ± 20 mg/d White women 673 ± 13 mg/d	Generalized logit model for quintile analysis by gender, age, study center, years of education, income, alcohol consumption, smoking, diabetes status, diabetes duration in participants with diabetes, and energy intake	In American Indians, %body fat and BMI (as adjusted mean differences in higher calcium quintiles compared with the lowest quintile) decreased as calcium intake increased after controlling for other confounders. In NHANES III US whites, no trend was observed in either BMI or %body fat across calcium-intake categories
Kruger et al. (2007)	102 black women, 106 white women	Food-frequency questionnaires Black women: 523 ± 63 mg/d White women: 1,054 ± 10 mg/d	Partial correlation adjusted for age, energy intake, and smoking	Significant negative correlation seen between dietary calcium:fat ratio and BMI in white women only No association observed between calcium intake and anthropometric indices in black women

(continued)

Table 179.1 (continued)

Author (year)	Study subjects	Method of measuring calcium intake	Statistical method and factors controlled for in analyses	Results
Women only				
Varenna et al. (2007)	1,771 healthy early postmenopausal women	Frequency of dairy-food consumption questionnaire of number of servings with 300 mg Ca. Calculated calcium intakes ranged between <300 and 685+ mg/d	ANOVA and chi-square test, stepwise multiple logistic regression adjusted for age, age at menopause, physical activity, and smoking	BMI and prevalence of overweight showed significant inverse trends with increasing dairy intake
Azadbakht et al. (2008)	926 women aged 40–60 y	Quantitative food-frequency questionnaire	Logistic regression analysis adjusted for age, medications, and BMI. Pearson correlation between dietary components and WHR. Analysis of covariance to compare the mean values of WHR in different lifestyle groups, with adjustment for BMI and age	Dairy consumption was inversely correlated with central fat accumulation (r = -0.2, $p < 0.05$) Low calcium intake (1.30; 1.07–3.78) was associated with central fat accumulation

This table summarizes cross-sectional studies of the relationship between calcium intake and anthropometric indices according to authors, study subjects, method of measuring calcium intake, statistical methods, factors controlled for in analyses, and key results

ANOVA analysis of variance, *BMI* body mass index, *Ca* calcium, *d* day, *HOMA-IR* homeostasis model assessment of insulin resistance, *kg/m²* kilogram per square meter, *mg* milligram, *NHANES* National Health and Nutrition Examination Survey, *y* year

Table 179.2 Longitudinal studies of the relationship between calcium intake and anthropometric indices

Author (year)	Study subjects and duration of follow-up	Method of intake assessment and mean intakes	Statistical method and factors controlled for in analyses	Results
Children				
Carruth and Skinner (2001)	53 children 70 ± 2 months (6 y) 4 years of follow-up	24-h recall +2-day diet records by personal interview; Boys: 791–949 mg/d Girls: 698–808 mg/d	General linear models; gender, dietary fat, protein, and monoun-saturated fat	Both dietary calcium intake and dairy product intake were significantly negatively associated with body fat
Skinner et al. (2003)	52 children, 8 years old; 6 years of follow-up	24-h recall +2 d diet records by interview Boys 912 mg/d Girls 805 mg/d	Multiple regression; total dietary fat, saturated fat, gender, sedentary activity, father's BMI, and mothers' percent body fat	Dietary calcium and polyunsaturated fat intake were negatively related to body fat in three statistical models, which predicted 28–34% of the variability in body fat among children
Adolescent to adult				
Boon et al. (2005)	391 subjects from age 13 years in 1977 to age 36 years; 23 years of follow-up	Cross-check diet history interview; Men 1,122–1,435 mg/d Women 921–1,264 mg/d	Linear regression analysis adjustment for age only, then with additional adjustment for total dietary energy intake, fiber intake, and level of habitual physical activity	For men in the age-adjusted model, a 1,000 mg/d higher dietary calcium intake was related to a 0.2 cm lower sum of four skinfolds ($p = 0.004$). For women in the age-adjusted model, the highest dietary calcium intake group (>1,200 mg/d) had a significantly lower sum of four skinfolds than those consuming <800 mg/d of calcium ($p = 0.04$). A comparable, not statistically significant trend was found for BMI. The significant associations disappeared after adjustment for putative confounders. No differences were observed between the middle (800–1,200 mg/d) and high (>1,200 mg/d) groups of calcium intake
Poddar et al. (2009)	65 women and 11 men; mean age 19.2 ± 0.2 y; 7 months of follow-up	7-day food records Dairy: 1.4 ± 0.1 servings/d; low-fat dairy: 0.5 ± 0.1 servings/d; calcium: 815 ± 41 mg/d	One-way multivariate analysis of covariance race, sex, and percent intake of estimated energy requirement were included as covariates	Higher low-fat dairy intakes (0.8 servings/d): gained less body weight and had reductions in waist circumference, percentage truncal fat, and percentage total body fat compared to those with lower intake (0.1 serving/d) Subjects who consumed a higher amount of low-fat dairy products (mean ± SE = 0.8 ± 0.1 servings/day) had better diet quality

This table summarizes longitudinal studies of the relationship between calcium intake and anthropometric indices according to authors, study subjects, duration of follow-up, method of measuring calcium intake, statistical methods, factors controlled for in analyses, and key results
BMI body mass index; *mg/d* milligram per day; *SE* standard error; *y* year

the methods and results of longitudinal studies done in children and young adults. The two studies in children show results of the same cohort (Carruth and Skinner 2001; Skinner et al. 2003) but with additional analyses done over 2 years in the second study (Skinner et al. 2003). All studies indicate an inverse association between dietary calcium intake over time and body fat or sum of skinfolds (Carruth and Skinner 2001; Skinner et al. 2003; Boon et al. 2005; Poddar et al. 2009).

No differences were observed between body composition of the middle (800–1,200 mg/d) and high (>1,200 mg/d) groups of calcium intake in Dutch subjects, suggesting a threshold of approximately 800 mg/d, above which calcium intake has no additional beneficial effect on adiposity (Boon et al. 2005). If it is considered that a minimum calcium intake of about 600 mg/d for an effect on adiposity has been proposed (Kruger et al. 2007), then a small range of calcium intakes of 600–1,000 mg/d is proposed for an effect on adiposity.

179.4 Randomized Controlled Trials

Randomized controlled trials provide the most powerful tool to assess a relationship between an exposure, such as calcium intake, and an outcome, in this case, anthropometrical indices indicating obesity. Components of the methods and results of randomized controlled trials of calcium intake and anthropometric indices are summarized in Table 179.3. In a relatively small study of 59 prepubertal girls, randomized to either a calcium-rich diet or their usual diet, no difference in increase in BMI, fat, or lean mass over 2 years was found, although the intervention group consumed nearly twice as much dietary calcium as the control group (Lappe et al. 2004). Similarly, Yanovski et al. (2009) found no difference between body weight or BMI of a calcium supplemented group and a placebo group of overweight adults after 2 years of intervention. However, in a study of only 51 young women, mean calcium intake over 18 months predicted changes in fat mass, suggesting that women on low calcium intakes will gain fat mass and those on high calcium intakes will reduce fat mass. Adjustment for total energy intake and physical activity did not alter the predicted changes (Eagan et al. 2006). Zemel et al. (2004) also found increased fat loss in the intervention groups with higher calcium intakes, with the highest fat loss in the group with the highest dairy food intake. Moreover, fat loss from the trunk region represented 19 ± 7.9% of total fat loss on the low-calcium diet, and 50 ± 6.4% and 66 ± 3% on the high-calcium and high-dairy diets, respectively.

Jacobsen et al. (2005) carried out a randomized cross-over study to assess the effects of calcium intake on energy expenditure, fat oxidation, and fat excretion, in an attempt to explain the mechanism underlying the inverse association between calcium intake and body fat. Calcium intake had no effect either on energy expenditure, measured in open-circuit respiratory chambers, or on fat oxidation, calculated from gas exchange in the chamber. Fecal fat excretion did, however, increase 2.5-fold when the participants took the 1,800 mg calcium diet with 15% of energy from protein, compared to the 500 mg calcium diet and the 1,800 mg calcium diet with 23% of energy from protein. The authors proposed that increased fat and energy excretion over time may contribute either to a decreased gain in fat mass, or to a loss of body fat.

179.5 Reviews and Meta-Analysis

Table 179.4 shows the results of a narrative review, reanalyses of several studies, and a meta-analysis of randomized controlled trials. Reanalyses of studies (Heaney et al. 2002; Heaney 2003; Zemel et al. 2000) showed a consistent association between higher calcium intakes and lower body fat and/or body

Table 179.3 Randomized controlled trials of the relationship between calcium intake and anthropometric indices

Author (year)	Study subjects and duration of the intervention	Mean calcium or dairy-food intakes of intervention and control groups	Statistical method and factors controlled for in analyses	Results
Lappe et al. (2004)	59 girls, 9 y; 2 years	Calcium-rich diet supplying at least 1,500 mg calcium per day or their usual diet (731 ± 105 mg calcium/day); 3-day food diaries	Analysis of covariance to model the effect of tertile (lowest vs. highest) of calcium on weight gain while adjusting for baseline weight, energy, and protein intake averaged over the 2 years of study as covariates/predictors. Mann–Whitney *U* test was used to test the differences in percentile ranking of BMI	Participants in the treatment group consumed nearly twice as much dietary calcium as the control group, primarily from dairy foods, but they did not have greater increases in body weight, body mass index, or fat or lean mass than the control group. Calcium-rich diets do not cause excessive weight gain in pubertal girls but do contribute positively to overall nutrition
Eagan et al. (2006)	51 normal-weight young women; 1-year dairy intervention 6 months after completion of the intervention	Control group (<800 mg Ca/d), medium dairy (1,000–1,100 mg Ca/d), and high dairy (1,300–1,400 mg Ca/d)	ANOVA, Pearson correlation, and general linear model were used as described in the results. Dependent variables include absolute values and changes in fat mass, lean mass, weight, and BMI. Predictive variables include dietary group assignment, calcium intake, and change in calcium intake. Covariates were absolute values and changes in BMI, energy intake, and 25-hydroxy-vitamin D	Mean calcium intake over the 18 months predicted a negative change in fat mass ($p = 0.04$). There was a trend for 18-month dietary calcium intake to correlate with change in fat mass when uncontrolled ($r = 0.25$; $p = 0.08$), and when controlled for baseline BMI ($r = 0.27$, $p = 0.06$). This trend was significant($r = 0.28$; $p = 0.05$) when analyses were controlled for group and baseline BMI. Physical activity or mean energy intake in the model did not alter the results. Mean calcium intake of 6-, 12-, and 18-month dietary records predicted the 18-month change in fat mass when controlled for baseline BMI in regression ($R^2 = 0.11$). Substituting calcium intakes into the regression equation yields for 500 mg/d, a fat mass gain of 1.26 kg over 18 months, and for 1,200 mg/d, a fat mass loss of 0.631 kg over 18 months. The difference in fat mass is 1.89 kg between dietary calcium intake exposures over 18 months in normal-weight young women

(continued)

Table 179.3 (continued)

Author (year)	Study subjects and duration of the intervention	Mean calcium or dairy-food intakes of intervention and control groups	Statistical method and factors controlled for in analyses	Results
Jacobsen et al. (2005)	Eight women, two men, 18–50 y; cross-over study of three isocaloric 1-week diets (3× 1-weeks)	Low calcium and normal protein: 500 mg calcium, 15% of energy (E%) from protein (LC/NP); high calcium and normal protein: 1,800 mg calcium, 15E% protein (HC/NP); and high calcium and high protein: 1,800 mg calcium, 23E% protein, (HC/HP)	Differences between the three diets were analyzed by a mixed model for analysis of covariance with values from after the diet period as the dependent variable and subjects as a random variable. Adjustments were made for various covariables. Baseline values were not included in the analyses. Differences in the fecal parameters were analyzed by analyses of variance, with subjects included as a random effect and Tukey correction for post hoc comparisons. Differences between values measured before and after the diet period were analyzed by a paired *t*-test. Correlation between calcium intake and fat excretion was calculated using Pearson's correlation. Linear regression was used to relate calcium intake to fat excretion	The calcium intake had no effect on 24-h energy expenditure or fat oxidation, but fecal fat excretion increased approximately 2.5-fold during the HC/NP diet compared with the LC/NP and the HC/HP diets (14.2 vs. 6.0 and 5.9 g/d; $p < 0.05$). The HC/NP diet also increased fecal energy excretion as compared with the LC/NP and the HC/HP diets (1,045 vs. 684 and 668 kJ/d; $p < 0.05$)
Yanovski et al. (2009)	340 overweight (BMI >/= 25–30 kg/m^2) adults, mean age 38.8 y, 2 years	Elemental calcium, 1,500 mg/d or placebo	Intention-to-treat sample of all randomly assigned participants Multiple imputation model for missing data under a missing-at-random assumption. All baseline, one y and two y outcome measures were used in an imputation model along with age, sex, race, baseline serum 25-hydroxy-vitamin D concentration, baseline calcium intake, and study group. The coefficients from analyses of 20 imputed data sets were combined into a single set of estimates. Multiple imputations were done to impute the missing 2-year weight measurements by using the same imputation model used for the main analysis. Fixed amounts were added to imputed values, and results were reanalyzed by using analysis of covariance	No statistically or clinically significant differences between the calcium and placebo groups regarding change in body weight (difference, 0.02 kg [95% CI:1.64–1.69 kg]; $p = 0.98$), BMI (difference, 0.32 kg/m^2 [CI:0.41–1.02 kg/m^2 $p = 0.39$), or body fat mass

Author (year)	Study subjects and duration of the intervention	Mean calcium or dairy-food intakes of intervention and control groups	Statistical method and factors controlled for in analyses	Results
Zemel et al. (2004)	32 obese adults, 24 weeks	Balanced 500 kcal/d deficit diets and 400–500 mg dietary calcium/d supplemented with placebo, a high-calcium diet supplemented with 800 mg calcium/d, or a high-dairy diet (1,200–1,300 mg of calcium/d)	Multivariate ANOVA to facilitate evaluation of both the repeated measures and independent group comparisons inherent to this study design	Adults on a standard diet lost 6.4 ± 2.5% of their body weight, those on a high-calcium diet lost 8.6 ± 1.1%, and those on the high-dairy diet lost 10.9 ± 1.6% of body weight Fat loss from the trunk region represented 19.0 ± 7.9% of total fat loss on the low-calcium diet, and 50.1 ± 6.4% and 66.2 ± 3.0%, respectively on the high-calcium and high-dairy diets

This table summarizes randomized controlled trials of the relationship between calcium intake and anthropometric indices according to authors, study subjects, duration of the intervention, mean calcium or dairy food intakes of intervention and control groups, statistical methods, factors controlled for in analyses, and key results
ANOVA analysis of variance; *BMI* body mass index; *kg/m²* kilogram per square meter; *mg/d* milligram per day; *y* year

Table 179.4 Reviews of the relationship between calcium intake and anthropometric indices

Author (year)	Study subjects	Mean calcium or dairy-food intakes of groups	Statistical method and factors controlled for in analyses	Results
Heaney et al. (2002)	564 women; reanalysis of published data from nine studies	In both groups of women, calcium intake was obtained from seven-d diet The calcium contents of the three regimens were not described, but can be estimated to be below 500 mg for the conventional regimen and from 1,500–2,100 mg for the milk-based diets	Comparison of prevalence of overweight by percentile of calcium intakes by odds ratio analysis. Estimates of calcium effect size calculated for a 1,200 mg difference between top and bottom quartiles of calcium intake	A reduction in overweight prevalence in the upper tail area from 25% to 4.2% and an estimated population standard deviation for weight at 18% of the mean. At the 25th percentile of calcium intakes, 15% of young women were overweight, compared to only 4% at calcium intakes at current recommendations. At midlife, women at the 25th percentile of intakes gained weight at an average rate of 0.42 kg/y. This change dropped to a weight loss of 0.011 kg/y at currently recommended calcium intakes
Heaney (2003)	564 women; reanalysis of six observational studies and three controlled trials	Data were reevaluated, focusing on the distribution of values around the regression lines relating calcium intake to BMI in young women and to weight gain at midlife. The calcium contents of the three regimens were not described but can be estimated to be below 500 mg for the conventional regimen and from 1,500–2,100 mg for the milk-based diets	The fraction of the population above any specified value was calculated from the integral of the normal distribution for the respective means and standard deviations. Error terms for these fractions were calculated from the confidence intervals of the slope of the relationship of the dependent variable on calcium intake, at the specifically tested calcium intakes. Regression was done relating dietary calcium:protein ratio to weight gain. Superimposed on this regression line are plots of the normal distribution with means at predicted weight gain for calcium:protein ratios of 9 and 20 mg Ca:g protein, set to the standard error of the estimate for the regression	Consistent effect of higher calcium intakes, expressed as lower body fat and/or body weight, and reduced weight gain at midlife. Predicted BMI at 10 mg Ca:g protein was 22.5, and the probability of having a BMI> 26 was 0.146. This probability drops to 0.04 at 20 mg Ca:g protein, and the relative risk of being overweight at the 25th percentile of calcium intakes, relative to the recommended intake, is thus 3.6. Similarly, the probabilities of being obese are 0.014 and 0.002 for the two calcium intakes, with a relative risk of 6.9 at the 25th percentile of calcium intakes, relative to the recommended intake

Author (year)	Study subjects	Mean calcium or dairy-food intakes of groups	Statistical method and factors controlled for in analyses	Results
Zemel et al. (2000)	NHANES III data set; secondary analysis	A large cross-sectional survey conducted between 1988 and 1994 Calcium intakes not reported per group	Relative risk analysis by quartile group, controlling for energy intake, ethnicity, and activity level. Odds ratios for percent body fat and 95% confidence intervals were estimated by multiple logistic regression analysis with a robust variance estimation method. Point estimates for all parameters were weighted to reflect the population distribution of each; variances were calculated to take the complex sampling design into account. Analyses were done separately for men and women; odds ratios were adjusted for age	After controlling for energy intake and physical activity, relative risk of being in the highest quartile of body fat was set to 1.00 for the lowest quartile of Ca intake and was reduced to 0.75, 0.40, and 0.16 for the second, third, and fourth quartiles of calcium intake for women ($n = 380$; $p < 0.0009$); there was a similar inverse relationship in men ($n = 7{,}114$; $p < 0.0006$)
Barba and Russo (2006)	Prospective studies on adults/ children and randomized controlled trials	Narrative review; calcium intakes not reported per group	Narrative review	A dairy-food-rich diet was associated with lower fat accumulation in most cross-sectional studies. Prospective studies and randomized controlled intervention trials have yielded inconsistent results
Trowman et al. (2006)	Persons >/= 18 y from 13 randomized controlled trials in a meta-analysis	Systematic review and subsequent meta-analysis of randomized controlled trials that used calcium supplementation as an intervention	ANCOVA to provide an estimated treatment effect when differences between the treatment groups at baseline were accounted for. Regression of final mean weights (dependent variable) versus treatment group (independent variable), adjusting for mean baseline weights (covariate), weighted by the sample size of each treatment group	No association between the increased consumption of either calcium supplements or dairy products and weight loss after adjusting for differences in baseline weights between the control and intervention groups ($p = 0.19$ and 0.85, respectively). Calcium supplementation had no statistically significant association with a reduction in body weight

This table summarizes reviews of the relationship between calcium intake and anthropometric indices
ANCOVA analysis of covariance; *Ca* calcium; *d* day; *kg* kilogram; *mg* milligram; *NHANES* National Health and Nutrition Examination Survey; *y* year

weight and reduced weight gain at midlife. Although calcium intake explains only a small fraction of the variability in weight or weight gain, shifting the mean of the distributions downward by increasing calcium intake can be estimated to reduce the prevalence of overweight and obesity by perhaps as much as 60–80% (Heaney 2003), with each 300 mg increment in regular calcium intake associated with approximately 1 kg less body fat in children and 2.5–3.0 kg lower body weight in adults. Taken together, these data suggest that increasing calcium intake by the equivalent of two dairy servings per day could reduce the risk of overweight substantially, perhaps by as much as 70% (Heaney 2003).

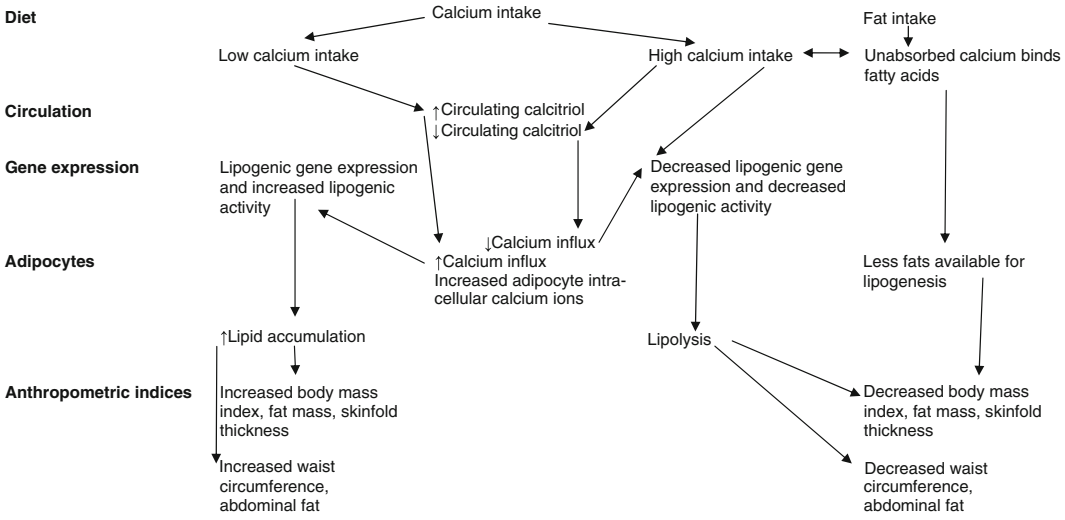
The narrative review states that available data do not unequivocally support the hypothesis of a causal relationship between high-calcium or high-dairy-food intake and lower gain in fat mass (Barba and Russo 2006). A systematic review and subsequent meta-analysis of 13 randomized controlled trials that used calcium supplementation as an intervention in persons older than 18 years found no association between the increased consumption of either calcium supplements or dairy products and weight loss after adjusting for differences in baseline weights between the control and intervention groups ($p = 0.19$ and 0.85, respectively). The authors concluded that calcium supplementation and/or increase intake of dairy foods had no statistically significant association with a reduction in body weight (Trowman et al. 2006).

179.6 Possible Reasons for Inconsistent Results of Studies of the Relationship Between Calcium Intake and Anthropometric Indices

Although many studies indicate an association between calcium intake and anthropometric indices of adiposity, inconsistent results could have been due to methodological problems in the assessment of dietary intake of either calcium or dairy foods. Moreover, multiple factors are involved in the regulation of body weight and skinfold thickness, and it is possible that confounders have not been sufficiently controlled for in the design and analyses of studies reporting either an effect or no effect (Barba and Russo 2006). The lack of relationship between calcium intake and BMI in older women may, for example, be due to differences in hormonal status (Marques-Vidal et al. 2006). Another possibility is that a low calcium intake tends to be a marker for a poor diet and that a poor diet is a good predictor of obesity. There are also indications that a high calcium intake and, especially a high intake of low-fat dairy foods, serve as a marker for a healthy lifestyle, which is associated with lower BMI and fat mass (Barba and Russo 2006).

179.7 Proposed Mechanisms for the Effect of Dietary Calcium Intake on Body Fat

Studies provided plausible explanations for an association between calcium intake as well as dairy foods and body fat, and there are also signs of a dose–response effect. Possible mechanisms for this effect include an inhibiting effect of calcium on fat absorption (Jacobsen et al. 2005). The mechanism by which calcium increases fat excretion is probably an interaction between calcium and fatty acids, resulting in the formation of insoluble calcium fatty acid soaps, and hence in reduced fat absorption. The mechanism for the interaction between fat and calcium is shown in Fig. 179.1. There was a difference between the low-calcium and the high-calcium diet of 1,190 mg/d in fecal calcium excreted. The maximum amount of fat that can be bound to this amount of calcium is about 60 mmol



(Zemel and Miller, 2004; Jacobsen et al 2005)

Fig. 179.1 Possible mechanisms to explain the relationship between calcium intake and anthropometric indices. This figure outlines possible mechanisms to explain the relationship between calcium intake and anthropometric indices. ↑ increase, ↓ decrease (Zemel and Miller 2004; Jacobsen et al. 2005)

Table 179.5 Key features of dietary calcium

Food sources of calcium	Milk, yogurt, cheese, sardines with bones, and tofu
Key roles of calcium in the body	Forms an integral part of bone structure; helps to maintain normal blood pressure and blood clotting
Recommended intakes of calcium (adequate intake, AI) (mg/day)	Infants 0–6 months old: 210, 6–12 months old: 270
	Children 1–3 y: 500, 4–8 y: 800, 9–18 y: 1,300
	Adults 19–50 y and pregnant women: 1,000, 51 + y: 1,200
	Pregnant and lactating girls </= 18 y: 1,300
Factors affecting bioavailability of calcium	Vitamin D and lactose enhance calcium absorption
	Phytates in grains and oxalates in greens inhibit calcium absorption

(Whitney and Rolfes 2008)

This table lists key features of dietary calcium, including food sources of calcium, recommended intakes, and factors affecting bioavailability of calcium
mg milligram; *y* year

fatty acids. Assuming a molecular mass of about 270 g/mol for fatty acids, this corresponds to a maximum increased fat excretion of 16 g/d. Not all calcium would, however, be available for binding fatty acids. The increase in excreted fat of 8.2 g/d found in the study of Jacobsen et al. (2005) could be a realistic loss of fat as calcium fatty acid soaps (Jacobsen et al. 2005).

This difference between effects of calcium intake on body fat and BMI of white women and black South African women could be attributed to the difference in dietary composition between the two groups. In this study, mean total dietary calcium intake was significantly higher in the white women (mean 1,054 mg/d, 95%CI 952, 1,156) than in black women (mean 523, 95%CI 437, 562 mg/d). Mean fat intake in the black women was 69 g/d, compared to 103 g/d in the white women. Thus, the calcium:fat-intake ratio in white women was higher than in black women (11 and 7.7 mg/g, respectively). For a sufficient amount of 8–10 g/d fat to be bound by calcium and excreted, a dietary calcium:fat ratio of 11 mg/g or more may be necessary (Kruger et al. 2007) (Table 179.5).

It has also been hypothesized that high-calcium diets protect against fat gain by creating a balance of lipolysis over lipogenesis in adipocytes. High calcium intake depresses 1,25-dihydroxy vitamin D, leading to decreases in intracellular calcium, thereby inhibiting lipogenesis and stimulating lipolysis (Zemel and Miller 2004). The mechanism for this interaction is shown in Fig. 179.1. The possibility that high-calcium diets promote greater rates of whole-body fat oxidation has also been studied (Jacobsen et al. 2005). In the study of Jacobsen et al. (2005), calcium intake had no effect on 24-h EE. The results of one study suggested that calcium and vitamin D intakes may have opposing effects on body weight, which is difficult to explain, given current knowledge of calcium metabolism (Kamycheva et al. 2003).

179.8 Applications to Other Areas of Health and Disease

A significant negative correlation was found between calcium intake and insulin resistance assessed by HOMA, as well as fasting insulin and insulin area under the curve, which all indicate that lower calcium intakes were associated with higher insulin resistance in white South-African women. Insulin resistance could favor fatty-acid synthesis and, with that, increased percentage body fat. After adjustment for body mass index, dietary calcium intake still correlated significantly negatively with HOMA insulin resistance ($r = -0.3$, $p = 0.02$) and fasting plasma insulin concentration ($r = -0.31$, $p = 0.02$). The association between calcium intake and plasma-insulin concentration seems to be independent of the association between calcium intake and body composition (Kruger et al. 2007). Calcium intake was not only inversely associated with body trunk fat, but also with insulin and HOMA-IR in Brazilian girls. The negative relationship between calcium intake and body fat and insulin resistance, mainly in obese girls, demonstrates the importance of an increased dietary calcium intake (dos Santos et al. 2008).

A negative correlation was found in South-African black women between dietary calcium intake and systolic blood pressure and diastolic blood pressure, respectively (Kruger et al. 2007). High-calcium diets in a study in Denmark also showed a trend to a minor but still important decrease in blood pressure in adults (Jacobsen et al. 2005).

Although there is no absolute proof that calcium-rich diets contribute to lower weight gain, such diets do contribute positively to overall nutrition. Low-fat dairy intake is generally associated with overall better diet quality (Poddar et al. 2009). These findings provide support for programs to promote calcium-rich diets, which are critical for attaining peak bone mass during childhood and adolescence (Lappe et al. 2004; Palacios et al. 2007).

179.9 Practical Guidelines

Low-fat dairy-food supplementation could be a simple public-health approach to prevent excessive weight gain and obesity. Primary-care providers should include recommendations about adequate calcium intake in standard dietary counseling not only for weight management but also for bone health and general optimal health. Calcium from dairy foods should be recommended, rather than calcium supplements, but for those allergic to milk proteins, calcium supplements could be an alternative.

179.10 Applications

Attention should be given to the calcium content of diets of people of all ages, to ensure intakes of at least close to the adequate intake of 1,000 mg/d. Parents should be encouraged to help children develop health-promoting habits that include regular intake of calcium-rich foods, such as skim, 1%, or 2% fat milk, and other low-fat dairy products. Intake of carbonated beverages and other low-nutrient beverages, such as fruit drinks, fruit 'ades', and tea, which could replace milk in the diet, should be restricted.

Summary Points

- Given the high prevalence of obesity globally, along with its significant medical consequences and the relative cost-effectiveness and safety profile of calcium and dairy supplementation, more research may be warranted to determine whether the body weight of overweight adults can be altered by either calcium or low-fat dairy food supplementation.
- Different reasons could explain these findings that consider the evaluation of either the exposure, for example, methodological problems in the assessment of dietary intake of calcium, or the outcome due to multiple factors involved in the regulation of body weight.
- Calcium supplementation seems unlikely to have clinically significant efficacy as a preventive measure against weight gain.
- Available data do not unequivocally support the hypothesis that a causal relationship exists between high-dairy-food intake and/or high-dietary-calcium intake and lower-fat-mass deposition.
- Daily calcium intake and dairy foods for those not allergic to milk proteins should be encouraged to achieve optimal bone strength and general health.

Chapter 180
Dietary Protein Intake and Anthropometric Indices of Muscle Mass in Elderly

Karine Perreault and Isabelle J. Dionne

Abstract The etiology of the loss of muscle mass with aging is not yet fully understood but compelling evidence supports the important contribution of lifestyle in its process. Physical activity and dietary protein intake were identified as efficient means of promoting muscle hypertrophy. One of the most important prerequisite for the accretion of muscle mass is the availability of amino acids, which are ingested through diet under the form of protein. It has been demonstrated that the anabolic response to a mixed-nutrient meal is blunted with aging. However, some interventions can overact this blunted response and allow muscle accumulation. The most important parameters identified to date are the sources of protein ingested and its content in essential amino acids, especially leucine, the amount and distribution of protein intake throughout the day, physical activity as co-intervention, especially resistance training, and the timing of ingestion with resistance training. According to the current knowledge, animal sources of protein are more likely to enhance muscle mass accretion than vegetable source of protein. Among essential amino acids, leucine is a key regulator of protein synthesis. The distribution of a sufficient amount of protein throughout three meals during the day (30 g/meal), as opposed to a large amount in one meal, is preferred. When resistance training and protein intake are combined, the most efficient timing for the ingestion is immediately (or within 2 h) after training. The stimulus of protein intake and physical activity promote protein synthesis and inhibit protein breakdown. In the long term, a positive balance between protein synthesis and breakdown would have significant impact on muscle mass, strength, physical capacity and quality of life.

180.1 Introduction

Skeletal-muscle-fiber atrophy, regardless of the underlying mechanisms, results from the imbalance between muscle-protein synthesis and breakdown. Over time, the age-associated bias toward skeletal muscle catabolism leads to a net loss of muscle proteins and to the associated decline in muscle mass and force production. Conversely, protein synthesis, which is dependent upon amino-acid availability, is the process that needs to be stimulated in order to promote muscle-mass gains. Therefore, the study of skeletal-muscle-protein metabolism is a very useful tool to assess the mechanism(s) that are involved in the loss of muscle mass with aging. For the past two decades, research pertaining to mechanisms and strategies aiming at the prevention and treatment of sarcopenia has received increasing attention. This chapter focuses on the potential role of nutrition, especially protein intake, in muscle size in the elderly.

180.2 Changes in Muscle Size with Aging

Cross-sectional area measures taken directly from whole muscles obtained post mortem showed an average reduction of 40% between 20 and 80 years of age. The average loss of muscle mass has been estimated to range between 3% and 8% per decade after the age of 30, and this rate of decline is even higher after the age of 60. Lean-muscle mass generally contributes up to ~50% of total body weight in young adults but declines with aging to 25% by the age of 75–80 years. The loss of muscle mass is typically concurrent with gains in fat mass (Fig. 180.1).

Several conditions are known to influence muscle size in older adults. Among those, cachexia represents the loss of muscle mass that is the result of a chronic inflammation state. Sarcopenia, however, is the loss of muscle mass and strength that occurs with aging and does not require the presence of an underlying illness. Finally, anorexia is also observed in older adults and leads to significant losses in muscle mass as well as in fat mass, resulting in an overall decrease in body weight. The prevalence of sarcopenia is approximately 13–24% for individuals younger than 70 years and up to 60% in individuals over 80 years of age. The number of individuals who fulfilled the definition of cachexia is about 20% of the total population (Tan et al. 2008), while anorexia is prevalent in about one-third of the population of older men and women (Thomas 2009). Most of the time, however, it is difficult to determine what condition exactly prevails, and it is possible that one individuals falls within more than one category. Regardless of the underlying condition, treatment will likely be to increase energy and protein intakes and to perform regular resistance training.

While cachexia may not be associated with changes in dietary intakes, sarcopenia is largely believed to occur following an inadequate protein intake. Anorexia is defined as an exaggerated restriction in energy intake, including proteins. Inadequate protein intakes fail to stimulate protein synthesis. Since sufficient amino acids need to be available at rest and following resistance exercise, a low intake would thus fail to provide the essential material needed to synthesize proteins and, in turn, muscle tissue. Because muscle mass is a dynamic tissue, synthesis needs to equal breakdown for muscle size to remain constant. If the proper amount of ‘building blocks’ is not provided, breakdown will surpass synthesis and, if protracted over time, muscle will decrease in size.

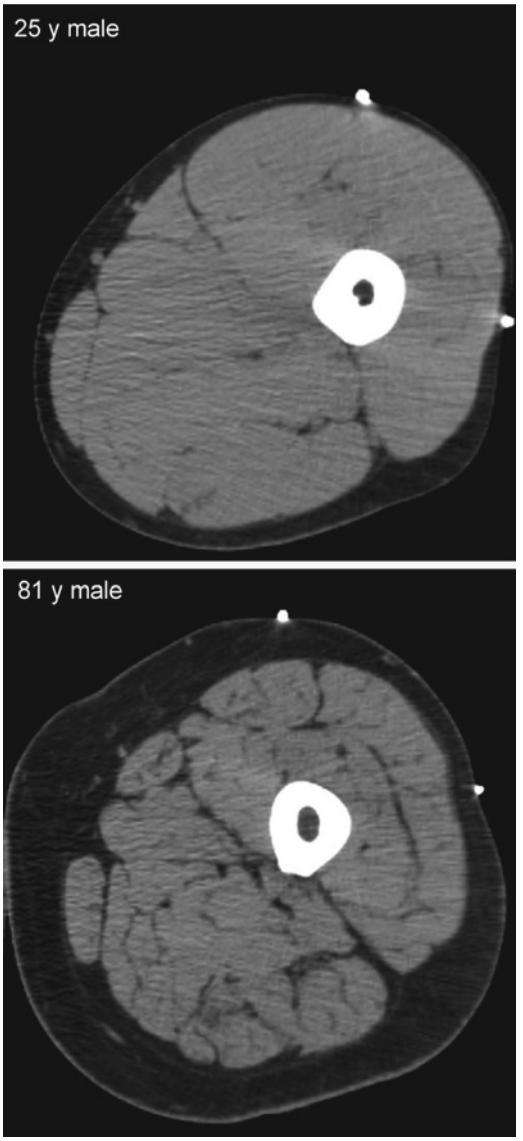

Fig. 180.1 Computed tomography (CT) scan of the upper leg (mid-thigh level) in a young and an old subject, matched for body mass and height. Computed tomography (CT) scan of the upper leg (mid-thigh level) in a young and an old subject, matched for body mass and height. Note the reduced muscle area, increased subcutaneous fat, and increased fat and connective-tissue infiltration into the muscle in the elderly subject (Source: Koopman and van Loon 2009)

180.3 Dietary Proteins

180.3.1 Protein Requirements in Aging

The adequacy of the recommended dietary allowance (RDA) for protein has been the subject of renewed debate in recent years. The current recommendation for protein intake for all men and women aged 19 years and older is 0.8 g/kg/day. It was established by the Institute of Medicine and based on short-duration nitrogen-balance studies in young adults. Much of the recent commentary has argued that the current RDA for protein, while fulfilling the criteria as the "minimal daily average dietary intake level that meets the nutritional requirements of nearly all healthy individuals," does not promote optimal health or protect elders from sarcopenic muscle loss. Although there is no

consensus on the degree to which dietary protein needs change with advancing age, there is general agreement that additional longer-term trials with defined health outcomes are needed to firmly establish the optimal protein intake range for various population groups. Nevertheless, experts agree that nitrogen balance may not be the best indicator of protein requirements in older adults and, for this reason, many studies suggest to increase the RDA to 1.0–1.3 g of protein/kg/day, especially in terms of maintaining muscle mass, strength, and metabolic function in aging populations or of 0.9 g/kg/day when combined with resistance training. That being said, there is actually no specific nutritional recommendations for protein intake in elderly individuals.

180.3.2 Essential and Non-essential Amino Acids

Each protein has its own specific number and sequence of amino acids. Amino acids can be classified as either essential or non-essential. Non-essential amino acids can be produced in the body from other proteins or carbohydrates. Essential amino acids, however, cannot be produced during metabolism by the body and therefore must be provided by the diet. Eight amino acids (leucine, isoleucine, valine, threonine, methionine, phenylalanine, tryptophan, and lysine) are considered essential for adults, while nine (those mentioned above plus histidine) are considered essential in specific conditions, including for children. Others (cystine, tyrosine, valine, arginine, alanine, aspartic acid, glutamic acid, glycine, proline, and serine) are considered non-essential.

Essential amino acids (EAAs), in particular, are able to stimulate muscle-protein synthesis in the elderly, whereas non-EAAs do not appear to provide such an effect. Among the EAAs, leucine has been shown to be a key regulator of muscle-protein synthesis in both humans and rats.

180.3.3 Biological Value

When a protein contains the essential amino acids in a proportion similar to that required by humans, it is considered to have a high biological value. When one or more essential amino acids are scarce, the protein is said to have low biological value. The amino acid that is in shortest supply in relation to need is termed the ‘limiting amino acid’. The limiting amino acid tends to be different in different proteins hence, when two foods providing vegetable protein are eaten at a meal, such as a cereal (e.g., bread) and a pulse (e.g., baked beans), the amino acids of one protein may compensate for the limitations of the other, resulting in a combination of higher biological value. High-biological-value proteins are provided by animal sources of protein, such as meat, poultry, fish, eggs, milk, cheese, and yogurt. Low-biological-value proteins are found in plants, legumes, grains, nuts, seeds, and vegetables.

180.3.4 Leucine

Leucine is an insulin secretagog with well-described effects on translation initiation and muscle-protein synthesis. With increasing age, muscle may become resistant to the stimulatory effects of normal postprandial concentrations of leucine. Although such a deficit could contribute to reduced muscle-protein anabolism and a loss of muscle mass, recent acute studies in both animals and humans suggest that the addition of supplemental leucine to normal mixed-nutrient meals may improve or normalize muscle-protein synthesis in aging muscle. In a follow-up study in older humans, the addition of leucine to a mixed-nutrient meal also resulted in a significant increase in muscle-protein synthesis.

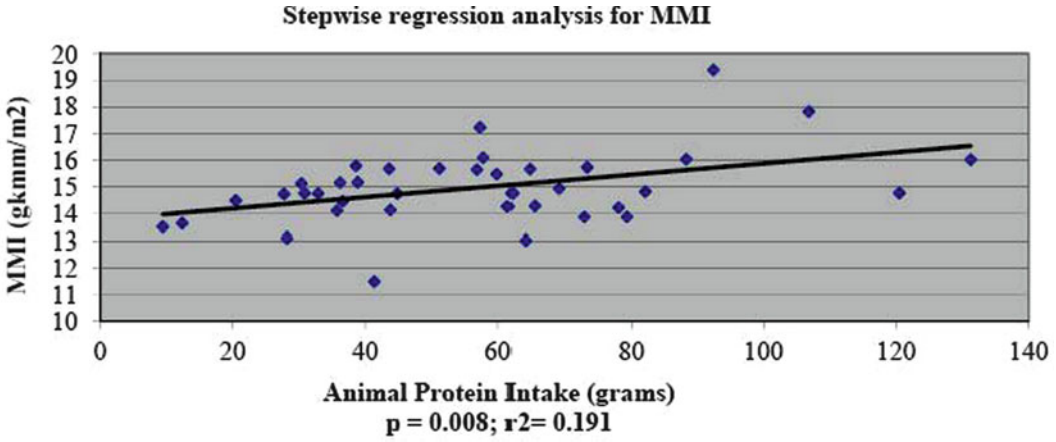

Fig. 180.2 Linear regression analysis between animal protein and muscle mass index (MMI). Individuals who consume more animal protein have a greater muscle mass index (MMI) than individuals displaying a lower animal-protein intake (Source: Lord et al. 2007)

180.3.5 Animal Versus Vegetable Proteins

Animal proteins contain all of the EAAs in appropriate ratios. Beef is a common source of dietary protein and contains all EAAs in a proportion similar to that found in human skeletal muscle. A standard serving of 113.4 g (4 oz) lean beef contains sufficient amino acids (~10 g EAAs) to increase mixed-muscle-protein synthesis by ~50% in both young and elderly men and women. Other foods, such as tuna fish, cheddar and cottage cheese, low-fat milk, and soy products, also contain significant amounts of EAAs (2–10 g of EAAs per portion; Canadian Nutrient File).

In addition to consuming inadequate amounts of total dietary protein, older adults may be at risk of consuming inadequate amounts of animal protein, a source of high-biological-value protein, because of age-associated factors including costs, difficulty in chewing, fear of consuming too much fat or cholesterol, and perceived intolerance of certain foods. Over a 3-year follow-up among older, community-dwelling adults, it was found that dietary-protein intake was associated with changes in lean mass and appendicular lean mass. Participants in the highest quintile of energy-adjusted protein intake lost ~40% less lean mass and appendicular lean mass than did those in the lowest quintile. Further, within a cohort of 2,732 participants, significant associations between animal-protein intake and changes in lean mass were found, but no such association was highlighted with vegetable protein. In a cohort of 12 elderly women, protein breakdown in the absorptive state was inhibited to a lesser extent in the high-vegetable-protein diet versus the high-animal-protein diet, resulting in less net protein synthesis during the high-vegetable-protein diet than during the high-animal-protein diet. In the same line, we observed that animal-protein intake was the only independent predictor of muscle mass in a group of 38 elderly women (Fig. 180.2). Hence, we and others showed a close relationship between animal-protein intake and lean mass but no such association with vegetable proteins. We also found that individuals with a high animal-protein diet displayed greater increases in muscle mass than those on a low animal-protein diet during resistance training (preliminary findings, to be published). The source of protein ingested thus seems to have an important role to play in the maintenance of muscle mass in older adults.

As far as we acknowledge, few studies have compared the effect of protein sources on muscle size of older adults. Further, no recent initiative has combined both nutritional and exercise intervention, despite the fact that these approaches benefit from a growing scientific support.

180.3.6 Mistaken Beliefs About Protein-Rich Food and CVD

The greatest obstacle to adequate consumption of dietary protein is the common belief that eating foods that contain cholesterol is a major factor in coronary heart disease; in fact, dietary risk factors for heart disease change with advancing age. Dietary cholesterol and other dietary fats become less of a factor in heart-disease risk than in young and middle ages, with cholesterol levels diminishing as people get older. Other risk factors become more highly correlated to coronary heart disease in later years, with systolic hypertension becoming a more reliable indicator of potential future coronary events. Diabetes tends to be a factor that contributes to the risk of a future heart attack. The combination of diabetes and systolic hypertension increases the likelihood that heart disease may contribute to premature death. The importance of dietary protein cannot be underestimated in the diets of older adults; inadequate protein intake contributes to a decrease in reserve capacity, increased skin fragility, decreased immune function, poor healing, and longer time to recuperation from illness.

180.3.7 Digestion Impairments

The presence of impairments in dietary protein digestion and/or amino-acid absorption might also be (partly) responsible for a blunted muscle-protein synthetic response to amino-acid/protein ingestion in the elderly. It has been proposed that the digestion rate of protein is an independent regulating factor of postprandial protein anabolism. Impaired protein digestion and/or absorption might attenuate and/or reduce the appearance rate of dietary amino acids in the circulation, thereby lowering the postprandial muscle-protein synthetic rate. Furthermore, amino-acid uptake in the splanchnic area has been shown to be elevated in the elderly, which implies that less of the ingested amino acids are available for muscle-protein synthesis.

Several recent studies showed that ingestion of a slowly digested protein (casein) leads to a more positive protein balance compared with the ingestion of a quickly digestible protein (whey) or a mixture of free amino acids in healthy, young subjects. However, in the elderly, the postprandial protein-anabolic response was observed to be the opposite. Ingestion of a fast protein (whey) was shown to result in greater net protein retention compared with a slow protein (casein), when provided in healthy, elderly men. The latter might be attributed to the proposed anabolic resistance of the muscle-protein synthetic machinery to become activated in elderly muscle (Table 180.1).

180.4 Nutritional Interventions Using Proteins and Muscle Mass

Several studies demonstrated that increased amino-acid- or protein availability can enhance muscle-protein synthesis and anabolism in young and older subjects. Based on these, it has been widely suggested that older adults should consume more proteins. Nevertheless, the use of high-protein diets alone (without exercise) to increase muscle mass and strength in the elderly has been mostly ineffective.

In agreement, studies utilizing a balanced meal consisting of protein, fat, and carbohydrate demonstrated no or few benefits from mixed nutritional supplements in older adults. Thus, when proteins are mixed with other nutrients, such as glucose and fat, it does not seem to lead to increases in muscle size. Consequently, the hypothesis that the muscle's ability to adapt to feeding may be impaired in aging under certain circumstances was raised. This blunted anabolic response is now believed to represent one of the key factors responsible for the age-related decline in skeletal muscle mass.

Table 180.1 Key facts about dietary proteins

The assembly of new proteins requires a source of amino acids. These 'building blocks' are generated by the digestion of proteins and their degradation within the cell.
Many cellular proteins are constantly degraded and resynthesized.
The main amino-acid reservoir in the body is skeletal muscle, which contains 50–75% of all proteins in the human body.
When muscle-protein synthesis is greater than muscle-protein degradation, the positive balance generates muscle gain. Inversely, a negative balance generates muscle loss.
The current recommended dietary allowance (RDA) for protein (0.8 g/kg/day) may not be sufficient in terms of preventing the loss of muscle mass with aging.
The non-essential amino acids (NEAA) represent the category of amino acids that can be synthesized in the body.
The essential amino acids (EAAs) are the amino acids that cannot be synthesized in the body and therefore must be provided by the diet.
The essential amino acids (EAAs) have been associated with a greater accretion of muscle mass in older adults.
Among the EAAs, leucine has been shown to be a key regulator of muscle tissue.
High-biological-value proteins are provided by animal sources of protein (meat, milk products, etc.), while low-biological-value proteins are provided by vegetable sources of protein (beans, soy products, etc.).
Animal sources of proteins represent a stronger predictor of muscle-mass gains than vegetable sources of proteins.
The importance of dietary protein cannot be underestimated in the diets of older adults, and it is important to promote proper information about protein-rich foods, cholesterol, and coronary heart diseases.
The digestion impairments often observed in older adults may cause a reduced rate of amino acids in the circulation and therefore may lower the amount of 'building blocks' available for muscle accretion.

This table lists the basic facts about dietary proteins related to amino acids, recommended dietary allowance, animal and vegetable sources of proteins, and the impact of digestion impairments

180.4.1 Meal Replacement

There are a number of reasons why these nutritional interventions may have failed to produce positive results. First, energy-dense supplements may act as a meal replacement, especially in elders, resulting in little or no change in daily protein intake and thus negate any anabolic effects associated with protein supplementation.

