Preface

There are a variety of theoretical and practical definitions of anthropometry, but in its simplest form anthropometry is the physical measurement of the human body and its parts. Methods can be very simple. On the other hand, advances in technology and computing have given rise to the development of more sophisticated apparatus which can be used to measure and characterise individual tissues and organs. Thus, anthropometric devices can range from a simple tape to measure head circumference to expensive electromagnetic image-capturing systems for characterising limb shapes. These methods can be used to obtain information on normal people at various life stages. Alternatively, anthropometry can be used and applied to understanding disease, including the responses to treatments, or to generate reference data. Understanding and applying concepts and techniques of anthropometry require a good source of written material that covers not only the theoretical basics but the practical applications in health and disease. Hitherto such sources on human anthropometry have been fragmentary, covering single facets without any cross-fertilisation between disciplines or sciences or between different intellectual divides. These deficiencies are, however, addressed in *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, where all facets and features of anthropometry are described. The book is divided into 26 different parts as follows:

Part I:	Tools and Techniques in Anthropometry: General Methods
Part II:	Tools and Techniques in Anthropometry: Water, Hydration and Surface Area
Part III:	Tools and Techniques in Anthropometry: Muscle
Part IV:	Tools and Techniques in Anthropometry: Adipose Tissue, Other Compartments and Relationships
Part V:	Regions and Anatomical Areas of the Body: Head and Face
Part VI:	Regions and Anatomical Areas of the Body: Limbs, Extremities and Bones
Part VII:	Regions and Anatomical Areas of the Body: Joints and Digits
Part VIII:	Regions and Anatomical Areas of the Body: Abdominal and Trunk Regions
Part IX:	Regions and Anatomical Areas of the Body: Sensory Organs
Part X:	Regions and Anatomical Areas of the Body: Internal Organs, Other Tissues and Regions
Part XI:	Anthropometry of Pregnancy: Prenatal and Postnatal Aspects
Part XII:	Anthropometry of Infants and Children

Part XIII: Anthropometry of Puberty and Adolescence in Health and Disease
Part XIV: Anthropometry of Middle-Aged and Aged in Health and Disease
Part XV: Anthropometry in Genetic Disease and Polymorphisms
Part XVI: Anthropometry in Cancer
Part XVII: Anthropometry in Exercise and Sport Activities
Part XVIII: Anthropometry in Metabolic Disease and Obesity
Part XIX: Anthropometry in Diabetes
Part XX: Anthropometry in Cardiovascular Disease
Part XXI: Anthropometry in Organ Disease
Part XXII: Anthropometry in Special Conditions and Circumstances
Part XXIII: Anthropometry in Ethnic Groups and Cultural and Geographical Diversity
Part XXIV: Anthropometry and Nutrition: General Aspects
Part XXV: Anthropometry and Nutrition: Micro- and Macro-Nutrients
Part XXVI: Biomechanical and Ergonomic Aspects

The chapters are written by national and international experts who are specialists in their field. Each chapter is self-contained. Sometimes experts in one field are novices in another. To bridge this intellectual divide, the authors have incorporated sections on applications to other areas of health and disease, practical methods and techniques, guidelines, and key points or features. The summary points presented in bullet form are designed for easier intellectual digestion. This book is for health scientists, doctors, nurses, physiologists, nutritionists and dietitians, public health scientists, epidemiologists, health workers and practitioners, exercise physiologists, physiotherapists, university faculty, undergraduates and graduates. It is also designed for policy makers, designers and ergonomists.

Biography

Victor R. Preedy is currently Professor of Nutritional Biochemistry in the Department of Nutrition and Dietetics, King's College London, and Honorary Professor of Clinical Biochemistry in the Department of Clinical Biochemistry, King's College Hospital. He is also Director of the Genomics Centre, Kings College London. He is presently a member of the School of Medicine, King's College London. King's College London is one of the leading universities, currently ranked consistently within the top 25 in the world. Professor Preedy gained his Ph.D. in 1981, and in 1992 he received his Membership of the Royal College of Pathologists (MRCPath), based on his published works. He was elected a Fellow of the Royal College of Pathologists (FRCPath) in 2000. In 1993, he gained his second doctoral degree (D.Sc.) for his outstanding contribution to protein metabolism. In 2004, Professor Preedy was elected as a Fellow to both the Royal Society for the Promotion of Health (FRSH) and the Royal Institute of Public Health (FRIPHH). In 2009, he was elected as a Fellow of the Royal Society for Public Health (FRSPH). He is also a Fellow of the Society of Biology (FSB). Professor Preedy has written or edited over 550 articles, which include over 160 peer-reviewed manuscripts based on original research and 85 reviews and 30 books. His interests pertain to matters concerning nutrition and health at the individual and societal levels.

Part I
Tools and Techniques in Anthropometry: General Methods

Chapter 1
Calculating Sample Size in Anthropometry

Carine A. Bellera, Bethany J. Foster, and James A. Hanley

Abstract Sample size estimation is a fundamental step when designing clinical trials and epidemiological studies for which the primary objective is the estimation or the comparison of parameters. One may be interested in the prevalence of overweight children in a given population; however, the true prevalence will remain unknown and cannot be observed unless the whole population is studied. Statistical inference is the use of statistics and random sampling to make inferences concerning the true parameters of a population. By choosing a representative sample, inference based on the observed prevalence leads to an estimation of the true parameter. But how many subjects should be sampled to obtain an accurate estimate of the prevalence? Similarly, how many subjects should we sample to show that this parameter is different from some fixed value?

We first review basic statistical concepts including random variables, population and sample statistics, as well as probability distributions such as the binomial and normal distributions. Principles of point and interval estimation, as well as hypothesis testing, are presented. We consider several commonly used statistics: single proportions, differences between two proportions, single means, differences between two means, and reference limits. For each parameter, point estimators are presented as well as methods for constructing confidence intervals. We then review general methods for calculating sample sizes. We first consider precision-based estimation procedures, where the sample size is estimated as a function of the desired degree of precision. Next, although there is greater emphasis on precision-driven estimation procedures, we also briefly describe power-based estimation methods. This approach requires defining a priori the difference one wishes to detect, the desired significance level, and the desired power of the test. Sample size estimation procedures are presented for each parameter, and examples are systematically provided.

Abbreviations and Notations

N	Population size
n	Sample size
ME	Margin of error
ε	Precision

DBP	Diastolic blood pressure

1.1 Introduction

Sample size estimation is a fundamental step when designing clinical trials and epidemiological studies for which the primary objective is the estimation or the comparison of parameters. One may be interested in the prevalence of a given health condition, e.g. obesity, in a specific population; however, the true prevalence will always remain unknown and cannot be determined unless the whole population is observed. Statistical inference is the use of statistics and random sampling to make inferences concerning the true parameters of a population. By selecting a representative sample, inference based on the **observed** prevalence leads to an estimation of the **true** parameter. But how many subjects should be sampled to obtain an accurate estimate of the prevalence?

Sample size estimation can be either precision-based or power-based. In the first scenario, one is interested in estimating a parameter, such as a proportion, or a difference between two means, with a specific level of precision. On the other hand, one might only be interested in testing whether two parameters differ. The sample size will be estimated as a function of the size of the difference one wishes to detect as well as the degree of certainty one wishes to obtain.

To understand the process of sample size estimation, it is important to be familiar with basic statistical concepts. We first review statistical principles, as well as general concepts of statistical inference, including estimation and hypothesis testing. Methods for sample size estimation are presented for various parameters using precision-based and power-based approaches, although there is greater emphasis on precision-driven estimation procedures (Gardner and Altman 1986, 1988).

Most concepts presented in this chapter are available in introductory statistical textbooks (Altman et al. 2000; Armitage et al. 2002) and texts focusing on the methodology of clinical trials (Machin et al. 1997; Friedman et al. 1998; Sackett 2001; Piantadosi 2005). We refer the interested readers to these works.