180.5 Nature and Amount of Protein Intake

Acknowledging that advancing in age is likely to induce a blunted anabolic response to the stimulus of protein ingestion, the optimal nature and amount of protein ingested both become of great interest.

180.5.1 Dose

Muscle-protein synthesis appears to respond in a dose-dependent manner to essential-amino-acid consumption. It was demonstrated that a dose of essential amino acids of approximately 10 g maximally stimulates rates of both myofibrillar and sarcoplasmic protein synthesis at rest. It was also found that 20 g of proteins (or approximately 8.5 g of essential amino acids) also maximally stimulates myofibrillar protein synthesis after resistance exercise, with minimal increases in amino-acid oxidation.

180.5.2 Potential Adverse Effects of High Protein Intake

Recommendations of protein intakes greater than the current RDAs, however, should be weighed against any potential increase in the risk of toxicity or impaired renal function. Although there is no official definition of what should be considered a *high-protein diet* (over 2.0 g of protein/kg/day has been suggested), a number of negative consequences have been associated with increased protein intake, most notably bone loss and renal impairment.

Because excess amino acids are deaminated and excreted by the kidney as urea, some view high-protein diets as "stressful" to the kidneys. In a recent review, it was concluded that there are no clear renal-related contraindications to high-protein diets in those with healthy renal function, but high-protein diets are contraindicated in those with renal impairment. It might be prudent to screen for proteinuria to rule out renal impairment in older individuals before they embark on diets more than double the RDA.

Still, the aging kidney appears to have a reduced capacity to excrete acid. Because bone acts as a buffer via bone resorption, the possible adverse consequences of the acid load from dietary protein is of particular concern in terms of bone health in older individuals. Recent studies have examined the association between dietary protein and skeletal health in elderly men and women. Some found a positive correlation between protein and bone mass density, while others found that higher protein intake was associated with increased fracture rates in the elderly.

Hence, proteins also interact with other nutrients to influence bone health. Adequate calcium is necessary to promote bone health with increased protein. When phosphorus intake increases with protein intake, calcium balance is preserved. Phosphorus intake generally increases with protein intake because many high-protein foods are also good sources of phosphorus. In addition, increased calcium excretion that might occur with high protein intakes might be attenuated with the consumption of alkali buffers, such as fruits and vegetables. It appears that, when taken in the context of a healthy diet (i.e., adequate in calcium and rich in fruits and vegetables), moderately high protein intake from commonly consumed foods is not harmful.

180.5.3 Is Supplementation Needed for Optimal Gain in Muscle Mass in the Elderly Population?

The rationale for the use of a nutritional supplement to slow or prevent sarcopenic muscle loss is based on the assumption that it will improve net muscle-protein synthesis above that afforded by regular meals alone. In some cases, protein–energy supplementation has been shown to be effective. Other trials, particularly those involving acutely ill or frail patients, have been unsuccessful. In some instances, protein supplementation increases satiety and simply replaces voluntary ingestion of regular menu items. For others, cost, availability, or medical complications, such as dysphagia or impaired kidney function, may limit the applicability or efficacy of protein-supplementation regimens. In such cases, maximizing protein anabolism while minimizing the amount or volume of supplementation ingested would be desirable.

180.5.4 A More Practical Approach: Protein-Rich Foods at Each Meal

It may not be appropriate to recommend the use of amino-acid supplements in older adults, and it is thus believed that the use of protein-rich food has several advantages over supplementation for

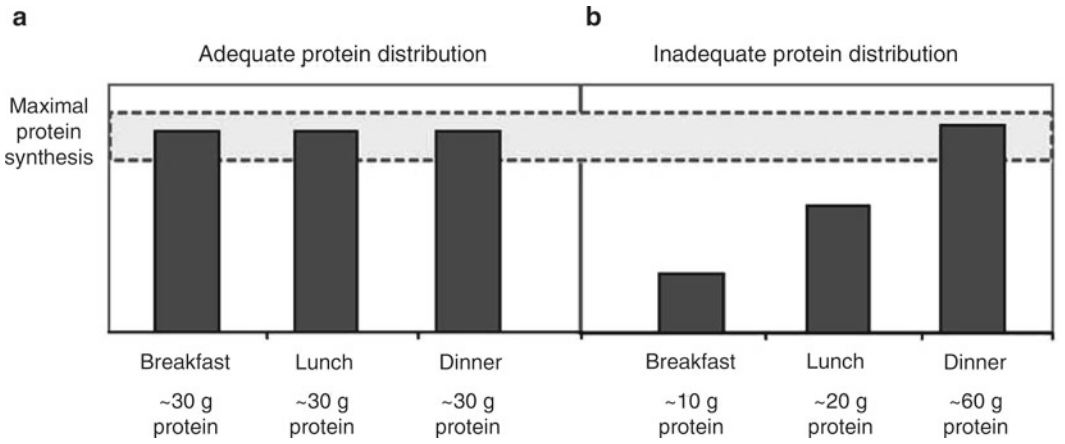

Fig. 180.3 A pictorial example of the proposed relationship between the amount of protein ingested per meal and the resultant anabolic response. (**a**) Ingestion of 90 g of protein, distributed evenly over three meals. (**b**) Ingestion of 90 g of protein unevenly distributed throughout the day. Stimulating muscle-protein synthesis to a maximal extent during the meals shown in Fig. 180.1a is more likely to provide a greater 24-h protein anabolic response than an unequal protein distribution (Source: Paddon-Jones and Rasmussen 2009)

several reasons: they are readily accessible, relatively inexpensive, palatable, and are not susceptible to engender secondary effects, such as an alteration in blood lipids and kidney problems, as supplements do.

As mentioned, numerous studies support the notion that ingestion of a sufficient amount of amino acids or protein results in similar benefits for muscle mass in young and elderly. However, several recent studies have adopted a more practical approach and have sought to examine the ability of protein-rich foods (e.g., milk) to stimulate muscle mass.

In the following sections, we argue that, whereas a modest increase in protein intake beyond 0.8 g/kg/day may indeed be beneficial for some elders, there is a greater need to specifically examine the dose and distribution of protein across each meal.

Although specialized supplementation with amino-acid products may be beneficial or necessary in specific elderly or clinical populations, the most practical means to favor muscle hypertrophy for the majority of older adults is to include a moderate serving of protein of high biological value during each meal. In fact, the distribution of proteins across three or more daily meals is highly important. For a 75-kg individual, the RDA represents 60 g of proteins/day, or if distributed evenly across three meals, 20 g of proteins/meal. A 20-g serving of most animal- or plant-based proteins contains 5–8 g of essential amino acids, which are the building material of muscles.

On the other hand, it was recently demonstrated that ingestion of a large, single 340-g serving of lean beef (90 g protein) in a cohort of healthy young and elderly individuals does not elicit a greater response than a serving one-third the size. Although this response may be influenced by physical activity (habitual and acute) and body size (it may be easier to increase muscle mass when it is initially low), the data suggest that, despite the additional protein and energy content, ingestion of more than 30 g of protein in a single meal may be useless. If we accept that 25–30 g of high-quality protein (~10 g EAA) is necessary to maximally stimulate skeletal-muscle protein synthesis, then it seems reasonable to suggest that ingesting this amount of high-quality protein at each meal could be a useful strategy to maintain muscle mass in the elderly (Fig. 180.3).

180.6 Exercise and Muscle-Protein Synthesis

Resistance-exercise- or strength training involves a relatively small number of muscle contractions against a heavy load. It has been shown that this type of exercise acutely increases whole-body insulin sensitivity, which can partly be attributed to a reduction in muscle-glycogen stores. However, the most apparent adaptation to resistance training is the increase in muscle mass and strength, or muscle hypertrophy.

The primary determinant of skeletal-muscle hypertrophy following resistance training is the external load that is applied. Several animal models have shown that loading results in an increased muscle mass and protein content per muscle. Increased loading amplifies muscle-protein synthesis and breakdown (protein synthesis is amplified by a greater extent than protein breakdown) and this training-induced elevation in muscle-protein turnover leads to a more rapid protein remodeling and, therefore, allows a faster adaptive response.

It generally takes weeks to months before these physical changes become apparent. The prolonged time course for hypertrophy is a reflection of a slow turnover rate of muscle protein – about 1% per day for contractile proteins. Muscle hypertrophy can only occur when muscle-protein synthesis is exceeding protein breakdown for a prolonged period of time.

Similar to feeding, the primary variable affected by resistance exercise is muscle-protein synthesis, which is stimulated 40–100% over and above resting levels with exercise. Although muscle-protein breakdown also rises with resistance exercise in the fasted state, the provision of amino acids or carbohydrate completely inhibits this response. A single session of resistance training accelerates the muscle-protein synthesis rate within 2–4 h. Accelerated protein-synthesis rates have been reported to last for 24–48 h. It could then be suggested that an appropriate frequency of exercise sessions would allow 1 day of rest between two training sessions.

180.7 Synergetic Use of Dietary Protein and Resistance Exercise

The synergetic effects of protein supplementation and resistance exercise on muscle mass and function in aging populations is unclear. Some authors showed that total daily protein intake does not influence muscle-mass gains when combined with resistance exercise. Despite numerous studies addressing the need for protein and/or carbohydrate ingestion before, during, and/or after exercise to allow net muscle-protein accretion, there is remarkably little evidence that dietary combined interventions can further augment the adaptive response to prolonged exercise training in the elderly. For example, dietary intervention using supplementation with carbohydrate, protein and fat, protein or branched chain amino acids (BCAAs), or by including changes in meal protein content have failed to promote muscle hypertrophy in response to exercise training.

When habitual dietary protein intake is standardized at 0.9 g/kg/day, exercise-induced increases in muscle mass become apparent, and a further increase in protein intake does not seem to have any additional effect. The latter might explain why most studies fail to observe any additional benefit of nutritional combined intervention on the skeletal-muscle adaptive response to prolonged resistance-type exercise training in the elderly.

However, both exercise and nutrition are required to obtain a positive protein balance and, as such, allow muscle hypertrophy. Although a single bout of resistance-type exercise stimulates muscle-protein synthesis to a greater extent than protein degradation, net muscle-protein balance remains negative in the absence of nutrient intake. Likewise, it appears that diet-derived amino acids

act as a prerequisite for muscle-protein synthesis. As mentioned in a recent review, the most important anabolic stimulus for muscle proteins is nutrient intake because it allows for replacement of the essential amino acids (EAAs) lost through oxidation. Carbohydrate and/or protein/amino-acid ingestion during recovery from exercise forms an effective strategy to stimulate muscle-protein synthesis, inhibit protein degradation, and, as such, to enable net muscle-protein accretion. Such an effect has been demonstrated both with the consumption of crystalline amino acids as well as whole proteins.

The absence of any benefits of nutritional combined intervention may also be attributed to a less-than-optimal timing of amino acid and/or protein supplementation that was applied (which should be immediately after each bout of resistance-type exercise, as opposed to before, during, or 2 h later).

180.7.1 The Timing of Protein Intake and Resistance Exercise

We know that, for resistance exercise to result in a positive net balance, feeding needs to occur sometime within the few hours following exercise. In fact, several studies suggest that provision of protein within the acute period following exercise may be quite important for hypertrophy. Most evidence indicates that the period immediately post exercise (or at least within approximately 2 h) produces a muscle environment that favors augmented protein synthesis over and above that provided by amino acids/protein alone. Although some controversy remains, chronic studies support this notion showing that individuals receiving protein in the post-exercise period gain greater lean mass compared with those receiving nothing or simply energy as carbohydrate, even in older adults. Recent evidence suggests that the type (i.e., source) of protein consumed may as well affect the anabolic response to resistance exercise.

180.7.2 Sources of Protein and Resistance Exercise

Differences in lean-mass gains with resistance training have also been observed when comparing other apparently complete and high-quality protein sources, such as whey and soy. Ingestion of milk, whey, casein, and soy following resistance exercise has been reported to stimulate muscle-protein synthesis when consumed either in isolation or in liquid supplements. It appears from a series of studies that not all 'high-quality' proteins are equal in how they are digested and how this variable affects protein retention. On examining the findings of these studies collectively, the results appear to indicate that milk proteins are superior to soy in supporting muscle-mass accretion with resistance training and that both are superior to carbohydrate (i.e., energy) alone (Fig. 180.4). It was hypothesized that these findings resulted because of minor differences in amino-acid composition and possibly protein-digestion rate. Such an effect could be because of the difference in energy content or how whole milk might be digested differently as versus fat-free milk. Data demonstrating how milk and soy proteins are partitioned for use between splanchnic and peripheral (i.e., muscle) tissues have shown that soy proteins are preferentially directed toward splanchnic-protein synthesis and are converted to urea to a greater extent than milk proteins.

Resistance exercise appears to augment the effect of whey protein in supporting lean-mass gains when compared to either casein or milk. In addition to digestion rate, the mechanism by which whey more effectively promotes protein gain than casein in the elderly may also be related to the slightly higher leucine content of whey, especially if the 'leucine trigger' has a higher set-point for older individuals. It was also speculated that the ability of whey to stimulate protein synthesis by either suppressing inflammation or possibly activation of satellite cells in aged muscle may also be important (Table 180.2).

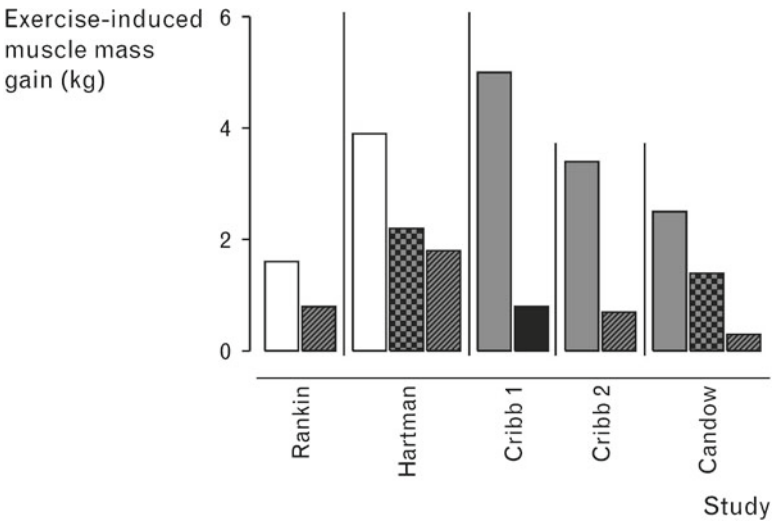

Fig. 180.4 Resistance training-induced changes in lean mass in studies of patients receiving supplemental protein sources – soy, whey, or casein, or an energy-matched carbohydrate drink. Values are presented as the absolute exercise-induced mean gain (±SD) in lean mass. The studies included are those of Rankin et al. (2004), Hartman et al. (2007), Cribb et al. (2006, 2007), and Candow et al. (2006) (Source: Tang and Phillips 2009)

Table 180.2 Key points of dietary protein with and without exercise to promote muscle hypertrophy in older adults

The muscle-protein synthetic response to the ingestion of a mixed-nutrient meal is attenuated in the elderly, and this represents one of the key factors responsible for the age-related decline in skeletal-muscle mass.
Protein supplementation may act as meal replacement, resulting in little or no change in daily protein intake.
Some potential adverse effects have been identified with high protein intake (over 2.0 g of protein/kg/day), most notably bone loss and renal impairment.
A novel dietary approach to prevent or slow down muscle loss suggests ingesting a sufficient amount of protein divided over a maximum of three meals per day. That represents ~25–30 g of high quality proteins (~10 g EAA) per meal.
Physical activity, in particular resistance-type exercise, is a powerful stimulus to promote net muscle-protein anabolism, resulting in specific metabolic and morphological adaptations in skeletal-muscle tissue.
Resistance-type exercise training can effectively increase muscle strength, muscle mass, and, as such, improve physical performance and functional capacity in the elderly.
Resistance training can promote muscle hypertrophy in older adults but amino acids/protein ingestion is still required to produce an anabolic effect.
The available data suggest that certain amount of amino acids/proteins should be ingested (0.9 g/kg/day) when combined with resistance training and that any additional intake would not produce further improvements.
Ingesting proteins within 2 h after resistance exercise has been identified as the best timing to maximizing post-exercise anabolism.
Several studies have indicated that high-quality proteins, such as milk, whey, casein, and soy, can support muscle-protein synthesis.
Differences in the rate of digestion of these high-quality proteins can modulate the muscle-protein synthesis response both after an acute bout of resistance exercise and following long-term training.

This table summarizes the main elements related to dietary protein intake and exercise to promote muscle hypertrophy in older adults

180.8 Conclusion

Aging is associated with a reduced ability to muscle hypertrophy in response to feeding. Among the conditions to this response, sources and amounts of proteins are particularly important. To promote optimal health or protect elders from muscle loss, it might be necessary to increase the current RDA up to 1.0 g/kg/day. A novel dietary approach to favor muscle mass is to ingest a sufficient amount of protein divided over a maximum of three meals per day. Resistance-type exercise is also a powerful stimulus to promote morphological adaptations in skeletal-muscle tissue. Such exercise training can effectively increase muscle strength and muscle mass, and, as such, improve physical performance and functional capacity. Altogether, the available data suggest that a certain amount of amino acids/proteins should be ingested (0.9 g/kg/day was suggested) when combined with resistance training and that any additional intake would not produce further improvements. Sufficient habitual protein intake combined with a normal meal pattern (i.e., providing ample protein three times per day) will allow substantial gains in muscle mass and strength following resistance-type exercise training in the elderly.

180.9 Applications to Other Areas of Health and Disease

180.9.1 Physical Capacity

Because muscle mass and strength are major predictors of physical capacity in older individuals, their evolution will greatly determine the trajectory of physical independence. In that sense, lifelong adequate consumption of proteins is an important component of physical dependency and quality of life.

180.9.2 Insulin Sensitivity

Although adding carbohydrate to an amino-acid meal (as in a normal mixed-nutrient meal) enhances muscle-protein synthesis in young subjects, no such results were found in older subjects. This is potentially due to insulin resistance of muscle-protein metabolism in aging, independent of glucose tolerance. This occurs possibly through an exercise-reversible reduced vasodilatory response of older human muscle to insulin, thus decreasing nutrient flow and availability. On the other hand, resistance exercise increases insulin sensitivity and improving this physiological function has been associated with an improved anabolic response of muscle proteins to insulin in older subjects. Therefore, it is possible that combining exercise with EAA would maximize its anabolic effect and then create substantial gains in muscle mass compared with exercise alone.

180.9.3 Frailty

Frailty is the sum of several conditions, including muscle weakness and/or sarcopenia. The functional benefits of resistance exercise training in a large-scale trial of 72–98-year-old physically frail nursing-home residents showed that lower-extremity resistance exercise training increased muscle

strength (113%), gait velocity (12%), stair-climbing power (28%), level of spontaneous physical activity, and thigh-muscle cross-sectional area (2.7%). In addition to physical dependence, frailty unfortunately leads to institutionalization. Again, adequate consumption of proteins over life can significantly retard institutionalization.

Summary Points

- The loss of muscle mass is typically observed with aging and is concurrent with gains in fat mass.
- Essential amino acids (EAAs), in particular, are able to stimulate muscle-protein synthesis in the elderly, whereas non-EAAs do not appear to provide such effects.
- Among the EAAs, leucine has been shown to be a key regulator of muscle-protein synthesis.
- Some studies have reported protein supplementation as an ineffective method of enhancing muscle-protein synthesis. The most reported reasons to explain that are the meal replacement theory, the blunted anabolic response to a mixed-nutrient meal, and the mistaken beliefs about protein-rich food and CVD.
- A dose of EAAs of approximately 10 g maximally stimulates rates of protein synthesis at rest.
- The current RDA for protein (0.8 g/kg/day) might not be sufficient in terms of promoting optimal health or protecting elders from sarcopenic muscle loss. Some authors have proposed that protein requirements for older individuals may be either greater than 1.0 g/kg/day or of 0.9 g/kg/day when combined with resistance training.
- A novel dietary approach to prevent or slow down muscle loss suggested ingesting a sufficient amount of protein with each meal (as opposed to a large amount of protein in one meal or in supplementation).
- There are compelling evidences supporting the efficacy of physical activity, especially resistance training, to counter the loss of muscle mass with aging.
- Resistance exercise performed in the absence of an increase in amino-acid availability improves net muscle-protein balance, but there remains a net loss of muscle protein.
- When resistance exercise is accompanied by an increased availability of amino acids, the result is a synergistic stimulation of protein synthesis and muscle accretion occurs.

Chapter 181
Anthropometry and the Prevalence of Child Protein–Energy Malnutrition in China and Japan

Liubai Li, Hui Li, and Hiroshi Ushijima

Abstract Protein–energy malnutrition (PEM) remains the top leading cause of death in children in the world. Stunting, underweight, and wasting are common indicators for estimating the prevalence of PEM. Anthropometrical indices (length/height-for-age, weight-for-age and weight-for-length/height) and BMI (body mass index)-for-age of children (0–18) are prerequisites for malnutrition screening. This chapter presents PEM relating anthropometrical indices (in *Z*-scores and percentiles) and cut-offs for PEM in Chinese and Japanese children. Most data were based on national data sets, and the cut-offs for PEM were recommended by the academic associations in the two countries.

Prevalence of stunting, wasting, and underweight in 2002 was 14.3%, 2.5%, and 7.8%, respectively, in Chinese children under 5 years old as estimated by the *Z*-score criterion recommended by the World Health Organization (WHO) in 1978. For children and adolescents aged 7–17 years, the prevalence of stunting and wasting was estimated as 2.7% and 10.5% in urban boys and 3.0% and 9.7% in urban girls in rural areas, the prevalence was 7.4% and 14.6% in boys, and 7.7% and 11.5% in girls, as estimated by the new WHO criterion (2006). Although the nutritional status in Chinese children has improved remarkably in the past two decades, it still remains a problem – especially in the rural areas of Western China. In Japan, the prevalence of thinness in boys and girls has been very low (under 4%) in the past three decades as estimated by the percentage of standard weight-for-height (POW).

181.1 Introduction

Protein–energy malnutrition (PEM) in children is a serious public-health problem that has been linked to a substantial increase in the risk of mortality and morbidity. It remains the leading cause of death in children in the world (WHO 2008) and was associated with 54% of child deaths (10.8 million children) in developing countries in 2001. (WHO 2004) In 2004, an estimated 32% of children aged less than 5 years were stunted and 20% were wasted (WHO 2008).

Stunting, underweight, and wasting are common indicators for estimating the prevalence of PEM. To assess the level of malnutrition, a child's height (or length) and weight anthropometric parameters are measured and compared with an internationally accepted reference standard (WHO 2006) or a national standard.

In this article, we report the prevalence of PEM in Chinese and Japanese children and present the anthropometric indicators and the relating cutoffs for malnutrition identification.

181.2 International Definition of Child PEM

Box 181.1 shows the internationally accepted definitions and the meaning of the indices for child PEM.

Box 181.1 Child PEM Screening Criterion

There are three primary anthropometric indices for child PEM screening: stunting, wasting, and underweight.
Stunting: Height-for-age below -2 standard deviation (SD) or -2 *Z*-score of the reference;
Underweight: Weight-for-age below -2 SD of the reference; and
Wasting: Weight-for-height below -2 SD of the reference.

Each indicator signals distinct biological processes.

Stunting reflects a failure to reach linear growth potential as a result of suboptimal health and/or nutritional conditions; *wasting* describes recent and significant weight loss, usually as a consequence of famine or severe disease; and *underweight*, or low weight-for-age, reflects both wasting and stunting and is thus a synthesis of the current status of body proportion and linear growth (De Onis et al. 1993; WHO 1995).

Body Mass Index (BMI), expressed as body weight (kg) divided by the square of height (m) (weight (kg)/height $[m]^2$), is also used in malnutrition definition for children in some age groups (WHO 2006). For adolescents, the WHO recommends using BMI-for-age as the criterion in defining PEM. The diagnostic criterion for defining *stunting in adolescents* is either a height-for-age less than the third percentile of the WHO reference data or less than -2 *Z*-score.

Undernutrition or thinness in adolescence is indicated by a BMI less than the fifth percentile of the reference data (WHO 1995).

181.3 Protein–Energy Malnutrition in China

181.3.1 Prevalence of Child PEM in China

The 2002 China National Health and Nutrition Survey (2002 CHNS) report analyzed the prevalence of PEM in Chinese children aged under 5 years using the WHO-recommended *Z*-score criteria (De Onis 1996). A data set of 15,851 urban and rural children aged less than 5 years was used. Figure 181.1 displays the rate of PEM in 2002 and 1992 (Wang 2005). Dramatic improvements occurred between 1992 and 2002. In 2005, nutrition-tracking survey data sets for 15,987 children aged under 5 years (50.4% were boys, 10,468 were rural children) were analyzed using the 2006 WHO child-growth standards (WHO 2006). Prevalence of stunting and underweight were 16.3% and 6.1%, respectively (Yuying 2007).

In China, there were significant differences in malnutrition prevalences between the urban and rural areas, with the rural area having higher malnutrition rates. In 2002, the prevalence of malnutrition among children under 5 years in the six-class economic areas was estimated by using the 2002 CHNS data sets and the reference recommended by WHO (De Onis 1996) (Fig. 181.2). Prevalence of malnutrition was different in the six areas, with big cities demonstrating the lowest (stunting was

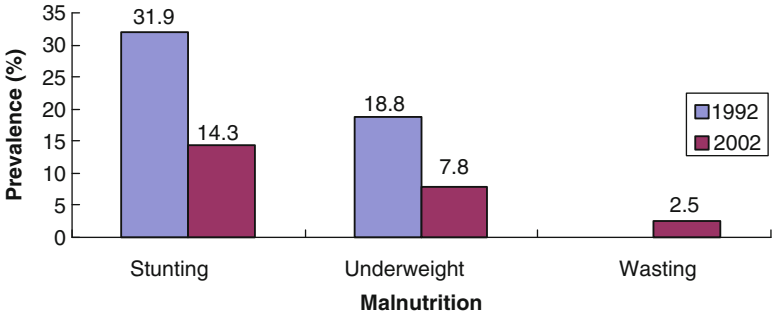

Fig. 181.1 Prevalence of malnutrition in Chinese children aged less than 5 years between 1992 and 2002. Prevalence of stunting and underweight in children aged less than 5 years decreased remarkably between 1992 and 2002 (Wang 2005)

Fig. 181.2 Prevalence of malnutrition in Chinese children aged less than 5 years in the six-class areas in 2002. The prevalence of malnutrition was higher in rural areas than that in urban areas, with the poorest area having the highest rate of malnutrition. Sample sizes were 3,279 in big cities, 3,747 in middle and small cities, 2,001 in Rural I, 2,177 in Rural II, 2,119 in Rural III, and 2,528 in Rural IV (Data source: Zhihong 2007)

Fig. 181.3 Prevalence of malnutrition in urban Chinese children aged 7–17 years between 1985 and 2005. The prevalence of malnutrition decreased remarkably from 1985 to 2005, but wasting still remained very high in 2005. The sample sizes were 204,727 in 1985 and 116,720 in 2005 (Cheng-ye 2008)

Fig. 181.4 Prevalence of malnutrition in rural Chinese children aged 7–17 years between 1985 and 2005. The prevalence of malnutrition decreased remarkably from 1985 but wasting still remained very high in 2005. The sample sizes were 205,219 in 1985 and 116,423 in 2005 (Cheng-ye 2009)

1.6%) and the rural IV (29.3%) the highest (Zhihong 2007). The stunting status of children under 5 years in 50 counties of Midwestern China (poorer areas) was 30.2% in 2005, as evaluated using the 2006 WHO Child Growth Standards (Wen-yuan 2008).

For schoolchildren, the prevalence of PEM in urban and rural areas was also evaluated using national data sets on student health survey and the new WHO criterion (WHO 2006). Stunting and wasting were screened by using height-for-age and BMI-for-age cutoffs, respectively. The results are shown in Figs. 181.3 and 181.4. Despite significant improvements in nutrition status during the recent 20 years, wasting was still a health problem in Chinese urban and rural students, with that in boys being relatively higher than in girls and in adolescents than in children (Cheng-ye 2008, 2009).

Socioeconomic developments in the recent two to three decades in China have improved the nutritional status in Chinese children. The overall prevalence of PEM decreased remarkably. However, nutrition and health inequity remain due to differences in natural conditions, economic developments, and family socioeconomic status. Rural children have a far higher rate of malnutrition than urban children, with the highest rate in Western China.

181.3.2 Anthropometry of Chinese Children and the Criterion for Undernutrition Identification

There are two ways to express how far an individual's nutritional status deviates from the reference population. It is expressed either as a percentage of the reference value, or as a *Z*-score. Tables 181.1–181.4 display *Z*-scores and percentiles of some anthropometric index (length/height-for-age, weight-for-age, and weight-for-length/height) references in Chinese children aged under 7 years. The data sets were constructed from well-nourished, healthy, urban children (healthy reference

population with both of the prevalence of malnutrition and overweight less than 5%) in nine Chinese cities in 2005 (Ministry of Health of China 2009).

Tables 181.5–181.7 display the mean (SD) and percentiles of height-for-age, weight-for-age, and BMI-for-age in Chinese children and adolescents aged over 6 years. The data sets were based on the anthropometric measurements in Han ethnic students of Beijing in The National Physical Fitness and Health Status Survey of Chinese Students in 2000. A weight-for-height criterion has long been used in PEM identification for Chinese schoolchildren aged over 6 years in China. However, it is

Table 181.3 Weight-for-length for Chinese children aged under 7 years (45–105 cm) (kg) (used in 0–3 year-old children) (Data source: Ministry of Health of China et al. (2009). With permission)

Data were from samples of Beijing children in 2000

181.4 Protein–Energy Malnutrition in Japanese Children

181.4.1 Prevalence of Malnutrition

Malnutrition in Japanese children has long been kept very low (less than 4%) since 1980. For children and adolescents aged over 5 years, the prevalence of PEM (thinness) in 2008 was estimated using the data sets of the annual school health check. It was less than 4% in all children (Fig. 181.5). Thinness in children was defined as body weight less than 20% of the standard weight-for-height (criterion for Japanese). Secular trends in thinness have also been below 4% since 1980 (School health statistics 2008).

181.4.2 Risk Factors of Child Malnutrition in Japan

Although there are many reasons for the thinness of Japanese children, voluntary dieting cannot be excluded from the reasons for the malnutrition of adolescent Japanese girls. In general, more Japanese adolescents diet for weight management and control. In addition, fad foods and an unhealthy eating pattern might have contributed to the thinness of Japanese children and adolescents.

181.4.3 Defining Criterion of PEM for Japanese Children

For defining malnutrition in childhood, the percentage overweight (POW), or percentage of standard weight-for-height, has been adopted as a parameter in screening malnutrition in all children. POW is based on the differences between the measured weight and the age- and sex-specific standard weight-for-height (Please see calculation in Box 181.2). The undernutrition/thinness is defined as *POW < 20%* for Japanese children of all ages (School health statistics 2008).

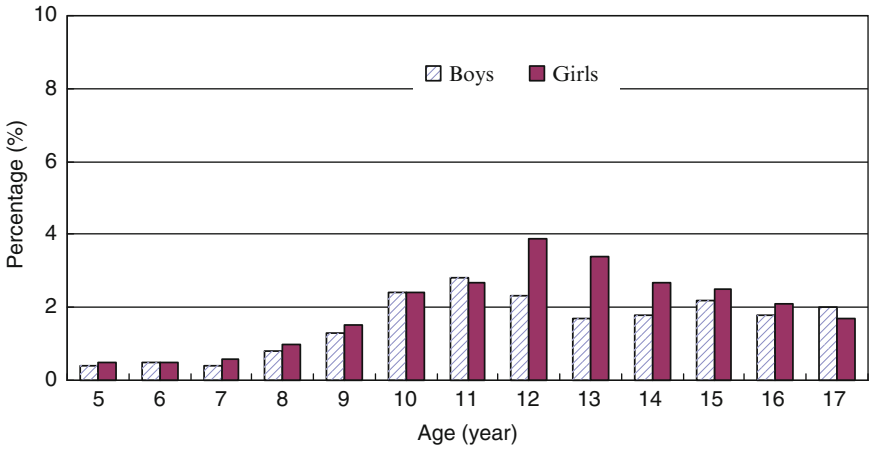

Fig. 181.5 Prevalence of thinness in Japanese children aged 5–17 years in 2008. Prevalence of thinness was less than 4% in Japanese children aged 5–17 years in 2008 (School health statistics 2008)

Box 181.2 Calculation for POW (%OW)

$$\text{Percentage overweight}\left(\text{POW},\%\text{OW}\right)=100\cdot\ (\text{measured weight}-\text{standard weight for height})\ /\ \text{standard weight for height}$$

Standard weight-for-height can be calculated by either using the following formula or searching from the website of the Japanese government (School health statistics 2008)

$$\text{Standard weight - for - height}\left(\text{kg}\right)=a\cdot\ \text{measured height}\ \left(\text{cm}\right)-b$$

The constants '*a*' and '*b*' are coefficients for calculating the *standard weight-for-height (kg)*. The values of '*a*' and '*b*' for children of a specific age and gender can be searched from the website of the Japanese government (School health statistics 2008).

181.4.4 Anthropometry of Japanese Children

The websites of the Japanese government display the percentiles for the length/height-for-age and the weight-for-age for Japanese children and the standard weight-for-height (Department of Maternal and Child Health 2000; School health statistics 2008).

Tables 181.8 and 181.9 display the mean (SD) and percentiles of BMI for Japanese children aged two to 18 years (Inokuchi1 2007).

Table 181.8 Mean (SD) and percentile references of BMI for Japanese boys aged 2–18 years (BMI in kg/m^2) (Data source: Inokuchi1 et al. (2007). With permission)

181.5 Applications to Other Areas of Health and Disease

Assessment of nutritional status is the primary step in the evaluation of all children whose growth differs from the norm and should be an integral part of the evaluation and management of all children with acute and chronic diseases. Almost all chronic medical conditions in a child can result in poor weight gain through a number of factors. These include decreased energy/nutrient intake (anorexia, food withholding, and altered mental status), increased caloric requirements (fever and infections), and/or inefficient utilization of ingested calories and nutrients (maldigestion and malabsorption). The common factors and diseases relating to child malnutrition are:

- Any chronic medical condition resulting in:
  - Inadequate intake (e.g., swallowing dysfunction and anorexia);
  - Increased metabolic rate (e.g., congenital heart disease and fevers); and
  - Maldigestion or malabsorption (e.g., AIDS and celiac disease);
- Premature birth (e.g., intrauterine growth retardation);
- Developmental delay;
- Congenital anomalies;
- Intrauterine toxin exposure (e.g., alcohol);
- Plumbism and/or anemia; and
- Lead intoxication.

181.6 Practical Methods and Techniques in Calculating Percentages and *Z*-Scores

Calculation of percentage and *Z*-scores of the anthropometric indices is the basic step in the nutrition evaluation of an individual or a group. Box 181.3 presents the method.

Box 181.3 Calculating Percentages and *Z*-Scores

Percentage of the median:

The percentage of the median is calculated as follows:

$$\text{Percentage} = \left[\text{observed value/median reference value}\right] \cdot 100$$

For example, if the child's weight is 8.0 kg and the reference value is 10 kg, the percentage of the median is (8.0 kg/10 kg) × 100 = 80%.

Z-score (Standard Deviation):

The *Z*-score of an observed point is calculated as follows:

$$Z\text{ - score} = [(\text{observed value}) - (\text{median reference value})] / Z\text{ - score of the reference population}$$

Summary Points

- Protein–energy malnutrition remains a problem in Chinese children, especially in rural areas. But, the prevalence of child malnutrition has been kept very low in Japan.
- An appropriate mix of nutrition-related indicators should be selected to measure nutritional status as well as to identify causes of malnutrition.
- The most commonly used anthropometric indicators of PEM in children are wasting, stunting, and underweight, which are determined respectively by low weight-for-height, low height-for-age, and low weight-for-age. Low body mass index (BMI) can be used for some age groups in children.
- Identification of PEM in Chinese children is in accordance with the WHO (2006) recommendations.
- Identification of child protein–energy malnutrition in Japan is based on percentage overweight (POW).
- Ranges of malnutrition vary greatly across populations. Thresholds may be used for guidance by decision makers to select nutrition-related interventions. However, they must be used with caution, taking into consideration contextual and trend analyses.
- Anthropometric measurements can assess growth cross-sectionally or longitudinally. If children are measured once, their growth status for age can be assessed by comparing this measurement with the appropriate reference. If children are measured more than once, growth-velocity data reflecting change can be obtained.

Key Points or Features of Moderate and Severe Malnutrition

Stunting, wasting, and underweight can have different levels of severity. Box 181.4 describes the cutoff points for different levels of PEM in children.

Box 181.4 The cutoff points for different levels of PEM

Index	Level of severity	Cutoff points
Stunting	Severe growth failure	Height-for-age index below -3 *Z*-scores or below 80% of the median
	Moderate growth failure	Height-for-age index between -2 and -3 *Z*-scores or between 80% and 90% of the median
Wasting	Severe acute malnutrition	Weight-for-height index below -3 *Z*-scores or below 70% of the median and/or presence of bilateral edema
	Moderate acute malnutrition	Weight-for-height index between -2 and -3 *Z*-scores or below 70% and 80% of the median
Underweight	Severe underweight	Weight-for-age index below -3 *Z*-scores or below 70% of the median
	Moderate underweight	Weight-for-age index between -2 and -3 *Z*-scores or between 70% and 80% of the median

Biomechanical and Ergonomic Aspects

Chapter 182
Anthropometry in Bipedal Locomotion: The Link Between Anatomy and Gait

Franck Multon, Guillaume Nicolas, Robin Huw Crompton, Kristiaan D'Août, and Gilles Berillon

Abstract Bipedal locomotion is a key point in many scientific domains including medicine, palaeoanthropology, biomechanics, physiology, neuroscience, robotics, computer animation and so on. The link between an anatomical property and its impact on gait relies on accurate anthropometrical data. While human bipedal locomotion and animal motion in general is often well depicted biomechanically, neurologically or physiologically, relatively little is known about the relationships between the normal bipedal gaits and the anthropometric data and its variation. In this chapter, we aim at describing recent work and knowledge concerning this problem. With regard to bipedal gait, we believe that considering humans among primates in a wider comparative framework would enable us to identify the fundamental relationship between anthropometry and biomechanics. It provides us with an original and complementary point of views to other approaches addressed in this volume. Indeed, it provides us with enlarged fundamental knowledge that could be reused in many application domains, such as explaining gait patterns in normal and pathological human locomotion. In this chapter, we propose a synthesis of relevant contributions addressing this assumption for the specific case of human and non-human primates bipedal gaits. We will address the common features and the main differences of this movement from the anthropometrical and functional point of views. General bipedal gait patterns are depicted with regards to biomechanical parameters including kinematics, dynamics and energy expenditure. We thus identify common properties of bipedal locomotion that seem to be independent from anatomical parameters. We conclude this chapter by describing modern approaches based on computer simulation in order to identify the use of anthropometry in understanding normal and pathological gait in humans.

182.1 Introduction

Bipedal locomotion is a key point in many scientific domains including medicine, palaeoanthropology, biomechanics, physiology, neuroscience, robotics, computer animation and so on. The link between an anatomical property and its impact on gait relies on accurate anthropometrical data. While human bipedal locomotion and animal motion in general are often well-depicted biomechanically, neurologically or physiologically, relatively little is known about the relationships between locomotor habits and anatomical traits. In this chapter, we aim at describing recent work and knowledge concerning this problem. We believe that considering humans among primates in a wider comparative framework would enable us to identify the fundamental relationship between anthropometry and biomechanics. It provides us with an original and complementary point of view to other approaches addressed in this volume. Indeed, it provides us with enlarged fundamental knowledge that could be reused in many application domains, such as explaining gait patterns in normal and pathological human locomotion.

Indeed, bipedal walking is a locomotor mode that is used by numerous taxa that are phylogenetically distant from each other, from humans (committed bipedal with a hyperspecialised locomotor anatomy) to macaques or baboons (anatomically specialised to terrestrial quadrupedalism). Analyses demonstrate that bipedal walking in primates differs both kinematically and kinetically from one taxon to another.

In this chapter, we propose a synthesis of relevant contributions addressing this assumption for the specific case of human and non-human primate bipedal gaits. We will address the common features and the main differences of this movement from the anthropometrical and functional point of view. General locomotor patterns are depicted with regard to biomechanical parameters including kinematics, dynamics and energy expenditure. We thus identify common properties of bipedal locomotion that seem to be independent from anatomical parameters. We conclude this chapter by describing modern approaches based on computer simulation in order to identify the use of anthropometry in understanding normal and pathological gait in humans.

182.2 (Comparative) Locomotor Anatomies of Human and Non-human Primates: Habitual Versus Facultative Bipedalism

The literature on primate locomotor anatomy has been steadily increasing, but studies focussing on bipedal locomotion are relatively limited. We will focus on the subset of morphological features associated with this particular locomotor mode.

182.2.1 Comparative Anatomies and Bipedal Walks

A prerequisite for static equilibrium is that the vertical projection of the body centre of mass should lie within the support polygon. The latter is strongly reduced in the case of bipedal locomotion, making static equilibrium (and probably, dynamic equilibrium) more challenging. In humans, a unique body arrangement is associated with balance and upright posture (e.g. Kummer 1962): a head positioned obliquely onto the neck, an upright trunk, extended hip joints, adducted and extended knee joints, a horizontal talocrural joint axis, a stiff plantigrade foot and a centre of gravity located in the mid-pelvis during habitual stance.

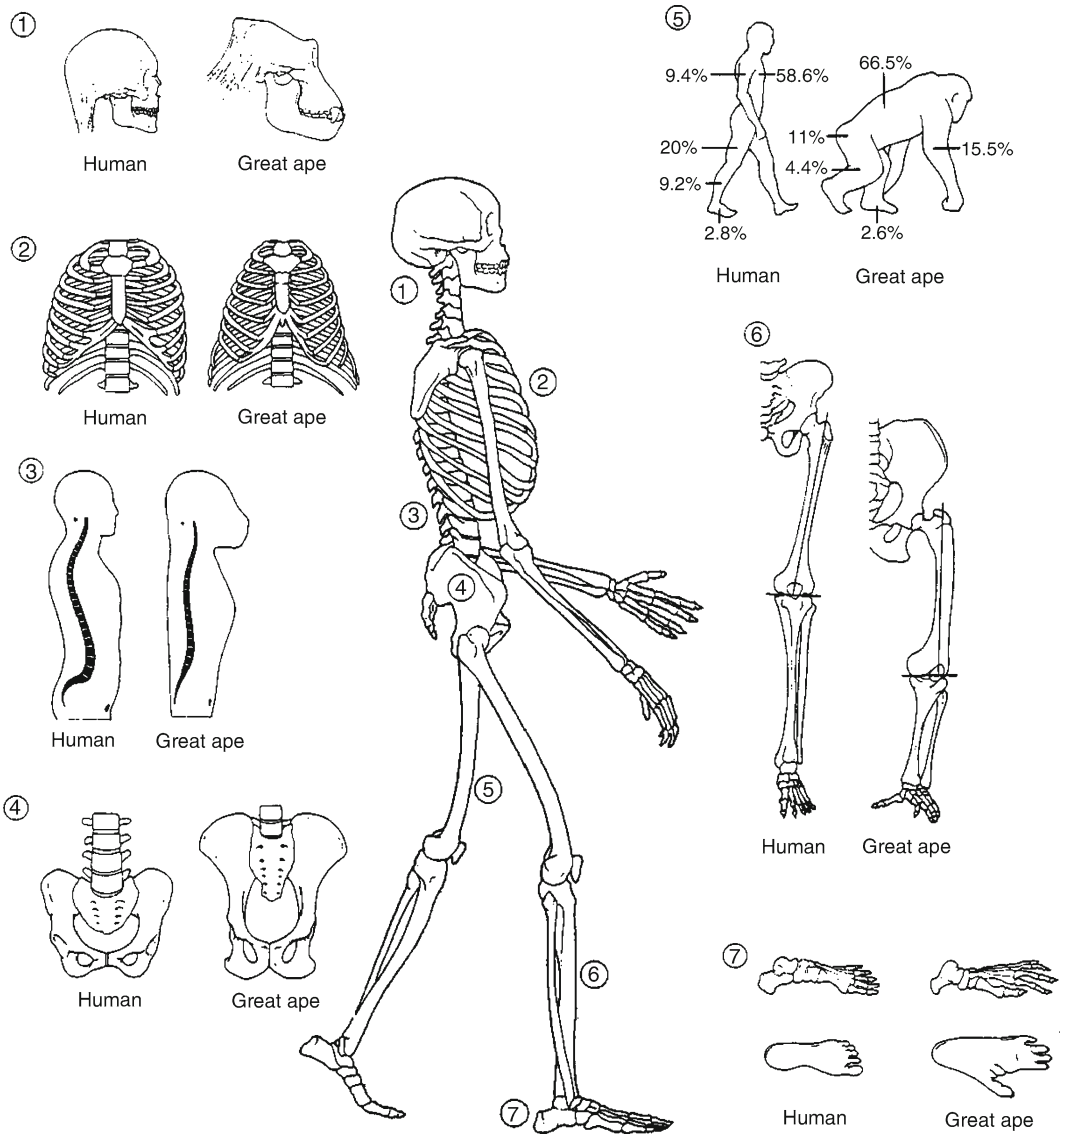

Fig. 182.1 Comparative features of bipedal locomotion in human and non-human primates (Modified from Jones et al. (1992))

In humans, several characteristic features are observed with regard to mass distribution and anatomy. We introduce some of these features identified on the spine, the pelvic girdle and hind limbs (Fig. 182.1):

- On average, body mass is distributed as follows: hind limbs: 32%, head and trunk (59%) and forelimbs (9%). Compared to other hominoids, the neck–head segment and the hind limbs are relatively long and the forelimbs are relatively short.
- The vertebral column displays four curvatures: two lordoses (lumbar and cervical) and two kyphoses (thoracic and sacral).

- The pelvic girdle is short and basin-shaped, with stout ilia on which well-developed gluteal muscles originate.
- The diameter of the anatomical hip joint (acetabulum and femoral head) is large and the femoral neck is relatively long.
- Concerning the general shape of the femur, the femoral diaphysis is elongated and straight, the angle of femoral torsion is large as is the bicondylar angle, which adducts and orients the knee axis in a frontal plane. At the knee level, the femoral condyles are antero-posteriorly elongated, the patellar field is deep, the tibial plates are slightly concave and perpendicular to the tibial shaft and the lateral meniscus has two areas of attachment. Such arrangement stabilises the knee during push-off and provides « locking » at maximal extension. In addition, knee motion is mainly parasagittal.
- At the shank level, tibial and fibular shafts are elongated and straight. Together, the distal tibia and fibula form a mortise which accommodates the talar trochlea, which widening distally, stiffens the talocrural joint as the foot dorsiflexes. The overall movement of the talocrural joint is in the parasaggital plane, and plantarflexion is powered by a well-developed triceps surae muscle inserting at the tuber calcanei by a long Achilles tendon.
- At the foot level, the joints of the tarsometatarsal complex are very congruent due to the joint areas' shape and the ligament arrangement. The tarsus and the metatarsus form an arch-like structure, both longitudinally and transversally. Proximally, this arch is delimited by a long calcaneus with an enlarged (due to a lateral process) plantar base. Distally, this arch is delimited by roughly parallel metatarsals. The first metatarsal is adducted with a very limited medio-lateral range of motion. The metatarso-phalangeal joint allows for a great degree of dorsiflexion. The base of calcaneus and the phalanges are mechanically coupled by means of a well-developed plantar aponeurosis.

The arrangement outlined here allows for a habitual bipedal locomotor mode and contrasts to non-human primates (Fig. 182.1). In their occasional bipedalism, the latter tend to have a head connected roughly in line with the neck, a forward inclined trunk, flexed hips and knees and compliant feet (see Aiello and Dean 1990, for a review), but this is not universally the case (see later).

Numerous variations are observed with regard to the degree of joint compliancy, knee abduction, foot orientation and type of foot contact to the ground (plantigrady or semiplantigrady). In African apes, it has been proposed that certain anatomical features are related to their proper type of bipedal locomotion (e.g. Jenkins 1972). Distally, the varus position of the foot and the extreme exorotation of the lower leg over the heel during push-off have a morphological basis in the arrangement of the talocrural joint: for example, a relatively wider lateral trochlea margin compared to the medial one, the oblique orientation of the distal tibia (Latimer et al. 1987) as well as an ovoid calcaneal tuberosity (no plantar lateral process). At push-off, a mid-tarsal break is observed (Elftman 1935), although this too may sometimes occur in clinically normal humans.