1.2 Basic Statistical Concepts

1.2.1 Random Variable

A random variable assigns a value to each subject of a population, such as weight, hair colour, etc. By random, it is implied that the true value of the variable cannot be known until it is observed. A variable

(for simplicity, we will often discard the term *random* throughout the rest of this chapter) is either **quantitative** or **qualitative**.

A quantitative variable is one that can be measured and can take a range of values, for example, waist circumference, size, age, or the number of children in a household. Quantitative variables include **discrete** and **continuous** variables. A discrete variable is one that can take only a limited range of values, or similarly, the possible values are distinct and separated, such as the number of children in a household. On the other hand, a continuous variable can take an infinite range of values, or similarly, can assume a continuous uninterrupted range of values, such as height or age.

A qualitative or categorical variable is one that cannot be numerically measured, such as the presence or absence of a disease, gender, or the colour of hair. A **dichotomous** or binary variable is one that can take one of two values, such as the presence or absence of a trait or state, or whether or not one is overweight.

1.2.2 Population Versus Sample Statistics

Suppose we are interested in describing the size of 10-year old girls attending English schools. Height in this population can be summarized by various quantities, such as the mean, the median or the variance. These quantities are called **population statistics** and are usually represented with Greek letters. Unless all 10-year old girls attending English schools are measured, the true value of population statistics, such as the mean height in our example, cannot be observed and is **unknown**. It is however possible to **estimate** the true value with some degree of certainty. This involves randomly sampling from the whole population of interest. Based on a random sample of 10-year old girls attending English schools, one observes the distribution of heights in this sample and calculates the observed mean. Quantities derived from an **observed sample** are called **sample statistics**, and are usually denoted using Roman letters.

Two random samples of equal size will usually not yield the same value of the sample statistic. The possible differences between the estimates from all possible samples (conceptual), or between each possible estimate and the true value are referred to as **sampling variation**. As a result, it is not possible to conclude that the observed sample mean corresponds to the true population mean. By using appropriate statistical methods, sample statistics can be used to make inferences about population statistics. In the next section, we present commonly used statistics.

1.2.3 Summarizing Data

1.2.3.1 Categorical Variables

Summarizing categorical variables involves counting the number of observations for each category of the variable. These counts are usually referred to as frequencies. The proportion of such counts among the total can also be represented.

1.2.3.2 Quantitative Variables

Continuous variables can be summarized using measures of **location** and **dispersion**. Measures of location, such as the mean or the median, represent the central tendency of distributions. Dispersion measures, such as the variance, represent the repartition of a variable around the central tendency.

Given a population of size N and a variable X with observed values $x_1,\ldots,x_N$, the population mean is given by: $\mu = \sum_{i=1}^{N} \frac{x_i}{N}$. If only a random sample of size n is available, the sample mean m is calculated similarly and given by $m = \sum_{i=1}^{n} \frac{x_i}{n}$.

If observations are ordered in increasing order, the median is the middle observation of the sample. If the number of observations in a sample is odd, the median is the value of the $\frac{1}{2}(n+1)^{\text{th}}$ observation of the ordered sample, while it is the mean of the values of the two middle observations if the number of observations is even.

The most common measure of dispersion is the variance, or its square root, the standard deviation. Given a population of size N, the variance σ^2 is given by $\sigma^2 = \frac{\sum_i (x_i - \mu)^2}{N}$, where μ is the population mean. The population standard deviation is $\sigma = \sqrt{\frac{\sum_i (x_i - \mu)^2}{N}}$. If a sample of size n is available, the sample variance s^2 is provided by $s^2 = \frac{\sum_i (x_i - m)^2}{n-1}$, where m is the sample mean. The denominator is slightly different from that of a population variance. This correction ensures that the parameter s^2 is an unbiased estimator of the population variance σ^2. Similarly, the sample standard deviation, usually denoted as SD, is calculated as $\text{SD} = \sqrt{\frac{\sum_i (x_i - m)^2}{n-1}}$.

Other measures of dispersion include the range, the inter-quartile range and reference limits. The range corresponds to the difference between the maximum and the minimum values. When in increasing order, the first or lower quartile corresponds to the value below which 25% of the data fall. The third or upper quartile corresponds to the value below which 75% of the data fall. There are several methods to compute quartiles: one involves calculating the first and third quartiles as the rank of the $\frac{1}{4}(n+1)$ th and $\frac{3}{4}(n+1)$ th observed values. Other methods are available, but will usually lead to relatively close results (Armitage et al. 2002).

The inter-quartile range is the difference between the upper and lower quartiles. Note that the second or middle quartile corresponds to the value below which 50% of the data fall, and as such, is equivalent to the median.

More generally, the 100p% reference limit, where $0 < p < 1$, is the value below which 100p% of the values fall. For example, the median is equivalent to the 50% reference limit. Reference limits are also called reference values, percentiles, or quantiles.

Example: A random sample of ten 20-year-old women leads to the following observed weights (in kg): 50, 55, 60, 61, 45, 52, 62, 54, 48, 53. The variable of interest X is the weight, which is a continuous variable. We first reorder this random sequence of $n = 10$ observations: 45, 48, 50, 52, 53, 54, 55, 60, 61, 62. Based on previous formulae, we have the following results:

- The sample mean is calculated as $m = \sum_{i=1}^{10} \frac{x_i}{10} = \frac{45 + \cdots + 62}{10} = 54$ kg
- The sample median is calculated as $\text{med} = \frac{53 + 54}{2} = 53.5$ kg

Table 1.1 Sample probability distribution for the categorical variable X defined as the number of copies of allele A

x	0	1	2
$P(X = x)$	3/10	5/10	2/10

- The sample variance is calculated as $s^2 = \dfrac{\sum_i (x_i - 54)^2}{10-1} = \dfrac{(45-54)^2 + \cdots + (62-54)^2}{9} = 32\ \text{kg}^2$
- The range is given by 62–45 = 17 kg

1.2.4 Probability Distributions

A distribution is defined as the set of frequencies of the values or categories of a measurement made on a group of persons. The distribution tells us either how many or what proportion of the group was found to have each value (or each range of values) out of all of the possible values that the quantitative measure can have (Last 2001).

Consider the variable X corresponding to the number of copies of a certain allele A. The variable X can take three distinct values: 0, 1, 2. Ten subjects are randomly selected from the general population and the following series of outcomes is observed: 0, 0, 2, 1, 1, 2, 1, 0, 1, 1. This series is called a random series, since previous values cannot be used to predict future observation. One can then calculate the proportion of subjects carrying two copies of the allele. This observed proportion equals 2/10 in our example. If subjects are randomly sampled indefinitely, this proportion will tend towards a limiting value, called the **probability** of carrying two alleles, denoted by $P(X = 2) = \pi$. The sample probability distribution of the variable X is represented in Table 1.1.

We have the following result: $\sum P(X = x) = 1$. This leads us to a fundamental property of probability distributions: for a given variable, the sum of the probabilities of each possible event equals 1.

1.2.4.1 Bernoulli and Binomial Distributions

Consider a dichotomous random variable X whose values can be either one state or the other, or the absence or presence of a specific trait. The true (unknown) proportion of the population that is in the index category of the state or trait (the probability that a randomly selected individual would be in this category ($X = 1$)) is denoted as π and the probability of being in the other (reference) category ($X = 0$) is thus $1 - \pi$. The parameter π defines the probability distribution of X, and is called the **Bernoulli distribution** (after J Bernoulli, a Swiss mathematician). The variable X is said to follow a Bernoulli distribution with parameter π. If, as here, the variable X is coded as 0 (reference category) or 1 (index category), its mean and variance are given respectively by $\text{mean}(X) = \pi$ and $\text{var}(X) = \pi(1-\pi)$.