The way in which posture and bipedal walking is achieved in primates varies markedly between species. The anatomical differences between humans and other primates, outlined earlier (Fig. 182.1), help us understand why non-human primates cannot engage in habitual bipedalism. Nevertheless, with the exception of African apes, very few studies explore potential links between anatomy and bipedal locomotion. However, new experimental data in less-well-studied species are acquired, along with the use of numerical techniques (see Sect. 182.5).

182.3 (Comparative) Biomechanics of Bipedal Walking in Humans and Non-human Primates

182.3.1 In Humans

Most experimental approaches enabled the provision of many fundamental parameters linked to the bipedal locomotion: spatiotemporal, kinematic, dynamic and energetic parameters.

182.3.1.1 Spatial and Temporal Parameters

People walk when travelling slowly but run when wishing to go faster, while moving the legs alternately, half a cycle out of phase with each other. Kinematics of human bipedalism is commonly depicted via various spatiotemporal parameters of the gait cycle (Fig. 182.2). A stride (or gait cycle) is a complete cycle of leg movements involving one step by each leg. The stride length λ is the distance travelled in a stride, and the stride frequency f is the number of strides taken in unit time. Thus, the speed is defined as $\lambda * f$ (Alexander 2003). Bipedal locomotion is composed of a succession of stance and swing phases that can be expressed as a percentage of the total duration of the gait cycle (Fig. 182.2). In humans, swing and stance phases represent approximately 40% and 60% of all of the gait cycle. This leads to two double-support phases, each of them representing around 10% of the gait cycle. A human gait cycle can therefore be considered from the duty factor β, that is, the fraction of the duration of the stride for which a particular foot remains on the ground. If the duty factor is greater than 0.5, there are periods of the stride in which both feet are simultaneously on the ground, and the gait is described as a walk. Otherwise, the gait is described as a run. In other species, such as the gibbons, it may be appropriate to use other criteria for separating running and walking; thus, Vereecke et al. (2006) describe running as that bipedal locomotion which uses a spring-mass not pendular-energy-saving mechanism, since the gibbon bipedal gait is compliant and high speed, but lacks a floating phase.

The step length is the distance travelled while a particular foot is on the ground and is approximately equal to $\beta * \lambda$ (it would be exactly equal to $\beta\lambda$ if the speed remained constant throughout the stride) (Alexander 2003).

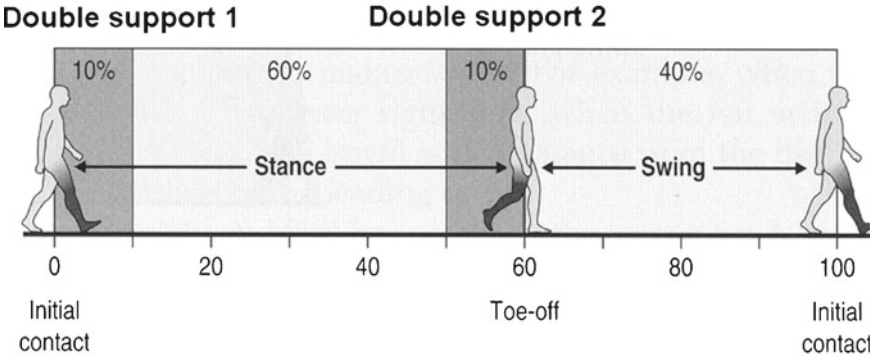

Fig. 182.2 Main phases of a gait cycle (Modified from Kirtley (2006))

Table 182.1 Interpretation of temporal spatial parameters in gait disorders (From Kirtley 2006)

Speed	Stride length	Cadence	Interpretation
N	N	N	Normal gait
N	↓	↑	Compensated gait
↓	↓	↑	Inadequately compensated gait
↓	↓	↓	Severe gait impairment

The spatial and temporal parameters of gait are recognised to be of clinical relevance in the assessment of motor pathologies. Consequently, they are considered as important functional measures (or *vital signs*) of gait (Kirtley 2006), the main applications of which are:

- Screening (e.g. detect elderly people at risk of falling);
- As a performance measure (e.g. to grade a patient's level of disability);
- Monitoring the efficacy of therapy (i.e. as a measure of outcome); and
- Normalisation of other gait measurements (in order to compare results from people walking at different speeds for example).

In order to compose a detailed and precise clinical report, complementary parameters have to be considered. For example, age (effect of maturation) or the size of the subject may potentially modify several of the gait characteristics. In order to highlight the fundamental and general aspects of locomotion, many researchers have proposed techniques to normalise the gait parameters (Alexander 2003). It was formally proposed that the motion of one animal could be predicted from that of another animal of different body size, if the two animals were geometrically and dynamically similar (see Alexander 2003 for a review). Two animals moving in a dynamically similar manner will have equal ratios of all lengths, times and forces. Because velocity is simply distance (a length) per unit time, two animals moving in a dynamically similar manner should also have equal ratios of their velocities. In this way, many parameters of one animal can be related to those of another. To allow direct comparison of motions of two animals which may be of different size or shape, a parameter called the Froude number (*Fr*) is used to compensate for differences in velocity, body size and gravity:

$$Fr = \frac{V^2}{g.L}$$

where g is the gravity (9.81 m s^{-2}) and L is a characteristic length (in m). The use of *Fr* to relate the motion of disparate animals is based on the mechanics of the pendulum, to which human walking has been likened. The characteristic length of choice is leg length or the distance from the acetabulum or greater trochanter to the ground. *Fr* can be shown to be equal to the ratio of potential and kinetic energy, when *h* is the characteristic length (Alexander 2003). From this description, it appears that the temporal–spatial parameters stabilise at around 4–5 years of age (Sutherland 1994). However, Li et al. (1996) found that the path of the centre of pressure under the foot and ground reaction forces as a whole do not mature until 7–8 at least.

In clinics, most gait problems result in decreased stride length, and increased cadence is a common compensation to maintain speed. In some diseases (e.g. Parkinson's disease), the increase in cadence is very marked (Morris et al. 1999). It is therefore best to measure all three parameters (Table 182.1).

Step-length differences are useful as a measure of symmetry. For example, the step length ratio (SLR) of the shorter to the longer step length is useful for tracking a patient's progress through their rehabilitation, the ratio rising to closer to 1 as the gait improves. Other symmetry indices have been described using variables, such as right and left stride times or double support times, but the SLR is probably the most widely used (Kirtley 2006).

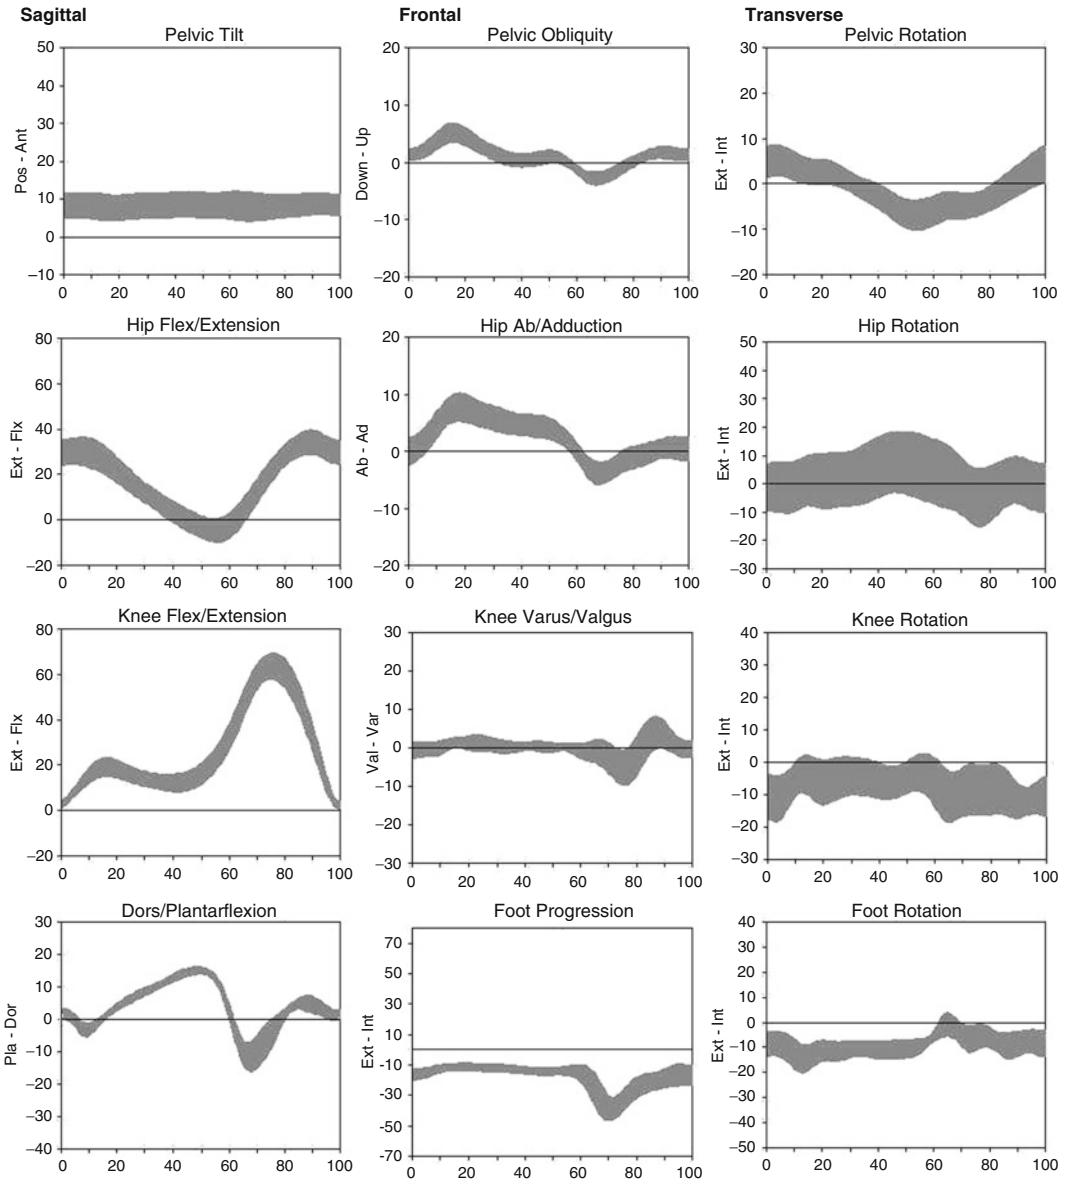

Fig. 182.3 Normative values of 3D joint angles during gait (Adapted from Kirtley (2006))

182.3.1.2 Joint Angles

Gait is also often described via 3D joint angles obtained by tracking the motion of a specific joint throughout the gait cycle. Many previous works depicted joint angles in all three planes (see Kirtley 2006 for a review); and it has been found that, during normal gait, the majority of motion occurs in the sagittal plane, whereas, in pathological gait, there is typically reduced motion in the sagittal plane and much greater motion in the coronal and transverse planes (see Fig. 182.3 for a normative range

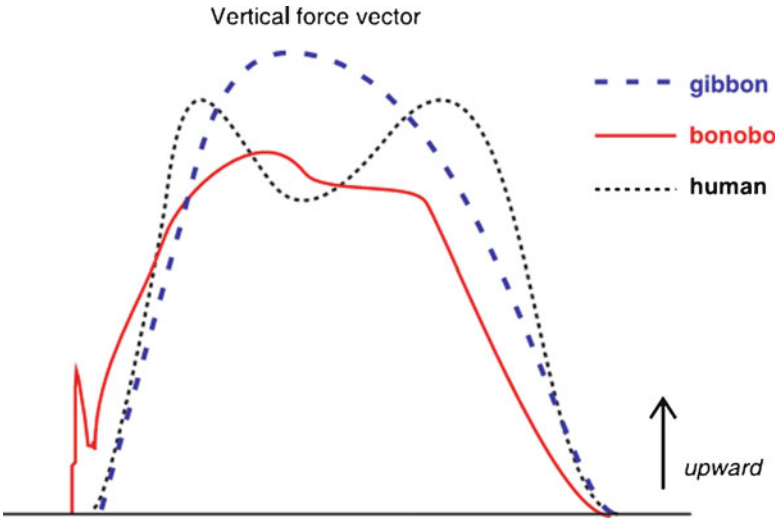

Fig. 182.4 Graph showing the average vertical ground-reaction force (scaled to body weight) for humans (*dotted line*), bonobo (*bold line*) and gibbon (*dashed line*) bipedalism. Ninety percent of voluntary bipedal walking by bonobos produces a single-humped vertical ground reaction force curve, 10% gives a mildly double-humped form. Gibbon bipedal running produces a single-humped curve, but, unlike human running, there is usually no floating phase. Note that gibbons do not show a heel-strike transient, which appears to be a great-ape feature. Also note the abrupt drop in vertical force prior to toe-off in humans and the more gradual decrease in vertical force in both apes (Crompton et al. 2008)

of joint angles during normal gait). Motion in these two planes is a function of compensation needed as coping responses for limited motions and deviations in the sagittal plane or as a direct result of the underlying conditions (Spivack 1995).

182.3.1.3 Dynamics and Energetics

During gait, relatively stiff lower limbs are used in such a way that our centre of mass is at its lowest point at heel-strike and rises to its highest point at midstance (Cavagna et al. 1977). This inverted pendulum-like gait allows for an effective exchange of gravitational potential and kinetic energy (Cavagna et al. 1977). The same style of walking is employed by other bipeds and probably by most quadrupeds (see Alexander 2003 for a review).

However, when people are asked to walk with minimal oscillations of the centre of mass, they adopt deeply flexed lower-limb postures like those of most apes (Schmitt 1999). Limb compliance leads to smaller oscillations of the centre of mass and alters the magnitude of the peak vertical substrate reaction force and the shape of the force–time plot. During normal walking, humans generate a vertical ground reaction force curve with two distinct peaks that are both greater than body weight (Crompton et al. 2008). This force pattern is characteristic of a stiff-legged gait in which the centre of mass is highest at midstance and lowest at double support (Fig. 182.4). By contrast, in most non-human primates, bipedal walking generates single-peaked force curves in which the peak is much closer to body weight (Fig. 182.4) (Kimura 1996).

As previously presented, gait kinematics is influenced by speed. Both in walking and in running, stride length increases with speed. From measurements of oxygen consumption, it can be shown that the adjustments of kinematic parameters aim at minimising the energy cost of locomotion at each

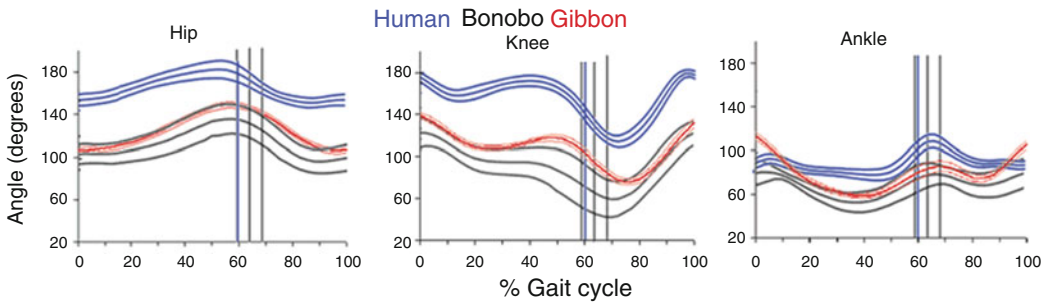

Fig. 182.5 Bonobos and gibbons: bent-hip, bent-knee gait; humans: 'stiff'-legged walking gait; gibbons have more extended hindlimb joints and more erect trunk position than bonobos (Adapted from Crompton et al. (2008), D'Aout et al. (2004))

particular speed. Transition from walking to running is made at approximately the speed at which walking and running have equal energy costs: walking is more economical than running below this energy cost, whereas running becomes more economical above (see Alexander 2003; Crompton et al. 2008). The stride length that is normally used at any given walking speed is the one that minimises energy consumption (see Alexander 2003).

182.3.2 In Non-human Primates

Biomechanical aspects of bipedal walking have been addressed in several non-human primate species, often with different questions in mind and with different techniques. Because of their close phylogenetic relationship to humans (Groves 2001), many studies have focussed on hominoids, especially the genus *Pan* (chimpanzees and bonobos). Other primate species are more distally related to humans but are particularly relevant for specific research questions and are essential in a broad comparative approach (D'Août and Vereecke 2010).

Many techniques used in human biomechanics have been applied to non-human primates as well (Schmitt 2003). These common techniques provide data from which human biometrics and biomechanics can be understood in a comparative framework, thanks to accurate comparisons with non-human primate biomechanics. Here, we will present general anthropometric and biomechanical characteristics of bipedal walking in non-human primates, even though this locomotor mode and the primate anatomy are variable. This aims to identify what (anthropometrically and biomechanically) in the human walking is shared by other primates and can be seen as "invariants" of the primate bipedal walker, and what is proper to the human walker.

Many studies have addressed spatiotemporal characteristics and joint motions during walking. Such studies typically use laboratory or captive setups, but some field data are available as well (see D'Août and Vereecke 2010).

One of the most striking aspects of bipedal walking in non-human primates is that they, unlike humans (who use extended hip and knee joints during walking), often adopt a relatively flexed (bent-hip bent-knee) and more compliant limb posture (Schmitt 1999) (Fig. 182.5). The trunk is typically inclined forward and bipedal strides are smaller (but at a higher frequency for a given velocity, e.g. Aerts et al. 2000) than quadrupedal ones, the latter being particularly long in primates when compared to other mammals (Reynolds 1987). Orangutans are again an exception, with bipedal strides being long and frequencies low, probably as an adaptation for dealing with support compliance.

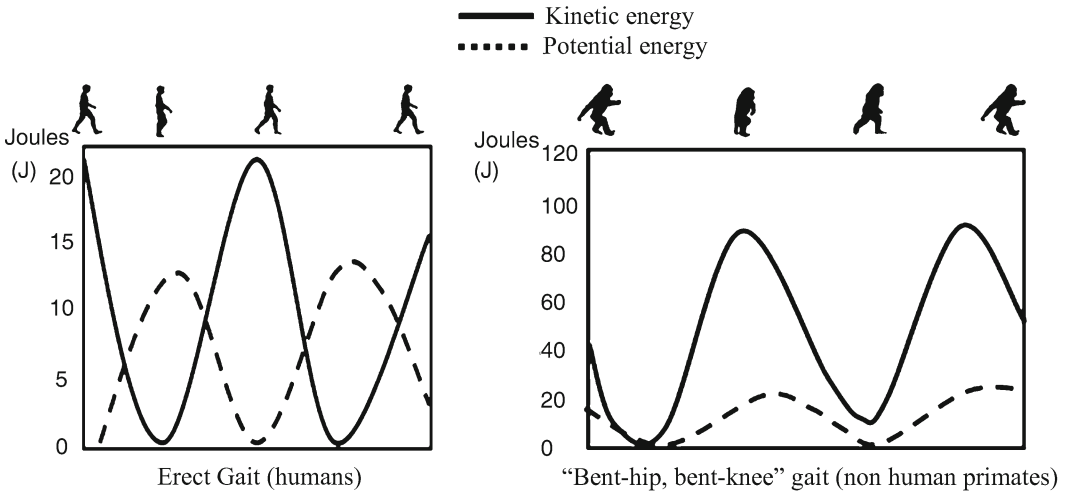

Fig. 182.6 Potential and kinetic energy during erect and 'bent-hip, bent-knee' walking in human and non-human primates

One aspect of locomotion in primates is the preferred use of diagonal-sequence gaits (Vilensky and Larson 1989), in which the left hindlimb moves in synchrony (albeit mostly, not perfectly) with the right forelimb. Whereas this is, obviously, a characteristic of quadrupedal gaits, such interlimb timing is often retained during bipedal locomotion, most clearly in the arm swing of humans.

Ground-reaction forces have been measured in several non-human primate species during bipedal walking (e.g. Kimura et al. 1977; D'Août et al. 2004; Sockol et al. 2007).

Bipedalism of untrained chimpanzees lacks the typical double-humped profile of the vertical force component seen in human walking (but not running) and does not show the associated "inverted pendulum" gait (Cavagna et al. 1977; Alexander 1991), in which mechanical energy can be conserved by the exchange of kinetic and potential energy as the centre of mass moves up and down while, respectively, decelerating and accelerating. However, bipedalism of untrained orang-utans, in at least 25% of cases, does show a double humped vGRF curve and one which overlaps in form with that in slow walking of humans, resulting in energy-exchange savings of some 50% versus 8% for untrained chimpanzees (Wang et al. 2003; Crompton et al. 2008). Further, some 10% of bipedalism of untrained bonobos shows a mildly double-humped curve (see Crompton et al. 2008).

With the data presently available, the general picture for non-human primates is that bipedalism has the same energetic cost as quadrupedalism and that the energetic cost of primate locomotion is similar to that of a generalised endotherm (Steudel-Numbers 2003) but higher than that of human bipedalism (Fig. 182.6).

182.3.3 Common Principles of Bipedal Walking

Gaits, that is, patterns of movement, may be expressed in terms of kinematics, where each limb has a stance phase, when it is in contact with the ground and a swing phase, when it is out of contact with the ground. The duty factor of a limb is the proportion of each complete cycle when it is in contact

with the ground, as described earlier. For bipeds, three kinds of gait are in common use, walking, running and hopping, while in human children, we may also recognise skipping. In hopping, either one limb at a time or both limbs at the same time exert propulsive (aft) force against the ground, with sufficient force to lift the whole body into a floating phase where there is no ground contact. There may also be a floating phase in running, and, in humans, the term 'running' is often limited to cases where there is a floating phase. However, in gibbons, running generally (but not always) lacks a floating phase (Vereecke et al. 2006). Minetti (1998) notes that most human children at some time voluntarily utilise skipping, a high-speed bipedal gait in which one foot has both stance and swing phases, followed by a small double-stance phase, then by the stance and swing phase of the opposite foot. Among our own Order, the primates, only humans and gibbons appear to be able to sustain non-hopping bipedalism.

Kinematic descriptions of gait are of particular value in the analysis of neural control mechanisms but, for an understanding of the mechanical work and cost of gaits, descriptions of gait based on force are more appropriate and, thus, recently more common. The best-established categorisation differentiates gaits that save energy by pendular mechanisms and the exchange of more or less out-of-phase potential and kinetic energies of the body centre of mass (COM) from those that save energy by spring–mass mechanisms, where energy is stored in elastic tissue. Modern human bipedalism is unique primarily for the extended or 'stiff' postures of the lower limb that characterise walking (Alexander 1991). It has been shown that in humans, 'stiff' limb postures allow for a high degree of energy recovery between strides by the exchange of nearly completely out-of-phase kinetic and potential energies of the COM (Cavagna et al. 1977). At speeds below about 2.2 m/s, human adults normally use such 'stiff' bipedal walking, which is accompanied by characteristic double-humped vertical ground-reaction forces, as the COM rises and falls twice within each complete gait cycle (Li et al. 1996). Such stiff gaits may conserve as much as 70% of energy between strides (Wang et al. 2003). Above nearly 2.2 m/s, humans switch to compliant running gaits, which by contrast produce higher peaks but single-humped vertical ground-reaction forces. The higher acceleration needed to lift the body off the ground is substantially paid back by elastic recoil (comparable with a bouncing ball) in tissues, such as the Achilles' tendon (tendo calcaneus). While humans are unique among the African apes (humans, chimpanzees and gorillas) in possessing a marked Achilles' tendon, the presence of a strongly marked Achilles' tendon in gibbons rather surprisingly does not seem to be related to its running bipedalism. As with several other mammals, gibbons may utilise a combination of pendular and spring-mass mechanisms, although the latter tend to predominate at higher speeds. Ruina and colleagues (2005) proposed a new model which concentrates on the energy of collisions of the limbs with the ground; it shows that energy of the COM may be substantially conserved by aligning the path of the COM to the trajectory of the ground-reaction force. A combination of several mechanisms is thus likely to contribute to energy conservation during bipedalism.

182.4 The Role of Anthropometry in Analysis of Locomotor Function

At the simplest level, bones act as levers which apply forces at joints. Their length therefore affects their effort or load arm with respect to the joint centre. The forces which they transfer are derived either from ground – and ultimately joint-reaction forces, or muscular contraction. Since most biological surfaces are curved, in most cases also joint motion is rotatory rather than linear, and so the forces exerted about joints are primarily turning forces: rotatory moments or torques. The torque which a muscle exerts at a joint is a function of the physiological cross-sectional area of a muscle and the

perpendicular distance from the line of action of a muscle about the joint's instant centre of rotation to that centre or moment arm. The joint's centre or axis of motion is rarely immobile but itself follows a curved path. The changing position of the origin and insertion of a muscle with respect to a joint centre throughout the physiological range of motion of a joint will thus change the moment arm through the range of motion. Further, the moment arm of a muscle will be affected by the passage of the muscle over bony protuberances, by the diameter of any sesamoid bones within the muscles' tendons, by its passage over deeper muscles which may bulge underneath it when they are activated, and even by passage of its tendons through pulleys comprised of bony or soft-tissue structures – or both.

Measurement of bone geometry may be done by linear measurements made with callipers, but, more recently, it is increasingly performed by building virtual models of bones by laser scanning or by reconstruction of CT imaging, which have the advantage that bone geometry may be recorded in articulation with other bones or even on the intact body. (Further, this approach allows the skeleton to be rigged with simulated muscles in forward dynamic modelling, see below).

These measurements require to be augmented with measurement of muscle moment arms, usually done by the tendon-travel method, simultaneously with measurement of joint angle and measurement of physiological cross-sectional area of muscles. A further parameter, which affects the range of motion over which forces may be effectively applied to joints, is the length of fibres within the muscle. All these parameters are normally gathered by dissection (for methods, see e.g. Thorpe et al. 2006), but digital goniometers and linear displacement recording can greatly aid data collection. Medical imaging may also be of value.

Motion of a limb segment, and, in particular, the forces which must be exerted to change its motion, are however affected by its mass distribution: not only its raw and relative mass but the geometric distribution of mass within the segment, and its inertial properties. In analyses based on pendular mechanics, for example, since the period of a pendulum is affected by its mass distribution, not its raw mass, analysis of stride frequency must take account of mass distribution; again, the inertial properties of a segment will affect the mechanical cost of bringing about changes in its angular motion. Although the forces exerted externally by any limb during the stance phase to power and control gait may be measured accurately for any living animal, calculation of the internal forces, such as joint torques from external forces, still requires inverse dynamic analysis, and, this in turn, necessitates knowledge of segment inertial properties.

Newton's second law states that the resultant force acting on a body, F, is the product of the mass of the body, m, and its acceleration, a:

$$F = ma$$

Forces acting on a body can thus be calculated from knowledge of its mass and acceleration. However, we have mentioned that, in biological entities, most motions are rotatory or angular rather than linear. Newton's second law can be restated in angular form:

$$T = I\acute{a}$$

where T is the torque acting on the body, I the moment of inertia of the body, and $\acute{a}$ its angular acceleration. In a three-dimensional analysis, torques, moments of inertia and angular accelerations must be resolved into their plane of rotation about X-, Y- and Z axes.

Thus, segment centres of gravity, moments of inertia and radii of gyration must be assessed three-dimensionally. While segment mass can be measured by use of balances, and simple water-displacement methods used for volumes, mass distribution of segments is much more demanding

to assess reasonably accurately. The three most important parameters are segment centre of gravity (the mean of the mass distribution of a segment), the radius of gyration (essentially, the standard deviation of mass distribution) and moment of inertia (the characteristic pattern of mass distribution acting to resist angular acceleration in a given plane of mass acting to resist a given angular acceleration). Methods for derivation of these parameters from complex pendulum experiments on segmented specimens, or from intact – and hence even living – specimens using external measurements (based on the uniform density assumption), via construction of geometric models, are provided by Crompton et al. (1996, and see also Isler et al. 2006). These data are essential for construction of computer simulation by dynamic modelling but can themselves provide direct insights: Isler et al. (2006) found that while all other non-human great apes show a mismatch of natural pendular period (NPP) between fore- and hindlimbs, the common chimpanzee alone has reduced distal mass in the forelimb and thus achieved a better match between fore- and hindlimb, suggesting that the common crown-hominoid ancestor was not a mechanically effective quadruped, but that the chimpanzee has undergone selection to enhance its effectiveness in quadrupedalism.

Whereas the description of translational inertia is straightforward (i.e. mass), rotational inertia can be presented in several ways, for example, moment of inertia around the proximal joint and principal moment of inertia (i.e. around the centre of mass), and it can be recalculated as the radius of gyration (which, in turn, can be expressed as a percentage of segment length). The latter measure does not directly relate to rotational inertia (it only does so after accounting for segment length and mass), but it allows for a comparison between subjects of different size, shape and mass.

Comparative and evolutionary biomechanics, especially that focussing on the origin of bipedal locomotion in humans, has been a fruitful study field. Various methods are being employed, and quantitative anatomical knowledge has been integrated in such studies. More specifically, studies have used segment inertial properties, muscle moment arms and architecture data and the general architecture of the articular chain.

As described earlier, the inertial properties of a segment document to what extent it resists accelerations and therefore have a substantial impact on the biomechanics and energetics of movements (including locomotion, although probably less than does joint kinematics). Energy is needed to propel the body (represented by its centre of mass) as a whole – this is external energy. Energy is also needed to move the body segments relative to each other – this is internal energy. By measuring or calculating inertial properties per segment, both types of energy can be calculated. The overall architecture of the body, as a linked-segment "skeletal" model, can be established either by imposing a specific posture, for example, erect or 'bent-hip, bent-knee' (e.g. Crompton et al. 1998) or it can be obtained by medical imaging techniques (e.g. Ogihara et al. 2009). Additionally, it can be reconstructed from isolated bones if available (e.g. Nicolas et al. 2009) (Fig. 182.7).

The muscles are often represented as functional units of which attachment may be measured directly on cadavers or from medical imaging (e.g. Ogihara et al. 2009).

Articulations have typically been represented as simplified 2D or 3D hinge joints (e.g. Nicolas et al. 2007), as they lead to a small set of variables which enables us to obtain reliable dynamic variables. However, recent studies increasingly account for anatomical complexity, for example, in the development of musculoskeletal models of the foot in a comparative perspective (Wang and Crompton 2004). However, the resulting set of variables is so large that it is difficult to obtain reliable dynamic data: the redundancy of the actuators leads to using hypotheses/constraints in computing muscle activation instead of measurements. Hence, according to the studied problem, one has to select the most appropriate model.

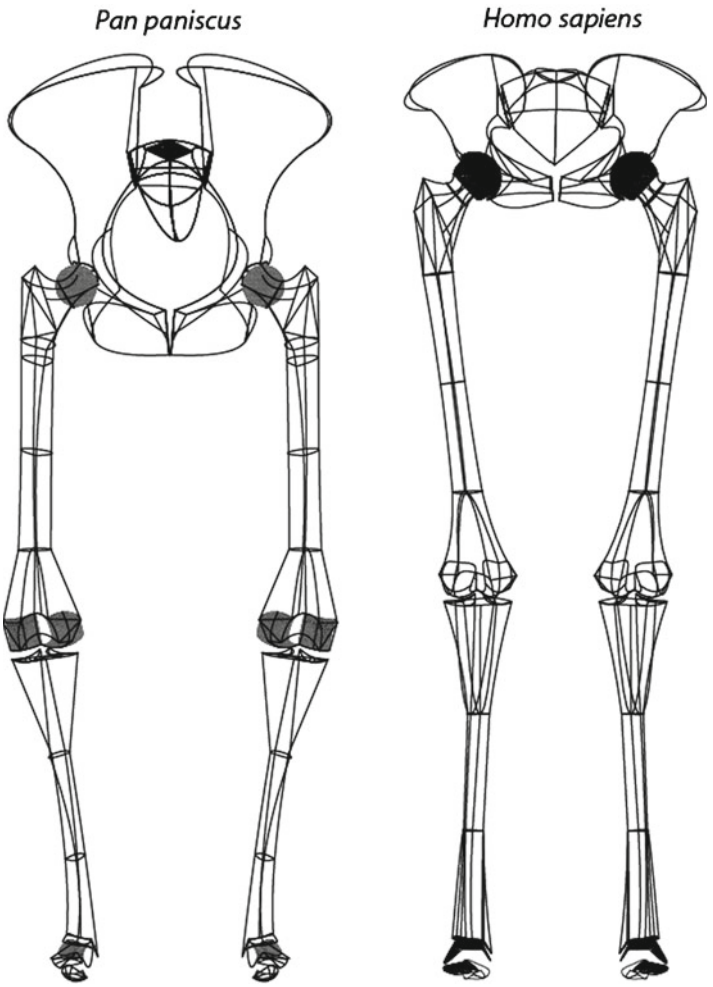

Fig. 182.7 Reconstructed pelvic girdle and hindlimbs in bonobo and human. They highlight the main architectural differences between human and bonobo. These articulated chains have been built using a procedure specifically designed for modelling and simulating analysis of bipedal locomotion in human and non-human primates (Nicolas et al. 2009)

182.5 Simulation for Associating Anthropometry and Bipedal Walking

182.5.1 Numerical Models of the Locomotor System

Simulating the locomotion of bipedal creatures by computer modelling requires an accurate modelling of the locomotor system. This modelling process has been widely explored in robotics (Shabana 1998) and computer animation (Badler 1999) for many years. The most accepted approach consists of modelling the locomotor system as an articulated multibody system composed of isolated bodies connected by idealised joints. These joints allow rotations and translations in order to capture all the possible geometric transformations between two adjacent bones.

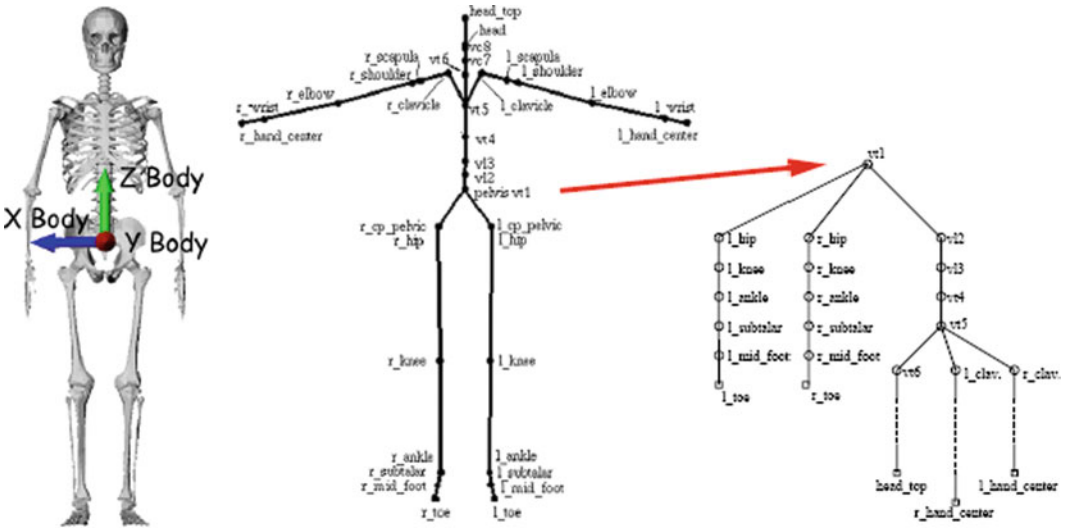

Fig. 182.8 Digital description of a human. This figure depicts how a digital human is represented. *Left*: A reference frame is placed on the pelvis in order to provide the global position and orientation of the subject. *Middle*: A set of connected bodies is used to model the subject and the joint. *Right*: A tree is used in order describe the relationships between adjacent bodies

Each isolated body is modelled with a set of biomechanical parameters, such as the mass, the location of the centre of mass and inertia that are generally obtained using anthropometric tables (e.g. Dempster and Gaughran 1967; Zatsiorsky et al. 1990, Crompton et al. 1996; Isler et al. 2006). This kind of modelling is based on the assumption that each body is rigid and cannot change shape during motion. For some populations, such as the obese, this assumption is too simple, and more complex models are required (Grüber et al. 1998). Equally, where structures such as the plantar aponeurosis are to be considered, models may require including compliant elements (e.g. Caravaggi et al. 2009). Whatever the type of model, bodies do not accurately correspond to actual bones but sometimes model a set of bones (such as a group of vertebrae, ribs and soft tissues for the abdomen and the torso). However, note that, for example, if the goal of the simulation is to study the load exerted on the lumbar region during a given motion, the anthropometric model of the trunk should include a complex description of the spine; conversely, if the goal of the study is to analyse knee rotations during gait, a single body may adequately model the trunk. Such adaptation of the model according to the aim of the study is a key point in anthropology.

Whatever the level of detail, the resulting model is generally presented as a hierarchy or tree: the nodes correspond to isolated bodies, while the links are associated with joints. If the pelvis is the parent of the femur in this hierarchy or tree, the femur inherits from the pelvis all the transformations applied to the pelvis, as depicted in Fig. 182.8. Using this tree structure enables us to provide only the relative geometric transformation between two adjacent bodies. In the previous example, whatever the orientation of the pelvis in space, the link to the femur only contains the local rotations of the hip, as generally employed in anatomy and biomechanics.

Thanks to this representation, a pose $q(t)$ at time t of the whole body is a simply a vector containing all the degrees of freedom for an n-joint multibody system:

$$q(t) = \left(x_r, y_r, z_r, \psi_r, \theta_r, \varphi_r, \left[x_i, y_i, z_i, \psi_i, \theta_i, \varphi_i\right]_{i=1\ldots n}\right)$$

where x, y and z stand for the three possible translations, and ψ, θ and φ stand for the three possible rotations either for the root global displacement (subscript r) or a joint (subscript i).

182.5.2 Numerical Methods for Simulation

As a pose is modelled with such a vector, the main role of the simulation is to calculate how this vector changes with time. A wide set of methods has been introduced to perform such a simulation for bipedal locomotion (see Multon et al. 1999 for a survey). The most intuitive approach consists in directly applying predefined locomotion data that generally come from motion capture. This so-called 'inverse dynamics' approach is mainly used to test a hypothetical motion on a given locomotor system, to check if it is mechanically plausible (Crompton et al. 1998). However, motion from one species may not be suitable to another, again a key point in anthropology.

Another method called 'inverse kinematics' consists in displacing the extremity of the locomotor system at each time step of the simulation and to calculate a pose which is compatible with this new constraint. In that case, the resulting motion is fully adapted to the anatomical structure. Hence, it is possible to check the influence of changes in anthropometric data on the resulting motion, as suggested in Nicolas et al. (2007). This method takes energy minimisation into account but does not consider other dynamic variables, which could lead to some unrealistic motions from the mechanical point of view.

To overcome the limitations of the two previous techniques, the 'forwards dynamics' approach predicts the dynamic equations of the mechanical system, which optimally correspond to the anthropometric data (this usually employs code from a physics engine, such as ODE 'Open Dynamics Engine'), together with code which systematically searches through parameters, such as simulated muscle-activation patterns to locate combinations which can achieve preselected optima, such as fastest possible speed or minimum possible cost. This approach allows computation of the motion of the system according to all external and internal forces that are acting on it. Although the resulting motion takes both anthropometric data and dynamic laws into account, it is computationally very demanding to obtain the most likely parameters to achieve a biologically likely motion, and it is in all cases necessary to validate such models by reference to real-world experimental measurements. Many approaches have been proposed to solve this problem, but it remains a research challenge. The next subsection presents some such approaches in work applied to anthropology.

182.5.3 Application to Anthropometry in Locomotion

As mentioned earlier, the mechanical costs of given gaits can be predicted from a knowledge of body proportions and estimates of masses and mass distributions, using inverse dynamic analysis. Equally, kinematics can be predicted from a knowledge of forces, by forwards dynamic analysis. These techniques are vital elements in the analysis of internal force and motion in biomechanics as a whole but, more recently, have begun to be accepted as powerful tools in reconstruction of the behaviour of extinct species, known only from fossils. This capability is particularly important in analysing the evolution of human bipedalism, where the traditional approach of reconstruction by analogy to living animals with similar morphologies is more or less impossible, in the absence of any living mammal other than humans with a similar habitual adaptation to striding terrestrial bipedal walking.

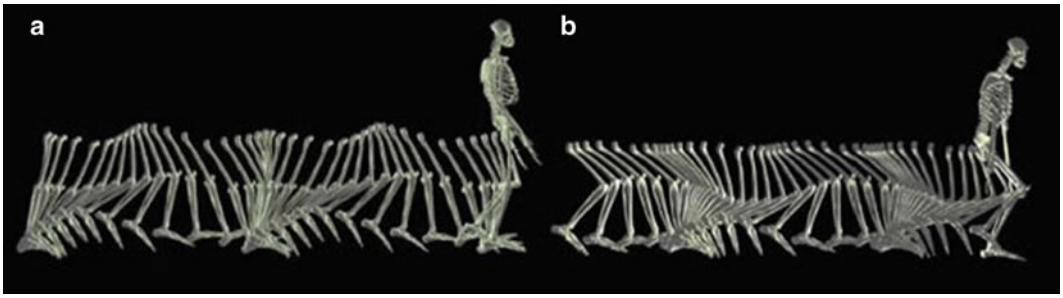

Fig. 182.9 Simulation of walking by Lucy (AL 288-1): (**a**) with motion functions derived from erect human walking; (**b**) with motion functions derived from 'bent-hip, bent-knee' human walking (Crompton et al. 1998)

The first such studies with a comparative focus were performed by workers, such as Yamazaki et al. (1996), who generated simulated bipedal gaits by forwards dynamics using a neuromuscular model with a pattern generator to generate muscle-activation patterns. A more overt application of dynamic modelling to gait reconstruction was that of Crompton et al. (1998), who used inverse dynamics to predict the mechanical energy cost (judged by the parameter of mechanical joint power) of the alternative hypotheses of bipedal gait in *Australopithecus afarensis*: upright, with extended hips and knees (see e.g. Latimer 1991) or 'bent-hip, bent-knee' (see e.g. Stern and Susman 1983) (Fig. 182.9).

This study ran sets of joint motion derived from humans walking upright and 'bent-hip, bent-knee' (BHBK) and from voluntary bipedalism of common chimpanzees through alternative inertial models representing *A. afarensis*' proportions but either common chimpanzee or human mass distribution (Fig. 182.9). The study suggested that BHBK walking by this early hominin would have lead to a doubling of the mechanical cost of locomotion and because of local imbalances in positive and negative joint power, would have lead to heat load. They also found, as did Yamazaki and colleagues (1996) that mass distribution seems to have a considerably smaller influence on costs than kinematics. This study was criticised, particularly by Stern (1999, 2000), who pointed out that the model was not validated and who argued for a more marginal difference in costs, based on studies of metabolic costs in humans walking in sand and snow and supposed advantages of compliant gait in lower peak reaction forces operating at the pelvis. However, Kramer (1999) independently performed an inverse dynamic modelling study of upright walking in *A. afarensis*, based on human-like kinematics, showing that, despite the short legs of this species, it could have been a very effective upright biped. Carey and Crompton (2005) carried out detailed physiological measurements on upright and BHBK walking in humans, which confirmed that the mechanical effects predicted for *Australopithecus afarensis* by Crompton et al. (1998) were reflected in metabolic costs of locomotion and increased heat load. In a series of studies, Wang et al. (e.g. 2004) extended inverse dynamic modelling to a consideration of the significance of evolutionary changes in body proportions on stability and effectiveness in carrying, showing that the changes in body proportions between *A. afarensis* and *Homo ergaster* give the latter major advantages in load carrying and walking over long distances. However, there is a limitation in the utility of inverse dynamic approaches, inasmuch as that they cannot readily generate optimal gaits for a given morphology. Forwards dynamic modelling can and, given a suitable muscle model, can directly predict metabolic energy costs from simulated muscle activity. This allows direct validation by comparing predicted costs in models of real humans to experimentally measured costs in the same individuals (e.g. Sellers et al. 2004). However, the computational demands of forwards dynamics models are very high compared to inverse dynamics, particularly during optimisation.

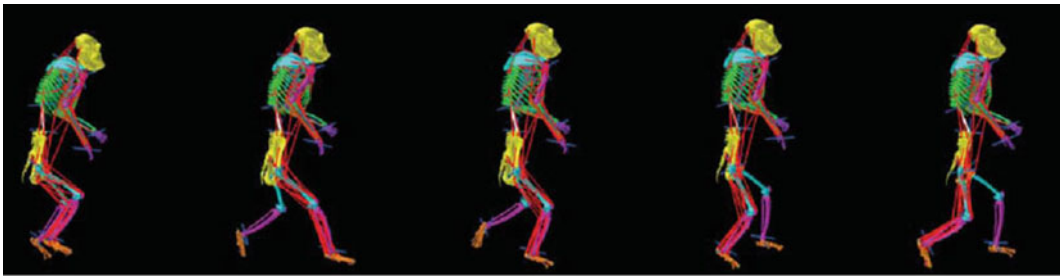

Fig. 182.10 Whole-body musculoskeletal kinematics of a Japanese macaque in bipedal walking (Ogihara et al. 2009)

Inverse dynamic models also require optimisation, but primarily to hone the smoothness of gait. Forwards dynamics models are usually searching for muscular-activation patterns that generate gaits which perform best according to preset optimisation targets: maximising speed, minimising energy costs, etc. Since forwards dynamics models are 'muscle'-driven, they are, therefore, more biorealistic than inverse dynamic models, and, despite utilising sophisticated optimisation techniques such as genetic algorithms, compromises are often necessary: either modelling in 2D only (e.g. Sellers et al. 2004) or limiting the number of cycles of locomotion modelled (e.g. Nagano et al. 2005). All these models have been based on rigid skeletons, with muscles simulated by force actuators and have not directly predicted the mechanics of compliant components (Fig. 182.10).

Even so, analyses may iterate 2,000 times or more and take several days on multiprocessor clusters. However, it is notable that Sellers et al. (2004) and Nagano et al. (2005) obtained very similar metabolic costs for simulated upright walking in *A. afarensis*, confirming Crompton et al. (1998) and Kramer's (1999) findings that this species could have been an effective upright biped. Sellers et al. (2004) found that the additional metabolic costs of BHBK locomotion would indeed have been near double but that total metabolic rates would have been less different in the two gaits. They went on to show (Sellers et al. 2005) that, at energetically optimal speeds, matching predicted stride lengths in *A. afarensis* to the stride lengths represented by the 3.75-Ma. Laetoli G footprint trails, if *A. afarensis* was indeed the maker, it was walking at absolute speeds within the human range, despite the difference in stature. Improvements in code and in processor availability have lead to progressively more sophisticated and more biorealistic models. Commercial code is readily available, well validated and powerful, allowing for example, for the first time, analysis of compliant effects in soft tissue, such as Caravaggi et al. (2009) study using MSC ADAMS of tension in human plantar aponeurosis.

With such type of tools, it is possible to define accurate musculoskeletal models of the locomotor system which have been successfully applied to studying pathological gaits. For example, it has been used to analyse the excessive tibial torsion, a rotational deformity about the long axis of the tibia, which is common in patients with cerebral palsy who walk with a crouch gait. Hicks et al. (2007) used a musculoskeletal model to simulate the effect of a range of tibial-torsion deformities on gait. Analysis of this model demonstrated that excessive external torsion reduces the extension capacity of soleus, which might be a significant contributor to crouch gait. Hence, using musculoskeletal models and dynamic analysis enables researchers to provide fundamental knowledge about the functionality of anatomical properties. In addition to this fundamental knowledge, this type of musculoskeletal-based analysis can help clinicians when making treatment decisions for such type of pathologies.

182.6 Discussion/Perspectives

In this chapter, we have described recent works and knowledge concerning the link between an anatomical property and its impact on gait. We have chosen to consider humans in a wider comparative framework to identify the fundamental relationship between anthropometry and biomechanics, instead of explaining gait patterns in normal and pathological human locomotion. We specifically focussed on the common features and the main differences of gait from the anthropometrical and functional point of views for human and non-human primates. One of the most promising approaches for the future consists of using simulation to identify the anatomical properties that are responsible for a given motor pattern. It could enable researchers to evaluate the role of a wide range of anatomical properties, including the consequence of some pathologies, on gait disorders.

To date, the available models allow for adequate descriptions of the upright walking in humans and compliant gait of non-human primate (e.g. Alexander 2003; Crompton et al. 1998; Sellers et al. 2004; Nicolas et al. 2009). Nevertheless, when accounting for the observed kinematic and kinetic variations within humans as well as differences between primate species (e.g. bipedal walking in bonobos, gibbons, macaques or baboons), it appears obvious that bipedal gaits cannot simply be categorised into these two single types: erected versus compliant gaits. As highlighted by the comparative anatomy, the anthropometric parameters that are potentially useful for locomotor modelling are numerous. The characterisation of general locomotor patterns (such as erected and compliant bipedal walks) are based on relatively simple anatomical model (built with few anatomical parameters). However the biomechanical characterisation of the varied patterns of bipedal gait should imply, in future developments, the use of anatomical models that are more complex and more faithful to the available anatomical data. In that perspective, the comparative approach provides some interesting ways of investigations: it increases the range of variation of the anatomical/anthropometric model and provides a functional interpretation of this variation in the frame of a normal functional pattern. In future studies, aiming at a more refined analysis of bipedal walking, the integration of additional and detailed taxon-specific anthropometric data, as well as larger ranges of variation will constitute a significant bonus. To date, their integration appears to be limited by at least: (1) the scarce kinematic and kinetic comparative data concerning normal bipedal gaits; and (2) tools of calculation which do not yet allow integration of sufficient parameters simultaneously to produce a truly biorealistic model. Research in both fields is in full development (cf. this chapter). The road to a modelling and simulating procedure that fully integrates all required anthropometric data is still long. Yet, it is not an Utopian dream to expect that anthropometric data will be increasingly used in the context of particular research, as it is already engaged in humans. We believe that a wide multidisciplinary research would constitute the ideal context in which to fill this gap.

182.6.1 Applications to Other Areas of Health and Disease

As discussed earlier, anthropology and bipedal locomotion have several applications. We know that anthropometric data reflect features which have some consequences for gait that could lead to some diseases. This is the case for obese people who exert high loads on the joints and require more muscle power to walk. Repetitive loading on the feet and other parts of the lower extremity may have structural consequences, such as musculoskeletal pain, tenderness over the calcaneal tuberosity at the point of attachment of the plantar fascia, or osteoarthritis of the knee (Hill and Cutting 1989). Just as for obese people, compensatory strategies can be found during gait in elderly people.

Table 182.2 Key facts of anthropometry in bipedal locomotion

1. The anatomical parameters that are potentially useful for locomotor modelling are numerous.
2. Thus, the biomechanical characterisation of the varied patterns of bipedal gait in primates should imply, in future developments, the use of complex anatomical models, such as the integration of detailed taxon-specific anatomical and anthropometrical data.
3. To date, their integration appears to be limited by at least: (1) the scarce kinematic and kinetic data concerning the bipedal locomotion of non-human primates; and (2) tools of calculation which do not yet allow integration of sufficient parameters simultaneously to produce a truly biorealistic model.
4. A wide multidisciplinary research would constitute the ideal context for developing more detailed models to understand the link between anatomical and anthropometrical parameters and corresponding movements for a wide range of species.

This table lists the key facts of anthropometry in locomotion and especially how anatomy could be taken into account in understanding and simulating human locomotion

These adaptations can be caused by strength and mobility impairment, rheumatic (arthritis) and orthopaedic (low back pain and joint replacement) pathologies. A walking style which engenders increased energy expenditure by the low-back- and hip muscles could result in either chronic muscle fatigue or increase the articular forces acting on the hip and spine, leading to degenerative changes in joint cartilage, both of which can lead to a sedentary lifestyle and thus further increase functional limitations.

Musculoskeletal models have been initially introduced in medicine and especially surgery for rehabilitation. Hence, shortening a muscle, a tendon or modifying the tibial plateau, etc., is performed in order to modify the movement of the patient. The software OpenSim (http://simtk.org/home/opensim) has been developed to help researchers and doctors to carry out our experiments on virtual patients to simulate the impact of changing anatomical data of the subjects on gait. Many works cited in the last section are based on the same type of approaches (reported in Table 182.2).

Summary Points

- The link between an anatomical property and its impact on gait relies on accurate anthropometrical data. Considering human among primates in a wider comparative framework would enable us to identify the fundamental relationship between anthropometry and biomechanics.
- The spatial and temporal parameters of gait are recognised to be of clinical relevance in the assessment of motor pathologies. Consequently, they are considered as important functional measures (or *vital signs*) of gait.
- Limb compliance leads to smaller oscillations of the centre of mass and alters the magnitude of the peak vertical substrate reaction force and the shape of the force–time plot. During normal walking, humans generate a vertical ground reaction force curve with two distinct peaks that are both greater than body weight. This force pattern is characteristic of a stiff-legged gait in which the centre of mass is highest at midstance and lowest at double support. By contrast, in most non-human primates, bipedal walking generates single-peaked force curves in which the peak is much closer to body weight.
- One of the most striking aspects of bipedal walking in non-human primates is that they, unlike humans (who use extended hip and knee joints during walking), often adopt a relatively flexed (bent-hip bent-knee) and more compliant limb posture.
- In biomechanics, the three most important parameters for a body segment are segment centre of gravity (the mean of the mass distribution of a segment), the radius of gyration (essentially the

standard deviation of mass distribution) and moment of inertia (the characteristic pattern of mass distribution acting to resist angular acceleration in a given plane of mass acting to resist a given angular acceleration).

- Recent studies increasingly account for anatomical complexity, for example, in the development of musculoskeletal models of the foot in a comparative perspective. However, the resulting set of variables is so large that it is difficult to obtain reliable dynamic data: the redundancy of the actuators leads to using hypotheses/constraints in computing muscle activation instead of measurements.
- A combination of several mechanisms are likely to contribute to energy conservation: pendular mechanisms involving exchange of out-of phase potential and kinetic energies, spring-mass mechanisms where energy is stored in elastic tissue and aligning the path of the COM and the trajectory of the GRF.
- Movement, including bipedal locomotion, depends on numerous anatomical parameters that affect the way turning forces are exerted about joints: physiological cross-sectional area of a muscle, moment arm of this muscle, the moving joint's centre or axis of motion, position of the origin and insertion of a muscle…
- Inverse and forward dynamic analysis are vital elements in the analysis of internal force and motion and have begun to be accepted as powerful tools in reconstruction of the behaviour of extinct species, known only from fossils.
- With these various advances in computer simulation, this approach is now a recognised technique in studies of the evolution of the human locomotor system and is likely to become increasingly a core element in the toolkit of biological anthropology and anthropometry.

Chapter 183
Use of Anthropometry for the Measurement of Lower Extremity Alignment

Annegret Mündermann

Abstract The measurement of lower extremity alignment is an important component of the diagnosis and prognosis of musculoskeletal diseases. In addition, poor lower extremity alignment has been identified as a risk factor for incurring injuries during physical activities. Relating anthropometric information and limb alignment to joint loads during daily activities enables the identification of risk factors for musculoskeletal injuries and diseases.

Lower extremity alignment can be assessed directly using medical imaging techniques or indirectly using established clinical measures. Palpation of anatomical landmarks and anthropometric information is currently used for many indirect methods assessing the alignment of the lower extremity. Current clinical methods for the measurement of lower extremity alignment include visual observation and methods using callipers, inclinometers or goniometers. A recent study showed the potential of using position capture similar to what is typically performed during gait analysis as an alternative method for the assessment of lower extremity alignment. Mechanical axis alignment assessed using this method correlated with radiographic measurements, the current gold standard, and with disease severity in patients with medial compartment knee osteoarthritis (OA). In addition, novel technology including functional joint center determination and markerless motion capture has a great potential in providing objective and thus reliable assessments of lower extremity alignment especially in populations that would not routinely undergo radiographic examination.

Indirect assessment of lower extremity alignment can be challenging in obese patients and in the elderly. Establishing relationships between anthropometric information, limb alignment and detailed information measured using novel techniques is an important step in increasing the relevance of simple and quick clinical measurements for a larger range of sub-populations in health and disease.

Abbreviations

ACL	Anterior cruciate ligament
ASIS	Anterior superior iliac spine
ICC	Intraclass correlation coefficient
OA	Osteoarthritis
MRI	Magnetic resonance imaging

183.1 Introduction

Proper alignment of the skeleton during stance, ambulation, and occupational and sports activities is critical for optimal function, energy, efficiency and preservation of a healthy musculoskeletal system. During static and dynamic activities, the lower extremity fulfills a range of biomechanical tasks, including supporting the trunk, force production, load transfer, and maintaining balance. Sub-optimal alignment of the lower extremity during these tasks increases the risk for acute injury to the musculoskeletal system and the development of chronic tissue damage and degeneration, leading to excessive wear and loosening of the prosthetic implant in total joint replacement patients. The importance of this fact is widely recognized in the areas of orthopedics, ergonomics, physical therapy, sports, and other disciplines concerned with the prevention, rehabilitation, and treatment of musculoskeletal injuries and diseases.

A range of methods have been developed for the measurement of lower extremity alignment. For instance, the use of radiographic images facilitates the direct measurement of skeletal alignment but is limited to specific static or quasi-static postures. While other methods allow for the measurement of lower extremity alignment in different postures or even in dynamic situations, these methods rely on the accurate palpation of anatomical landmarks and the use of anthropometric information to estimate skeletal alignment indirectly.

In this chapter, common definitions of lower extremity alignment are given, and the role of lower extremity alignment for injury and disease development and for the aging population is discussed. Established and novel methods for the measurement of lower extremity alignment are described with a focus on methods that use anthropometric information. In the final section of this chapter, challenges and limitations of applying these methods and the use of anthropometric information to specific patient groups, including obese persons and the elderly, are considered.

183.2 Common Measures of Lower Extremity Alignment

For optimal function, the lower extremity should be properly aligned in all three planes, which are the frontal, sagittal, and transverse planes. Common measures describing the alignment of the femur and tibia in the frontal plane are the *anatomical axis*, the *mechanical axis*, and the *quadriceps angle* (*Q*-angle). The *sagittal plane mechanical axis* describes the alignment of the lower extremity in the sagittal plane in full extension. Lower extremity alignment in the transverse plane is described by the *natural foot position* during stance. While these measures are applicable to the general population, they might not be appropriate measures for the assessment of limb alignment in patient groups with severe limb deformities. Table 183.1 summarizes the definitions of these parameters.

183.2.1 Anatomical Axis

The anatomical axis of a bone is the mid-diaphyseal line represented by a line through the medullary cavity of the bone. The angle between the anatomical axis of the femur and the anatomical axis of the tibia represents the anatomical axis angle which normally is 6° of valgus (Schünke et al. 2005).

The anatomical axis of a long bone can only be measured accurately using imaging methods such as radiography, magnetic resonance imaging (MRI), or ultrasonograms. While the anatomical axis

Table 183.1 Key features of measures describing lower extremity alignment

Parameter	Definition	Anatomical plane
Anatomical axis of a bone	Mid-diaphyseal line represented by a line through the medullary cavity of the bone	Sagittal and frontal
Anatomical axis angle	Angle between the anatomical axis of the femur and the anatomical axis of the tibia	Frontal
Mechanical axis of a bone	Straight line connecting the joint centers of the joints proximal and distal to the joint of interest	Frontal
Mechanical axis angle	Angle between a line from the center of the femoral head to the center of the femoral intercondylar notch, and a line from the center of the tips of the tibial spines to the ankle talus	Frontal
Quadriceps angle (Q-angle)	Angle formed by the longitudinal axis of the femur and a line from the center of the patella to the center of the tibial tuberosity	Frontal
Natural foot position	Angle formed by the longitudinal bisection of the foot and the posterior–anterior axis	Transverse
Leg length discrepancy	Difference in leg length	NA

This table lists the definitions of measures that describe lower extremity alignment and anatomical planes in which alignment is described by these measures

alignment is of great importance in malaligned limbs, such as recurvatum deformity of the tibia or flexion deformity of the femur, these deformities can be poorly assessed by methods using anthropometric measurements. Hence, methods to assess anatomical axes (for instance, Cooke et al. 1991) are not described in this chapter.

183.2.2 Mechanical Axis

The mechanical axis of a bone is defined as the straight line connecting the joint centers of the joints proximal and distal to the joint of interest. The mechanical axis of the lower extremity is defined by a line running through the center of the hip joint to the center of the ankle joint. In a neutrally aligned leg, this line passes through the center of the knee joint. The mechanical axis angle is defined as the angle between a line from the center of the femoral head to the center of the femoral intercondylar notch, and a line from the center of the tips of the tibial spines to the ankle talus (Fig. 183.1) (Moreland et al. 1987). In the normal femur, the mechanical and anatomical axes deviate, whereas, in the normal tibia, the mechanical and anatomical axes are essentially represented by the same line.

In a varus knee, the mechanical axis passes medial to the center of the knee joint resulting in positive values for the mechanical axis angle, and, in a valgus knee, the mechanical axis passes lateral to the center of the knee joint resulting in negative values for the mechanical axis angle. The mechanical axis angle in normal volunteers is 1.3° ± 2° (Hsu et al. 1990; Moreland et al. 1987). In older females, the mechanical axis angle measures 0° (Glimet et al. 1979). Patients with OA of the medial compartment have varus aligned knees with mechanical axis angle of 6.0° ± 4.5° (Mündermann et al. 2004). As the disease progresses, mainly cartilage in the medial compartment deteriorates leading to gradually increasing varus alignment.

The distance between the line of action of the ground reaction force and the knee joint center increases with greater varus alignment for a given patient. This change in the geometric alignment typically translates into a greater dynamic knee varus moment. The greater the varus moment, the more load is transferred through the medial compartment of the knee, leading to a faster deterioration

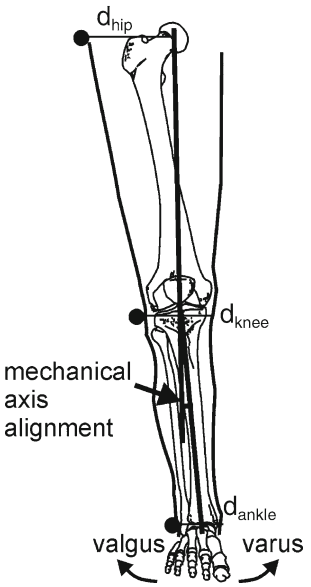

Fig. 183.1 Definition of the mechanical axis alignment of the lower leg in the frontal plane. Mechanical axis alignment was defined as the angle between a *line* from the *center* of the femoral head to the *center* of the femoral intercondylar notch, and a *line* from the *center* of the tips of the tibial spines to the ankle talus (Moreland et al. 1987). Joint centers were determined based on skin markers on the greater trochanter, lateral joint line of the knee, and lateral malleolus combined with measured joint correction factors. Positive values indicate varus alignment, and negative values indicate valgus alignment. The limbs were aligned with the laboratory coordinate system for the position capture method (Reprinted from Mündermann et al. (2008) with permission of Elsevier)

of cartilage (Andriacchi et al. 2004). This vicious cycle can be broken by interventions aimed at realigning the lower extremity such as osteotomies (Schipplein and Andriacchi 1991), braces, or footwear (Fisher et al. 2007).

In full extension, the normal sagittal plane mechanical axis passes anterior to the center of rotation of the knee joint allowing the knee to be locked in full extension and the quadriceps muscle to relax. In patients with a hamstring contracture, the mechanical axis runs posterior to the knee joint center requiring continuous quadriceps muscle effort to maintain upright stance. In hyper-extended knees, the mechanical axis runs anterior to the knee joint center placing additional load on soft-tissue structures to stabilize the joint in this position. However, because the knee moves in the sagittal plane during locomotion and other physical activities, static sagittal plane alignment generally provides limited value for lower extremity function during dynamic activities in healthy persons. By contrast, a pathological hamstring contracture prevents full extension of the knee that can be assessed statically and is manifested dynamically as crouch gait (Rab 1992).

183.2.3 Quadriceps Angle (Q-Angle)

The quadriceps angle or *Q*-angle is defined as the angle formed by the longitudinal axis of the femur, representing the line of action of the quadriceps muscle, and a line that represents the direction of the

patellar tendon. Clinically, the angle is obtained as the angle between a line connecting the center of the patella with the anterior iliac spine above and a line connecting the center of the patella with the tibial tuberosity. The *Q*-angle is normally 11.5° ± 2.4° in men and 13.9° ± 2.6° in women, with their quadriceps in a relaxed position (Medina McKeon and Hertel 2009). The angle becomes smaller when the quadriceps muscle is contracted.

Among other factors, the *Q*-angle is affected by foot position (Olerud and Berg 1984), and thus foot position should be controlled during its assessment. While a greater *Q*-angle is commonly associated with an increased likelihood of the quadriceps pulling the patella laterally, its importance for the risk of knee disorders such as patellofemoral pain syndrome or anterior knee pain is controversial (Fredericson and Yoon 2006). One main concern with using the *Q*-angle as an estimate of patella alignment is that in cases of lateral patellar subluxation, the *Q*-angle decreases. Hence, lateral subluxation masks the measurement that is designed to evaluate it.

183.2.4 Natural Foot Position

The natural foot position is defined as the angle formed by the longitudinal bisection of the foot and the posterior–anterior axis and is usually assessed during natural bipedal stance. The longitudinal bisection of the foot normally falls between the center of the plantar heel and the second and third metatarsals (Aharonson et al. 1980). Dynamically, the alignment in the transverse plane is assessed as the foot progression angle, which is the angle formed by the longitudinal bisection of the foot and the line of forward progression.

The natural foot position and foot progression angle show a large variability even in normal populations ranging from 6° to 21° (Seber et al. 2000). Several factors can influence the natural position and foot progression angle, including hip external rotation, femur torsion, and tibia torsion. Thus, these parameters can indicate a range of pathologies or functional abnormalities, such as muscle paresis or tibia torsion following fracture. Excessive internal or external rotation of the foot during gait affects the mechanical load placed on the joints of the lower extremity.

183.2.5 Leg Length Discrepancy

Leg length discrepancy is defined as a difference in leg length. Normally, both legs have close to the same length, facilitating symmetry during stance and dynamic activities. Leg length discrepancy can be caused by a true structural difference between the tibiae or the femora. This discrepancy can simply be a natural variation between the two sides of the body. Other causes for anatomical leg length discrepancy include injury to a bone, bone infection, bone dysplasias, arthritis, or neurological conditions. In addition, leg length discrepancy can have functional reasons such as joint dysfunction or be caused by differences in muscle mass.

However, even with two legs of the same length, the patient may present with functional leg length discrepancy because of a pelvic tilt, curvature in the back, or other parameters (see Chap. 44). While leg length discrepancy can be assessed using anthropometric measurements as described below, it is frequently assessed dynamically during a symmetric functional task.

183.3 Common Methods for the Measurement of Lower Extremity Alignment

183.3.1 Direct Measurement Methods

Direct methods for the measurement of lower extremity alignment are based on imaging of the skeleton itself using radiography or MRI techniques and subsequent manual or automatic measurement of the angle between the line connecting the hip and knee joint centers and the line connecting the knee and ankle joint centers (Table 183.2).

183.3.1.1 Radiographic Measurements

Lower extremity alignment is typically measured from frontal plane radiographs of the entire lower extremity during double-support standing. Using the gold standard or traditional method for the measurement of lower extremity alignment, single weight-bearing radiographs including the hip, knee, and ankle joints are captured (Moreland et al. 1987). To minimize measurement variation related to limb rotation, each patient is positioned with the tibial tubercle anterior. Using a ruler, lines are then drawn on the film from the center of the femoral head to the center of the femoral intercondylar notch, and from the center of the tips of the tibial spines to the ankle talus. Subsequently, a goniometer is used to measure the angle between these two lines on the X-ray film. These full-limb radiographs require administration of radiation to the pelvis, a grid, and a large film, as well as the expertise of the personnel to overcome the technical difficulties such as choice of radiation dose because of the considerable difference in the amount of soft tissue at the hip and the ankle joints in most patients.

In some cases, partial radiographs are sufficient for obtaining acceptable estimates of lower extremity alignment. For instance, Kraus et al. (Kraus et al. 2005) measured the anatomical axis angle on a fixed-flexion posterior–anterior knee radiograph with the feet 10° externally rotated, the knees and thighs touching the vertical platform anteriorly, and the X-ray beam angulated 10° caudally. The anatomical axis was defined as the angle formed by the intersection of two lines originating from points bisecting the femur and tibia and converging at the center of the tibial spine tips. The origin of these lines was 10 cm from the knee joint surfaces. The angle of the anatomical axis was also determined on an anterior–posterior full-limb radiograph using the same landmarks, originating 10 cm from the knee-joint surfaces. The anatomical axis angles obtained using these partial-view radiographs correlated moderately with the mechanical axis angle obtained from full-limb radiographs. However, an offset between anatomical axis angles and mechanical axis angles of 3.5° in women and 6.4° in men was found. This fact must be taken into consideration when choosing an appropriate method for determining lower extremity alignment.

Advances in computer technology allow capturing radiographs in digital formats. Electronic drawing tools are commonly used to superimpose lines onto the digital image and for the automatic calculation of the angle between these lines (Sailer et al. 2005). However, to achieve acceptable reproducibility with these methods, a standardized set of anatomic landmarks is required (Wong et al. 2009). Recently, fully automated methods for the measurement of lower extremity alignment from digital radiographs have been introduced (Fakhrai et al. 2009) that eliminate errors potentially introduced by the tester, thus improving the measurements' reproducibility.

Table 183.2 Key features of measurement of lower extremity alignment

Method	Description	Reliability – Comments
Direct methods		
Full limb weight-bearing radiographs	Lines are drawn on the X-ray films connecting joint centers; the angle between these lines is measured using a goniometer.	1 – gold standard
Partial limb weight-bearing radiographs	Lines are drawn on the X-ray films extrapolating the orientation of the bones; the angle between these lines is measured using a goniometer.	2 – tester is guessing the orientation of the bone
Magnetic resonance images	Lines are drawn on the images connecting joint centers; the angle between these lines is measured using software.	2 – potential image distortion; generally non-weight bearing
Indirect methods		
Visual observation	Classification of alignment based on the criteria during adducted stance: varus – medial malleoli touch first; valgus – knees touch first; neutral – knees and ankles touch simultaneously.	Not available – no grading within alignment category
Caliper	Adducted stance. For varus knees: distance between the medial knee joint lines; for valgus knees: distance between the medial malleoli.	1 – combined measurement for both knees
Plumb line	Plumb line positioned between knees. For varus knees: distance between the plumb line and the medial knee joint line; valgus knees: distance between plumb line and medial malleolus	1 – separate assessment of each knee
Inclinometer	Gravity inclinometer attached to calipers. Shoulder width foot position. Angle between a line connecting tibial tuberosity and neck of talus with respect to the vertical.	1 – orientation of the tibia
Goniometer	Shoulder width foot position. Origin of goniometer over center of patella, arms aligned with mid-thigh and with patellar tendon. Angle between goniometer arms.	2 – patellar tendon estimation difficult because of its short length
Novel methods		
Photogrammetry with palpation	Calculation between lines connecting adjacent joints determined by anatomical landmarks and joint correction factors with skin markers.	2 – depends on palpation of anatomical landmarks
Photogrammetry with functional joint center	Calculation between lines connecting adjacent joints determined by segment motion through joint range of motion with skin markers.	1 – tester independent joint centers, segment defined by tester
Markerless motion capture	Calculation between lines connecting adjacent joints determined by segment motion through joint range of motion without markers.	Not available – tester independent joint center and segment identification

This table lists direct and indirect methods for the measurement of lower extremity alignment. Direct methods are measurements of the alignment of the bone themselves using imaging techniques. Indirect methods are measurements utilizing anthropometric information for the estimation of joint center locations or bone orientation. The reliability of each method is graded where *1* good reliability; *2* acceptable reliability; *3* poor reliability

183.3.1.2 Magnetic Resonance Imaging (MRI) Measurements

Compared to radiography, MR imaging systems do not emit any radiation, and are thus considered safer for the patient. The main advantage of using MRI techniques for the assessment of lower extremity alignment is the fact that musculoskeletal structures can be evaluated in three dimensions. However, only open-bore MRI systems allow the patient to be positioned in an upright weight-bearing

position that is similar to the patient's position during the traditional radiographic method. Hinterwimmer et al. (Hinterwimmer et al. 2008) developed and applied a uniform radiation-free measurement technique for the analysis of leg geometry. MR images of the hip, thigh, knee, shank, and ankle were obtained sequentially in matching imaging planes and without artificial shortening. Reproducible results were obtained using a phantom leg. In patients, leg length was generally underestimated compared to values obtained from reference radiographs. Long-range measurements across the entire field of view produce an underestimation of acquired distances because of lower strength gradients at the imaging margins. Mechanical axis alignment angles in all knees were generally underestimated with a significant underestimation of −3.6° in knees with valgus alignment. While this technique entails a cumbersome setup to align the patient's limb in the magnet, it does not expose the patient to radiation and imaging time is around two minutes. Moreover, using additional axial images along the femoral head and neck, the knee and the ankle facilitate torsion measurements of the femur and tibia, and thus allows the assessment of lower extremity alignment in all three anatomical planes.

183.3.2 Indirect Measurement Methods

Indirect methods for the measurement of lower extremity alignment are based on estimating joint center positions through palpation and anthropometric correction factors and the subsequent measurement of the angle between the line connecting the hip and knee joint centers and the line connecting the knee and ankle joint centers using tools including inclinometers, calipers, goniometers, and, more recently, photogrammetric systems. All indirect measurement methods for the assessment of lower extremity alignment are typically validated against the traditional radiographic method before being established in clinical practice or research.

183.3.2.1 Joint Center Determination

Joint centers of lower extremity joints cannot be readily identified. However, databases of cadaveric and radiographic data link joint center positions to anatomical landmarks that can be *palpated* under the skin. For instance, a variety of essential anatomical landmarks has been proposed for locating the hip joint center. The method proposed by Andriacchi et al. (Andriacchi et al. 1980, 1982; Andriacchi and Strickland 1985) identifies the medio-lateral hip joint center coordinate 2.5 cm inferior to the point halfway between the anterior superior iliac spine (ASIS) and the pubic tubercle with the anterior–posterior and proximal–distal coordinate defined by the greater trochanter. Alternate methods (Bell et al. 1989, 1990; Seidel et al. 1995; Tylkowski et al. 1982) locate the hip joint center as a percentage of the distance between the ASIS and various anatomical landmarks. Methods based on greater trochanter position have been criticized for unacceptable accuracy (Cappozzo 1991; Neptune and Hull 1995). Only few methods have been validated in large sample sizes that include both men and women and, in some cases, children. The Andriacchi and Strickland method (Andriacchi and Strickland 1985) has been validated against radiographs in a cohort of 39 normal-weight children and 31 normal-weight adults resulting in a maximum error of 3.6 cm with 95% certainty (Bell et al. 1989). The Tylkowski method (Tylkowski et al. 1982) alone resulted in 3.3 cm mean error with 95% certainty, while the combination of the Andriacchi and Strickland method and the Tylkowski method resulted in an improved accuracy of 2.6 cm error with 95% certainty (Bell et al. 1989; Bell et al. 1990). Seidel et al. (Seidel et al. 1995) measured pelvic bones from 30 male and 35 female cadavers to develop an alternate palpation method that locates the hip joint center as a percentage of

pelvic depth, height, and width. Other studies reported validations of palpation methods for as few as two subjects using radiography (Kirkwood et al. 1999; Tylkowski et al. 1982), roentgen stereophotogrammetric analysis (Leardini et al. 1999), computer tomography scanning (Fieser et al. 2000), and MRI (Aguinaldo et al. 2003).

Similarly, different definitions of the knee and ankle joint center locations exist. For the knee, the joint center for radiographic measurements is defined as the femoral intercondylar notch (Moreland et al. 1987). Using palpation methods, the knee joint center has been defined as the midpoint between the most medial and lateral aspects of the tibia plateau or as the midpoint between the most prominent medial and lateral aspects of the femur epicondyles (Andriacchi et al. 1998; Schipplein and Andriacchi 1991). For the ankle joint, the joint center for radiographic measurements is defined as the center of the tips of the tibial spines to the ankle talus (Moreland et al. 1987). Using palpation methods, the ankle joint is typically defined as the midpoint between the tips of the medial and lateral malleoli (Wu et al. 2002). While the effect of using any of these definitions on mechanical axis angle measurements is negligible, the proper definition of the joint centers is very critical for other applications such as the estimation of joint loads using kinetic analysis and anatomical modeling.

183.3.2.2 Goniometer, Inclinometer or Caliper Measurements and Visual Observation

Clinically, several non-radiographic methods for the measurement of knee alignment have been used, including visual observation, goniometry, and caliper and inclinometer methods of measurement. *Visual observation* is used for the method described by Magee (Magee 1992) to categorize varus, valgus, or neutral alignment. Patients are asked to adduct their lower limbs slowly until either the knees or ankles touch. If the medial malleoli touch first, the participant is classified as having varus malalignment. If the knees touch first, the participant is classified as having valgus malalignment. If knees and ankles touch simultaneously, alignment is considered neutral. Malalignment that is evident using Magee's method can be quantified using a *caliper* marked in 1-mm increments (Hinman et al. 2006). In patient with varus knees, the distance between the left and right medial knee joint lines is recorded (Fig. 183.2a). In patients with valgus knees, the distance between the left and right medial malleoli is recorded. Because the caliper method is influenced by the alignment of both knee joints, a modification of this method can be used to more accurately assess alignment of the affected knee only. A *plumb line* is positioned between the lower limbs (Hinman et al. 2006; Jonson and Gross 1997). For varus knees, the distance between the plumb line and the symptomatic medial knee joint line is measured using a caliper (Fig. 183.2b). For valgus knees, the distance between the plumb line and the medial malleolus of the symptomatic side is measured using a caliper.

A novel method for assessing lower limb alignment has been recently introduced by Hinman et al. (Hinman et al. 2006) to assess orientation of the tibia with respect to the vertical. A *gravity inclinometer* is attached to a set of calipers. Patients are positioned with their weight distributed equally over both feet with their feet shoulder width apart. The tibial tuberosity and neck of talus are identified. The caliper arms are placed on these landmarks (Fig. 183.2c). The angle of the tibia with respect to the vertical (180°) is recorded.

For the measurement of alignment using a long-arm *goniometer*, patients are asked to stand with their weight distributed equally over both feet with their feet positioned shoulder width apart (Kraus et al. 2005). The origin of the goniometer is positioned over the center of the patella, and the arms are aligned with the mid-thigh above the knee and with the patella tendon below the knee (Fig. 183.2d).

The inclinometer, caliper, and plumb line methods have been shown to be reliable in patients with knee OA (ICC > 0.94; (Hinman et al. 2006). The goniometer method was slightly less reliable with an ICC of 0.84, and reliability for the visual observation method has not been reported. All of these

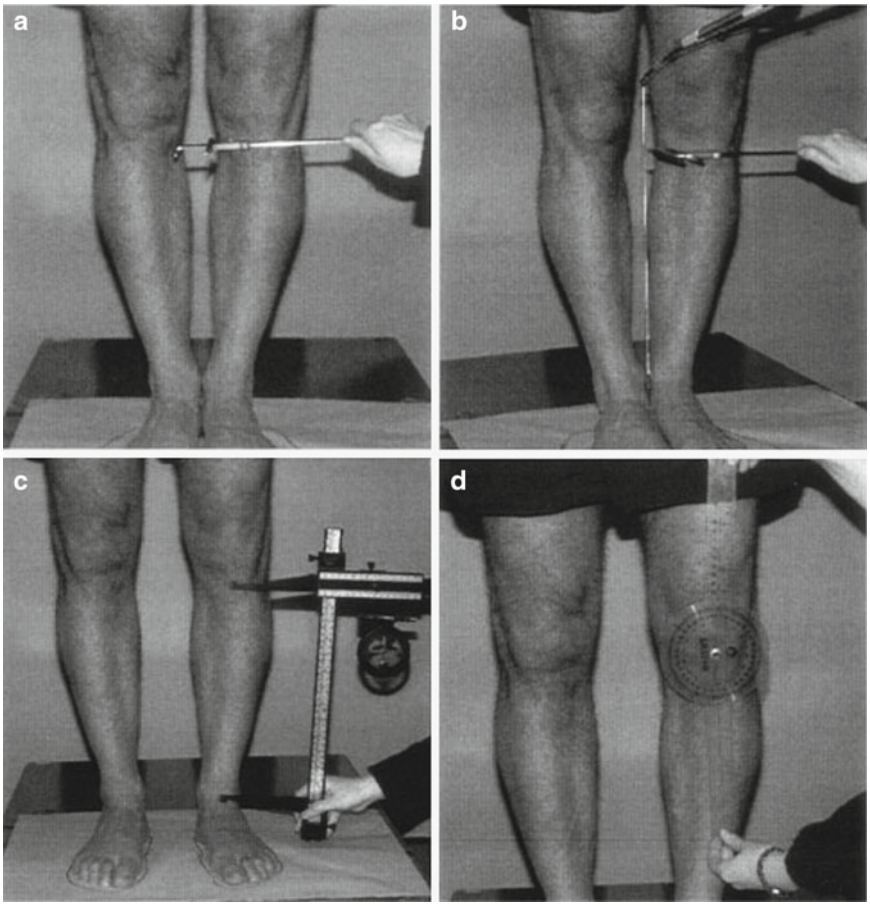

Fig. 183.2 Determination of knee alignment using common clinical measures. Determination of knee alignment using (**a**), the caliper method (for a varus knee), (**b**), the plumb-line method (for a varus knee), (**c**), the inclinometer method, and (**d**), the goniometer method (Reprinted from Hinman et al. (2006) with permission of John Wiley & Sons, Inc.)

Table 183.3 Key features of calipers, goniometers, and inclinometers

1. Calipers are devices that measure distances between two points or two landmarks.
2. Goniometers consist of two arms that are connected in a hinge joint.
3. The arms of goniometers are typically aligned with two body segments to measure the angle between these two segments.
4. Inclinometers measure the angle between the device arm and the vertical (inclination).
5. The angle between two segments can be calculated from the inclination of both segments.
6. These tools are common clinical tools mainly because of their low cost, because they are simple and provide instant results.
7. The reliability of these tools depends on the clinician's ability to locate anatomical landmarks correctly.

This table lists the key facts of clinical tools for measuring lower extremity alignment including calipers, goniometers, and inclinometers

methods offer great clinical application with regard to cost, simplicity of use, and speed of result. However, these methods require considerable tester training and experience to achieve acceptable results. Hence, the use of objective methods for the assessment of lower limb alignment is advised to allow for comparisons between studies and centers (Table 183.3).

183.3.3 Novel Measurement Methods

183.3.3.1 Photogrammetry Measurements

Joint motion and joint load during walking are commonly assessed using gait analysis based on stereophotogrammetric systems and reflective markers attached to the skin. Frequently, anthropometric measurements of patients' lower extremity joints are taken to determine the joint center locations relative to these skin markers. The knowledge of the joint center location is a prerequisite for the calculation of joint load during dynamic activities.

The goal of a recent study (Mündermann et al. 2008) was to investigate if the mechanical axis alignment can be estimated using anatomical landmarks and anthropometric measurements during stance and a stereophotogrammetric system and if the association with OA severity is similar for both measurements. It was hypothesized that the mechanical axis alignment measured from standing radiographs can be predicted from the mechanical axis alignment measured using anatomical landmarks and anthropometric measurements, and that mechanical axis alignment predicted from anatomical landmarks is associated with OA severity.

Reflective markers were placed by the same tester on the proximal aspect of the greater trochanter, the most lateral aspect of the joint space between tibia and femur, the most lateral aspect of the lateral malleolus, and the 5th metatarsal head in 62 patients with bilateral OA in the medial compartment of the knee. Marker data were captured using four high-speed cameras (120 frames/s; MCU240, Qualisys Medical AB, Gothenburg, Sweden). Anthropometric measurements were taken to determine the distance from the skin markers to the joint centers in the frontal plane. In this study, the hip joint center was assumed to be located 2.5 cm distal of the midpoint of a line connecting the ASIS to the pubic tubercle (Andriacchi and Strickland 1985). The hip joint correction factor was measured as the distance between this point and the most lateral aspect of the skin overlying the greater trochanter. The knee joint center was assumed to be located at the midpoint of the knee joint line. The knee joint correction factor was measured as half the distance between the skin overlying the medial and lateral joint line. The ankle joint center was assumed to be located at the midpoint of the trans-malleolar line. The ankle joint correction factor was measured as half the distance between the skin overlying the medial and lateral malleoli. The marker radius (0.5 cm) was taken into consideration when determining the joint center locations.

The mechanical axes alignment of all knee joints was calculated as the angle between a line from the hip joint center to the knee joint center, and a line from the knee joint center and the ankle joint center from a single standing trial taking into account the radius of the skin markers. To minimize measurement variation related to limb rotation, the patient's position was aligned to the laboratory coordinate system. The angle γ between the vector from the heel to the fifth metatarsal head (v_{foot}) and the anterior–posterior axis (y) was calculated as

$$\gamma = 180 / \pi * \arccos(v_{foot} \bullet y / (|v_{foot}| * | y |)$$

The entire limb was then rotated by γ about a rotation axis passing through the ankle and hip joint centers. The mechanical axis δ was then calculated as

$$\delta = 180 / \pi * \arccos(v_{femur,zx} \bullet v_{tibia,zx} / (|v_{femur,zx}| * | v_{tibia,zx} |),$$

where $v_{femur,zx}$ was the vector connecting the knee joint center with the hip joint center and $v_{tibia,zx}$ was the vector connecting the ankle joint center and the hip joint center projected into the zx-plane. Neutral alignment was defined as zero, varus alignment as positive angles, and valgus alignment as negative angles.

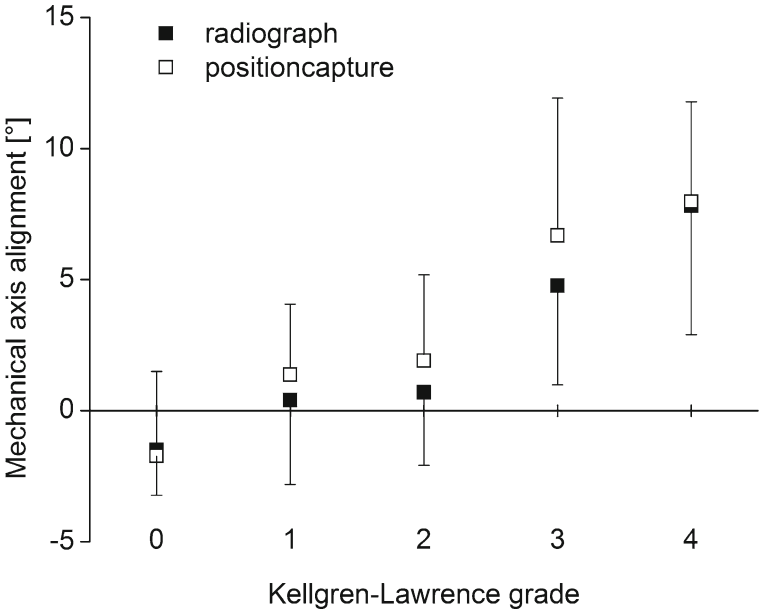

Fig. 183.3 Association between mechanical axis alignment and severity of knee osteoarthritis. Varus alignment based on mechanical axis alignment from radiographs and from position capture increased with increasing osteoarthritis severity (Kellgren–Lawrence grade; *0* no signs of osteoarthritis to *4* complete loss of articular cartilage). Values are mean values ± one standard deviation (Reprinted from Mündermann et al. (2008) with permission of Elsevier)

The mechanical axis alignment measured from radiographs ranged from −6° to +15° (6° valgus to 15° varus alignment). The average mechanical axis alignment based on position capture was 1.2° greater than the average mechanical axis alignment based on radiographs (position capture: 3.8 ± 4.7°; radiograph: 2.6 ± 4.4°; $P = 0.001$). A significant correlation was found between the mechanical axis alignment measured by position capture and by radiographs ($R = 0.738$; $P = 0.001$). The mechanical axis alignment based on position capture was not associated with age ($P = 0.902$), sex ($P = 0.849$), or BMI ($P = 0.568$), but was associated with Kellgren–Lawrence grades ($R^2 = 0.807$; $P < 0.001$). Varus malalignment measured from position capture increased with increasing OA severity (Fig. 183.3).

The strength of estimating the mechanical axis from position capture is that the measurement can be taken automatically during a reference trial in gait analysis. In addition, the information presented in this study could also be obtained from two-dimensional frontal view still images of the subject's lower extremity with markers on anatomical landmarks and anthropometric measurements. The measurement of the mechanical axis alignment using anatomical landmarks and anthropometric measurements would allow the estimation of the mechanical axis alignment in populations that are typically not subjected to a full-limb radiograph including healthy control subjects, subjects after anterior cruciate ligament (ACL) or meniscus injury or surgery, and even children when they undergo gait analysis. Information on limb alignment in these publications will allow the determination of the role of limb alignment as a risk factor for injuries and for the development and progression of degenerative joint diseases. However, the possibility of varying results depending on the marker set chosen for the measurements warrants the use of a consistent marker set such as the one used in this study.

183.3.3.2 Functional Joint Center Determination

Because of the difficulty of palpating anatomical landmarks for locating joint centers, joint center positions have been defined *functionally* in recent years. These methods require motion analysis equipment that is used to record the motion of one segment (e.g., the high) relative to an adjacent

segment (e.g., the pelvis). These methods have been shown to produce more reproducible results than methods based on palpation of anatomical landmarks (Besier et al. 2003).

All functional methods identify a joint center as the functional center of rotation between two adjacent segments. The various functional algorithms require data describing rotations of the specific joint being studied throughout its range of motion. For instance, in order to estimate the hip joint functional center of rotation, the thigh and pelvis are equipped with markers and the movement of the segments are recorded while the thigh is actively or passively rotated relative to the pelvis. Algorithms proposed for functional methods using reconstructed marker positions are based on the assumption that the distance between femoral markers, or their centroid, and the center of rotation does not vary. Methods that entail no geometric constraints between markers include quadratic best sphere fitting (Cappozzo 1984), quartic best sphere fitting (Gamage and Lasenby 2002), and quasi-intersection between mid-orthogonal planes and vectors connecting each marker position in two arbitrarily chosen instants of time (Halvorsen et al. 1999). Other methods impose that the distance between femoral markers must be invariant, that is, the femoral marker cluster must be rigid (Holzreiter 1991; Woltring 1990). Other factors including stereophotogrammetric error, type and amplitude of the relative movement between the pelvis and femur, number of markers used, and geometry and location of the femoral marker cluster may influence the performance of functional methods.

Similar to the palpation methods, only few functional methods have been validated against hip joint center locations measured using three-dimensional medical images. Bell et al. (Bell et al. 1989; Bell et al. 1990) reported that functional methods were less accurate than palpation methods when compared against dual radiographic images in ten able-bodied males. However, in these studies, the thigh segment was defined by a single marker. By contrast, Leardini et al. (Leardini et al. 1999) defined the thigh segment by a minimum of three markers and found that functional methods were more accurate than palpation methods when compared to dual radiographic images in 11 able-bodied males (8–16 mm vs. 25–30 mm error, respectively). Functional methods have been suggested for use in populations in which the anatomical landmarks required by palpation techniques are difficult to find and mark during activity (Besier et al. 2003).

183.3.3.3 Markerless Motion Capture

While the use of a functional joint center definition using traditional motion capture methods requires extensive patient preparation time, novel methods for motion capture have been introduced. The most significant technical advance has been the development of a markerless motion capture system (Corazza et al. 2006; Mündermann et al. 2006). This novel technique requires no preparation time. Multiple synchronized video sequences are captured while the patient performs the task of interest. The patient's silhouette is identified in each image, and the three-dimensional body surface is reconstructed for each frame. An anatomical model is then fit to the surface, and joint motion, forces, and moments are computed. Similar to the functional determination of the joint centers using skin markers, the functional joint centers can be identified by capturing markerless data of the patients while moving each joint throughout its range of motion (Corazza et al. 2007). Using the information on joint center location, limb alignment can be calculated as described above.

The main strength of these novel techniques is the objectivity of the measurement. Because this technique does not require the palpation of anatomical landmarks, the result will be independent of the tester or the laboratory. However, this technique is yet to be validated against standard radiographic assessments of lower limb alignment. This methodology can be expanded to assess the alignment of other segments of the body.

183.4 Challenges and Limitations of the Measurement of Lower Extremity Alignment in Sub-populations

183.4.1 Obese Population

Soft tissue overlying anatomical landmarks as it is present in overweight and obese subjects may greatly increase the error associated with correct palpation of these landmarks. While functional methods represent a promising advancement in the estimation of the hip joint center location in populations where the palpation of anatomical landmarks is difficult, their accuracy has not been quantified in an obese or overweight population.

183.4.2 Elderly Population

Special considerations must be undertaken in the selection of the most appropriate method for the measurement of lower extremity alignment in the elderly population. For instance, bone quality decreases with increasing age, and, hence, additional exposure to radiation may have detrimental consequences in patients who already present with poor bone quality. Further, functional methods for the determination of joint center locations may not be feasible in this subpopulation because of the limited active range of motion in some joints of the lower extremity and the reduced balance capability when performing required motion tasks.

183.5 Applications to Other Areas of Health and Disease

183.5.1 Joint Loading

During walking, the ground reaction force vector passes medially to the knee joint center causing an external adduction moment (Fig. 183.4). This represents greater forces being transferred through the medial than through the lateral compartment of the knee (Schipplein and Andriacchi 1991). Typically for a knee with varus malalignment, the line of action of the ground reaction force likely passes more medially to the knee joint center, thus creating a greater external knee adduction moment during single limb support (Fig. 183.4). Naturally, static alignment of the lower extremity is even more important for activities involving quasi-static postures.

The knee adduction moment is one component describing joint loading during physical activities such as walking. Joint loading in general is important for maintaining healthy tissue and is affected by the proper functioning of the entire musculoskeletal system. Specifically, muscle strength, neuromuscular coordination, balance, integrity of passive structures including ligaments and joint capsulae, and skeletal alignment are among the most important components affecting joint load.

183.5.2 Injury Mechanisms in Sports and Physical Activity

Static and dynamic alignment plays an important role in identifying the risk of an athlete or person for getting injured while playing sports or being physically active. For instance, a greater knee valgus

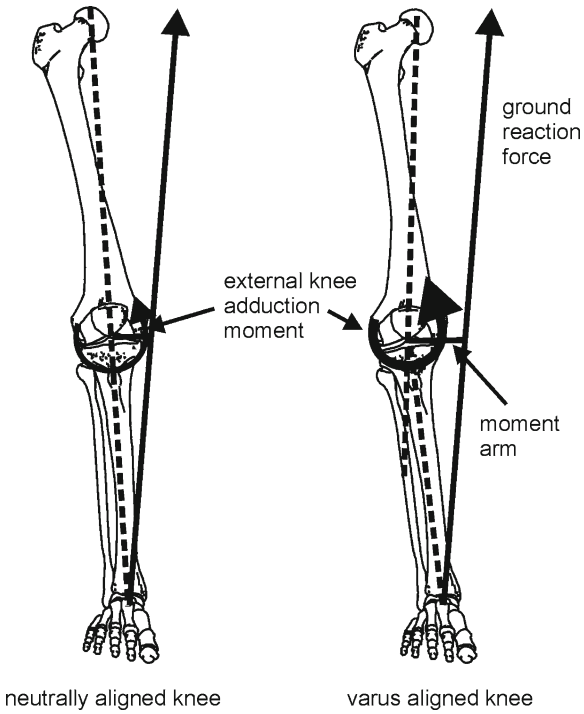

Fig. 183.4 Implications of longer moment arms of the ground reaction force in varus versus neutrally aligned knees. The external knee adduction moment tends to be greater in varus-aligned knees (*right*) compared to neutrally aligned knees (*left*) due to a greater moment arm of the ground reaction force about the knee joint center (Reprinted from Mündermann et al. (2008) with permission of Elsevier)

angle has been associated with greater knee valgus load during landing or sidestepping activities (McLean et al. 2005). Knee valgus load during sports movement is viewed as an important predictor of non-contact ACL injury risk, particularly in females. Hence, lower extremity alignment in athletes or in the generally physically active population may be used for assessing a person's risk for incurring an ACL injury.

183.5.3 Disease Development and Progression

In clinical practice, the static alignment of the osteoarthritic knee is frequently measured as the mechanical axis alignment using full-limb radiographs with the goal to estimate the load distribution between the medial and lateral compartments of the knee. Indeed, the dynamic load distribution at the knee measured as the external knee adduction moment is related to the mechanical axis alignment (Hurwitz et al. 2002). Dynamic alignment or the knee adduction moment during walking is related to the mechanical axis alignment (Hurwitz et al. 2002) and is a strong predictor for the presence (Baliunas et al. 2002), severity (Mündermann et al. 2004), and rate of progression (Miyazaki et al. 2002) of medial compartment knee OA. In addition, patella cartilage volume decreases with increasing varus alignment assessed using radiographs (Teichtahl et al. 2008). This association might be even more critical in obese patients because of their excessive weight.

In diseases or conditions involving severe malalignment such as recurvatum deformity of the tibia or flexion deformity of the femur, the specific alignment of the skeleton will affect the line of action

and hence the function of individual muscles. The contribution of aforementioned components to the overall function cannot be generalized for patients with these conditions.