Define the random variable Y as the observed number of subjects with a particular state of interest out of n randomly selected subjects. If the probability that this state is present is π, the variable Y, that is, the sum of Bernoulli random variables with parameter π, is said to follow a **binomial distribution** with mean and variance given respectively by $\text{mean}(Y) = n\pi$ and $\text{var}(Y) = n\pi(1-\pi)$. The probability that this state is present for k out of n subjects is given by: $P(Y = k) = C_n^k \pi^k (1-\pi)^{n-k} = \dfrac{n!}{(n-k)!k!}\pi^k(1-\pi)^{n-k}$.

Table 1.2 Probability distribution for the categorical variable *Y* defined as the number of subjects with state *S* out of 3 randomly selected subjects

y	0	1	2	3
$P(Y = y)$	1/8	3/8	3/8	1/8

When n is large, the distribution of Y will converge to a normal distribution with mean $n\pi$ and variance $n\pi(1-\pi)$.

Example: The presence of a health state S is assessed in $n = 3$ randomly selected subjects. The variable Y corresponds to the number of subjects with state S out of the $n = 3$ subjects, and can thus have 4 possible values: 0, 1, 2, or 3. Assume that the state S is present in $\pi = 50\%$ of the population. The probability of observing $k = 2$ subjects with state S out of $n = 3$ randomly selected subjects is given by: $P(Y=2) = C_3^2\pi^2(1-\pi)^{3-2} = \frac{3!}{(3-2)!2!}(0.50)^2(0.50)^{3-2} = \frac{3}{8}$.

The complete probability distribution of Y can be computed and is represented in Table 1.2.

1.2.4.2 The Normal Distribution

Consider a continuous random variable with values that vary between –∞ and +∞. The most important continuous probability distribution is the **Gaussian distribution** (after Karl Gauss, a German mathematician), also called the **normal distribution**, which is indexed by two parameters: the mean and the variance. If X follows a normal distribution with mean μ and variance σ^2, we use the following notation: $X \sim N(\mu,\sigma^2)$.The curve representing the normal distribution is symmetric, so that the mean and the median fall at the centre of the symmetry. It is described by the function $f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2}$. The probability that a random variable falls between two values, A and B, is represented graphically by the area under the curve of the probability distribution and between the two vertical lines with coordinates $x = A$ and $x = B$, as illustrated in Fig. 1.1.

Numerically, this probability is obtained by computing the integral $P(A < x < B) = \int_A^B f(x)dx = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} dx$. Calculation of this integral is not feasible using simple calculation tools; however, the properties of the normal distribution simplify the probability estimation in some cases. For example, the probability that any random normal variable $X \sim N(\mu,\sigma^2)$ falls within one standard deviation of the mean is known to be about 68%, that is $P(\mu - \sigma < x < \mu + \sigma) = 68\%$, as presented in Fig. 1.2.

Similarly, about 95% of the distribution falls within two standard deviations of the mean ($P(\mu - 2\sigma < x < \mu + 2\sigma) = 95\%$), and 99.7% within three standard deviations ($P(\mu - 3\sigma < x < \mu + 3\sigma) = 99.7\%$). For other values of the normal distribution, one has to either calculate the integral $P(A < x < B) = \int_A^B f(x)dx$ (by hand or using a mathematical or statistical software) or rely on statistical tables for which these probabilities are tabulated for values of μ and σ. There is however an infinite number of values for these parameters, and it is therefore not possible to have tables for all of them. Interestingly, every normal distribution with parameters μ and σ can be expressed in terms of a normal distribution with mean 0 and variance 1, called the **standard normal distribution**. Indeed, if $X \sim N(\mu,\sigma^2)$, then one can define the variable Z such that $Z = \frac{X-\mu}{\sigma}$. It can be shown that $Z \sim N(0,1)$.