183.5.4 Obesity

Despite the technical difficulties in assessing lower extremity alignment in the obese population, these measurements presumably are highly relevant in the context of comorbidities such as degenerative joint disease, or bone diseases that are associated with an altered metabolism, disuse, and overloading the musculoskeletal system. For instance, limited information is available on gait mechanics and joint loading during walking in obese subjects. Obese subjects walk at slower self-selected speeds and reduced step length and cadence than non-obese subjects (DeVita and Hortobágyi 2003; Spyropoulos et al. 1991). When walking at similar speeds, obese subjects experience similar sagittal plane joint moments and power at the ankle, knee, and hip (DeVita and Hortobágyi 2003). While joint kinetics in the secondary planes of motion have not been reported for obese subjects, these subjects step with their feet twice as far apart than non-obese subjects during walking (Spyropoulos et al. 1991). This greater base of support may result in a greater lever arm of the ground reaction force (distance of the ground reaction force to the knee joint center), thereby increasing the knee adduction moment and the load on the medial compartment of the knee. Thus, to date it is not clear if obese subjects are at greater risk for OA primarily because of mechanical or biological differences to a healthy population.

183.5.5 Aging

Radiographic evidence of OA increases with increasing age (Felson et al. 1987). Biological tissues undergo significant changes during the aging process and these biological changes, for instance, in cartilage may be the cause for decreased tensile stiffness and strength (Kempson 1982). Articular cartilage aging does not cause OA, but the age-related metabolic and phenotypic decline of the chondrocytes increases the risk of articular cartilage degeneration and limits the ability of the cell to repair the tissue once degenerative changes occur (Martin and Buckwalter 2002). Similar changes have been observed in menisci and ligaments. Simultaneously, reduced muscle activation, cross-sectional area, force per cross-sectional area, and maximum muscle strength have been observed (Jubrias et al. 1997; Stackhouse et al. 2001).

The primary changes in gait that occur with increasing age are slower walking speeds, reduced step length, and increased double-support time (Winter et al. 1990). It has been suggested (DeVita and Hortobágyi 2000) that age causes a redistribution of joint torques and powers, with the elderly using their hip extensors more and their knee extensors and ankle plantar flexors less than young adults when walking at the same speed. This shift in power generation could be caused by the physiological changes in muscle (Jubrias et al. 1997), where the knee extensor muscles in the elderly are simply not capable of producing similar forces than in young adults. However, due to a lack of information on joint kinetics in the secondary planes of motion little is known about how these changes affect mechanical load at the joints of the lower extremity, especially at the knee. It has been proposed (Andriacchi et al. 2004) that kinematic changes associated with aging may lead to a shift in the normal load-bearing regions in a manner similar to the kinematic changes following ACL injury.

183.6 Guidelines for the Use of Anthropometry for the Measurement of Lower Extremity Alignment

While anthropometric information is used for many methods for the measurement of lower extremity alignment described above, the importance of using valid information cannot be emphasized enough.

- Appropriate anthropometric information should be selected based on the primary purpose of the lower extremity alignment measurement.
- Advantages and disadvantages of using direct versus indirect methods for the measurement of lower extremity alignment, including exposure to radiation, ease of use, technical requirements, and comparability across studies and users, must be considered.
- Direct measurements of lower extremity alignment should be used in patients with severe limb malalignment and in conditions that require capture of radiographic imaging for other diagnostic purposes justifying the exposure to radiation.
- Indirect measurements of lower extremity should be taken using the inclinometer in settings where position capture equipment is not available.
- Indirect measurements of lower extremity alignment should be included in all studies and protocols utilizing motion capture equipment and should be performed using the functional method.
- For two-dimensional position capture systems, an alignment of the subject with the laboratory coordinate system is critical since rotation about the vertical axis could lead to cross-talk between the flexion–extension angle and the mechanical axis alignment.

Summary Points

- Lower extremity alignment can be assessed directly using medical imaging techniques or indirectly using established clinical measures.
- Palpation of anatomical landmark and anthropometric information is currently used for many indirect methods assessing the alignment of the lower extremity.
- Novel technology enables more objective and thus more reliable assessment of lower extremity alignment.
- Relating anthropometric information and limb alignment to joint loads during daily activities enables the identification of risk factors for musculoskeletal injuries and diseases.
- Lower extremity alignment plays an important role in the presence, severity, and rate of progression of knee OA and in injury mechanisms of ACL rupture.
- Indirect assessment of lower extremity alignment can be challenging in obese patients and in the elderly.
- Establishing relationships between anthropometric information, limb alignment, and detailed information measured using novel techniques is important to increase the relevance of simple and quick clinical measurements for a larger range of sub-populations.

Acknowledgments The author would like to express her appreciation to Prof. Thomas Andriacchi and Chris Dyrby for their contribution to the study on measuring mechanical axis alignment using position capture.

Chapter 184
Anatomical Reference Frames for Long Bones: Biomechanical Applications

Luca Cristofolini

Abstract The definition of anatomical reference frames is necessary both for *in vitro* biomechanical testing, and for *in vivo* human movement analyses. Different reference frames have been proposed in the literature, for the different applications. Reference frames for *in vivo* use must rely on anatomical landmarks that can be accessed non-invasively in living subjects. This limits the operator to certain regions of the bone segments, and possibly to anatomical landmarks that are scarcely reproducible. Conversely, when the bone is fully accessible *in vitro*, direct measurements are possible of diameters, lengths, and angles. This enables the selection of anatomical reference planes that rely upon anatomical landmarks that are better reproducible. In this section, anatomical reference frames are discussed for the most important long bones of the human skeleton: femur, tibia, fibula, metatarsal bones, humerus, radius, ulna, metacarpal bones, and phalanges. The different reference frames proposed for each bone segment are discussed: this includes the guidelines proposed by the Standardization and Terminology Committee of the International Society of Biomechanics (ISB) for *in vivo* movement analysis, and also reference frames proposed by different authors for *in vitro* testing. Optimal reference frames are proposed for each bone segments. Detailed guidelines (including suggested materials and methods) are provided to correctly identify the anatomical landmarks and the anatomical frames. For each bone segment, an estimate of the intra-operator repeatability (i.e. when the same operator repeatedly identifies the reference frame on the same specimen) and of the inter-operator repeatability (i.e. when different operators identify the reference frame on the same specimen) is reported for the recommended reference frame. This confirms the reliability of the approach proposed.

Abbreviations and Acronyms

3D	Three-dimensional
BLF	Biomechanical length of the femur
BLH	Biomechanical length of the humerus
BLR	Biomechanical length of the radius
BLT	Biomechanical length of the tibia-fibula complex

BLU	Biomechanical length of the ulna
CLT	Landmark for the humerus: center of the most lateral part of the humeral trochlea
CMT	Landmark for the humerus: center of the most medial part of the humeral trochlea
CT	Computed tomography
DFL	Landmark for the femur: on the distal femoral diaphysis in the center of the concavity present on the anterior surface, proximal to the lateral epicondyle
HF	Landmark for the shank: apex of the head of the fibula
IM	Landmark for the shank: midpoint of the line joining MM and LM (coincides with MPM)
ISB	International Society of Biomechanics
LC	Landmark for the shank: most medial point on the edge of the lateral tibial condyle
LFC	Landmark for the femur: posterior side of the lateral femoral condyle
LHDL	Living Human Digital Library
LM	Landmark for the shank: apex of the lateral malleolus
LTC	Landmark for the tibia: centre of the lateral tibial condylar plateau
MC	Landmark for the shank: most medial point on the edge of the medial tibial condyle
MFC	Landmark for the femur: posterior side of the medial femoral condyle
MM	Landmark for the shank: apex of the medial malleolus
MP	Landmark for the tibia: medial point between MTC and LTC
MPM	Landmark for the shank: midpoint of the line joining MM and LM (coincides with IM)
MTC	Landmark for the tibia: centre of the medial tibial condylar plateau
PFL	Landmark for the femur: on the proximal diaphysis, center of a flat region immediately distal to the lesser trochanter
SP	Landmark for the radius: most distal point of the styloid process
TAS	Landmark for the tibia: centre of the talar articulation
TN1, TN2, TN3	Landmark for the ulna: three points in the trochlear notch in the proximal ulna
TT	Landmark for the shank: tibial tuberosity
UN	Landmark for the radius: central point of the ulnar notch
VPH-OP	Virtual Physiological Osteoporotic Human

184.1 Introduction

Univocal definition of reference frames (Table 184.1) is extremely important in musculoskeletal biomechanics (Currey 1982; Fung 1980; Van Sint Jan and Della Croce 2005). During in vivo motion analysis, reference frames enable tracking of segments and joint motion and calculation of joint moments (Cappozzo et al. 1995). Reference frames in vitro enable correct alignment of specimens and the test loads and the definition testing conditions so that these can be replicated (O'Connor 1992; Cristofolini 1997). In general, anatomical reference frames are based on anatomical landmarks (Table 184.2) that must be identified on the bone(s). This applies to all bone segments.

In general, two types of errors can affect measurements in general (Taylor 1997), and also the identification of anatomical landmarks, as well as the associated anatomical reference frames:

1. Lack of repeatability: The same operator will indicate slightly different points (and will consequently define slightly different reference frames) if he observes the same specimens a number of times.

Table 184.1 Key facts of anatomical reference frames

1. Reference frames are needed for the sake of measurement methodology and data comparability
2. Anatomical reference frames are useful in biomechanics to univocally identify the relative pose (i.e., position and orientation) of the different parts of the body (e.g., the forearm with respect to the arm or with respect to the trunk)
3. Anatomical reference frames are also fundamental for in vitro tests involving bone segments, in order to identify univocally the pose of the specimen on the testing system, the position and direction of the applied loads, the position of the transducers, etc
4. Anatomical reference frames consist (like most other reference frames) of a system of three planes, which must be perpendicular to each other (Cartesian frames)
5. In general, the planes of an anatomical reference frame related to a bone segment are aligned (or nearly aligned) with the frontal, sagittal, and coronal planes of the entire body
6. Definition of anatomical reference frames for a bone segment relies on the identification of reference points on the bone (anatomical landmarks, see Table 184.2)

This table lists the key facts of anatomical reference frames, including their most general features, their identification, and application

Table 184.2 Key facts of anatomical landmarks

1. A landmark literally means a geographic feature used by explorers to find their way back or through an area
2. In anatomy and in biomechanics, anatomical landmarks are used to provide some reference point in a structure that is otherwise too irregular in shape to enable quantitative location of relative positions and orientations
3. Anatomical landmarks in in vivo musculoskeletal biomechanics are generally based on bony prominences that can be easily located by palpation
4. In vitro, more choices are possible through the anatomical landmarks that can either be based on bony prominences (like those used in vivo), but also on special points that can be easily located/measured on the bone surface
5. In all cases, anatomical landmarks must be defined based on features that: (1) are consistent in different subjects/specimens and (2) can be consistently located by different operators on the same subject/specimen
6. Landmarks are generally the starting point for the definition of anatomical reference frames

This table lists the key facts of anatomical landmarks, including their definition and use in biomechanical testing

2. Lack of reproducibility: Different operators will possibly interpret definitions in slightly different fashions and will perceive the bone surface in a subjective way. This leads to inter-operator differences in the identification of anatomical reference frames.

Depending on the type of application, reference frames are defined to meet different needs and facing different constraints:

- Reference frames intended for in vivo use (such as motion analysis) are based on anatomical landmarks that need to be palpable in living subjects (Cappozzo et al. 1995; Van Sint Jan and Della Croce 2005). Original identification of bony prominences rather than anatomical planes and axes leads to more repeatable measurements in gait analysis (Leardini et al. 2007). Similar criteria are also adopted in case virtual palpation is adopted, although in this case, also, points that are not directly accessible in vivo (noninvasively) (Salvia et al. 2009) can be included. A systematic approach to the consistent definition of skeletal anatomical landmarks using manual and virtual palpation was recently proposed (Van Sint Jan 2007). In all in vivo cases, direct physical measurement of lengths, widths, or thicknesses of bone segments are not possible. Hence, identification of anatomical landmarks and of the associated reference frames is affected by errors due to the uncertainty in identifying such points.
- Reference frames intended for in vitro use (e.g., mechanical testing of cadaver bones) can be based on anatomical landmarks that can only be accessed invasively. In addition, direct measurement of lengths, diameters, widths, cross sections, and angles using calipers, goniometers, etc., is feasible as the surface of the physical specimen is directly accessible. Hence, in general, measurement

of such dimensions is more accurate in vitro than in vivo. This generally enables a more accurate identification of anatomical landmarks, which has the potential to define reference frames with better repeatability and reproducibility.

As a consequence, it is clear that optimal anatomical landmarks (and associated reference frames) will generally be different for in vivo and in vitro studies (Wu et al. 2002).

In the biomechanics community, there is strong awareness of the need for defining unambiguously the anatomical reference frames, which was voiced by the International Society for Biomechanics (ISB) (ISB 1995; Wu and Cavanagh 1995). This has generated an effort toward standardization, led by the Standardization and Terminology Committee of the ISB: a consensus was slowly reached on reference frames for the lower limb and spine (Wu et al. 2002) and for the upper limb (Wu et al. 2005). All such reference frames are mainly intended for in vivo use, having as a priority consistent reporting of kinematic data.

Definition of anatomical reference frames for in vitro testing is somewhat less consolidated. While reference in vitro frames have been recommended for specific bone segments, no concerted action was developed such as that for in vivo reference frames. For instance, whereas a number of definitions have been discussed for the femur (Della Croce et al. 2003), little has been reported for the tibia and fibula, and even less has been reported for the upper-limb bones. One of the first reference frames for the lower-limb bones was proposed by (Ruff 1981; Ruff and Hayes 1983). This frame was based on identification of anatomical landmarks and geometrical measurements that are possible only in vitro on dissected femur and tibia segments. Although this method was originally intended for anatomical analyses, it was adopted successfully for in vitro biomechanical tests both on the femur (Cristofolini 1997) and tibia (Cristofolini and Viceconti 2000; Gray et al. 2007, 2008; Heiner and Brown 2001).

184.2 General Guidelines

184.2.1 Ideal Definition of Anatomical Reference Frames for Biomechanical In Vitro Testing

It is clear that an ideal reference frame should be based on anatomical landmarks that are easily and reproducibly identified in all subjects and in case of severe bone deformity. For instance, anatomical landmarks associated with bony prominences that strongly vary between subjects (such as those related to the insertion of muscle with different possible insertions between subjects) should be avoided. Similarly, reference systems based on specific points on the edge of the articular cartilage should be avoided as much as possible as aging can cause deformities associated with arthritis, calcification, etc. Serious implications of incorrect identification of anatomical landmarks and reference frames have been reported both in vitro (Gray et al. 2007; Cristofolini and Viceconti 2000) and in vivo (Della Croce et al. 2005; Thewlis et al. 2008).

As a general approach, identification of reference frames includes the following steps:

1. Coarse alignment of the bone specimen: This step allows subsequent measurements for accurate identification of anatomical landmarks and reference planes.
2. Identification of the neutral position about the long axis of the bone (this typically corresponds to identifying the neutral position in internal/external rotation. Such anatomical landmarks lie in a plane that is perpendicular to the long axis of the bone [i.e., at a relatively small distance from

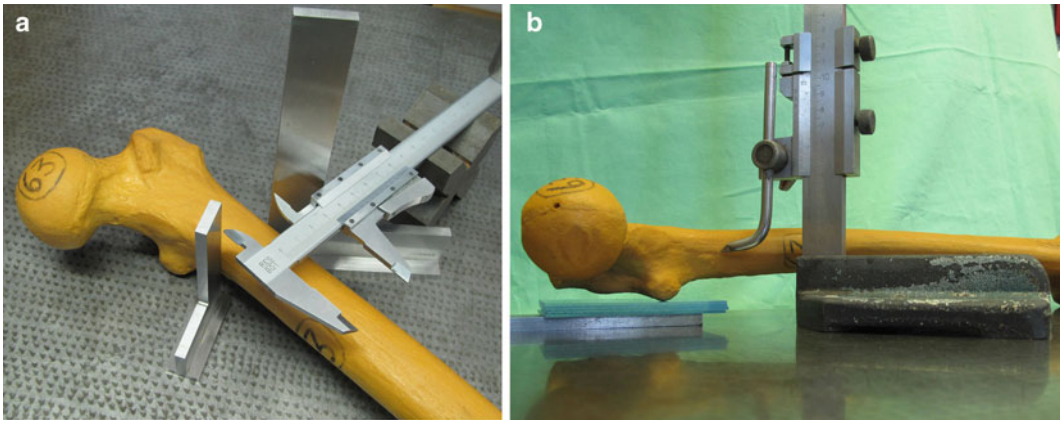

Fig. 184.1 Tools for accurately measuring anatomical dimensions. Tools for accurate measurement of anatomical landmarks and identification of reference frames: (**a**) vernier calipers and square block and vertical rulers used to measure the width of the femoral diaphysis using a level surface; and (**b**) scribing block and supports used to mark the reference planes on a femur, using a level surface

such axis]): Anatomical landmarks that are as far as possible from such an axis should be adopted to minimize errors related to their inaccurate identification.

3. Alignment of the bone in the two planes passing from the bone long axis (typically defining the neutral position in flexion/extension and abduction/adduction): Anatomical landmarks close to the opposite bone extremities should be chosen to minimize errors in identification of such planes.

184.2.2 Recommended Tools and Methods

Once the reference frame and the associated anatomical landmarks are defined, the problem of identifying them on the bone specimen remains. The easiest and most inexpensive method is based on building an osteometric board (Ruff 1981; Ruff and Hayes 1983). This provides accuracy of the order of 1 mm, which is sufficient for many applications, especially on large bones. To improve measurement accuracy, the osteometric board should be used in combination with metal angled squares, scribing blocks, surface gauge, and Vernier calipers (Cristofolini 1997) (Fig. 184.1). Identification and marking of anatomical landmarks and reference planes involves holding the bone specimen at an assigned position and orientation; to avoid undesirable movements during specimen preparation, dedicated clamps and fixtures can be extremely useful.

In our laboratory, we developed a clamp that allowed rotating the bone specimen in a controlled fashion about three axes and translating it along three axes with accuracy of the order of 0.1 mm (Fig. 184.2).

With the recent development of accurate three-dimensional (3D) digitizers (Fig. 184.3), acquisition of coordinates has become more accurate (of the order of 10 μm). Digitizers consist of a probe that is mounted on an articulated arm with several degrees of freedom (typically five or six), each equipped with an accurate electrogoniometer, enabling the exploration of complex three-dimensional space and recording the spatial coordinates of selected points. Thus, 3D digitizers help marking reference frames more accurately and, at the same time, relation of the reference frame on the physical specimen with the geometry of computer models that are built based on the same specimen (Schileo et al. 2008; Schileo et al. 2007).

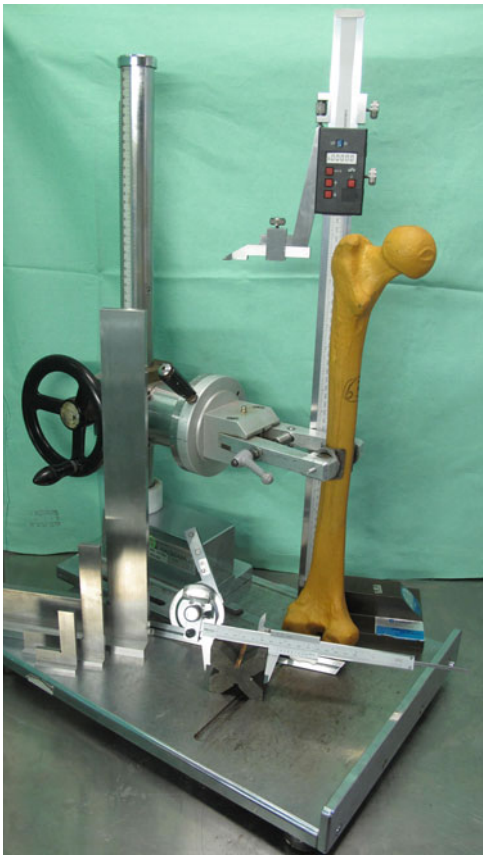

Fig. 184.2 Clamp and tools to control the alignment of a bone specimen. Picture of a clamp that allows rotating the bone specimen (a femur, in this instance) in a controlled fashion about three axes and translating it along three axes. Also shown are a scribing block, Vernier calipers, a vertical gauge, and a goniometer

Fig. 184.3 Three-dimensional digitizer. Points on the bone surface can be acquired with a 3D digitizer with an accuracy of microns. In this instance, a tibia, prepared with proximal and distal pots and strain gauges is being digitized (Mod. Gage-Plus-V1.5, Faro-Europe, Stuttgart-Weilimdorf, Germany, in this instance). This can assist in accurately measuring planes and measuring spatial coordinates

Relative orientation of reference frames can be expressed using the same approach used by Grood and Suntay (1983) for referring one anatomical segment to the other. This entails defining flexion/extension as the relative orientation about the medio-lateral axis of a first frame, internal/external rotation as the relative orientation about the vertical axis of the second frame, and abduction/adduction as the relative orientation about a 'floating' axis orthogonal to the previous two.

184.3 The Femur

184.3.1 Review of Published Reference Frames for the Femur

Although countless anatomical studies address the femur, apparently no agreement has ever been sought on the reference frame to be adopted for biomechanical testing. Probably the most extensively defined first reference frame for the femur was proposed by Ruff (1981) and Ruff and Hayes (1983). This method was originally intended for anatomical analyses; it was adopted successfully for in vitro biomechanical tests and numerical simulations on the femur (Cristofolini 1997; Waide et al. 2001; Schileo et al. 2006).

For completeness, an alternative reference frame must be discussed: the Standardization and Terminology Committee of the International Society of Biomechanics proposed a slightly different reference frame (Wu et al. 2002). It is based on the center of the head and on the (palpable) lateral and medial femoral epicondyles. Such a reference is quite different from that defined by Ruff (1981) and Ruff and Hayes (1983), especially in the proximal part, the rationale being that, in this case, markers that are palpable or easily identifiable in movement analysis were preferred. Such method is also valuable for anthropometric measurements in living subjects (see the chapter by Annegret Mündermann).

184.3.2 Guidelines for Identifying the Reference Frame for the Femur

In several studies (e.g., Harman et al. 1995; Cristofolini 1997), it was chosen to define the longitudinal diaphyseal axis as that axis passing through the mid-section at two well-defined levels of the diaphysis following Ruff and Hayes (1983) and Ruff (1981). The reference frame proposed by Ruff (1981) and Ruff and Hayes (1983) and consistent with past definitions of the femoral axis Backman (1957), identifies the axis of the femur with the diaphyseal axis. The procedure proposed by Ruff (1981) and Ruff and Hayes (1983) and later modified (Cristofolini 1997) is as follows (Fig. 184.4):

1. The biomechanical length of the femur (BLF) is defined as the minimal distance between the trochanteric fossa and the condylar notch.
2. The femur must be laid on a level board, posterior side down. The posterior sides of the two femoral condyles (LFC and MFC) must be resting on the board; the proximal part resting on the lesser trochanter. Such alignment already defines the neutral rotation as far as internal/external rotations are concerned.
3. Two sections must be identified along the diaphysis, which are later used for identifying the frontal and sagittal planes.
4. A landmark (DFL) is located on the distal femoral diaphysis in the center, or lowest point, of the concavity present on the anterior surface, just proximal to the lateral epicondyle.

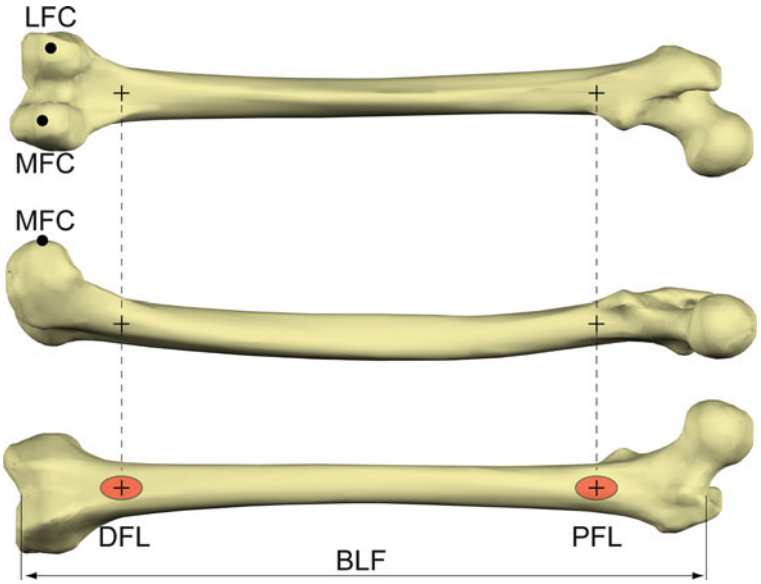

Fig. 184.4 Anatomical landmarks and dimensions of a human femur. Posterior, medial, and anterior view of a *left* femur. The most posterior points on the lateral and medial condyles (*LFC* and *MFC*) are used to define a neutral position about the long axis of the femur. The biomechanical length of the femur (*BLF*) is defined as the minimal distance between the trochanteric fossa and the condylar notch. Two anatomical landmarks must be identified (*PFL* and *DFL*), where a small depression (*highlighted in dark*) is visible on the proximal and distal portions of the anterior face

5. A second landmark (PFL) is located on the proximal diaphysis, at a site immediately distal to the lesser trochanter, where a similar depression is found.
6. The mid-section at two such levels must be found using Vernier calipers and a vertical ruler, both in the frontal and in the sagittal plane (Fig. 184.1a).
7. The frontal plane is defined as a plane parallel to the one tangent to the posterior side of the condyles (LFC and MFC), and passing through such two center points.
8. The sagittal plane is a plane perpendicular to such a frontal plane and passing through such two center points.

To mark such planes and axes, clay or an adjustable clamp should be used to hold the femur by aligning the reference points described earlier in a vertical/horizontal plane, as needed (Fig. 184.5).

184.3.3 Assessment of the Reference Frame for the Femur

The reference system proposed by Ruff (1981) and Ruff and Hayes (1983) and later adapted by Cristofolini (1997) has been extensively tested after refinement. Based on the extensive experience on over 100 composite and over 50 cadaveric femurs (Cristofolini 1997; Waide et al. 2001; Cristofolini et al. 2007a, b, c), it is possible to assess:

- the intra-operator repeatability (i.e., when the same operator repeatedly identifies the reference frame on the same specimen); and
- the inter-operator repeatability (i.e., when the different operators identify the reference frame on the same specimen).

The intra-operator repeatability in identifying the individual anatomical landmarks was 0.1–0.5 mm; the inter-operator repeatability was 0.3–1.0 mm. The largest errors were associated with the axial position of the two sections along the diaphysis (however, this was found to have a lesser effect on the final alignment of the reference frame). The smallest errors were associated with the position of the two points on the posterior side of the condyles (LFC and MFC).

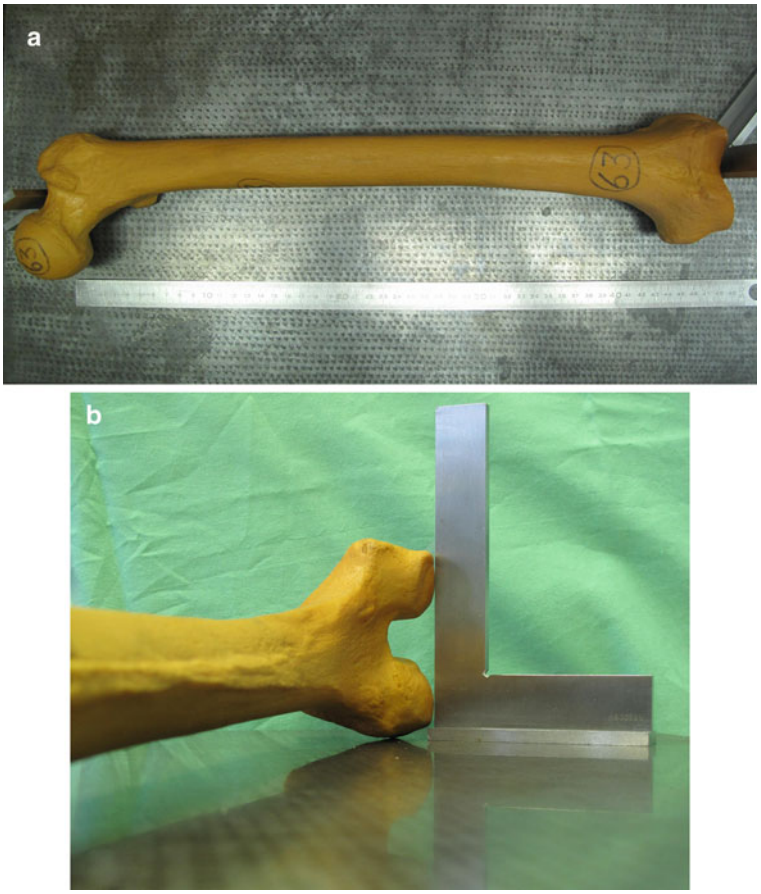

Fig. 184.5 Femur ready for identification of anatomical planes. (**a**) Picture of a femur resting on the posterior side of the condyles and the lesser trochanter (anterior face up), ready for measuring the biomechanical length (between two metal angles). (**b**) Detail of the distal femur being aligned so that the posterior side of the condyles rest on a right angle to ensure correct alignment in internal/external rotation

Table 184.3 Repeatability of the reference frame for the femur

Intra-operator repeatability	Abduction/adduction	0.05–0.15°
	Flexion/extension	0.05–0.15°
	Internal/external rotation	0.20–0.60°
Inter-operator repeatability	Abduction/adduction	0.10–0.30°
	Flexion/extension	0.10–0.30°
	Internal/external rotation	0.3–1.10°

Repeatability for the same operator and between different operators for the identification of the reference frame for the femur according to Ruff and Hayes (1983) and Ruff (1981). The range is reported based on extensive experience on over 100 composite and over 50 cadaveric femurs (Cristofolini 1997; Waide et al. 2001; Cristofolini et al. 2007a, b, c)

The intra-operator repeatability was nearly one order of magnitude better than the inter-operator repeatability (Table 184.3). The largest errors were always associated with the correct identification of the reference frame in internal/external rotation. In fact, the anatomical landmarks used to identify such an angle are close to each other, thus, even a small error in the identification of such anatomical landmarks propagates to a large error in terms of rotation. Errors were smaller for the flexion/extension and abduction/adduction angles, with similar repeatability in both planes.

Introduction of the reference frame proposed by Ruff and Hayes (1983) and Ruff (1981) improved repeatability and reproducibility of strain measurements in the femur by nearly one order of magnitude (Cristofolini 1997).

184.4 The Tibia and Fibula

184.4.1 Review of Published Reference Frames for the Tibia and Fibula

One of the first reference frames for the tibia was proposed by Ruff (1981) and Ruff and Hayes (1983). Although this method was originally intended for anatomical analyses, it was adopted successfully for in vitro biomechanical tests on the tibia (Cristofolini and Viceconti 2000; Gray et al. 2007, 2008; Heiner and Brown 2001). The reference frame *Ruff-coord* (Fig. 184.6) proposed by Ruff (1981) and Ruff and Hayes (1983) is based on the centers of the articulating cartilage areas at the proximal and distal tibia, with no anatomical landmarks on the fibula. The *Ruff-coord* can only be

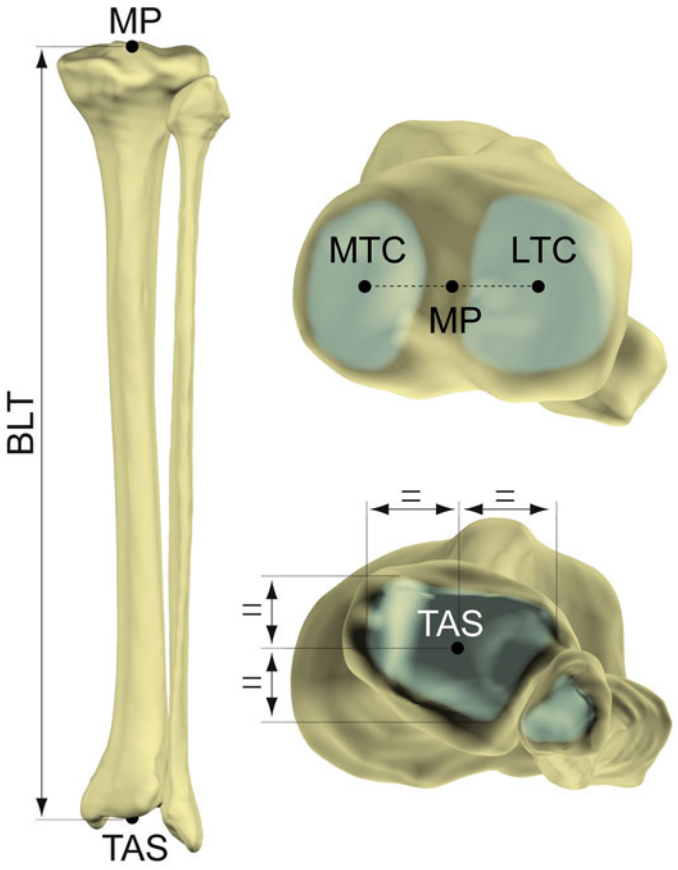

Fig. 184.6 Anatomical landmarks proposed by Ruff 1981 and Ruff and Hayes 1983 for the tibia–fibula complex. Anatomical reference frame proposed by Ruff 1981 and Ruff and Hayes 1983 for a left tibia–fibula complex: anterior view, transverse view from *above*, and transverse view from *below*. The centers of the two tibial condyles (*MTC* and *LTC*) and of the surface articulating with the top of the talus (*TAS*) are initially identified. This is performed by locating (with calipers) the midpoints in the antero-posterior and medio-lateral directions on each cartilage surface (as this procedure relies on an estimated provisional alignment, the procedure must be iteratively repeated – typically twice – until no significant further correction is needed). As an example, the location of TAS is shown in (**c**). The midpoint (*MP*) between the two tibial condyle center points (*MTC* and *LTC*) is then calculated. The frontal plane is the one passing through *MTC*, *LTC*, and *TAS*; the sagittal plane is perpendicular to the frontal plane and goes through points *TAS* and *MP*. Also indicated is the biomechanical length of the tibia (*BLT*)

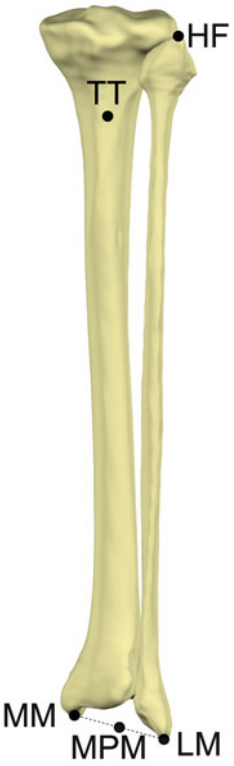

Fig. 184.7 Anatomical landmarks proposed by Cappozzo et al. (1995) for the tibia–fibula complex. Anatomical reference frame proposed by Cappozzo et al. 1995 for a left tibia–fibula complex (anterior view). First, the tibial tuberosity (*TT*), the apex of the head of the fibula (*HF*), and the distal apices of the medial and lateral malleoli (*MM* and *LM*) are identified. The midpoint (*MPM*) of the line joining *MM* and *LM* is then calculated (this point coincides with IM of the reference frame proposed by the *ISB* (Wu et al. 2002)). The frontal plane passes through *HF*, *LM*, and *MM*; the sagittal plane is perpendicular to the frontal plane and goes through points *TT* and *MPM*

identified in vitro when the bone surface is visible. As Ruff (1981) and Ruff and Hayes (1983) did not suggest a separate reference for the fibula, we propose to use the same reference frame for the entire tibia–fibula complex (Conti et al. 2008).

For completeness, other reference frames must also be described: a different anatomical reference frame was proposed by Cappozzo et al. (1995) to provide consistent identification of anatomical landmarks for a more repeatable motion analysis. The reference frame *Cappozzo-coord* (Fig. 184.7) proposed by Cappozzo et al. (1995) is based on anatomical landmarks of the tibia and fibula that need to also be palpable in vivo. Later, the Standardization and Terminology Committee of the International Society of Biomechanics (ISB) proposed a slightly different reference frame (Wu et al. 2002) (Fig. 184.8): it is based on the same anatomical landmarks as *Cappozzo-coord* distally, but on different anatomical landmarks proximally (with anatomical landmarks over only the tibial plateau). Both *Cappozzo-coord* and *ISB-coord* rely on the anatomy of the entire tibia–fibula complex. It must be stressed that the *Cappozzo-reference* and the *ISB-reference* are designed for in vivo use. A similar reference is also proposed for anthropometric measurements in living subjects (see chapter by Annegret Mündermann).

184.4.2 Guidelines for Identifying the Reference Frame for the Tibia and Fibula

As remarked, we propose to use the same reference frame for the entire tibia–fibula complex (Conti et al. 2008). Therefore, the ligaments of the proximal and distal tibiofibular articulations (syndesmosis) must be left intact to preserve the original relative position and orientation. Thus, once the reference

Fig. 184.8 Anatomical landmarks proposed by the International Society of Biomechanics (Wu et al. 2002) for the tibia–fibula complex. The anatomical reference frame proposed by the Standardization and Terminology Committee of the International Society of Biomechanics (Wu et al. 2002) for a left tibia–fibula complex (anterior view). First, the most medial and lateral points on the edge of the relevant condyles (*MC* and *LC*) and the tip of the medial and lateral malleoli (*MM* and *LM*) are identified. The inter-malleolar point (*IM*, which coincides with *MPM* in the reference frame proposed by Cappozzo et al. 1995 located midway between *MM* and *LM* and the inter-condylar point (*IC*) found midway between the *MC* and *LC* are calculated. The frontal plane passes through *IM*, *MC*, and *LC*; the sagittal plane is perpendicular to the frontal plane and containing the points *IC* and *IM*

frame is marked on the femur, it can immediately be projected on the fibula as well. The procedure proposed by Ruff (1981) and Ruff and Hayes (1983) is as follows (Fig. 184.6):

1. Provisionally aligning the tibia on a level surface;
2. Identifying (by means of calipers and rulers) the centre of the talar articulation (TAS) and of the two tibial plateaus (MTC and LTC);
3. Identifying the midpoint (MP) between the two centers of the tibial condyles;
4. The biomechanical length of the tibia–fibula complex (BLT) is defined as the distance between TAS and MP;
5. The frontal plane of the tibia is the plane containing the talar (TAS) and the two plateau center points (MTC and LTC); and
6. The sagittal plane of the tibia is perpendicular to such frontal plane and goes through the midpoint of the tibial condyles (MP).

In addition, we suggest the following steps to identify the reference planes on the fibula (while still rigidly connected to the tibia):

7. Identifying two sections that are respectively 20% of the biomechanical length of the tibia–fibula complex (BLT) from the distal and proximal extremity;

8. In such sections, by means of a caliper and a vertical ruler the mid-point of the cross-sections in the antero-posterior and medio-lateral directions must be identified; and
9. The frontal and sagittal planes of the fibula go through the center points just identified (in general, these planes will not be parallel to the corresponding one previously identified for the tibia).

To mark such planes and axes, clay or an adjustable clamp should be used to enable aligning of the bone by aligning the reference points described earlier in a vertical/horizontal plan, as needed.

184.4.3 Assessment of the Reference Frame for the Tibia and Fibula

As such, reference frames were defined independently from each other, the relative orientation of one system respect to the other is unknown. A study was recently carried out (Conti et al. 2008) to compare these three reference frames for the tibia–fibula complex (Ruff and Hayes 1983; Cappozzo et al. 1995; Wu et al. 2002), with the following goals:

- Assess the intra-operator repeatability;
- Assess the inter-operator repeatability; and
- Assess if the three reference frames overlap and, if not, to assess the relative poses.

Six specimens, consisting of intact tibia–fibula complexes were visually inspected and CT-scanned to document bone quality and lack of abnormality or defects (Conti et al. 2008). The anatomical landmarks described earlier were acquired with a 3D digitizer (Mod. Gage-Plus-V1.5, Faro-Europe, Stuttgart-Weilimdorf, Germany) with an accuracy of 10 μm. The specimens were held in space by an adjustable vice. From these anatomical landmarks, the position and orientation of the three reference frames (*Ruff-coord*, *Cappozzo-coord*, and *ISB-coord*) were obtained for each specimen.

To assess the intra-operator repeatability, each reference frame was identified ten times by the same operator on one randomly selected specimen. To assess the inter-operator repeatability, three operators with a good knowledge of musculoskeletal biomechanics were asked to identify the anatomical landmarks of the three reference frames on each specimen.

For *Ruff-coord*, the intra-operator repeatability in identifying the individual anatomical landmarks was 0.58–0.98 mm; the inter-operator repeatability was 1.64–2.34 mm. For *Cappozzo-coord*, the intra-operator repeatability for the anatomical landmarks was 1.17–2.19 mm; the inter-operator repeatability was 3.18–6.96 mm. For *ISB-coord*, the intra-operator repeatability for the anatomical landmarks was 0.94–1.42 mm; the inter-operator repeatability was 3.18–7.07 mm.

The intra-operator repeatability was of the same order of magnitude for the three reference frames (Table 184.4). In abduction/adduction, *Cappozzo-coord* was significantly less repeatable than *Ruff-coord* and *ISB-coord*. The repeatability was similar for the three reference frames in flexion/extension. In internal/external rotation, *Cappozzo-coord* was more repeatable than *Ruff-coord* and *ISB-coord*. The inter-operator repeatability of the reference frames was worse than the intra-operator repeatability (Table 184.4). In the frontal plane (abduction/adduction), *Cappozzo-coord* was one order of magnitude less repeatable than *Ruff-coord* and *ISB-coord*; the difference between *Ruff-coord* and *ISB-coord* was not significant. In the sagittal plane (flexion/extension), *Ruff-coord* was more repeatable than *Cappozzo-coord* and *ISB-coord*. In the transverse plane (internal/external rotation), the only significant difference was that *Ruff-coord* was more repeatable than *ISB-coord*.

The most obvious difference was the external rotation of *Cappozzo-coord* with respect to the other two reference frames (Fig. 184.9). This is accounted for by the definition of the frontal plane of *Cappozzo-coord*, which includes the two apices of the malleoli, with the lateral malleolus being much more posterior than the medial one. No significant difference existed between the pose of *Ruff-coord*

Table 184.4 Repeatability of the reference frame for the tibia–fibula complex

		Ruff-coord (Ruff and Hayes 1983)	*Cappozzo-coord* (Cappozzo et al. 1995)	*ISB-coord* (Wu et al. 2002)
Intra-operator repeatability	Abduction/adduction	0.06°	0.39°	0.07°
	Flexion/extension	0.16°	0.27°	0.15°
	Internal/external rotation	0.88°	0.30°	1.11°
Inter-operator repeatability	Abduction/adduction	0.25°	1.55°	0.29°
	Flexion/extension	0.27°	0.68°	0.54°
	Internal/external rotation	2.78°	3.51°	5.71°

Repeatability for the same operator and between different operators for the identification of the three reference frames examined for the tibia–fibula complex

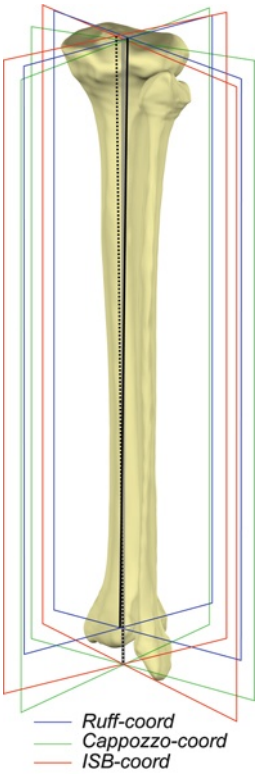

Fig. 184.9 Comparison of three reference frames for the tibia–fibula complex. Comparison of the alignment of the three reference frames on a left tibia–fibula complex in an antero-lateral view. The three frames had similar alignments in the sagittal and transverse planes. However, *Cappozzo-coord* was translated laterally and externally rotated with respect to *Ruff-coord* in the frontal plane. No significant rotation existed between *Ruff-coord* and *ISB-coord*

and *ISB-coord* (Fig. 184.9). *Cappozzo-coord* was significantly flexed and externally rotated with respect to *ISB-coord*. *Cappozzo-coord* was significantly flexed and externally rotated with respect to *Ruff-coord*. The fact that the two malleoli (used in *Cappozzo-coord*) are more posterior than the points on the tibial tray identified by *Ruff-coord* and *ISB-coord* explains such differences.

Ruff-coord was more repeatable because it relied on anatomical landmarks that could be accurately measured (i.e., by calipers) on the bone surface. In fact, *Ruff-coord* (Ruff and Hayes 1983) is intended for in vitro use, where the bone surface can be easily accessed and measured. The main problem reported with *Cappozzo-coord* (Cappozzo et al. 1995) was with point TT on the tibial tuberosity. The main problem reported with *ISB-coord* (Wu et al. 2002) was the identification of the most medial and lateral points on tibial condyles (MC and LC), which were quite subjective because of the large and nearly linear crest; this affects the repeatability in identifying internal/external rotation.

Thus, the reference frame proposed by Ruff and Hayes (1983) is preferable when the full bone surface is accessible, typically during in vitro tests. No clear advantage of one system over the others appeared for mixed conditions, where the proximal part of the shank bones is accessible directly and the distal part is covered by soft tissue (surgical navigation of total knee replacement) or vice versa (surgical navigation of total ankle replacement).

184.5 The Humerus

184.5.1 Review of Published Reference Frames for the Humerus

Apparently, no reference frame for the humerus has ever been conceived to provide optimal accuracy for in vitro measurements and biomechanical testing. Conversely, different reference frames have been proposed for in vivo use. The Standardization and Terminology Committee of the International Society of Biomechanics (ISB) has recently issued a recommendation concerning the entire upper limb (Wu et al. 2005). The reference frame for the humerus put forward by the ISB is based on palpable markers (Wu et al. 2005): the most caudal points on the medial and lateral epicondyles and the centre of rotation of the glenohumeral articulation must be identified; alignment of the reference planes is based on the midpoint of the two epicondylar points and the center of the glenohumeral articulation. While this reference is certainly suitable for in vivo use, identification of such points in vivo is associated with errors that can be avoided by using other anatomical landmarks. In fact,

- The precision of different in vivo palpation methods for the humerus has recently been assessed (Salvia et al. 2009): the repeatability when the same observer was identifying the two epicondylar points was of the order of 2–4 mm; such error doubled between different observers.
- The glenohumeral center of rotation can be identified, even using the most sophisticated multiple regression approaches, with an error greater than 2.5 mm (Sholukha et al. 2009).

Therefore, in vitro reference frames for the humerus should be based on different anatomical landmarks than the in vivo ones. Dunlap et al. (2008) recently tested the structural properties of composite models of the humerus. They provide a partial indication of the alignment they used: it is not clear what criterion was used to define the long axis of the humerus; they defined the frontal plane as a plane between the medial and lateral epicondyles (only two points were indicated for identifying one plane in space).

As in vivo definitions are not fully satisfactory for in vitro use and in vitro reference frames are only partially defined, we made an effort to define an unambiguous reference frame for the humerus that can be accurately implemented in vitro, and (a) is as compatible as possible with the ISB recommendations (Wu et al. 2005), and (b) is as consistent as possible with the criteria previous adapted from Ruff and Hayes (1983) and Ruff (1981) for the lower limb.

184.5.2 Guidelines for Identifying the Reference Frame for the Humerus

The reference frame proposed below for the humerus adopts some of the criteria proposed by Ruff (1981) and Ruff and Hayes (1983) for the femur and tibia (measurement of the center of cross sections of the diaphysis at a given position along the diaphysis). In addition, as the humerus articulates with the ulna as a hinge joint, its neutral position in internal/external rotation is defined in a way that

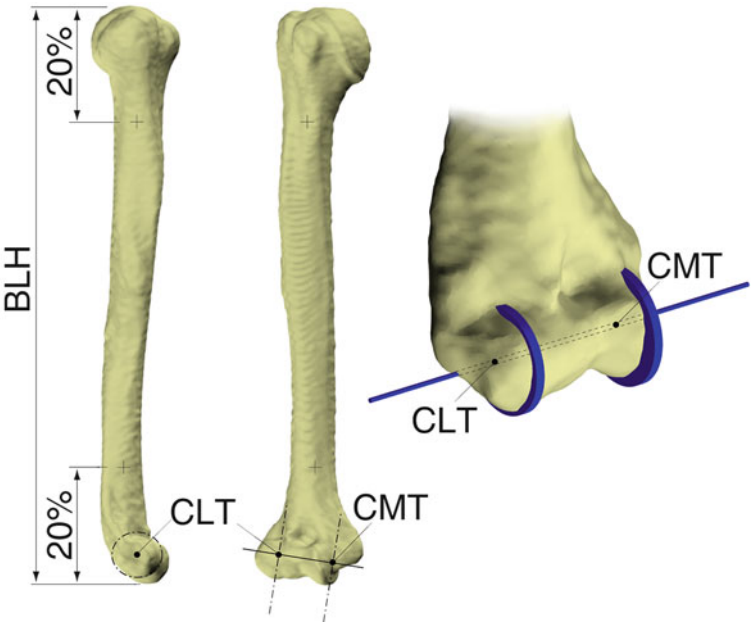

Fig. 184.10 Anatomical landmarks and dimensions of a human humerus. Lateral and anterior views of a right humerus, showing the biomechanical length (*BLH*) and the two sections where the center point must be identified. The detail (antero-lateral view) shows the circular shape of the most medial and lateral parts of the trochlea: the centers (*CMT* and *CLT*) of such circles define the frontal plane

can also be reported on the ulna (see later). The procedure can be summarized as follows (Figs. 184.10 and 184.11):

1. First, the biomechanical length of the humerus (BLH) must be measured (this is the full length of the bone).
2. Two levels along the bone, each at 20% of BLH from the most proximal and distal extremity, must be identified and marked.
3. The humerus must be laid on a level board, resting on the two posterior surfaces of the epicondyles and on the posterior face of the humeral head (posterior face up, Fig. 184.11a).
4. The centers of the cross sections at two such levels must be identified and marked both in the antero-posterior and in the medio-lateral views.
5. As the articulation between the humerus and the ulna operates as a perfect hinge joint, the trochlea is nearly perfectly circular when seen laterally (although the radius varies from lateral to medial). Therefore, the diameter of the most medial and lateral part of the trochlea can be measured. The centers of the most medial and lateral portions can be accurately identified (CMT and CLT, Fig. 184.10, detail).
6. Clay or plates of assigned thickness must be inserted underneath one of the two parts of the trochlea (typically the lateral part, which is smaller) so as to place the two centers of the trochlea on the same plane.
7. Similarly, clay or plates of assigned thickness must be inserted under the head of the humerus so that the centers of the two cross sections (point 4 above) lie in the same plane.
8. The frontal plane is defined as the plane passing through two such center points and parallel to the line joining the centers of the trochlea (CMT and CLT).
9. The sagittal plane is defined as a plane perpendicular to the frontal plane and passing through two such center points (Fig. 184.11b).

Fig. 184.11 Humerus ready for identification of anatomical planes. (**a**) Medial view of right humerus resting posterior side up: plates of the desired thickness (*arrow*) were placed below the anterior side of the lateral trochlea to ensure that the medial and lateral centers of the trochlea (*CMT* and *CLT*) lie in the same plane; another plate (*arrow*) is placed under the head, to align the diaphysis to the level plane; a scribing block can be used to mark the frontal plane. (**b**) Left humerus resting on its medial side; blocks and plates of constant thickness (*arrow*) are used near the lateral part of the trochlea to ensure that the frontal plane lies vertical; thus, a scribing block can be used to mark the sagittal plane

184.5.3 Assessment of the Reference Frame for the Humerus

The reference system described earlier has been tested in vitro to assess:

- The intra-operator repeatability (i.e., when the same operator repeatedly identifies the reference frame on the same specimen): the same bones were prepared with anatomical landmarks and reference planes ten times by the same operator. Each time, the reference frame was acquired with a digitizer and erased to avoid bias between repeats.
- The inter-operator repeatability (i.e., when the different operators identify the reference frame on the same specimen): the same bones were prepared with anatomical landmarks and reference planes by three independent operators. Each time, the reference frame was acquired with a digitizer and erased to avoid bias between operators.

Table 184.5 Repeatability of the reference frame for the humerus

Intra-operator repeatability	Abduction/adduction	0.18°
	Flexion/extension	0.13°
	Internal/external rotation	1.65°
Inter-operator repeatability	Abduction/adduction	0.50°
	Flexion/extension	0.17°
	Internal/external rotation	1.98°

Repeatability for the same operator and between different operators for the identification of the reference frame for the humerus

The inter-operator repeatability was larger but comparable to the intra-operator repeatability (Table 184.5). The largest errors were always associated with an incorrect identification of the reference frame in internal/external rotation. In fact, the anatomical landmarks used to identify such an angle are close to each other; thus, even a small error in the identification of such anatomical landmarks propagates to a large error in terms of rotation. Errors were smaller for the flexion/extension and abduction/adduction angles, with similar repeatability in both planes.

184.6 The Radius and Ulna

184.6.1 Review of Published Reference Frames for the Radius and Ulna

In fact, the radius and ulna have seldom been tested in vitro, and few methodological details have been reported. For this reason, no detailed reference frame has ever been proposed to provide optimal accuracy for in vitro measurements and biomechanical testing of the radius and ulna. Hsu et al. (1993) investigated the ulna and radius together. They defined the mechanical axis of the forearm, based on the radius, as the line passing through the center of the radial head and the middle of the interfossa ridge, between the scaphoid and lunate fossae on the distal radial articular surface.

Conversely, reference frames have been proposed for in vivo use. The recommendation recently issued by the Standardization and Terminology Committee of the International Society of Biomechanics (ISB) (Wu et al. 2005) includes details for the forearm. In this reference frame (like in any other for in vivo use), the forearm is most of the time treated as a whole, as it is difficult to accurately identify the radius and ulna noninvasively. Moreover, for most in vivo purposes (e.g., movement analysis), modeling the forearm as a whole provides satisfactory results.

The reference frame for the forearm proposed by the ISB is based on palpable markers (Wu et al. 2005): distally, the most caudal points on the ulnar and radial styloid must be identified; proximally, the reference frame is based on the two epicondyles of the humerus. Therefore, identification of anatomical axes of the radius and ulna is possible only in a whole upper limb, according to this recommendation (Wu et al. 2005). While this reference is certainly suitable for in vivo use, identification of such points in vivo is associated with errors that can be avoided by using other anatomical landmarks. In fact, even using the most sophisticated multiple regression approaches, the glenohumeral center of rotation can be identified, with an error greater than 2.5 mm (Sholukha et al. 2009).

Therefore, in vitro reference frames for the radius and ulna should be based on different anatomical landmarks than the in vivo ones. However, in the very few in vitro studies involving either the radius or the ulna (e.g., Edmonds et al. 2000) no clear definition of an anatomical reference frame has been provided.

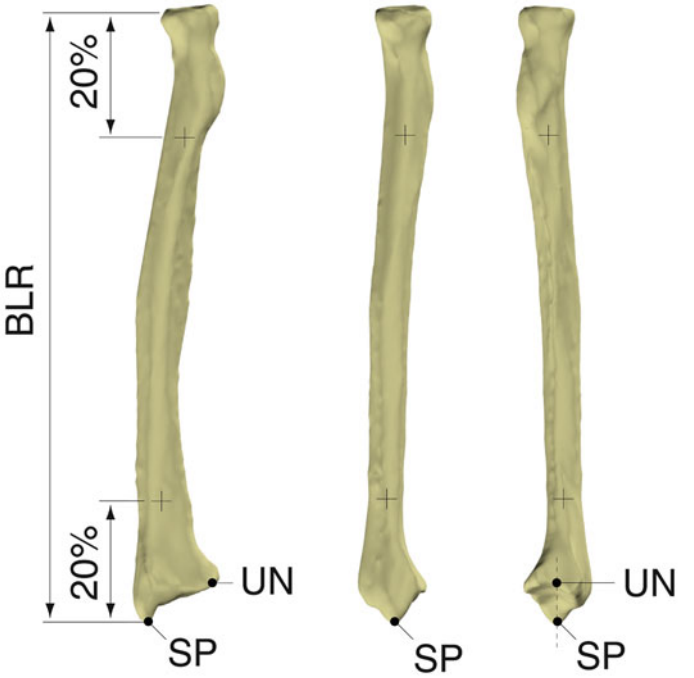

Fig. 184.12 Anatomical landmarks and dimensions of a human radius. Anterior, lateral, and medial views of a right radius, showing the biomechanical length (*BLR*) and the two sections where the center point must be identified. The anatomical landmarks used to identify the frontal plane are indicated: the most distal point of the styloid process (*SP*) and the center of the ulnar notch (*UN*)

As reference frames of the forearm intended for in vivo use are not fully satisfactory for in vitro use, and in vitro reference frames are only partially defined, we made an effort to define unambiguous reference frames for the radius and ulna that can be accurately implemented in vitro, and (a) are compatible with the ISB recommendations (Wu et al. 2005), and (b) are consistent with the criteria previous adopted by Ruff and Hayes (1983) and Ruff (1981) for the lower limb.

184.6.2 Guidelines for Identifying the Reference Frame for the Radius

Because of its curved shape, reference planes for the radius should be centered at selected sections along the diaphysis, as opposed to some center point in the epiphyses (in order to ensure that the long axis does not lie outside the bone contour at some section along the (curved) diaphysis). The description of the procedure to define the reference frame for the radius follows (Figs. 184.12 and 184.13):

1. The biomechanical length of the radius (BLR) is defined as the full length from the center of the nearly flat proximal surface of the head to the most distal point of the radial styloid process.
2. Two levels along the bone, each at 20% of BLU from the most proximal and distal extremity, must be identified and marked.
3. The centers of the cross sections at two such levels must be identified and marked both in the antero-posterior and in the medio-lateral views.
4. The most distal point of the styloid process (SP) and the central point of the ulnar notch (UN) must be marked (Fig. 184.13). Such points define the alignment of the frontal plane.
5. The radius must be laid anterior face up, either on a level plane (using clay to support it) or using adjustable clamps. The most distal point of the styloid process (SP) and the central point of the

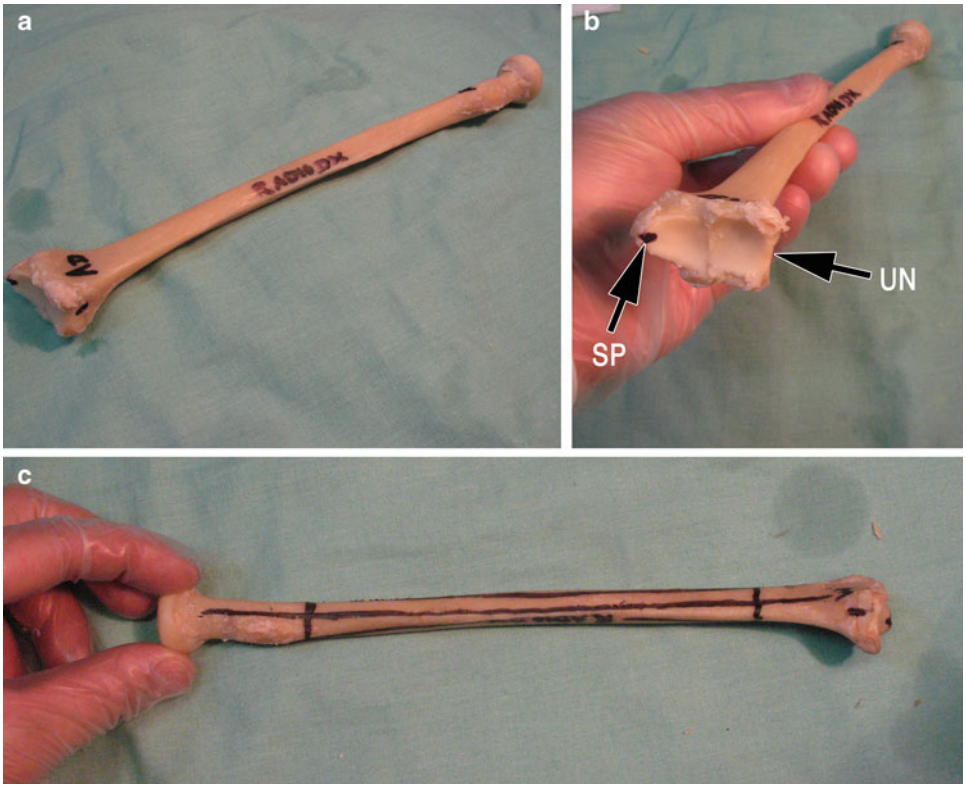

Fig. 184.13 Radius ready for identification of anatomical planes. (**a**) Medial and (**b**) distal views of right radius resting anterior side up: the tip of the styloid process (*SP*) and the center of the ulnar notch (*UN*) are visible. (**c**) Medial view of the radius, where the *black lines* indicate the frontal and sagittal planes

ulnar notch (UN) must be used to identify the neutral position in internal/external rotation: when both lie in a vertical plane, the radius lies in a neutral position.

6. Clay or plates of assigned thickness must be inserted under the two extremities so that the centers of the two cross sections (point 3 above) lie in the same plane.
7. The frontal plane is a plane parallel to the two distal points (SP and UN) and passing through the centers of the two sections above.
8. The sagittal plane is perpendicular to the frontal plane and goes through the center of the two sections above.

184.6.3 Guidelines for Identifying the Reference Frame for the Ulna

As the joint between the humerus and the ulna is a hinge joint, we chose to define the neutral position about the ulnar long axis in a way that is consistent with the frame adopted for the humerus. Therefore, the trochlear notch is used to identify the correct rotation about the ulnar long axis. Because of the curved shape of the ulna, reference planes should be centered at selected sections along the diaphysis, as opposed to some center point in the epiphyses (in order to ensure that the long axis does not

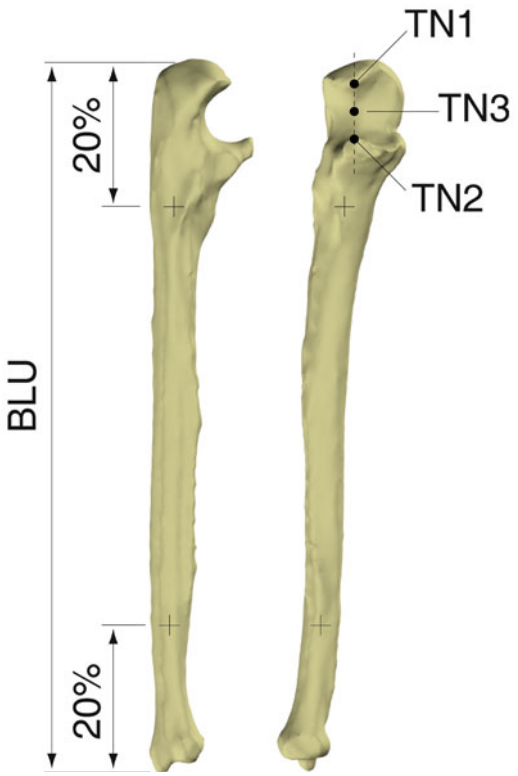

Fig. 184.14 Anatomical landmarks and dimensions of a human ulna. Lateral and frontal views of a right ulna, showing the biomechanical length of the ulna (*BLU*) and the two sections where the center point must be identified. Also shown are three points that must be identified on the ridge inside the trochlear notch (*TN1*, *TN2*, and *TN3*)

lie outside the bone contour at some section along the (curved) diaphysis). Following is a description of the procedure to define the reference frame for the ulna (Figs. 184.14 and 184.15):

1. The biomechanical length of the ulna (BLU) is defined as the full length from the proximal most point of the olecranon to the most distal point of the ulnar styloid process.
2. Two levels along the bone, each at 20% of BLU from the most proximal and distal extremity, must be identified and marked.
3. The centers of the cross sections at two such levels must be identified and marked both in the antero-posterior and in the medio-lateral views.
4. A ridge is visible in the trochlear notch, which runs in a frontal plane (it corresponds to the groove in the trochlea of the humerus). Three points must be marked in the trochlear notch (TN1, TN2, and TN3, Fig. 184.15), which are useful in the following steps.
5. The ulna must be laid anterior face up, either on a level plane (using clay to support it) or using adjustable clamps. The three points in the trochlear notch must be used to identify the neutral position in internal/external rotation: when all three points (TN1, TN2, and TN3) lie in a vertical plane, the ulna lies in a neutral position.
6. Clay or plates of assigned thickness must be inserted under the two extremities so that the centers of the two cross sections (point 3 above) lie in the same plane.
7. The sagittal plane is a plane parallel to the three points in the trochlear notch and passing through the centers of the two sections above.
8. The frontal plane is perpendicular to the sagittal plane and goes through the centers of the two sections above.

Fig. 184.15 Ulna ready for identification of anatomical planes. (**a**) Anterior view of left ulna: The *black line* in the trochlear notch was used to align the ulna so that its sagittal plane lies vertical. (**b**) Medial view of left ulna, where the anatomical planes are marked in *green*

184.6.4 Assessment of the Reference Frame for the Radius and Ulna

The reference frames described earlier for the radius and ulna have never been tested systematically. Based on past experience on the other bone segments, and on limited experience on the radius and ulna, it can be said that the intra-operator and the inter-operator variability are:

- Comparable to those reported for the humerus (Table 184.5) for the correct identification of the long axis of the radius and ulna in the frontal and sagittal plane and
- Nearly twice as large as those reported for the humerus (Table 184.5) for the correct identification of the neutral position in internal/external rotation about the axis of the radius and ulna.

184.7 The Metacarpal and Metatarsal Bones

184.7.1 Review of Published Reference Frames for the Metacarpal and Metatarsal Bones

To the author's best knowledge, no detailed anatomical reference frame has ever been proposed for the individual metacarpal and metatarsal bones. Conversely, reference frames have been proposed for in vivo use. However, in movement analysis, the hand and the foot are often described either as single bodies or divided in two or three parts. In fact, the recommendation issued by the Standardization and Terminology Committee of the International Society of Biomechanics (Wu et al. 2002) for the

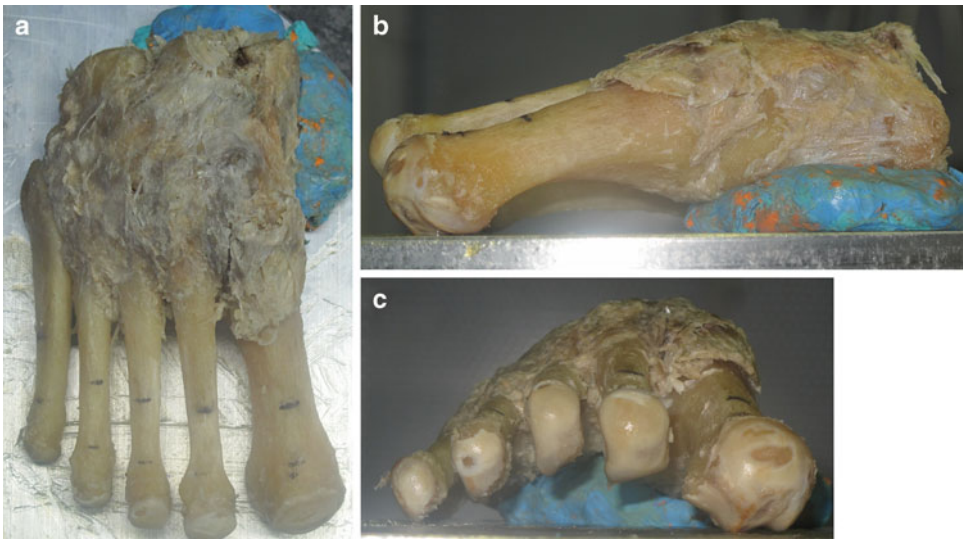

Fig. 184.16 Metatarsal bone preparation. Portion of a right foot including selected tarsal (cuneiforms, cuboid, and scaphoid) and all metatarsal bones: (**a**) view from above, (**b**) from medial, and (**c**) frontal. The medial part of the foot (medial cuneiform) is supported by clay to restore the natural curvature of the plantar arch

lower limb assigns a reference frame to the ankle joint complex and one to the calcaneus, with no further detail for the metatarsal region. The recommendation recently issued by the Standardization and Terminology Committee of the International Society of Biomechanics (Wu et al. 2005) for the upper limb provides some more detail for the metacarpal bones: the origin of the reference frame for each of the metacarpals is located midway between the base and head of each metacarpal. In the transverse plane, it will be at the approximate center of the tubular bone. The sagittal plane is defined as that plane that splits the metacarpal into mirror images.

As no reference frame has ever been proposed for in vitro applications, we devised a procedure to identify the reference frame of each metacarpal and metatarsal bone that is inspired by the ISB guidelines (Wu et al. 2005) and is compatible with the criteria adopted for the other bones, consistent with Ruff and Hayes (1983) and Ruff (1981).

184.7.2 Guidelines for Identifying the Reference Frame for the Metacarpal and Metatarsal Bones

A similar procedure is proposed for the metacarpal and metatarsal bones. For brevity, the procedure for the metatarsal bones is described below (only minor changes apply to the metacarpal ones). The metacarpal bones do not have sufficient detail or transversal dimension that enable accurate alignment about their longitudinal axis if they are removed from the rest of the foot. The procedure described below is designed to transfer the anatomical planes of the entire foot to each of the metatarsal bones (Figs. 184.16–184.18):

1. The foot can be freed of the most proximal part (calcaneus, etc.) while preserving the other tarsal bones (cuneiforms, cuboid, and scaphoid) and their ligaments to preserve the physiological alignment in internal/external rotation.

Fig. 184.17 Preparation of alignment pots for the metatarsal bones. Portion of a right foot including selected tarsal (cuneiforms, cuboid, and scaphoid) and all metatarsal bones: (**a**) The distal extremity of each metatarsal bone is included in bone cement while resting on a flat surface; (**b**) First metatarsal, after complete dissection: the flat pot on the distal extremity provides alignment about the long axis of the bone in the subsequent steps

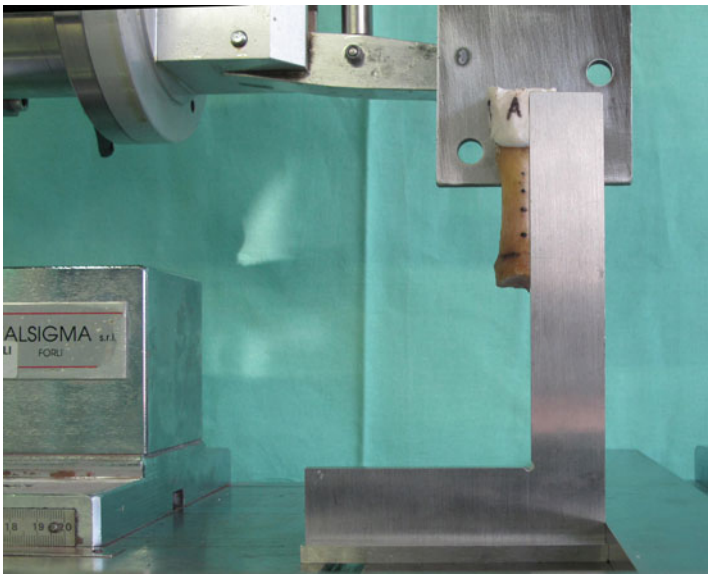

Fig. 184.18 Alignment of the first metatarsus. First metatarsal supported in an adjustable clamp: the acrylic pot is used to ensure correct alignment about its axis, while vertical alignment is checked using a vertical ruler

2. The biomechanical length of each metatarsal is defined as the full length from the most proximal point to the most distal point. As this is not measurable directly before dissection is completed, the distal portion should be measured first (while the proximal part is still included in the ligamentous structures) up to an arbitrary point that must be marked along the diaphysis. When the distal part is potted and the proximal part is free of all soft tissue, the remaining proximal length must be measured and summed to the previous measurement.
3. The medial part of the foot (medial cuneiform) must be supported by clay to restore the natural curvature of the plantar arch (Fig. 184.16).
4. The distal extremity of each metatarsal bone must be included in high-viscosity bone cement while resting on a flat surface to provide alignment about the long axis of the bone in subsequent steps (Fig. 184.17).
5. Two levels along the bone, each at 20% of biomechanical length from the most proximal and distal extremity, must be identified and marked.

6. The centers of the cross sections at two such levels must be identified and marked both in the antero-posterior and in the medio-lateral views.
7. With the aid of the flat surface of the distal pots of bone cement and the center points of the two sections (see point 6 above), the frontal and sagittal planes can be identified (Fig. 184.18).

184.7.3 Assessment of the Reference Frame for the Metacarpal and Metatarsal Bones

The reference frame described earlier has only provisionally been assessed. Because of the small dimension of the bones involved, alignment errors are larger (and more difficult to assess). It can be provisionally estimated that the uncertainty affecting rotation about the long axis of these bones is of the order of 5–10°, while the uncertainty affecting identification of the frontal and sagittal planes is of the order of 2–5°.

184.8 The Phalanges

184.8.1 Review of Published Reference Frames for the Phalanges

To the author's best knowledge, no detailed anatomical reference frame has ever been proposed for the phalanges for neither the hand or the foot. As already pointed out, the hand and the foot are often described either as single bodies in movement analysis or divided in two or three parts. In fact, the recommendation by the Standardization and Terminology Committee of the International Society of Biomechanics (Wu et al. 2002) for the lower limb does not suggest any specific reference frame for the phalanges of the foot. The recent recommendation by the Standardization and Terminology Committee of the International Society of Biomechanics (Wu et al. 2005) for the upper limb provides some more detail for the phalanges: similar to the metacarpal bones, the origin of the reference frame is located midway between the base and head of each phalanges. In the transverse plane, it will be at the approximate center of the tubular bone. The sagittal plane is defined as that plane that splits the phalanges into mirror images.

As no reference frame has ever been proposed for in vitro applications, we devised a procedure to identify the reference frame of each phalanges bone that is inspired by the ISB guidelines (Wu et al. 2005) and is compatible with the criteria adopted for the other bones, consistent with Ruff and Hayes (1983) and Ruff (1981).

184.8.2 Guidelines for Identifying the Reference Frame for the Phalanges

The procedure for the phalanges is quite similar to that described for the metacarpal and metatarsal bones and is consistent with the methods described for the other bones:

1. Because of the small size of the phalanges, accurate identification of the palmar plane is critical on isolated bones. Therefore, alignment of the phalanges about their long axis must be derived from that of the adjacent metacarpal or metatarsal bones prior to complete dissection (similar to the method explained for the metacarpal and metatarsal bones).

2. The biomechanical length of each phalanx is defined as the full length from the proximal most point to the most distal point.
3. Two levels along the bone, each at 20% of biomechanical length from the most proximal and distal extremity, must be identified and marked.
4. The centers of the cross sections at two such levels must be identified and marked both in the antero-posterior and in the medio-lateral views.
5. Clay or plates of assigned thickness must be inserted under the two extremities so that the centers of the two cross sections (point 4 above) lie in the same plane.
6. The sagittal plane and frontal planes can now be marked.

184.8.3 Assessment of the Reference Frame for the Phalanges

The reference frame described above has only provisionally been assessed. Because of the small dimension of the bones involved, alignment errors are larger (and more difficult to assess). It can be provisionally estimated that the uncertainty affecting identification of the frontal and sagittal planes is of the order of 2–5° (similar to that of the metacarpal and metatarsal bones). However, the uncertainty affecting rotation about the long axis of these bones is necessarily larger than that of the neighboring metatarsal and metacarpal bones, as alignment of the phalanges is only derived from such bones): errors greater than 10° should be expected.

184.9 Applications to Other Areas and Future Work

In the last few years, following the Physiome initiative that has been put forward by many research centers and grant agencies, the musculoskeletal system is often investigated using a multiscale approach (Viceconti et al. 2008). This implies that the same bone specimen has to be tested at different dimensional scales (see, for instance, the Living Human Digital Library project (LHDL: http://www.biomedtown.org/biomed_town/LHDL/users/repository/ and http://www.livinghuman.org/); or the Virtual Physiological Osteoporotic Human (VPH-OP: http://www.biomedtown.org/biomed_town/vphop and http://www.vphop.eu/). When a skeleton has to be investigated at different scales, first as a whole, by extracting individual bone specimens, down to the tissue and sub-tissue level, new reference frames and new methods for propagating them across the different dimensional scales are needed. As an example, in the LHDL project, the human femur was investigated as a whole, at the tissue level (mechanical properties of cortical and trabecular bone) and at the sub-tissue level (collagen orientation, etc.) (Cristofolini et al. 2009). To achieve this, specific references and practical tools to transfer them from one scale to the other had to be developed (Juszczyk 2009).

Summary Points

- Identification of reference frames based on anatomical landmarks is fundamental for the correct execution of reproducible in vitro tests on bone segments.
- While reference frames for in vivo use must rely on anatomical landmarks that are accessible noninvasively by palpation, reference frames for in vitro use can rely upon physical points on the bone surface and direct measurement of bone dimensions.

- The possibility of directly accessing the bone surface in vitro enables more accurate identification of anatomical landmarks and reference frames than when the same task is performed in vivo.
- Bone anatomical landmarks for in vitro use should be defined so that they rely upon points, features, and dimensions that are available in all subjects and are not altered during aging.
- For long bones, the most critical alignment is that about the long axis of the bone: inaccurate identification of such anatomical landmarks causes large error in internal/external rotation because of the small dimensions in a direction perpendicular to the long axis.
- For most long bones, reliable anatomical landmarks for the identification of the long axis are based upon the mid-section at two well-defined levels, both in the frontal and sagittal plane. Direct measurement of cross section by means of Vernier calipers enables accurate identification of such points (typical error: 0.2–0.4 mm).
- Similar criteria are proposed to define consistent reference frames of most long bones (femur, tibia, fibula, humerus, radius, ulna, metatarsal and metacarpal bones, and phalanges).
- Typical inter-operator uncertainty in the identification of the neutral position about the long axis of long bones (internal/external rotation) is 0.5°–5°, the largest error being found for the smallest bones.
- Typical inter-operator uncertainty in the identification of the neutral position in the frontal plane (adduction/abduction) and in a sagittal plane (flexion/extension) is 0.1°–1°, the largest error being found for the smallest bones.

Acknowledgments The authors wish to thank Massimiliano Baleani, Mateusz Juszczyk, and Serge Van Sint Jan for the stimulating discussions. Giorgia Conti, Valentina Danesi, and Paolo Erani greatly contributed to the development of the reference frames. Andrea Malandrino, Doriana Lionetti, and Caroline Öhman patiently contributed to the inter-operator variability assessment. Luigi Lena provided the artwork. Daniel Espino carefully revised the script.

The European Community co-funded this study (grants: IST-2004-026932 "Living Human Digital Library - LHDL" and #223865 "The Osteoporotic Virtual Physiological Human – VPHOP").

Chapter 185
Using Three-Dimensional (3D) Anthropometric Data in Design

Jianwei Niu and Zhizhong Li

Abstract With the emergence of 3D scanning technology, it is now possible to generate a large database of 3D models of humans from different demographic backgrounds. Unfortunately, one major drawback is that there is no clear link between 3D anthropometric data and engineering design. Sizing is regarded as an effective way to design properly fitted products. This chapter aims to show the usefulness of 3D anthropometry for the development of product sizing systems, taking helmet design using 3D head data as a case study. Current 3D scanning technology, the representative large-scale 3D anthropometric surveys, the diverse applications of 3D anthropometry in ergonomic product design, and the historical development of military helmet sizing systems were reviewed. Emphasis was then put on the proposed sizing method for helmet design by combining a multi-resolution representation of 3D anthropometric data and k-means clustering on the decomposed data. By using a novel block-based distance, each 3D head was transformed into a multi-dimensional vector. Clustering validation was implemented by using two measures, i.e., size-weighted variances and Clustering Validity Indices (CVI). The results show that the proposed block distance-based descriptor is superior to traditional sizing dimensions. Comparative studies were conducted as well to investigate the robustness of the proposed method. The proposed method provides a systematic method for properly grouping 3D anthropometric samples into clusters according to their 3D shape.

185.1 Introduction

Anthropometry is a requisite for ergonomics and user-centered design (Liu et al. 2009). It has been recognized that anthropometric data could improve the quality of product design, usability, and workstation planning. Modern anthropometry can be traced back to 1870, when Quelet attempted to obtain measurements of the average man in order to provide better-fitting uniforms for Napoleon's army (CUErgo 2009).

Traditionally, anthropometric data were manually collected using tapes, calipers, and other such measurement tools. Traditional anthropometry has many sociological, logistical, and technical drawbacks. It takes prolonged time, requires a skilled researcher for consistency and accuracy during measuring, and brings about undesirable physical contact between the subject and the researcher (Deo 2006). Over the past few years in anthropometric research, it has been found that observer error – such as inaccurate instrument placement and readings, the subject's attitude, and the imprecise placement of landmark locations – is extremely problematic in traditional anthropometry (Gordon and Bradtmiller 1992). 3D anthropometry is the quantitative study of the regions of the human body and characteristics of the surfaces, volume, and shapes of organs using noninvasive methods (Vannier and Robinette 1995). As the cost of scanning technology declines, research utilizing 3D techniques is becoming widely accessible to academia and industry (Lerch et al. 2007).

An effective way to design properly fitted products is to analyze human body forms and to classify them into several groups (Mochimaru et al. 2000), commonly referred to as 'sizing' in anthropometry. A sizing system classifies a specific population into homogeneous groups by using certain key body dimensions, such as stature and waist girth (Chung et al. 2007). For a traditional sizing system, sizing programs are established by dividing the range of key dimensions into appropriate intervals.

There are some drawbacks in traditional sizing methods. The most important is that, in traditional univariate or bivariate sizing methods, only one or two dimensions are referenced. Geometric characteristics and the internal structure of human surfaces are not adequately considered. This leads to design deficiencies on fit and comfort.

The aim of this chapter is to summarize several previously published papers (Niu et al. 2007, 2008; Niu and Li 2008; Niu et al. 2009a, b, c) demonstrating the usefulness of 3D anthropometry with regard to sizing and ergonomic design requirements. A novel sizing method for helmet design by combining a multi-resolution representation of 3D anthropometric data and k-means clustering on decomposed data was presented. In order to understand the robustness of the new sizing method, several further comparative studies were conducted, for example, the sensitivity to the decomposition level.

185.2 3D Scan Technique and Large-Scale 3D Surveys

Even before 3D scanning technologies were available, there were several methods for capturing human body surfaces (Gordon et al. 1989; Li 2006). Nowadays, capturing human body surface data can be accomplished in many ways. They include, but are not limited to, coordinate measurement machine (CMM) technology, computed tomography (CT) scanning, optical scanning, industrial laser scanning, etc. Although 3D data can provide a rich array of information on human body shapes, researchers usually have to face the daunting task of first processing the data. Data processing work includes filling holes, data filtering, surface modeling, registration, and alignment of multiple scans, etc. Currently, one major part of 3D data processing focuses on landmark labeling and extraction of human body dimensions

from 3D scanning (Li 2006). No 3D systems are commonly used in anthropometry. An efficient, reliable, and non-contact solution to 3D data acquisition would be a very significant step forward.

Currently, a number of major ergonomic studies are underway, undertaken by consortiums of universities, governments, and industries to create large accurate 3D anthropometric data sets. CAESAR (Civilian American and European Surface Anthropometry Resource), regarded as the first large-scale civilian 3D survey in the West, was the result of a comprehensive research project that brought together representatives from various industries including apparel, aerospace, and automotive in order to assist these industries with their ergonomic needs by making anthropometric measurements of large populations of citizens (Robinette et al. 2002). SizeUK (www.fashion.arts.ac.uk) and SizeUSA (www.tc2.com) are two other representative 3D surveys. France, China, Korea, Mexico, and Brazil are also conducting or have conducted similar national 3D anthropometric surveys. WEAR (World Engineering Anthropometry Resource project, http://wear.io.tudelft.nl) brings together a wealth of different anthropometric data collected around the world as well as methods for the use of these data in a wide variety of innovative applications. Through collaboration between experts in anthropometry from ten countries in six continents, the project unifies access to 145 existing databases, including 3D body scans. Its aim is to develop data models and software tools of an on-line worldwide information system for utilization in the latest anthropometric databases in engineering environments (http://ovrt.nist.gov).

185.3 Application of 3D Anthropometry in Ergonomic Product Design

The large variety of working or living environments presents a challenging task for the designers. Fitted clothing, worn items, equipment, and/or workstations must be designed with careful consideration of the size and shape of the target population (Reed and Parkinson 2008). The interfaces between user and designed products can affect fit, safety, and other performances. For example, if an aircraft seat cannot be sufficiently adjusted for height, a pilot with short stature cannot see over the instrument panel (Vannier and Robinette 1995). The traditional design process is usually both costly and time consuming.

3D anthropometry has the potential to accelerate the design process using 3D data, and has inspired the interests of designers. Unfortunately, automatic processing of 3D scan data is still currently under development. This is why designers are often confused regarding how to use anthropometric theory to guide their designs (Kouchi et al. 1996). Therefore, development of new methods and tools for the exploitation of 3D anthropometric databases is urgently needed for designing and functional evaluation of products. Only in this way can the time and cost of launching products be reduced, the fit and comfort of products be improved, and design aspects such as protection, functionality, and style be integrated.

Computer-aided software systems have assisted in enhancing the efficiency of engineering design. Many researchers are working on developing a virtual environment to be used for product design where 3D anthropometric data are important. A number of 3D software tools have been developed for ergonomic design of consumer products, machines, workplaces, and occupational devices. For instance, Mochimaru et al. (2000) proposed a homologous modeling method. Well-fitted products can be designed by applying deformed control lattice points which convert a standard body form into other body forms. Brodeur and Reynolds (2004) presented a method for converting the CAESAR full-body scanned data into human body models for use in the ERL (a comprehensive automobile interior design tool). CAESAR data can be incorporated into the ERL software for ergonomic design and evaluation. McKean et al. (2005) presented the development and testing of a tool for designing

vehicle operator workstations using 3D anthropometry. Goonetilleke and his colleagues showed an approach to automating foot measurements using 3D scanned data, as well demonstrating how to model foot height and foot shape-related dimensions (Witana et al. 2006; Xiong et al. 2008). Veitch and Davis (2009) presented their use of 3D anthropometric data in the selection and design of life-like apparel fit manikins, which then resulted in 2D apparel blocks, patterns, and grading.

3D anthropometry also finds applications in the individualized design and fabrication of total-contact seating systems, etc. For example, Hsiao et al. (2007) evaluated the fit efficacy of fall-protection harnesses by using 3D anthropometric data to help reduce the number of fall-related injuries and fatalities among construction workers. Successive and increasingly revealing studies have resulted in improved specifications for new harness designs (National Fallen Firefighters Foundation and Total Contact Inc. 2008).

The design of airline and automotive interiors is also facilitated by the use of 3D human models. For the automotive industry, comfortable seating is considered a consumer requirement. High-resolution human models can provide ergonomic information regarding appropriate seat height and necessary legroom space and then generate a computerized pressure map (Reed et al. 2002). NIOSH recently completed a 3D anthropometric study of agricultural workers to enhance tractor safety and performance.

An important category of wearing products required to be extremely fitted are head and face-related products, such as masks, helmets, goggles, respirators, etc. Traditional helmet design usually depends on certain linear measurements, for example, head length, head breadth, or head circumference. During the 1990s, with the rapid development of scanning techniques, 3D head data became popular in helmet design. Meunier et al. (2000) proposed a method involving the use of 3D laser scanned geometry as a means of measuring helmet standoff distance (distance between the inside of the helmet and the skull). Their method provides a valuable tool to design ergonomic helmets by providing objective feedback for information regarding compatibility. By using 3D head data, a computer-aided tool based on a semi-parametric helmet shell model was proposed by Liu et al. (2007). This tool can quickly generate a helmet shell after several critical parameters are set. It speeds up the development of customized safety helmets and offers improved comfort and better protection for the wearer. Zhang and Molenbroek (2009) introduced their method to model and design the glasses based on 3D head scan data with the computer design software Rhinoceros (www.rhino3d.com).

In contrast with traditional linear anthropometry, 3D anthropometry brings tremendous benefits to accommodate various and diverse groups of users, and leads to much improvement in product ergonomic design.

185.4 Historical Development of Military Helmet Sizing Systems

Early during World War I and II, soft leather helmets were first designed and considered the headgear of choice for battle aircraft aviators. These soft helmets usually came in only one size and had a drawstring or cloth strap for adjustment around the face and neck for a closer fit. Face length served as the key dimension of a sizing system developed in 1942 (Randall and Damon 1942). In 1944, a new Four Size Head Circumference Program using the cadet anthropometric series was established (Koepnick and Benton 1944).

Subsequently, head breadth and head length as key dimensions were also considered when rigid crash helmets became a necessity with the advent of high-speed aircraft, and led to the 1954 Headform Series (Zeigen et al. 1960). A major drawback of the 1954 system was its complexity. Zeigen et al. (1960) reported a method for the sizing and design of rigid and semi-rigid helmets based on a single

key dimension: head circumference. Another early sizing system was the 1954 Head Length–Head Breadth System (Zeigen et al. 1960). As pointed out by researchers, helmets designed based on such sizing systems were usually bulky and uncomfortable.

More recently, Sippo and Belyavin (1991) described a method of sizing using three key dimensions: head length, head breadth, and pupil-vertex height. The authors used multivariate statistical analysis on anthropometric data from a 1970/1971 survey of 2,000 Royal Air Force Aircrew members. Robinette and Whitestone (1992) reported an approach for characterizing the human head in the design process. They selected head length and head breadth to divide the population into groups. They then arbitrarily selected target head length and head breadth points within these groups for selection of heads to represent the group. Bradtmiller and Beecher (1993) introduced their approach for helmet sizing. The authors developed vectors from a central point on the head to points on the surface from a data set of 475 males and 462 females in a nationwide survey. The authors stated that the vectors form variables that can be manipulated in traditional ways and that they were pursuing two analytical approaches with the radii. A similar concept was also adopted by Elliott (1998).

In conclusion, this brief survey clearly demonstrates that helmet sizing is a complex issue, and has been a hot spot in the research of anthropometry, especially with the rapid progress of 3D technique.

185.5 Use of 3D Anthropometric Data for Helmet Sizing

Helmets have become increasingly specialized for a variety of tasks and functions. Types of helmets include helmets used by construction workers, motorcyclists, football players, baseball players, divers, welders, bicyclists, fire fighters, wrestlers, aviators, etc. The issue of properly fitting helmets has been studied for a long time. Numerous reports have referred to the high incidence of head injuries and the resultant fatalities in aircraft accidents. The extreme complexity and variability of the head and face exaggerate the limitations of traditional linear dimensions.

The demand for new methods arose when traditional sizing systems proved to be inadequate for current helmet-design problems. Protective helmets that are too loose may become displaced from the wearer's head during an accident and even result in head injury. Conversely, too tight a protective helmet will be uncomfortable and may cause the wearer to position the helmet incorrectly on the head, or cause an unnecessary distraction. This is critical for jobs requiring a great degree of concentration. Operation of a fighter aircraft during wartime would be just one example where a poor-fitting helmet would be extremely undesirable.

Helmet-mounted displays (HMDs) are becoming increasingly popular for both military and civilian use. Medical operations, such as endoscopic surgery, and robotic applications, such as bomb disposal, are just a few examples of the use of HMDs where a poor-fitting helmet could reduce human performance and result in disaster (Elliott 1998). Properly fitting modern flight helmets means not only comfort, but also proper placement of accessorial components (e.g., headphones, helmet-mounted optics, etc.), stability, and proper location of the center of gravity on a helmet (Harrison and Robinette 2005).

A new attempt to implement sizing based on 3D anthropometric data is presented in our research. First, by using B-spline wavelet analysis, a multi-resolution description of 3D anthropometric data is established. Then, a block-division method is used to convert each 3D surface into a block-distance vector, which reflects both size and shape information. Next, such vectors become the input of the k-means clustering algorithm, which segments samples into groups according to inter-individual distances rather than range division of key dimensions. Finally, a case study on 3D head data demonstrates the effectiveness of the proposed method and provides results on sizing head shapes.

Fig. 185.1 NURBS surface of the head scan at decomposition level 3. This figure depicts THE NURBS (Non-uniform rational B-spline) surface of a head scan at decomposition level 3. The decomposition is based on B-spline wavelet decomposition algorithm

185.5.1 Data Acquisition and Preprocessing

Head data of 510 young male Chinese soldiers (ages 19–23) were collected with a computerized tomography (CT) scanner at a low dosage by a military department in 2002. However, the head postures of some subjects were not properly settled and stabilized for scanning, and thus the corresponding head scans were rejected for analysis. The final sample size dropped to 447. The slice-to-slice distance was set at 5.0 mm. The original data format was Digital Imaging and Communications in Medicine (http://medical.nema.org). Coordinates of head surfaces were calculated from the original data. The number of points varies from a minimum 38,420 to a maximum 56,200. Under the aid of the CAD software, Unigraphics, noise data on each section can be removed manually by visual check. Since we are mainly concerned with the shape of the whole head, the data for the ears, other than the shape and geometry of the ears, were not analyzed. Using Unigraphics software, the non-uniform rational B-spline (NURBS) surface of the head was generated, as shown in Fig. 185.1.

185.5.2 Multi-resolution Description of a 3D Head

To obtain a multi-resolution description of a 3D head, B-spline wavelet decomposition for heads in our database has been conducted with the aid of the Unigraphics user function developed by our research team.

Multi-resolution decomposition of a head sample is illustrated in Fig. 185.2. Surfaces (a), (b), (c), (d), (e), and (f) correspond to the original surfaces and the decomposed surfaces on the first, second, third, fourth, and fifth levels, defined by 17,161, 4,489, 1,225, 361, 121, and 49 control points, respectively. It can be seen that the decomposed surfaces can describe the main shape of the original ones. Quantitative approximation errors, which reflect the approximation of the decomposed surface to the original surface, have been investigated with respect to various decomposition levels and reported in Niu et al. (2007).

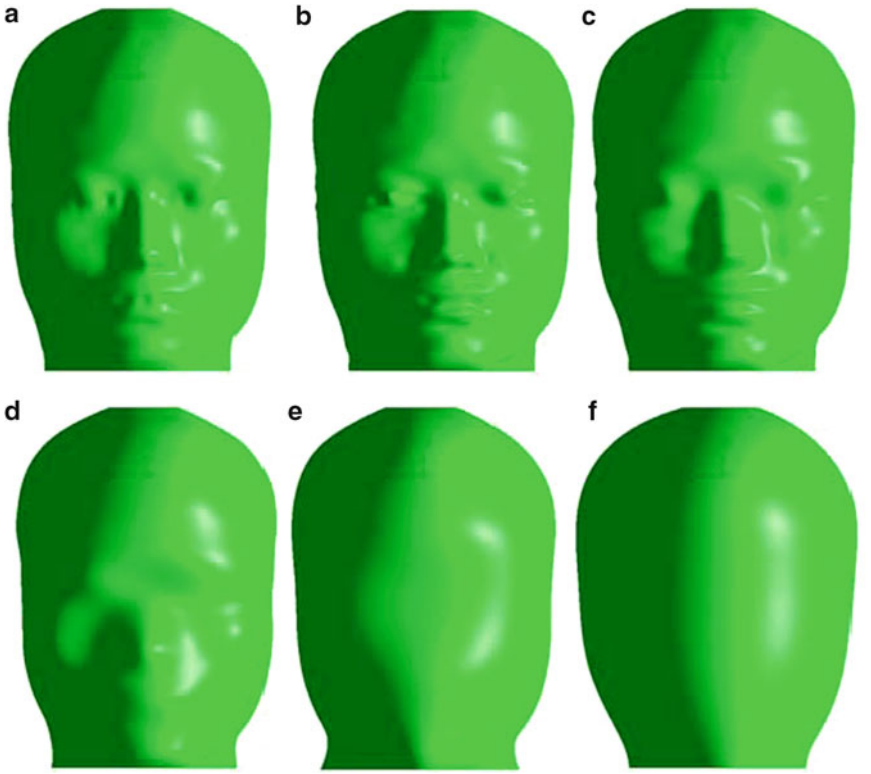

Fig. 185.2 Multi-resolution modeling of a sample (Niu et al. 2009a). This figure depicts multi-resolution modeling of a sample. The original head surface was decomposed based on B-spline wavelet decomposition algorithm. The main shape information can be preserved by the decomposed head surface, while the details were ignored

185.5.3 Block Distance-Based Vector Descriptor for 3D Head Surfaces

The sample surfaces are normally expressed in 3D Cartesian coordinates. To facilitate later shape analysis, a 'vector descriptor' is proposed. A vector descriptor consists of a number of block distances. Here, the term of block means a regular patch on the 3D surface. The block division result of a sample is shown in Fig. 185.3 with different colors and symbols in front and side views.

The distance between the two corresponding blocks on a sample surface i and the inscribed surface, namely $S(i)$, can then be constructed with two parts, namely $S_1(i)$ and $S_2(i)$, that reflect macro-size and micro-shape differences, respectively (Niu et al. 2009a). $S_1(i)$ can be calculated as

$$S_1(i) = \sum_{j=1}^{n_i} dis(p_{i,j}), \quad i = 1,2,3,\ldots,m \tag{185.1}$$

where $p_{i,j}$ is the jth point, and n_i represents the number of points falling into the ith block. Euclidean distance was used to calculate the distance between two corresponding points. $S_2(i)$ can be calculated as

$$S_2(i) = \sum_{j=1}^{n_i} \left| dis(p_{i,j}) - \frac{S_1(i)}{n_i} \right|, \quad i = 1,2,3,\ldots,\mathrm{m} \tag{185.2}$$

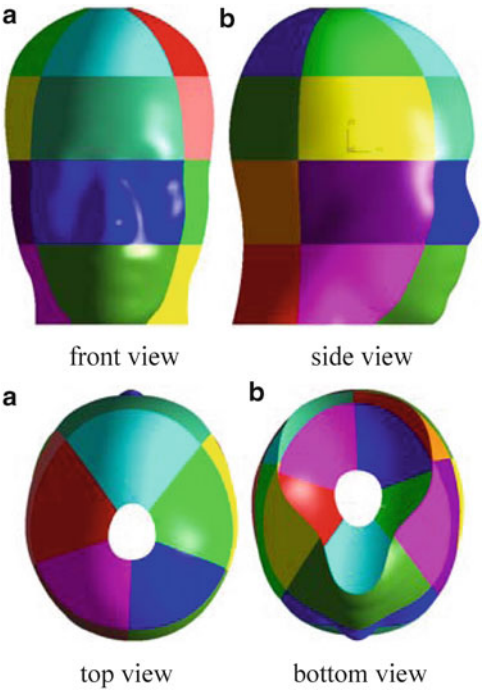

Fig. 185.3 Block division of a head (Adapted from Niu et al. 2009b). This figure depicts the result of block division of a head sample. The whole head surface was divided into 20 blocks, where the block number is 4 in the vertical direction and 5 in the horizontal direction respectively

S_2 describes the shape variation in the corresponding local areas of two 3D surfaces. Different local areas on a surface can have different shapes and geometrical characteristics; therefore, they contribute differently to dissimilarity of the entire shape between a sample surface and the inscribed surface.

Using the above method, the shape of a surface can be characterized by a vector (S_1 (1), S_2 (1), S_1 (2), S_2 (2),…, S_1 (m), S_2 (m)). The vectors are the input of the following k-means clustering algorithm.

185.5.4 K-Means Clustering for 3D Head Surfaces

Clustering has been applied to accommodate various demographic groups and designs for sizing systems. In the case study, k-means clustering was applied to different sets of sample data for comparison, including:

- The head length and head breadth data set.
- The top five PCA components of the proposed block distance-based vectors.
- Directly applied to the proposed block distance-based vectors.

The three clustering alternatives will be compared with two other criteria as described in the next section to see the difference of clustering on traditional sizing measurements and the proposed block distance-based vectors, as well as the necessity of PCA before clustering.

185.5.5 Evaluation of Clustering Results

Cluster evaluation is the process of assessing the quality and reliability of the cluster sets derived from various clustering processes. The Turi & Ray index (Ray and Turi 1999) was revised for clustering

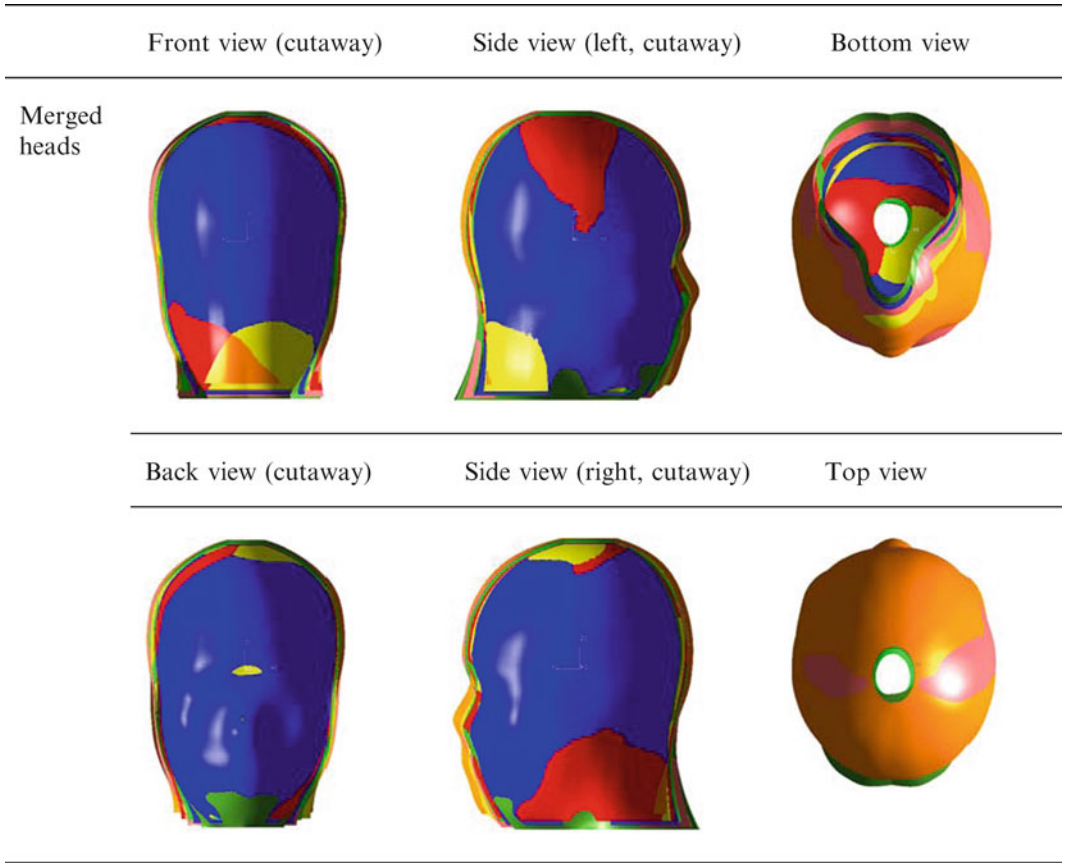

Fig. 185.4 Different views of the merged heads of clusters ($N = 447$, decomposition level = 3). This figure depicts the different views of the merged representative heads of clusters, where the sample size is 447, and the wavelet decomposition level is three. It can help readers distinguish the shape and size difference between different clusters more easily

evaluation (Niu et al. 2009a). Another criterion for clustering evaluation adopted is size-weighted variance. The statistical results of the size-weighted variances of the variables in different clustering alternatives can be referred to in Niu et al. (2009a). Results show that all of the size-weighted variances of S_1 (i) and a majority of the size-weighted variances of S_2 (i) of block distances formed by clustering on the vector descriptor were smaller than those formed by clustering on the head length and head breadth. There is no obvious difference of size-weighted variances between clustering on the vectors with and without PCA. It can be concluded that PCA has little influence on the sizing results. Therefore, PCA can be used for dimension reduction and calculation efficiency improvements.

Different views of average heads of clusters ($N = 447$, decomposition level = 3) by clustering on block distances are shown in Fig. 185.4.

It must be mentioned that a validity index is not a clustering algorithm itself but a measure to evaluate the results of clustering algorithms and gives an indication of a partitioning that best fits a data set. After the cluster results were evaluated with CVIs, domain experts may further analyze the validation procedure results. Using this method, the appropriate partitioning scheme can be selected.

Table 185.1 Headform distribution of Chinese male soldiers (GJB5477-2006)

	Head height–length index (%)		
Head breadth–length index (%)	≤119.99	120–129.99	≥130
≤79.99	I (12.98%)	II (10.96%)	III (0%)
80–89.99	IV (18.79%)	V (43.62%)	VI (7.16%)
≥90	VII (0%)	VIII (3.80%)	IX (2.68%)

This table depicts the headform category accommodation rates of Chinese male soldiers adopted in the latest China military standard GJB5477-2006, where the head breadth–length index and head height–length index were used as the two key measures for head sizing system

185.5.6 Comparative Studies

Some subsequent comparative studies have been conducted to evaluate the effectiveness and robustness of the new methods.

It is interesting to compare sizing results by the proposed method and the current method adopted for the development of a Chinese national military standard of 3D head–face dimensions of male soldiers (GJB5477-2006) (Niu and Li 2009). Head breadth–length index (the ratio between head breadth and head length) and head height–length index (the ratio between head height and head length) are adopted as two key variables in GJB5477-2006. Based on the two indices, the population of Chinese male soldiers is divided into nine groups. The accommodation rate of each group is depicted in Table 185.1. If the 3D heads are classified by using our block distance-based sizing method, the representative heads of each size will fall into the fifth group where head breadth–length index ranges between 80 and 89.99, and head height–length index ranges between 120 and 129.99. However, this is not rational since actually the nine representative heads evidently vary in 3D shape between each other. This emphasizes the necessity to take shape information into consideration in the revision of the military standards in the future.

A case study was done to evaluate the sensitivity of clustering results on block-division number (Niu et al. 2009b). In the case study, each head surface was divided into 20 (5 × 4), 30 (6 × 5), and 90 (16 × 6) blocks, respectively. Multiple comparisons of the means of the proposed block-based distances between different block divisions were conducted using one-way ANOVA. Thus, no significant differences were found between the block-division numbers at the confidence level of 0.05. In other words, this reveals the robustness of the 3D clustering method with block division.

The influence of decomposition levels on clustering results of 3D head data sets was also investigated (Niu et al. 2009c). Cluster membership accuracy rates (CMARs) on different resolution levels, namely from the first to the fifth decomposition levels, were investigated. High CMAR values imply that the wavelet decomposition level does not have a significant influence on shape clustering before the decomposition level reaches five. Considering the difference of the product interface with the human body's surfaces, engineers could be encouraged to adopt the CMAR value as a valuable reference to select a proper decomposition level for the design of a specific product based on the corresponding fit requirements (Table 185.2).

Finally, the influence of alignment, that is, aligned at the centroid and aligned at the top of the head, was investigated (Niu et al. 2008). Cluster membership variation of different alignment methods indicated that the reference can greatly influence the k-means clustering results of 3D anthropometric data.

Table 185.2 Key points of this chapter

1. K-means is one of the simplest unsupervised clustering algorithms. It is to classify the samples based on attributes into K groups by minimizing the sum of squares of distances between data and the corresponding cluster centroid
2. Sizing system development aims to establish sizing systems of whole body or body segment types from the anthropometric data of population by using various approaches. The establishment of the standard sizing systems requires the anthropometric data as reference
3. Ergonomic fit evaluation is to evaluate fit of the wearing items, working places, and tools or equipments made for population with various anthropometric characteristics. It aims to improve the safety, fit, comfort, and other ergonomics levels of products or working places for the customers
4. Computer-aided ergonomic design is an engineering discipline using computers for the design of objects, real or virtual, to solve complex ergonomic problems involving interaction between the human body and its environment
5. Three-dimensional anthropometry is the science of measuring and quantifying the human body or body segments in a three-dimensional space

This table lists the key points of this chapter including k-means clustering, sizing system development, ergonomic fit evaluation, computer-aided ergonomic design, and three-dimensional anthropometry

185.6 Conclusions

In contrast with traditional linear anthropometry, 3D anthropometry brings tremendous benefits to accommodate diverse groups within a population, and leads to improvement in the product ergonomic design. However, researchers must recognize the gap between 3D anthropometric data and the design process. It is urgent to analyze 3D data and to present it to designers by means of anthropometric tools while satisfying design requirements in terms of ergonomics.

In this chapter, a method for analyzing 3D shape is introduced. A multi-resolution description of 3D anthropometric data, which enables data analysis progressively in a coarse-to-fine fashion, was established first. The fundamental properties of wavelets guarantee that the lower dimensionality is able to preserve the major information and describe the main shapes. The multi-resolution description of 3D anthropometric data makes use of not only the coordinates of data points, but also the geometric characteristics and internal structure among the points. Each decomposed surface was divided into a specific number of patches, namely blocks. Shape description was defined based on block distance. In this manner, each surface can be transformed into a block distance-based vector. K-means clustering was performed on the vectors. Clustering results were evaluated with two measures, that is, size-weighted variances and the revised Turi & Ray index. Some subsequent comparative studies, that is, comparison between sizing results by the proposed method and the current Chinese national military sizing standard for 3D head–face dimensions of male soldiers, as well as the sensitivity of clustering results on block-division number and the influence of alignment, have also been conducted. The results emphasize the necessity to take shape information into consideration in the development of future sizing systems.

It is necessary to point out that a sizing system design cannot merely rely on the clustering routine. The suggestions from domain experts and end users should also be considered. Cost and manufacturing issues must be taken into consideration as well. Utilization of 3D anthropometric data for use in design is still at an early stage of development.

185.7 Applications to Other Areas of Health and Disease

Beyond end-user design, 3D anthropometry can also be applied in numerous health and medical fields. It has been used in a number of different applications for comparing morphological differences, including craniofacial growth, craniofacial abnormality, and artificial cranial modifications.

As for rehabilitation treatment and aesthetics applications, 3D anthropometric shape comparison will aid to quantitatively describe and compare facial proportions in a virtual environment, especially from an aesthetic point of view. It can be utilized for investigating 3D facial changes for unilateral cleft lip repair, and for studying organ growth in organ transplants.

3D anthropometry also attracts attention from the forensic sciences, and is expected to be used in determining the identity of crime suspects. A system comparing 3D facial geometry and 2D facial imagery has been proposed by researchers (Kumhyr 2005). This system is capable of automatically scanning and analyzing suspects and will expedite the process of identification or the selection of suspects from a larger number of suspects. Undoubtedly, more and more successful applications in the health and medical fields will be accomplished by using 3D anthropometry. 3D anthropometry will surely also make rapid progress as applications accelerate.

Summary Points

- 3D anthropometry brings tremendous benefits to product ergonomic design.
- There is no clear link between 3D anthropometric data and the design process.
- A multi-resolution description of 3D anthropometric data, which enables data analysis progressively in a coarse-to-fine fashion, was established.
- A 3D sizing system was presented by conducting k-means clustering on block distance-based vectors. Clustering evaluation was performed by using two measures.
- The proposed method provides a systematic method for properly grouping samples into clusters according to their 3D shape.
- Use of 3D anthropometric data in design is still at the early stage of development. It is urgent to understand how to analyze 3D data and to present them to designers by means of computer-aided anthropometric tools.

Chapter 186
Use of Anthropometric Measures and Digital Human Modelling Tools for Product and Workplace Design

Lars Hanson and Dan Högberg

Abstract This chapter addresses and demonstrates the application of digital human modelling (DHM) tools to consider anthropometric diversity in product and workplace design. A number of additional methods for evaluating ergonomics conditions are also illustrated. Three cases show how DHM tools can be applied in different design settings and for different design undertakings, focusing on user variation in anthropometry. A number of methods for user representation in the DHM tool are briefly presented. Method selection depends on the design problem at hand, and the chapter exemplifies the use of different methods for different design tasks. Examples are the use of one-dimensional percentile based statistics data, the use of predefined collections of manikins, and the creation of representative cases by using multidimensional statistics. The chapter takes a designer's view of the uses of DHM tools for anthropometry-related issues and illustrates how the tools can be of value in the design process.

Abbreviations

CAD	Computer-aided design
CAE	Computer-aided engineering

186.1 Introduction

The employment of user-centred approaches in design to understand and meet the variety of targeted users' needs and expectations is acknowledged as a path to successful business for companies that develop and produce products. Computer-aided engineering (CAE) tools can be utilised to support the consideration of some of these user-centred design issues. This chapter describes how digital human modelling (DHM) tools can be utilised to consider issues such as anthropometry, postural comfort and biomechanics in product and workplace design. DHM tools are particularly useful for proactive ergonomics consideration in design processes where computer-aided design (CAD) tools are used to define products and workplaces and where no physical prototypes exist or are to be produced (e.g. due to cost or time). Ergonomics is defined as the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and methods to design in order to optimise human well-being and overall system performance (Wilson 2000).

The DHM tools illustrated in this chapter consist of four essential parts: (1) a manikin: a digital replica of the human, including skeleton, segments, and (sometimes) muscles; (2) a CAD tool to build or import digital components describing products and process equipments/environment; (3) a manikin posture and/or motion generator; and (4) ergonomics evaluation methods. The DHM tools are applied in the design, modification, visualisation and analysis of human workplace layouts and/or product interactions. The simulations and visualisations are frequently used to provide information about body posture, biomechanics, human comfort, reachability, field of view and clearances for arms, hands and tools, to serve as a basis for ergonomics evaluations and design improvements.

The following three cases aim to illustrate how DHM tools can be applied in user-centred design processes for the consideration of anthropometric diversity in product and workplace design. The first case illustrates how vehicle designers work with the tool to determine an appropriate seat adjustment range. A wide variety of users occupies a vehicle cockpit, and some even have the cockpit as their place of work. These users all have their unique anthropometry and posture preferences. Hence, the objective is to design the vehicle interior so that all targeted users can find a safe, functional and comfortable arrangement in the vehicle. A DHM tool can support the designers in meeting that objective. The second case describes a scenario from the healthcare sector. The design engineers are to develop a foot support for a bathtub, which should accommodate elderly residents as well as be easy to handle by caregivers. The biomechanical load on the caregiver when bathing a resident is also analysed. The third case is from the vehicle industry, where DHM tool users are challenged to simulate a worker's wrist motions when performing a work sequence. The wrist motion analysis is intended to optimise the assembly workplace and minimise the biomechanical load on the worker. The three cases are fabricated but realistic examples of how DHM tools are used in product and workplace design.

186.2 Case 1: Seat Adjustment Range for a New Vehicle Platform

A large vehicle development project is launched where a number of car brands co-operate in order to develop a new common car platform. The mission is to create a platform suitable for a wide range of cars, from roadsters to sport utility vehicles. Alfred is responsible for seat-related issues in the platform project. After reading the newspapers and discussing with Lina, who is responsible for the platform's human factors characteristics, he is aware of the general anthropometric trends of people getting taller and more corpulent. With this in mind, Alfred and Lina have decided to conduct a deeper analysis of the seat adjustment range required to ensure that the targeted population will be accommodated by the proposed design. They discuss using the in-house test group in the flexible

buck (basically an adjustable car structure) and DHM tools to find a suitable adjustment range. They then contact Emil who is the human factors simulation engineer responsible for the use of the DHM tool *Ramsis* at the car company. We follow Alfred and Lina's first meeting with Emil where he guides them through a standardised ergonomics simulation ordering process (Hanson et al. 2006). After that, we follow Emil's thoughts and actions when he generates manikins, describes the physical environment, defines the tasks and runs the DHM tool. Finally, we depict Emil delivering the results to Alfred and Lina and storing the analysis report in a documentation database.

Emil, Alfred and Lina meet to begin the DHM analysis of an appropriate seat adjustment range for the platform. Their discussion is structured and follows the predefined ergonomics simulation process available through the company's intranet system. The meeting starts with Alfred and Lina describing the background: the new platform, the anthropometric trends and their uncertainties about the appropriate seat adjustment range. Emil takes notes and fills in the blanks in the process protocol. The protocol is linked to a database, to which all employees in the company have access. Emil summarises the background and enters the data in the protocol. He expresses the analysis objective as follows: "To describe the appropriate seat adjustment range for European and American vehicles launched in 10 years, as well as the location of the seat adjustment range relative to the accelerator heel point." Alfred and Lina agree upon this formulation. Emil adds his name and contact data as the one who is performing the analysis, and Alfred as the requester of the simulation. When all have a common picture of the aim, the desired output is discussed. Alfred is interested in illustrating differences and similarities with the proposed adjustment range and existing car models, for both their own cars and competitor cars. Lina highlights the importance of comparison with SAE (Society of Automotive Engineers) standards. She also suggests that the analysis should include comfort ratings as a complement to the hip-point locations predicted by the DHM tool. Emil confirms these requests by adding them to the protocol and promises to deliver tables and pictures for illustrative purposes. Finally, the group discusses the desired completion date. The agreed date, 2 weeks from today, is entered into the protocol. This concludes the first of three stages in the human simulation process. Before Alfred and Lina leave, Emil gathers the information required to perform the analysis properly, such as information about the targeted market segments and the physical environment as CAD geometry.

Emil is now left alone to start the analysis by searching the human simulation database on the intranet, hoping to find earlier similar studies to save time and gain from previous simulations. He uses "seat adjustment range" as a keyword. Unfortunately, he gets few hits. This is not surprising since DHM is a relatively new tool in the company and seat adjustment ranges are set when car platforms are designed, platforms that may last for decades. He finds one interesting investigation about adjustable pedals and how they affect the seat adjustment range. He also asks an experienced packaging engineer, who is responsible for the SAE requirements, how such studies have been performed previously. She tells Emil that the size and shape of the adjustment range and its location have been based on results from studies in the flexible buck and SAE seat adjustment curves, SAE J1100 ergonomics standard (Roe 1993). She also reminds him that ASPECT guidelines have been introduced and are now working in parallel with SAE recommendations (Schneider et al. 1999).

Emil continues the work by reading the market analysis report. There he finds that the premium mid-segment vehicle that Alfred, Lina and he chose as an example car is aimed at Western Europe and USA. The vehicle will be produced as a sports sedan and wagon, and is projected to attract young people and families. Emil understands the underlying marketing issues, because he knows that vehicle buyers are relatively brand faithful, and, consequently, it is good business strategy to attract younger people. With this in mind, Emil starts to search for updated anthropometric data for the countries with expected large market shares for the future vehicle. In the DHM tool *Ramsis*, he finds up-to-date American, German and Swedish anthropometric data. The American and German anthropometric data are standard in the tool. The Swedish anthropometric data are a company-specific feature developed to get information about a large market. He uses a tool feature that adjusts the anthropometric

data for secular trends so that the manikin sizes are likely to correspond to the customers' sizes when the car is eventually introduced on the market and throughout the car platform's market life cycle.

Emil uses a manikin collection suggested by Speyer (2005) to represent anthropometric diversity. This collection consists of manikins that represent anthropometric diversity suitable for occupant packaging in vehicle design. The collection consists of both central users and boundary users (elaborated in the Discussion section). Based on these data, he generates a set of manikins, six females and six males for each nationality of interest. In total, 36 manikins are generated by combining three key anthropometric variables in cockpit design: stature, waist circumference and sitting height. This approach is based on the assumption that the definition of the characterising properties of stature, corpulence and proportion (ratio of the sitting height to length of the legs) of an individual is sufficient to predict all other body dimensions for this person (Flügel et al. 1986; Bubb et al. 2006). The combinations of percentile values are presented in Table 186.1. The other body dimensions for each manikin are defined by the anthropometric functionality in the DHM tool itself, using existing correlation data to these three key dimensions.

Information about the manikin generation procedure is described in the process protocol that Emil utilises. He also decides to include manikins with the same anthropometrics as each person in the in-house test group, which is to facilitate comparison with the flexible buck study. He models Alfred, Lina and himself as well to support discussions between the people involved in ordering and performing the analysis.

Alfred, Lina and Emil decide to use a mid-segment vehicle as an example in the investigation. Emil enters the PDM (Product Data Management) system and searches the database for the latest CAD geometry definition of the vehicle. He imports floor, pedals with their motion line, steering wheel with its adjustment area, proposed seat adjustment area, inner roof and top of dashboard into *Ramsis*. He tries to keep a minimal description since exchange between computer systems is often time consuming and conversion errors sometimes occur. In addition, Emil believes that a simple description of the physical environment allows the viewer of the illustrations to focus on the ergonomics issues in terms of posture and accommodation. It also indicates that the analysis has been performed at an early design stage with relatively rough assumptions, and that design corrections are both possible and recommended if required. Before the physical environment definition is completed, he makes sure that the steering wheel adjustment areas are located for a quarter-to-three handgrip and moves the accelerator halfway down along the motion line.

Table 186.1 Speyer (2005) manikin family to represent anthropometric diversity

	Stature (percentile)	Waist circumference (percentile)	Sitting height (percentile)
Male 1	5.7	60.2	9.7
Male 2	50.7	47.6	52.5
Male 3	96.4	8.5	76.0
Male 4	94.0	35.7	89.7
Male 5	92.5	95.1	88.0
Male 6	94.3	81.6	98.8
Female 1	6.3	15.1	2.5
Female 2	6.6	48.2	10.9
Female 3	7.8	99.4	12.8
Female 4	4.6	94.2	29.8
Female 5	50.8	43.4	53.0
Female 6	95.1	38.0	91.2

Stature, waist circumference and sitting height as key anthropometric measures and a percentile value combination for a set of manikins

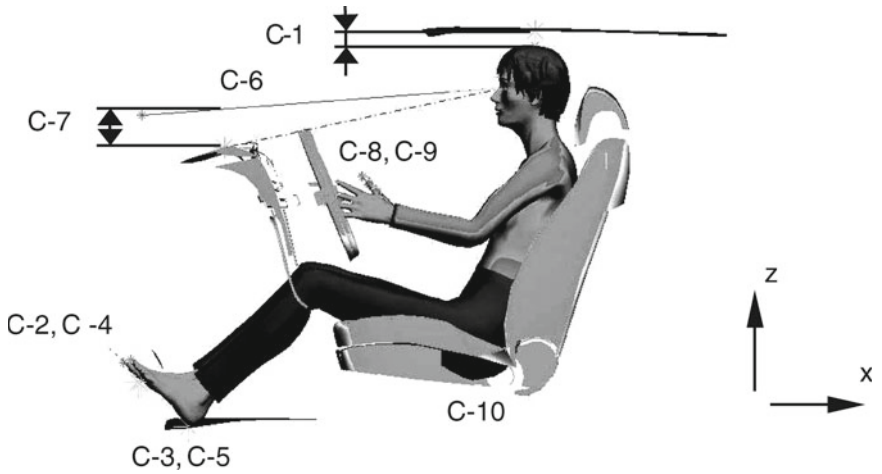

Fig. 186.1 Constraints used in Case 1. Clearance (e.g. C-1 head under ceiling), Line of sight (e.g. C-7 vision line above dashboard) and Fixation (e.g. C-8 hand on steering wheel) are constraints used to determine a seat adjustment area required. When investigating seat adjustment, C-10 (hip-point) is not used as a constraint

The next step in the process is to define the tasks: a normal driving task, which Emil usually defines with the following constraints in *Ramsis* (Fig. 186.1).

- Head clearance. Minimum 25 mm vertical distance between head top (vertex) and inner roof.
- Right pedal point on accelerator, pressed down halfway.
- Right heel point on floor.
- Left pedal point on foot support.
- Left heel point on floor.
- Line of sight. 5° down from horizontal line.
- Line of sight clearance. Minimum 70 mm vertically between line of sight and top of instrument panel.
- Right grasp point within steering wheel adjustment area.
- Left grasp point within steering wheel adjustment area.
- H-point (hip point) within greatly extended seating adjustment area (non-constraining in x and z direction).

Since he does not want to restrict the seating adjustment area in the simulation (that is the aim of the study), he greatly enlarges that area so that it will be non-constraining. With the constraints and physical geometry defined, Emil enters the *Ramsis* automatic analysis procedure. He inputs the manikins and the constraints to be used. In the output section, he describes that he is interested in receiving information about comfort and coordinates for the H-point. Before running the automatic analysis, he remembers that he should change the settings so that the company's unique posture descriptions are used instead of the default *Ramsis* values. When this is done, he pushes the start button and takes a coffee break while the computer is working. After the break, the computer calculation is ready and he has plenty of interesting output data to consider. However, he temporarily ignores the new information and instead starts to use the SAE packaging kit in *Ramsis*. By entering the accelerator heel point and the desired vertical distance between the heel point and the seating reference point (SgRP), that is, the H30 value (Roe 1993), seat reference curves automatically appear. He now has a very interesting picture (Fig. 186.2) with SAE seat reference curves, marks for each manikin's H-point (grey diamonds) and the previously proposed seat adjustment area for the platform.

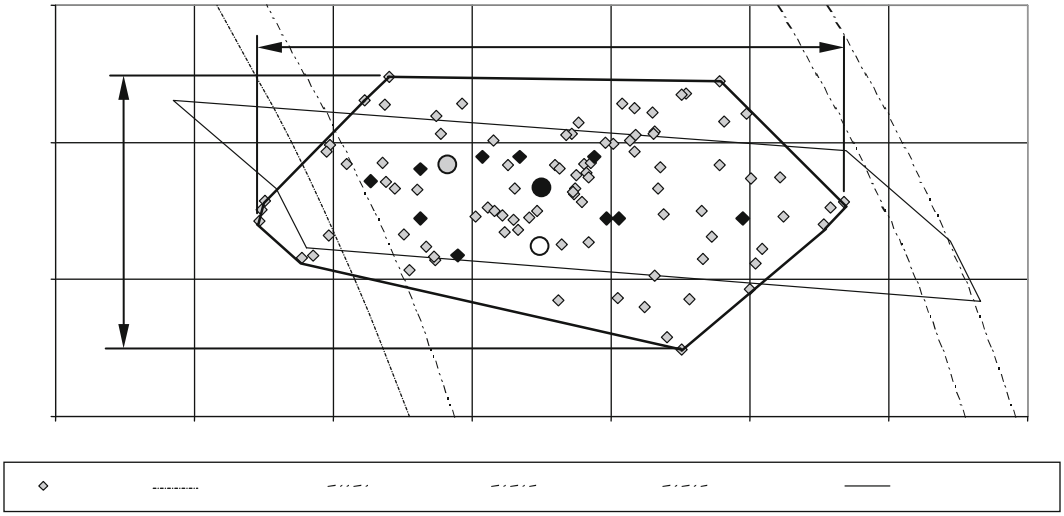

Fig. 186.2 Seat adjustment range and hip points. Example of illustration presented at the Case 1 meeting. *Grey diamonds* represent hip points from the manikin family. *Black diamonds* illustrate hip points for manikins representing the internal test group. *Circles* represent hip points for the key project members. The *dotted line* shows the proposed adjustment range from SAE guidelines. The *thin black line* is the current seat adjustment proposal

Table 186.2 Comfort data from the analysis

	Target population *Mean (SD)*	In-house test group *Mean (SD)*	Alfred	Emil	Lina	Previous car model *Mean (SD)*	Concept car with flexible pedals *Mean (SD)*
Overall	9.0 (2.2)	7.8 (1.8)	9.5	7.6	6.5	8.3 (1.9)	9.2 (2.1)
Neck	7.5 (1.9)	7.9 (2.0)	8.8	8.1	7.4	7.4 (1.6)	7.7 (2.0)
Arms	8.7 (1.3)	7.5 (1.1)	8.5	6.3	4.8	8.5 (1.2)	9.1 (1.4)
Back	9.5 (1.8)	8.1 (1.9)	10	8.0	7.1	9.1 (1.8)	9.9 (1.8)
Legs	6.9 (2.0)	6.9 (2.1)	7.1	6.9	4.6	7.1 (2.3)	8.8 (1.7)

Comfort data (mean and standard deviation) for Target population, in-house test group and key project members (Alfred, Emil and Lina) as well as results from previous studies (previous car models and concept cars with flexible pedals). Comfort data are presented on a ten graded scale, where ten is maximum comfort

Emil also arranges the comfort data in an illustrative table, showing mean and standard deviation values for the target population and the in-house test group (Table 186.2). Data for Alfred, Emil and Lina are also presented, as are data from a previous analysis. As further benchmarking, Emil uses the kind of drawings that vehicle companies share with each other to find out competitors' designs of seat adjustment ranges. With this information in hand, Emil contacts Alfred and Lina for a meeting to deliver the results.

Emil has stored all pictures and tables generated in the analysis in the database. He uses the unique project number, and pictures and figures together with his own comments. Emil starts the presentation by showing Alfred and Lina illustrations similar to Fig. 186.2.

He describes how the previously proposed seat adjustment range is shown by the thin line in the figure. The adjustment range required to accommodate the target group is represented by the thicker line. The black diamonds represent H-points for the in-house test group, and the white, black and grey circles represent Alfred, Emil and Lina's H-points, respectively. The SAE seat

adjustment range is presented with dotted lines. They discuss the differences and conclude that the previously proposed seat adjustment area is sufficient, at least in length. The size and the shape are also comparable to competitors in the premium mid-segment vehicles. Alfred and Lina are convinced that a horizontal extension of the adjustment range, which was their thought before seeing Emil's pictures, is not required. Instead, a decrease in length and increase in height seem preferable. However, Alfred's view is that even though obviously advantageous, a larger height adjustment range is likely to be complicated to realise and difficult to get approval for in the new platform. Alfred also believes that the decrease of the seat adjustment range in length may not be an option in a conservative design environment. Based on the discussion, they together update the comments and conclusions about the seat adjustment range. Lina who has short legs finds the comfort ratings interesting. Her ratings in Table 186.2 are lower than all others, indicating a lower comfort level. She admits that she has difficulty reaching the pedals without sitting too close to the steering wheel. Overall, the comfort ratings look promising, though, with high numbers close to the maximum of ten. However, the absolute comfort values are of minor interest. It is the value compared to different concepts that is interesting. In this case, the seat adjustment range proposed by the DHM tool is almost as good as the concept car with adjustable pedals, and better compared to the previous car model. The issues that come up during Emil, Alfred and Lina's final discussion are entered into the protocol as a complement to the comments that Emil stored earlier about the analysis results. Alfred and Lina thank Emil for a good job and sign their names and date in the approval section in the protocol, which concludes the digital human simulation and visualisation mission. Before leaving, they promise Emil that they will come back with information about H-point locations and comfort ratings from the tests with the in-house test group in the flexible buck, information that Emil can use for validation of the software.

After the meeting, Emil is satisfied with his job and the positive feedback. He thinks he showed the strengths of the DHM approach. He is glad that he was consulted since it indicates that the possibilities of the DHM tool are recognised and considered advantageous. Another positive point is that the study was initiated at an early design stage where it is possible and comparatively easy to perform design changes when necessary. An extra bonus was Alfred and Lina's assurance to provide him with H-point locations and comfort ratings from the tests with the in-house test group, information that Emil can use for validation of the software, in his work, and in convincing colleagues about the qualities and advantages of the DHM tool.

186.3 Case 2: New Bathtub Footrest Optimised for Elderly Home Residents and Caregivers

The project is initially aimed at designing a new footrest to be integrated into a new bathtub design, complementing the healthcare company's product portfolio. Three design engineers, Bork, Mattis and Lovis, attend the start-up meeting from the company, along with two DHM tool users, Ronja and Birk, from a university nearby (in this case, representing regular DHM tool users). The analysis follows the human simulation process proposed and used in the automotive industry (Hanson et al. 2006). The meeting starts with Mattis describing the background: the new bathtub, the anthropometric trends, their uncertainties about the appropriate footrest adjustment range as well as the high biomechanical loads on the caregiver when adjusting the footrest. Bork also presents the company's *Mobility Gallery* (Arjo 2005). This is a user characteristics representation approach that has proven to be successful in the way it supports descriptions and

communication about product users' abilities and requirements, for people inside and outside of the company. In the gallery, residents are classified according to their degree of functional mobility, from the most mobile and independent to the most dependent and entirely bedridden resident. Five mobility levels are described and labelled using alphabetical names: *Albert*, *Barbara*, *Carl*, *Doris* and *Emma*. Each resident is described with different personal characteristics and background details and an illustration. Residents can be represented by a female or male, regardless of their gender-specific names.

Birk takes notes and fills in the blanks in the prepared human simulation process protocol, which is linked to a database that all involved in the project have access to. After the discussion, the project group formulates the following objective for the analysis: "To analyse the bathtub ingress and describe an appropriate bathtub footrest position and adjustment range for typical residents, as well as a confirmation that the footrest is easily manually adjusted by typical caregivers. The footrest is to be designed for mobility levels represented by Albert, Barbara and Carl." They all agree upon this formulation. Birk adds his name and contact data as the person responsible for the analysis; one of the design engineers fills in her data as the requester of the analysis. When all have a common picture of the aim, the desired output is discussed. Mattis, Bork and Lovis are interested in illustrating differences and similarities with the proposed adjustment range and the current one, for both their own bathtub and competitors' designs.

Ronja and Birk ask for national and company design standards for comparison purposes. However, no such standards exist. Instead, the company has reports from tests of physical prototypes describing preferred bath postures, among other things. Ronja receives copies of the reports. The design engineers ask Ronja and Birk to utilise ergonomics evaluation methods integrated in the DHM tool when analysing the caregivers' situation when adjusting the footrest. This request is added to the protocol as confirmation, and they agree that the analysis results shall be complemented with tables and pictures for illustrative purposes. Finally, the group discusses the desired completion date. The agreed date, 2 weeks from today, is entered into the protocol. This concludes the first of three stages in the human simulation process. Before Ronja and Birk leave, they gather information required to perform the analysis properly, such as the targeted market segments and the physical environment as CAD geometry.

The DHM tool users, Ronja and Birk, are now left alone to start the analysis by searching the human simulation database on the intranet, hoping to find earlier similar studies to save time and gain from previous simulations. Ronja uses keywords such as "bathtub" and "footrest position." Unfortunately, she gets no hits. This is not surprising since DHM is a new tool at the company. Ronja continues the work by reading the market analysis reports. Here, she finds that the new bathtub is planned to be sold as a high-quality brand product and is aimed at Swedish people living in elderly service apartments. With this in mind, she starts to search for updated anthropometric data for mid-age and elderly Swedish people. Ronja finds up-to-date detailed data for Swedish people aged 18–65 (Hanson et al. 2009). Unfortunately, she does not find detailed anthropometric data for the elderly population when searching through research literature. Instead, she uses an article by Dey et al. (2001) where stature and weight have been studied.

Ronja uses the anthropometric information for the Swedish female working force and generates three female manikins to replicate the caregivers: one central user, 50th percentile in stature, as well as two boundary users, 5th percentile and 95th percentile in stature measure. Ronja only generates female manikins since the majority of caregivers are female. In the same manner, she calculates 5th percentile, 50th percentile and 95th percentile manikin data to represent residents (i.e. female and male Alberts, Barbaras and Carls). Ronja generates these 18 resident manikins in the DHM tool *Delmia V5*. Stature is selected as the key dimension in this case, and all other body measures are automatically calculated in the DHM tool to give the manikins normal proportions. Ronja is well aware that no "normal" proportions or mean persons exist when considering several anthropometric

measures together (Daniels 1952; Robinette and Hudson 2006). However, the approach with one key anthropometric variable (stature) is used to keep the problem simple and is considered good enough in this case. In addition to these manikins, Ronja creates manikins that are anthropometric replicas of the ones involved in the development project (e.g. the design engineers). She does this to support discussions about the analysis results among the people involved in ordering and performing the analysis.

To more accurately simulate elderly people, Ronja adjusts the joint flexibility of the manikins (exemplified in Table 186.3) based on range of motion (ROM) data from Older Adultdata (Smith et al. 2000). Three levels of mobility are relevant for this bathtub design (Albert, Barbara and Carl). The appearances of the residents are adjusted to the company standard described by the Mobility Gallery according to mobility level (Fig. 186.3) (Högberg et al. 2009). The default appearance and joint ranges of motion in the DHM tool are used for the caregivers. By using this method, Ronja cre-

Table 186.3 Range of motion data for Albert, Barbara and Carl

			ROM angle		
Resident	Gender	Percentile	Hip flexion	Shoulder extension	Shoulder flexion
Albert	Male	50	110	38	160
	Female	50	111	49	169
Barabara	Male	20	101	29	151
	Female	20	101	38	161
Carl	Male	10	96	24	146
	Female	10	96	32	157

Albert, Barbara and Carl are members of the Mobility Gallery. This table shows their range of motion in hip (flexion) and shoulder (extension and flexion) as examples of joint flexibility

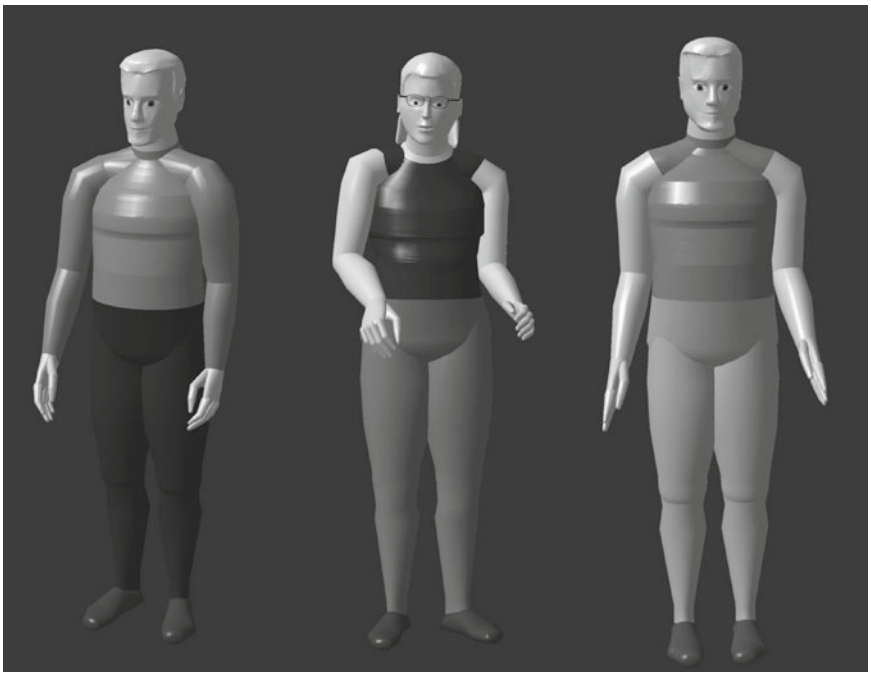

Fig. 186.3 Albert, Barbara and Carl, from *left to right*, members of the Mobility Gallery. Manikin representations of Albert, Barbara and Carl and their appearance

ates a set of 26 manikins: three mid-aged caregiver manikins, 18 elderly resident manikins and five manikin replicas of the team members.

The next step is to load the CAD geometry, and Ronja imports the bathtub and competitors' adjustable footrests from a USB memory stick. She tries to keep a minimal physical environmental description since exchange between computer systems still is quite time consuming and conversion errors sometimes occur, especially when using CAD and DHM systems from different suppliers. A simple description of the physical environment encourages the viewer of the illustrations to focus on the ergonomics issues. It also indicates that the analysis has been performed at an early design stage with relatively rough assumptions, and that design corrections are both possible and welcome if they improve the design.

The next step in the human simulation process is to define the tasks performed by the resident and the caregiver. Ronja performs a basic task analysis and defines the tasks in bullet form as follows:

Bathtub ingress task

Resident	Caregiver
• Sitting relaxed	• Standing relaxed
• Hands on the support handles	• Feet attached to floor
• Left leg straight forward	• Right hand on the lifting device control
	• Left hand lifting resident's leg
	• Eye focus on hand lifting leg

Footrest adjustment task

Resident	Caregiver
• Sitting in preferred posture	• Standing relaxed
• Head above water surface	• Feet attached to floor
• Back attached against bathtub backrest plane	• Right hand on foot adjustment device
• Buttocks attached against bathtub bottom plane	• Eye contact with resident

With the manikins, the physical geometry environment and the tasks defined, Ronja starts to manipulate the manikins. She saves the preferred bathing posture described in the report as a predefined posture in the DHM tool. She uses the preferred bathing posture as a starting point for residents. The manikin is moved to the bathtub and manikin joints are manipulated only when needed to fulfil the task description. This is done for all 23 manikins. Ronja then uses the relaxed standing posture as a starting point for the caregivers. The joints in the back, arms and neck are adjusted minimally to fulfil task criteria. After repeating this for the manikins representing caregivers, a more detailed ergonomics analysis can be made. The team member manikins act as both residents and caregivers.

Ronja generates plots of the position of the sole of the foot for each manikin representing residents (Fig. 186.4). As a benchmark, she inserts the adjustment range of the competitor product, and adds dots representing likely positions of the project group members. Joint comfort values for each manikin are automatically calculated by functionality in the DHM tool.

For caregivers, Ronja generates reach envelopes and calculates a RULA (Rapid Upper Limb Assessment) score (McAtamney and Corlett 1993) (exemplified in Fig. 186.5). All illustrations, tables and comments are stored in the database. With this information accessible, Ronja discusses the results with her university colleague Birk and they agree to arrange a meeting with the design engineers at the healthcare company to deliver the results. When at the healthcare company, they gather around a bathtub and open the project database. In the database, they study the foot sole positions of potential users. Mattis enters the bathtub and they visually compare his preferred foot position with the positions suggested by the DHM tool. It seems to match quite well and the design engineers conclude that they will base the prototype on the facts proposed by the DHM tool.

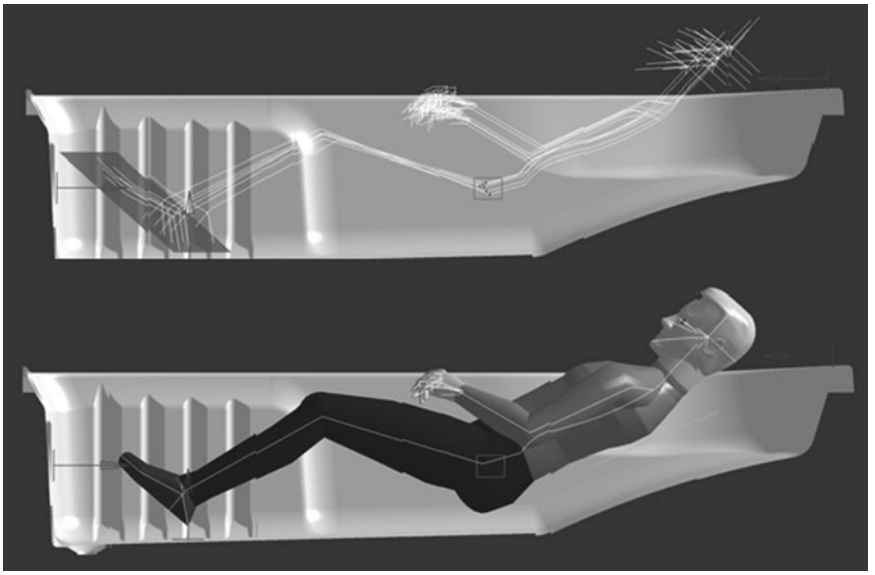

Fig. 186.4 Albert bathing and investigating required footrest adjustment range. Stick figures representing residents (*above*), and 50th percentile Albert in a preferred bathtub posture (*below*)

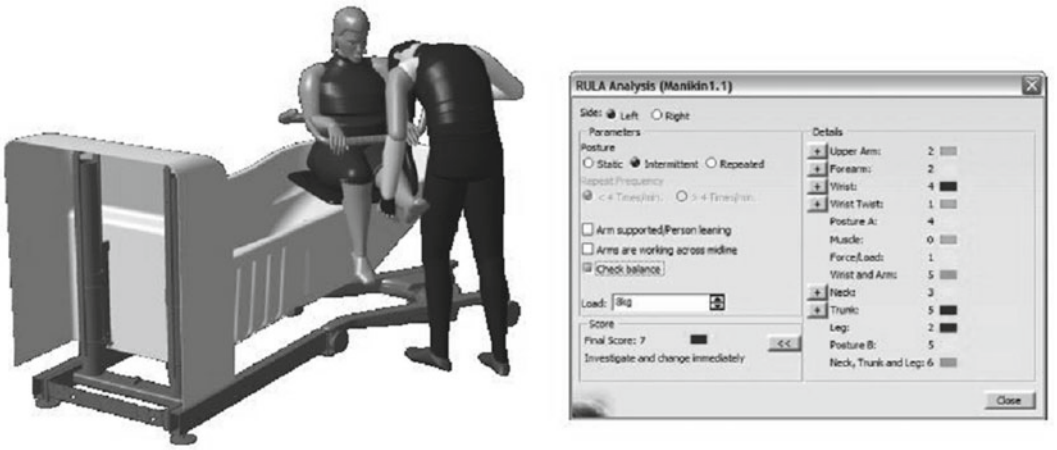

Fig. 186.5 Ergonomic analysis of caregiver when helping resident into bathtub. *RULA* Rapid Upper Limb Assessment analysis of a caregiver's working task when the resident enters the bathtub

Lovis imitates the caregiver, lifting her colleague's legs and adjusting an imaginable footrest with a similar adjustment solution as the competitors use. She admits that the posture feels a bit awkward and she can understand the high physical loads on the caregiver. Mattis, Bork and Lovis come to the insight that they have to rethink the adjustment principle used in order to reduce the workload on caregivers.

Birk enters all comments made at the meeting in the database. The design engineers thank Birk and Ronja for a good job and sign their names and date in the approval section in the human simulation protocol, which concludes the digital human simulation and visualisation mission. Ronja and Birk are satisfied with the job and the positive feedback. They think they showed the strengths

of the DHM approach. They are glad that they were consulted since it indicates that the possibilities of the DHM tool are recognised and considered advantageous. Another positive aspect is that the study was initiated at an early design stage where it is possible to affect the design of the product. The design engineers are very happy to find out that less adjustability seems to be needed to accommodate the target users. This enables the footrest to be designed smaller, lighter, more inexpensive and easier to handle than they first expected.

186.4 Case 3: Design of an Assembly Station to Minimise Wrist Injuries

Psychotherapist Prysselius and Dr. Kling work at a vehicle company. They have noticed an increase in assembly workers' complaints about wrist pain, and so have contacted the human factors specialist, Klang. Together they performed a wrist study with direct measurements to record the exposure. The study was carried out on one subject, who was mounting a sealing on a car. The results showed that the worker performed a task that included awkward and constrained wrist postures as well as repetitive movements with high wrist angular velocity. These postures and movements have been shown to be risk factors for musculoskeletal disorders (Wells et al. 2007). To reverse this trend of increasing wrist pain and injuries among assembly workers, an analysis and modification project of existing assembly stations is initiated. Another project is initiated that focusses on future assembly lines and how wrist problems among assembly workers can be detected and avoided proactively at early design phases. To initiate the second project, Prysselius, Kling and Klang invite Pippi, Tommy and Annika who are working as senior production engineers and DHM users.

The meeting starts with Dr. Kling describing wrist pain among assembly workers and Klang describing the results from their study for Pippi, Tommy and Annika. They ask if the company has any tool or process that could detect these problems at an early design phase before an assembly line is set up. The DHM users are interested since they realise that the DHM tool has the potential to find such ergonomics problems. Currently, however, the tool is mainly being used for analysing frozen postures. In order to predict angular velocity and other time-dependent measures, a dynamic simulation of the assembly worker performing the working task is needed. Pippi, Tommy and Annika like the challenge and agree to investigate the possibilities with DHM. Tommy logs in to a computer and enters the DHM web-based work process protocol. Pippi summarises the background and proposes the following project aim: "To illustrate how time sensitive wrist exposure data can be extracted from a manikin." The others in the group read simultaneously what Tommy is writing while the web protocol is projected on a large screen. They all agree on the text and set the project closure day to 6 months ahead. By then, Pippi, Tommy and Annika promise to deliver results in the same form as those retrieved in the pilot study, where goniometers were used to acquire objective measures of wrist joint angles, in addition to the company standard assessment method based on visual observations of joint angles. The expected result deliveries are entered in the protocol before the kick-off meeting is adjourned.

Pippi, Tommy and Annika return to their department. On the way back, they divide up the tasks. Tommy will develop a small computer program that transforms the output from the DHM tool *Jack* into the format used by the analysis tool for the direct measures. Annika will define manikins representing the assembly workers and define the tasks in order to generate a simulation of the work sequence. Senior engineer Pippi would support Tommy and Annika.

Tommy writes a MATLAB script that resamples data generated in *Jack* into a lower frequency (from 30 frames per second to 10 frames per second) and rotates the coordinate system to fit definitions in the wrist motion analysis software. The script also selects the relevant data from the *Jack*

Table 186.4 Boundary manikins generated by using PCA approach

Manikin family member	Body stature (cm)	Body weight (kg)
c1	178.2	72.6
c2	158.4	58.8
c3	155.2	56.6
c4	175.0	70.4
i1	180.8	74.4
i2	169.0	66.2
i3	152.7	54.9
i4	164.4	63.0

Body stature and Body weight for the eight boundary manikins generated by using principal component analysis (PCA) approach

output data and generates output files in a format recognised by the wrist angle analysis software. Annika begins her work of defining the users. She decides to use the anthropometrics and principal component analysis tool (PCA) available in the DHM tool. The PCA approach (Zehner et al. 1993) enables the generation of boundary manikins (Dainoff et al. 2003). Eight manikins, representing both females and males, are generated according to her settings (95% coverage and two principal components) and data available in the tool (a description file with detailed anthropometric measures of 100 Americans). The eight boundary manikins are expected to cover 95% of the anthropometric diversity of the population represented by the 100 Americans, both females and males, in the sample file (Table 186.4). The rationale for using boundary manikins in this case is that if the assembly work is studied using these eight boundary manikins (which might be seen as extreme cases), the assessment would cover other anthropometric configurations as well (i.e. cases within the multidimensional distribution enclosed by the eight boundary manikins).

Annika enters the manikin description in the web-based protocol and continues with the procedure. The following steps in the procedure are the definition and creation of the environment and the tasks. She searches the database after the rear part of the vehicle of interest. She uses the Task Simulation Builder (TSB) integrated in *Jack* (Raschke et al. 2005) to generate manikin movements. The TSB module enables animation sequences to be created simply by using basic MTM (Methods-Time Measurement) language. She uses the code *Touch* and selects the positions evenly distributed around the gasket. The DHM tool generates the manikin motion and Annika uses the data reporter to export wrist angles into a file. She lets all eight manikins perform the task, controlled by the same task description. A unique wrist motion file is generated for each manikin. Annika also uses the company-specific ergonomic evaluation method to get an indication about the workload when each manikin positions the sealing in the highest position. She uses the animation and stops the film sequence when the manikin reaches the point of interest. A screenshot from the animation is seen in Fig. 186.6. The manikin posture is exported to the company-specific ergonomics evaluation tool. Other information, such as weight of sealing and grip surface type, is added manually. The objective company-specific analysis results for the eight manikins are generated and stored in the database with supporting illustrations.

Annika sends the eight wrist angle files to Tommy, who has developed the script to convert the file to suit the analysis tool for the direct measures. The file conversion is successful and the wrist angle files are analysed by the software used for the direct measures. Tommy runs the software and calculates exposure data for the eight manikins. He compiles the data and calculates mean values for the eight manikins and corresponding standard deviations. Tommy creates a table (Table 186.5), where DHM output is placed next to the results from the psychotherapist, doctor and human factors engineer's study and determines if the results are significantly different using statistical methods.

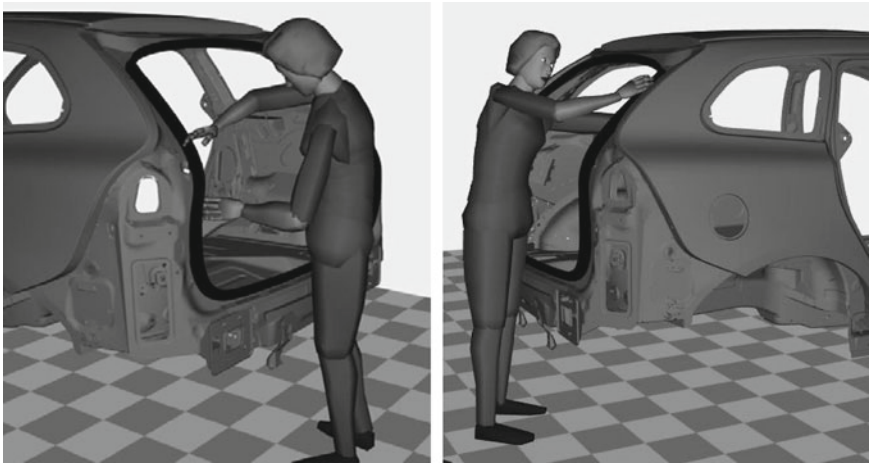

Fig. 186.6 Manikin applying a sealing. The manikin motion when applying a sealing is controlled by a motion database and wrist angles are exported to other software for in-depth exposure studies

Table 186.5 Exposure data for wrist

Wrist position, right hand (°)	Motion from field test (°)	Motion from *Jack* TSB (°)	*p*-Value for difference in means between wrist position from field tests and generated with *Jack* TSB
Flexion, 5th percentile	–51 (7.4)	–78 (2.6)	$p < 0.005$
Flexion, 50th percentile	–26 (3.9)	0 (0)	–
Flexion, 95th percentile	32 (6.3)	71 (5.9)	$p < 0.005$
Deviation, 5th percentile	–41 (9.4)	–43 (2.5)	$p < 0,05$
Deviation, 50th percentile	–3 (5.6)	0 (0)	–
Deviation, 95th percentile	18 (8.6)	44 (0)	–
Wrist velocity, right hand [°/s]			
Flexion, 10th percentile	2 (9.0)	0 (0)	–
Flexion, 50th percentile	18 (5.0)	1.4 (0.5)	$p < 0.005$
Flexion, 90th percentile	65 (9.0)	94 (5.9)	$p < 0.005$
Deviation, 10th percentile	3 (9.8)	0 (0)	–
Deviation, 50th percentile	25 (4.3)	1 (0)	–
Deviation, 90th percentile	105 (8.6)	62 (9.1)	$p < 0.005$

Wrist position (flexion and deviation) and Wrist velocity (flexion and deviation) from the field test for the manikins (mean value) guided via the Task Simulation Builder (TSB) in Jack. Standard deviations in brackets. Positive values denote extension

After completion, Tommy goes to Pippi and Annika to discuss the wrist angle study results as well as the results from the company standard. With all results stored in the database and a common idea of how to explain them, the DHM users arrange a meeting with the psychotherapist, doctor and human factors specialist.

Tommy, Pippi and Annika meet Prysselius, Kling and Klang. Annika shows an animation of the manikin worker applying the sealing. Prysselius, Kling and Klang state unanimously that the manikin motions look awkward. This statement initiates a long discussion about what a "natural/average" motion really is. The outcome of the discussion is that all agree that the manikin motions do look a bit awkward, but are ones that are possible for most humans to perform. They move on and look at the

tables. Now it become obvious that the manikin performed motions that differ from what the test subject did in the field test. The manikin used a larger joint range and centred the motions round a neutral wrist position. The real-life subject did not flex and extend his wrist as much and had his wrist slightly flexed all the time. Psychotherapist Prysselius, Dr. Kling and human factors specialist Klang are quite happy to see that the DHM simulation and visualisation tool is able to present measures that are in the same format as their objective field measures. This looks promising for the future. The DHM tool enables the use of the same methods in early design stages as in later field tests. Some years ago, the company-specific ergonomics assessment method was integrated into the DHM tool (Fig. 186.7); this evaluation method is mainly based on performing visual observations. Now it has been shown that the DHM tool can provide information that is comparable with data from direct measures. It will also be advantageous to be able to show that a manikin can perform an assembly task with a motion sequence that can be performed by humans, and that complies with ergonomics guidelines all the time. If the workers can be trained later on to use the same or a similar motion pattern as the manikin, musculoskeletal disorders can be reduced. This is a step forward from the common praxis of analysing static postures. All project members see the potential in starting to use ergonomics simulations. However, they are also aware that plenty of work is needed before such simulations can be used for all new workstations. Tommy concludes the discussion and summarises the essence in the web protocol. Before closing the meeting, they have a brief discussion about motion capture techniques, an alternative for manipulating the manikin. Tommy, Annika and Pippi leave the room. On the doorstep, Tommy remembers a large redesign project of an assembly line. He returns and asks the psychotherapists, doctor and human factors engineer if they would be interested in digging deeper into the problems identified in the case. They are, and Tommy promises to do everything he can to initiate a parallel project as soon as possible, including his new friends from the health sector.

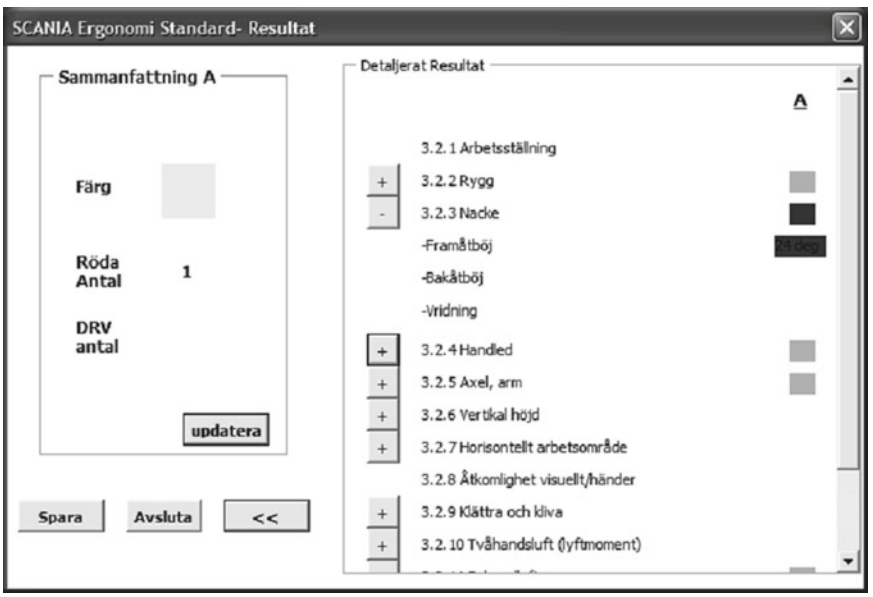

Fig. 186.7 Screenshot from the DHM integrated company-specific ergonomics evaluation method. The DHM integrated company-specific ergonomics evaluation method, based on an established observation method used for field tests. The method considers overall work posture and detailed neck, wrist, shoulder posture. Furthermore, the method considers accessibility, visibility and biomechanical load. The method gives result in terms of recommended actions: no action required (*green*), action required in near future (*yellow*) and action required at once (*red*)

186.5 Discussion

Human anthropometric diversity makes user-centred design processes challenging. A rule of thumb is that if the users of products or workplaces are few and known, designers prefer to take anthropometric measures of the actual users and create computer manikins representing them (Fig. 186.8). If the number of users is large and/or unknown, distributed or boundary manikins are preferred. According to the best practices of the Human Factors and Ergonomics Society (Dainoff et al. 2003), central manikins and boundary manikins based on one-dimensional percentile statistics (e.g. 1st percentile,

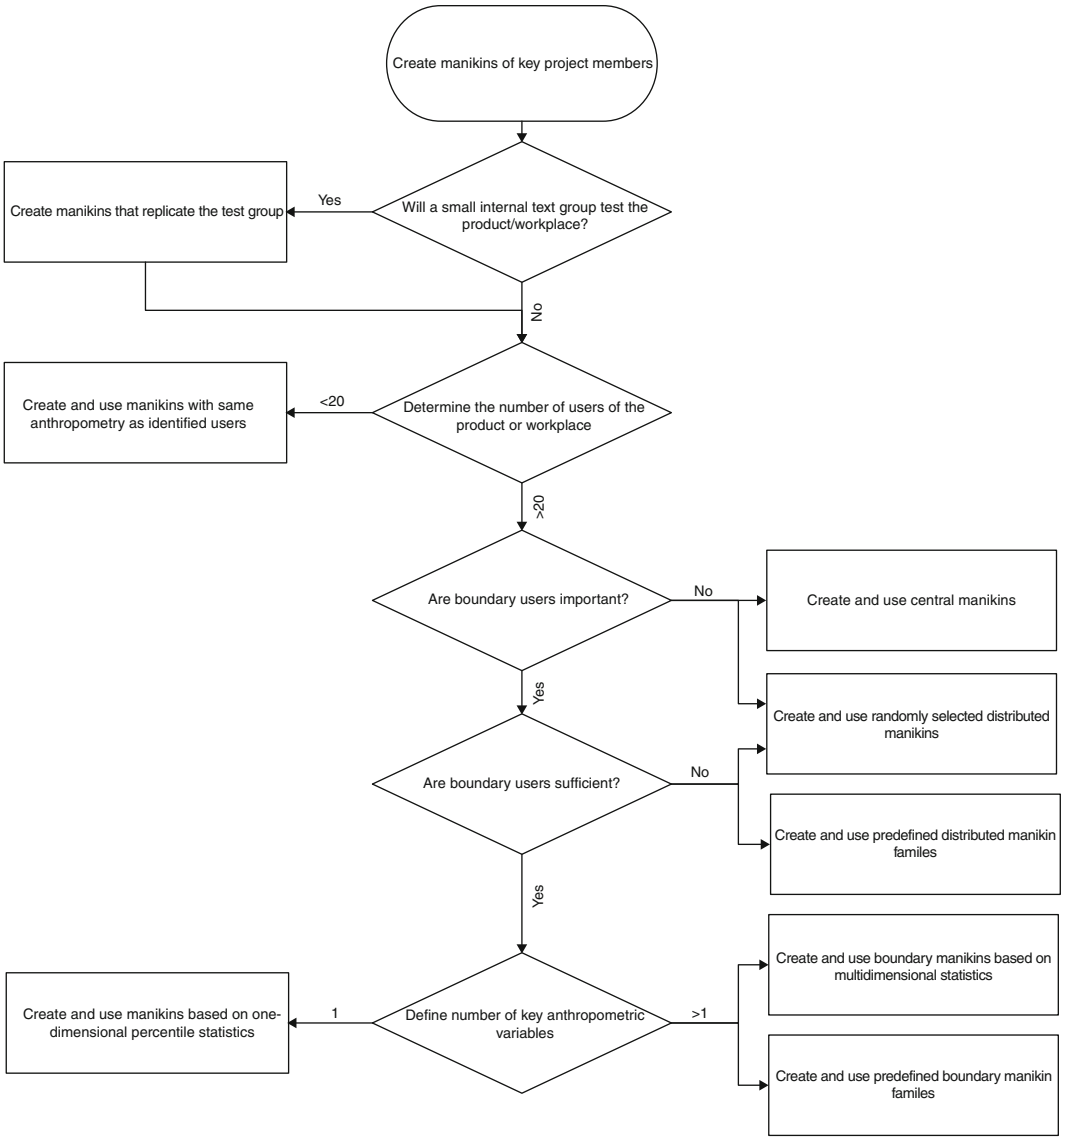

Fig. 186.8 Practical methods and techniques for anthropometric user representation. Modified decision tree from Dainoff et al. (2003). The tree is a guide to select user representation method: replicas of identified users, central, distributed or boundary manikins. The different methods are preferably combined

50th percentile and 99th percentile statures) can be used if one key anthropometric variable is considered important for the design problem at hand. If two or more key anthropometric variables need to be considered simultaneously (two-dimensional or multidimensional design problems), boundary manikins based on ellipse or ellipsoid statistics are preferred (such as those defined by using PCA in Case 3). For some design problems, it is appropriate to define manikins within the distribution as well (i.e. distributed cases) (Dainoff et al. 2003). As presented in this article, several different methods for user representation exist and a method can be used in isolation or combined with other methods.

As illustrated in the three cases, DHM tools are helpful in considering anthropometric diversity, and other ergonomic issues, at early stages of the design process. In the cases, three different DHM tools are presented: *Ramsis* (Case 1), *Delmia V5 Human* (Case 2), and *Jack* (Case 3). Other digital human modelling tools exist such as *Anybody*, *Pro/Engineer Manikin* and *Sammie*. The *Handbook of Digital Human Modeling* presents a detailed list of digital human modelling tools (Bubb and Fritzsche 2009). In addition, the following four user representation methods were applied in the three cases:

- Predefined manikins for user representation (Speyer's approach, Case 1).
- Boundary and central manikins to consider one key anthropometric variable (Case 2).
- Boundary manikins to consider several anthropometric variables (Case 3).
- Distributed manikins. Randomly selected persons were replicated (the project members were modelled in Cases 1 and 2).

DHM tools have great flexibility in that it is possible to generate manikins according to one's own settings (Fig. 186.9). However, the tools typically do have some ingenuity regarding manikin creation where extreme manikins with combinations of non-existing anthropometrics measures cannot be generated. The possibilities to create one's own manikins enable the use of predefined

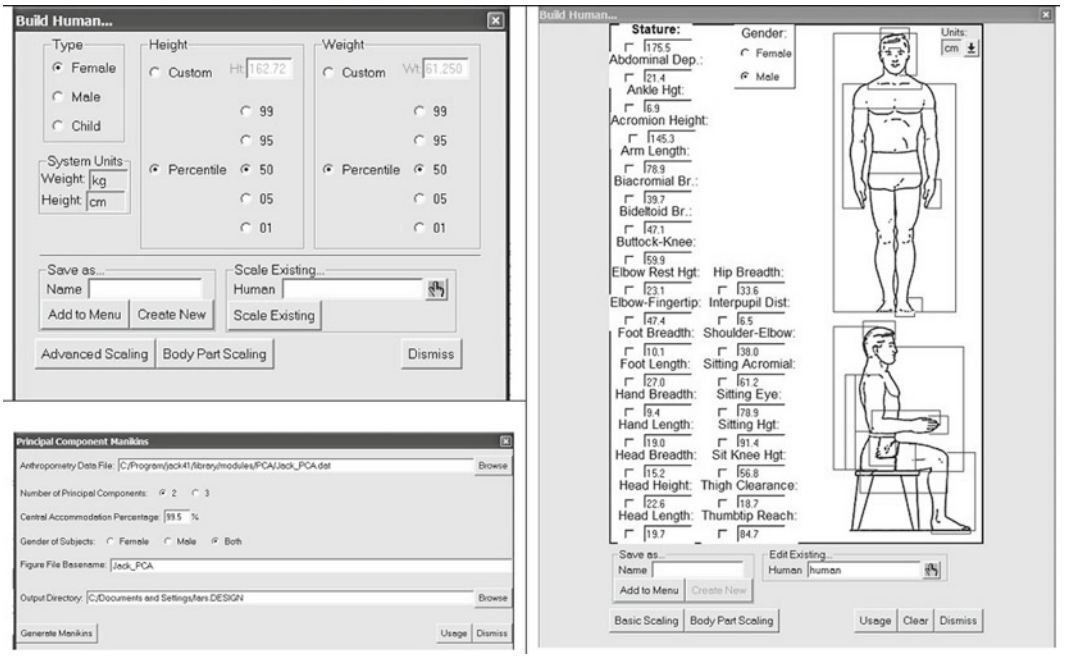

Fig. 186.9 User representation methods in a DHM tool. Screenshot from Jack illustrating (*1*) the possibility to define one's own manikin (*right*), (*2*) by defining height and weight percentiles (*top left*) and (*3*) method for creating boundary manikins (*bottom left*)

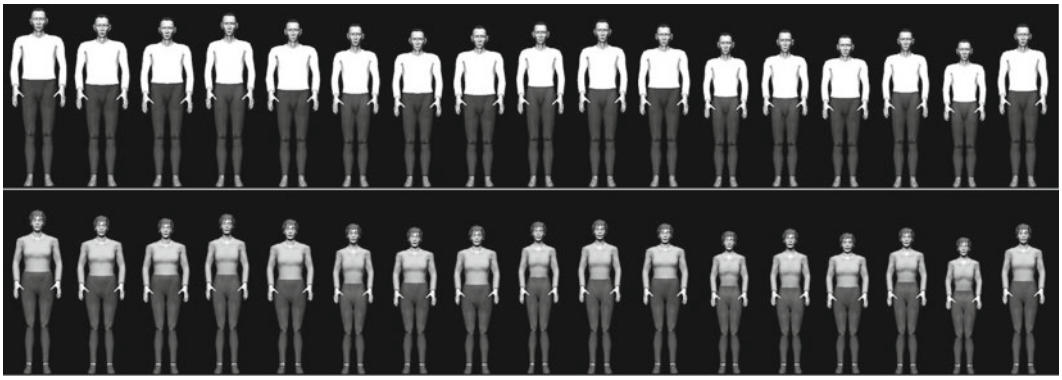

Fig. 186.10 A-CADRE, a manikin family to consider user diversity. A-CADRE, a manikin family configuration defined by Bittner (2000) for the evaluation of workplaces

manikin families and any other method for the consideration of users' anthropometric diversity. A-CADRE (Bittner 2000) is one example of a manikin family developed for this purpose in workplace design. Male and female manikins modelled according to the anthropometric data in A-CADRE are illustrated in Fig. 186.10. DHM tools also enable the creation of manikins that replicate test dummies (e.g. crash dolls and certification dolls used in the design and development process). In some DHM tools, the SAE standard test manikins are integrated.

In the user-centred design process, it is essential to define the users and their requirements and desires for products and workplaces. These requirements and desires include such aspects as being easily accessible, easy to handle, comfortable and the requirements are, preferably, transformed into measurable parameters, such as minimum clearances or maximum biomechanical loads. In the three cases presented, the following ergonomics analysis methods were illustrated: comfort values, reach, clearance, RULA and wrist angles. A number of different evaluation methods are integrated into the DHM tools such as field of vision, NIOSH lifting equation, OWAS, SSPP, Snook and Garg. A brief description of common ergonomics analysis methods is included in the *Handbook of Digital Human Modeling* (Lämkull et al. 2009). Companies frequently customise DHM tools by implementing their own standard ergonomics evaluation method in the tools (Chiang et al. 2008; Högberg et al. 2008). All these methods being integrated in the DHM tools give a quantitative measure in return. The results from the ergonomics assessment tools indicate whether the product or workplace is ergonomically acceptable or needs to be redesigned. It is acceptable if it fulfils the user requirements and desires. If not, this indicates that the users may experience discomfort or exposure to unacceptable workloads, and the design of the product or workplace then needs to be changed. The product or workplace is typically modified, and new analyses are performed on the redesigned product or workplace. The design, analysis, redesign, analysis loop continues until satisfying ergonomics results are retrieved for all manikins used in the user tests.

Summary Points

- Digital human modelling (DHM) tools are applied in the design, modification, visualisation and analysis of human workplace layouts and/or product interactions.
- A manikin is a digital replica of the human including skeleton, segments and (sometimes) muscles.
- In an initial state, define the users in terms of age and nationality and other factors that affect anthropometrics, and define key anthropometric variables for the design problem.

- Three main general user representation methods exist: boundary, central and distributed. DHM also enables the generation of manikins according to one's own anthropometric settings.
- In the DHM tools, a number of different ergonomics evaluation methods are integrated, such as field of vision, biomechanical analysis, collision and clearance analysis, comfort assessment, NIOSH and Snook lifting equations, posture evaluation methods such as OWAS, RULA, as well as Garg energy prediction.
- The user-centred design approach is a continuous, iterative design–analysis–redesign–analysis loop, carried out until satisfactory ergonomics results are retrieved for all manikins used in the user tests.

Chapter 187
Anthropometric Indices in the Philippines for Manufacturing Workers

Jinky Leilanie DP Lu

Abstract This chapter discusses anthropometry among Filipino manufacturing workers and its application to the design of the workstation and personal protective equipment. The anthropometry is also discussed as to its importance to the prevention of work-related health problems. The data on anthropometry was taken from a study of the author of 1,805 manufacturing workers who were measured for their anthropometry and given survey questionnaires related to work hazards and illnesses. The study showed that those with poor posture were twice more likely to report exhaustion. The walk through survey revealed that workers assumed poor posture because of non- anthropometrically designed work equipment. Backache was common among assembly line workers because of the lack of application of ergonomics in workstation design and incorrect biomechanics. This chapter concludes by emphasizing the importance of anthropometry to workstation design, personal protective equipment design, worker's quality of work life, and prevention of work-related illnesses such as musculoskeletal disorders.

Abbreviations

PPE	Personal protective equipment
TNC	Transnational corporation
s.d.	Standard deviation
CAD	Computer-aided design
BMI	Body mass index
DBP	Diastolic blood pressure
BP	Blood pressure
WC	Waist circumference
cm.	Centimeters
kg.	Kilogram
n	Sample population
Mdn	Median
Std Dev	Standard deviation

187.1 Introduction

Anthropometry is the science of measurement and the art of application that establishes the physical geometry, mass properties, and strength capabilities of the human body. The uses of anthropometry in the workplace include: (1) evaluating postures and distances to reach controls; (2) specifying clearances separating the body from hazards such as surrounding equipment; (3) identifying objects or elements that constrict movement; and (4) assisting in the biomechanical analysis of forces and torque.

An anthropometric measurement for Filipino manufacturing workers was conducted by the author, which was the first ever study conducted in the Philippines. Currently, there is increasing demand for this kind of information among researches and occupational health practitioners who develop measures to prevent occupational injuries. In the United States, they found that the body size or body segment measurements of some occupational groups differ significantly compared to others. This implies that caution must be exercised in selecting databases for the design and evaluation of machinery, human–machine interfaces, and personal protective equipment (PPE) (Barley et al. 2008). This chapter gives the anthropometric data of Filipino manufacturing workers in the Philippines.

Considering the great cost to human life, safety, and economy, it is worthwhile to look into possible measures to make the working environment hazard-free for the common worker. One way to do this is through the ergonomic design of workstations. Ergonomics has been described as "…the study of human characteristics for the appropriate design of the living and working environment (Kroemer 2002)." Meanwhile, the workstation is the immediate working environment of the individual, which includes working surfaces, tables, chairs, and equipment layout. It has been shown that proper design and layout of equipment that is tailored to the individual needs of the worker lead to lower physiological stress, increased efficiency, lesser workload, and, thus, greater productivity. In a study on carpet weavers whose posture was mostly constrained by the design of workstations, it was found that improving postural variables resulted in lesser occurrence of musculoskeletal disorders (Choobineh et al. 2004). A within-subject controlled experiment among bricklayers and bricklayers' assistants also found that the use of ergonomic measures significantly decreased lower back discomfort (van der Molen et al. 2004).

In dealing with machines in manufacturing, techniques can be designed to support both user interface development and workstation layout (Johnson 1996). Personnel, equipment, and environmental and systems ergonomics should be harnessed to maintain user acceptance and overall man–machine–system efficiency (Trispel 1982). He suggested a task approach in systems design that can create improved man–machine interfaces.

A survey was carried out among 31 different kinds of manufacturing industries in export zones in the Philippines. Export zones are important employment sites for Filipino workers. Export zones are special economic and social enclaves in developing countries where multinational companies operate with special benefits and privileges. The benefits given to transnational corporations (TNCs) in export zones in the Philippines include 100% ownership, free duties, exemption on taxes or license fees on imports to the zone, the privilege to borrow from Philippine banks, exemption from minimum investment requirement, and unrestricted repatriation of capital and profits (Rowbotham and Mitter 1994).

The sample for the anthropometric study consisted of 1,805 manufacturing workers. Body physique or anthropometric measurements were measured using tape measure, goniometers, calipers, and anthropometers in order to measure body segment length, height, breadth, depth, and circumference. Examples of such measurements included hip breadth, crotch length, functional leg length, buttock–knee length, knee height, and popliteal height, among others. A walk-through survey was also conducted to investigate the work equipment and workstation design in relation to standards. The walk-through survey included evaluation of postures and distance to reach controls, for example, whether person was seated too far or too near to the reach control. In order to assess the extent of hazard and injury exposure of the target population, 500 workers were also interviewed using a survey questionnaire in a subsequent study of the author from the same target population.

187.2 Anthropometric Data Among Filipino Manufacturing Workers

Among the 1,805 individuals selected, 53.3% were females while 46.7% were males. Majority were single (60.4%) and aged below 30 years (77%), indicating a relatively young working population. Majority (80.50%) of the participants were between 150 and 174 cm in height (s.d. = 8), with the shortest being 54 in. and the tallest 71 in. Most of respondents (92.7%) weighed less than 80 kg, with measurements ranging from 40 to as high as 170 kg.

The study showed the anthropometric measurements of the workers as shown in Tables 187.1–187.9. The mean standing height for males was higher than for females at 167.0 cm (s.d. = 8.03) and 153.9 (s.d. = 8.08) cm, respectively. Meanwhile, the mean sitting height was 84.8 cm for males (s.d. = 5.81) and 79.9 (s.d. = 4.5) cm for females.

187.3 Health Issues Related to Ergonomic Problems

A subsequent study showed that those with poor posture were twice more likely to report exhaustion. The walk-through survey revealed that workers assumed poor posture because of nonanthropometrically designed work equipment. Backache was also common among assembly-line workers because of the lack of application of ergonomics in workstation design and incorrect biomechanics.

Eyestrain was also associated with the type of work such as dealing with minute electronic part and detailed work. This was also aggravated by the slouching posture of the worker because the mounting table was far below the visual range. In this situation, there is a need for ergonomic design of the workstation.

In the study of the 31 industries, all workstations did not meet ergonomic standards. Working surfaces were too low for the workers and were cramped. Repetitive movements and prolonged posture were also prevalent. As for work activities, majority reported lifting objects weighing from 1 to 25 kg (47.1%), standing and carrying objects for prolonged periods (41.9% and 36.2%, respectively), and performing high-precision movements (33.7%). See Table 187.10.

The workers in the selected manufacturing industries were exposed to ergonomic hazards such as poor workstation design, poor biomechanics, and poor quality of air inside the work area. To address the problem on biomechanics and workstation design, anthropometric data of the manufacturing workers are necessary. This is also more pressing since most of the equipment in the Philippine manufacturing sector are imported and, thus, do not conform to the body physique of Filipino workers.

187.4 Application of the Anthropometric Data to Workstation and PPE Design for Filipino Workers

Based on these principles, equipment and workstation design should conform to the measurements culled from the study. For instance, a fit-tested hardhat and dust mask for Filipino workers should incorporate certain dimensions (Fig. 187.1). In the same manner, prototype design for computer-seated work for Filipino manufacturing worker using the 95th percentile (Fig. 187.2) should be incorporated. Figure 187.3 also shows the application of the anthropometry gathered in this study for the prototype design for personal protective equipment and protective clothing.

187.5 Anthropometry and Workers' Quality of Worklife

For the past few years, ergonomic initiatives have been growing in Asia due to increasing local needs. A number of studies in some developing countries in the region have contributed in improving the working conditions of locals in terms of materials handling, workstation design, and work organization through utilization of locally available resources. This was done in Mexico where anthropometric database for the working population was produced for the manufacturing sector (Lavender et al. 2002). In Hong Kong, the increasing popularity of computer-aided design (CAD) prompted

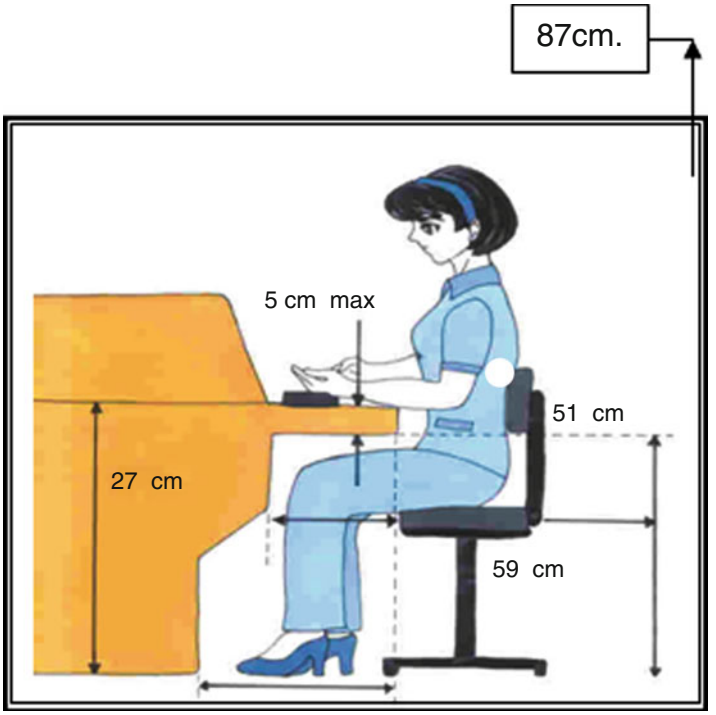

Fig. 187.2 Prototype design for computer-seated work for filipino manufacturing workers using 95th percentile. *cm* centimeter (Source: Int J Occup Saf Ergon. 2004;10:349–59)

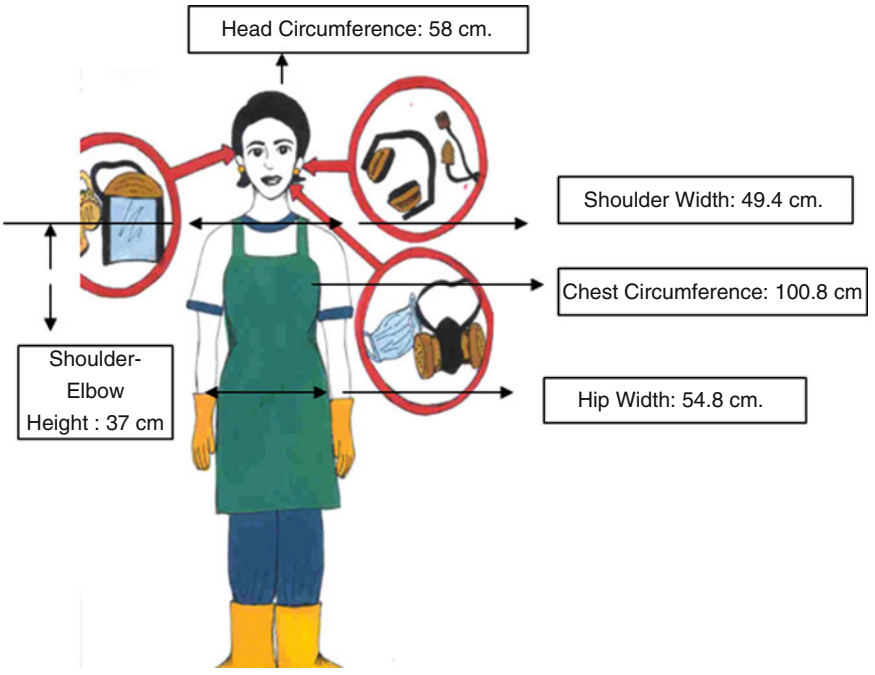

Fig. 187.3 Prototype design for personal protective equipment and clothing for filipino manufacturing workers using 95th percentile. *cm* centimeter (Source: Int J Occup Saf Ergon. 2004;10:349–59)

researchers to look into the design of a suitable workplace for CAD operators using anthropometric data to enhance performance and reduce musculoskeletal problems (Chan and Jiao 1996).

Industrial ergonomics uses much of anthropometric data in the design of machinery and interventions in the workplace. Use of anthropometric data can help in the proper design of equipment for better efficiency and more human comfort (Gite and Yadav 1989). Since mismatches in anthropometric dimensions have been postulated to be one of the main causes of work-related fatigue and occupational illness (Chan and Jiao 1996), steps must be taken to gather anthropometric data that can aid in the formulation of ergonomic interventions in the workplace.

The anthropometric data in the study can have many applications. It can be used as a reference for body mass index (BMI) and obesity index. This was done in a previous study (Eckhardt et al. 2003) where authors tried to look into the ability of BMI to predict body fat (BF) among youths in four Asian countries and identify the degree to which additional anthropometric measures improved this prediction. Data came from 456 Filipinos, Chinese, Russians, and black South African youths, with ages ranging from 6 to 16 years. Weight and height measures were collected and percentage body fat (BF) was regressed on BMI.

The anthropometric data gathered can also be used for the design of equipment and clothing for Filipino workers in manufacturing industries. This application was used in determining anthropometric characteristics of biologically admixed population in the United States (Yokota 2005). The purpose of this study was to examine multivariate craniofacial anthropometric distributions among biologically admixed male populations and single racial groups of Black and White males. The author suggested that nose breadth and lip length were different between Blacks and Whites. This was then used for the design of equipment and clothing for the US Army and other large organizations.

Adequate posture, work height, normal and maximum working areas, lateral clearance, and visual requirement provided a conceptual basis for a good workstation design (Das and Sengupta 1996). Those who worked in computer workstations that have ergonomic deficiencies reported eyestrain, shoulder pain, back pain, arm pain, wrist pain, and neck pain (Shikdar and Al-Kindi 2007).

The need for fitness testing of respirators was also reiterated (McKay and Davies 2003). Respirator fit testing is necessary before entering hazardous working environments to ensure that the respirator, when worn, satisfies a minimum fit and that the wearer knows when the respirator fits properly. Many countries do not have fit testing or total inward leak (Kim et al. 2003). In research facilities, specific regulations and guidelines define safety standards, along with medical evaluation, training, inspection, maintenance, and care.

187.6 General Application of Anthropometric Data

Anthropometric data have many applications and uses. The dimensions of the workplace, including furniture, machines, working tables, and protective equipment, can match the body physique and strength requirements through baseline anthropometric measurement. These anthropometric measures and the ergonomics aspects of objects and workplace provide elements that will allow the design and the implementation of surveillance programs for the control and the prevention of work-related musculoskeletal disorders, a relation to the personnel's inadequate selection and to the redesign of interior spaces, and the selection of the machinery and tools to use in the technological processes (González et al. 2000). The need to adopt school furniture was done among Turkey students aged 3–5 (Barli et al. 2005). A set of 18 body dimensions was taken from 154 males and 132 females to eventually design school furniture, fittings, and equipment, the purpose of which was to prevent or minimize musculoskeletal, visual, and circulatory problems resulting from badly designed elements.

In a study on hand anthropometrics, it was found out that Nigerian females' hands are wider and thicker but shorter than compared with those for females from the UK, Hong Kong, and from America. Such differences have implications for design and evaluation of hand tools for the Nigerian female population (Okunribido 2000). Anthropometric design was also used for automobile seat comfort and automobile seat design specifications (Kolich 2003).

Anthropometry is also helpful among farmers such as in human–tractor interface designs and well-accommodated operator enclosures (i.e., cabs and protection frames). One such study was done where authors found that knee height (sitting) was found to affect the cab-enclosure accommodation rating (Hsiao et al. 2005). The study also showed that multiple anthropometric dimensions interactively affected the steering wheel and gear-handle impediment.

Anthropometry can also be used in garment sizes. This was done among European women to adapt garment sizes with the changing body physique of new generations that may be different from previous ones (Ujevi et al. 2005).

Anthropometry can also be used, among other risk factors, in determining certain diseases such as blood pressure elevation. In a study, ethnic difference in blood pressure (BP) among British adolescents was observed (Harding et al. 2006). Results showed that apart from higher diastolic blood pressure (DBP) for Indian girls, BP in minority groups was generally lower than their white UK counterparts. The authors recommended that targeting intervention in adolescence may be a critical opportunity for preventing ethnic differences in BP in later life. In a similar study, body fat deposition between Japanese and Australian-Caucasian men was done (Kagawa et al. 2006). The authors concluded that Japanese men have greater body fat deposition than Australian-Caucasians at the same BMI value. Japanese men may, therefore, require lower BMI cut-off points to identify obese individuals compared to Australian-Caucasian men.

Conversely, simple and reliable anthropometric measurement tools were developed for multiple metabolic disorders for 361 Japanese and 252 Mongolians aged 30–60 years (Shiwaku et al. 2005). Mongolians of both genders had significantly higher values for all anthropometric measurements than did the Japanese. The study suggested that BMI (body mass index) and WC (waist circumference) were useful for predicting multiple metabolic disorders in non-diabetic Mongolians and Japanese. It also suggested that the use of plasma triglyceride and high-density lipid-cholesterol levels in combination with BMI and WC may enhance the ability of predicting metabolic parameters in the Japanese.

Even snoring can be predicted with anthropometric data. Anthropometric data, particularly neck, chest, and abdominal girth, were significantly associated with the snoring group in both men and women (Park and Shin 2005).

The anthropometric measurements gathered in this study can be applied in the improvement of manual materials handling, posture, interface and furniture design, workplace design, and workstation layout, among many others. The use of anthropometry and ergonomics in design systems has proven to reduce human error in system performance, minimized hazards to individuals in the work environment, reduced adverse health effects, and improved system efficiency.

187.7 Applications of Anthropometry to Other Areas of Health and Disease

The Filipino physique should be incorporated in the design of working equipment and working spaces in the manufacturing sector in particular, and in the wider working sector in general. Equipment that is difficult to operate leads to body strain and other musculoskeletal disorders that are debilitating and costly.

Table 187.11 Key points

Definition of anthropometry	Anthropometry is the science of measurement and the art of application that establishes the physical geometry, mass properties, and strength capabilities of the human body. The uses of anthropometry in the workplace include: (1) evaluating postures and distances to reach controls; (2) specifying clearances separating the body from hazards such as surrounding equipment; (3) identifying objects or elements that constrict movement; and (4) assisting in the biomechanical analysis of forces and torque
Results of the study conducted by the author	• In the study, 53.3% were females while 46.7% were males. Majority (80.50%) of the participants were between 150 and 174 centimeters in height (s.d. = 8), with the shortest being 54 inches and the tallest 71 inches • The mean standing height for males was higher than for females at 167.0 cm (s.d. = 8.03) and 153.9 (s.d. = 8.08) centimeters, respectively. Meanwhile the mean sitting height was 84.8 centimeters for males (s.d. = 5.81) and 79.9 (s.d. = 4.5) centimeters for females • Workers with poor posture were twice more likely to report exhaustion. • All the workstations in the study of the 31 industries did not meet ergonomic standards. Working surfaces were all too low for the workers and were cramped. Repetitive movements and prolonged posture were also prevalent
Applications of anthropometry in the study conducted	• Anthropometry can be used for design of personal protective equipment • Anthropometry can be used for workstation design • Anthropometry can be used for the prevention of work-related illnesses • Anthropometry can be used for improving worker's quality of work life

The use of personal protective equipment (PPE) is vital in protecting workers from hazards in the workplace. However, the PPE may not suit the body physique of the Filipino worker, thereby forfeiting the benefit of the PPE. For instance, gas masks do not snugly fit the worker's face, thus allowing hazardous substances to get into the breathing zone of the worker.

Reduction of occupational hazards can also be done through the use of personal protective equipment. However, many problems have been encountered in implementing compliance in the use of protective gears. Even in hospitals where a mandate exists requiring the use of universal precautions, it was observed that rate of compliance on the use of protective gadgets was very low, and protective equipment labeled as impenetrable or uncomfortable to wear had a high failure rate (Ahmad et al. 1998). This was also observed in the study conducted by the author. Table 187.11 shows the key points of this chapter.

187.8 Conclusion

The gathering of anthropometric data is a much needed and worthwhile pursuit in light of the increasing incidence of work-related accidents and injuries, as well as in response to the growing demand for safer and more ergonomic working conditions. The gathered data from the 1,805 workers in the study can be applied to the ergonomic design of workstations, tools, equipment, layout designs, and interventions that are uniquely well suited for Filipino workers. In addition, this information is envisioned to be used in the improvement of local working conditions, targeting key problem areas to minimize ergonomic problems.

Summary Points

- The uses of anthropometry in the workplace include: (1) evaluating postures and distances to reach controls; (2) specifying clearances separating the body from hazards such as surrounding equipment; (3) identifying objects or elements that constrict movement; and (4) assisting in the biomechanical analysis of forces and torque.
- Since mismatches in anthropometric dimensions have been postulated to be one of the main causes of work-related fatigue and occupational illness, steps must be taken to gather anthropometric data that can aid in the formulation of ergonomic interventions in the workplace.
- The anthropometric measurements gathered by the author can be applied in the improvement of manual materials handling, posture, interface and furniture design, workplace design, and workstation layout, among many others, for Filipino manufacturing workers.
- Anthropometry can be used for the prevention of work-related illnesses such as musculoskeletal disorders.
- Anthropometry can be used for improving worker's quality of work life.

Acknowledgment This is to acknowledge the funding support of the National Institutes of Health, University of the Philippines Manila, the valuable support and participation of the Bureau of Working Conditions, Department of Labor and Employment Manila through Engr. Jomar Batino, as well as publication of the study in Anthropometric Measurement of Filipino Manufacturing workers, International Journal of Industrial Ergonomics, 2007, 37:497–503, Asian Journal of Ergonomics, 2004, 5:19–29, and International Journal of Occupational Safety and Ergonomics, 2004, 10: 349–359.

DOI 10.1007/978-1-4419-1788-1_188

In chapter 22, "Body Fat Measurement by Air Displacement Plethysmography: Theory, Practice, Procedures, and Applications" the following errors were found:

Page 403: Figure caption 22.3, part (d) is incorrectly displayed as:
"(d) To measure the lung volume, the person is instructed to breathe normally through the tube attached inside the instrument. The measurement is performed twice after the chamber is closed. The instrument will then calculate the final results"
The caption should read as:
"(d) To measure the lung volume, the person is instructed to breathe normally through the tube attached inside the instrument. The instrument will then calculate the final results"

Page 408, line 6: The value "±3.30%" is incorrect.
It should display as: "±3.39%"

Page 409, line 8, under head "22.14 Calculation of Body Density and % Body Fat by ADP" is incorrectly displayed as:
"In adults, D_{fm} is mostly constant…"
It shoud display as:
"In adults, D_{ffm} is mostly constant…"

Line 9 is incorrectely displayed as:
"Because D_{fm} changes during growth…"
It should display as:
"Because D_{ffm} changes during growth…"

Page 410, line 5 of the caption for table 22.4 is incorrectly displayed as:
"permission of WOHers"
It should display as:
"permission of Wolters"

Page 410, line 1 of the footnote at bottom of table 22.4 is incorrectly displayed as:
“Table 22.3 shows the densities of”
It should display as:
“Table 22.4 shows the densities of”

Page 412:
Reference line that begins with “Ruppell” is incorrectly spelled as “Ruppell”
It should be spelled as “Ruppel”