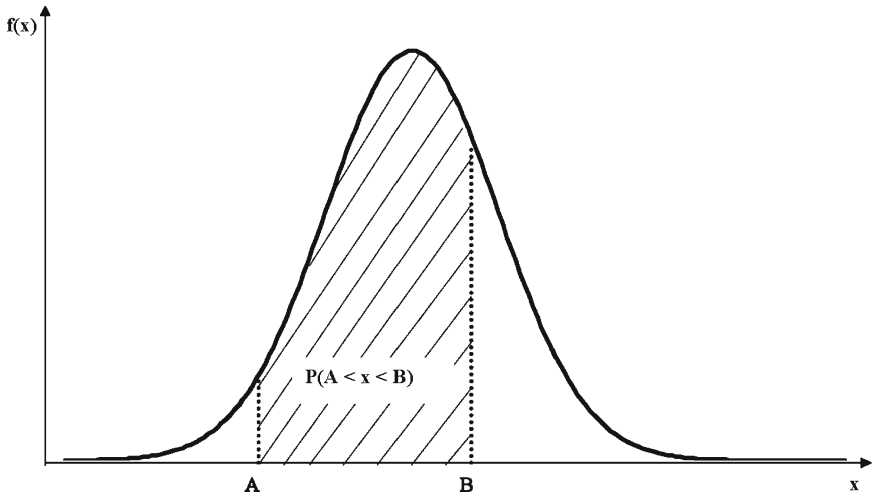

Fig. 1.1 Normal probability distribution function for a variable *X*. The *shaded area* represents the probability that the variable *X* falls between *A* and *B*. Numerically, this probability is obtained by computing the integral $P(A < x < B) = \int_A^B f(x)dx = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} dx$

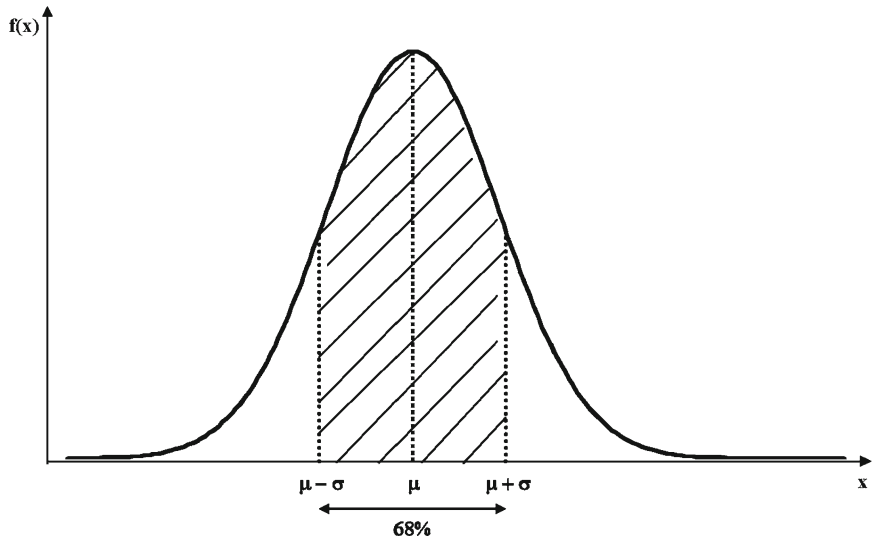

Fig. 1.2 Probability distribution function for a normal random variable *X* with mean μ and variance σ^2. The *shaded area* represents the probability that the normal variable *X* falls within the interval from the mean minus one standard deviation to the mean plus one standard deviation, that is $P(\mu - \sigma < x < \mu + \sigma)$, which is about 68%

Thus, computing the probability that a variable $X \sim N(\mu,\sigma^2)$ belongs to the interval [A;B], is equivalent to computing the probability that a variable $Z \sim N(0,1)$ belongs to the interval $\left[\frac{A-\mu}{\sigma}; \frac{B-\mu}{\sigma}\right]$. Tables of the standard normal distribution are available in most statistical textbooks. Important tables are associated with the standard normal distribution, including the table $P(z)$, which provides for each

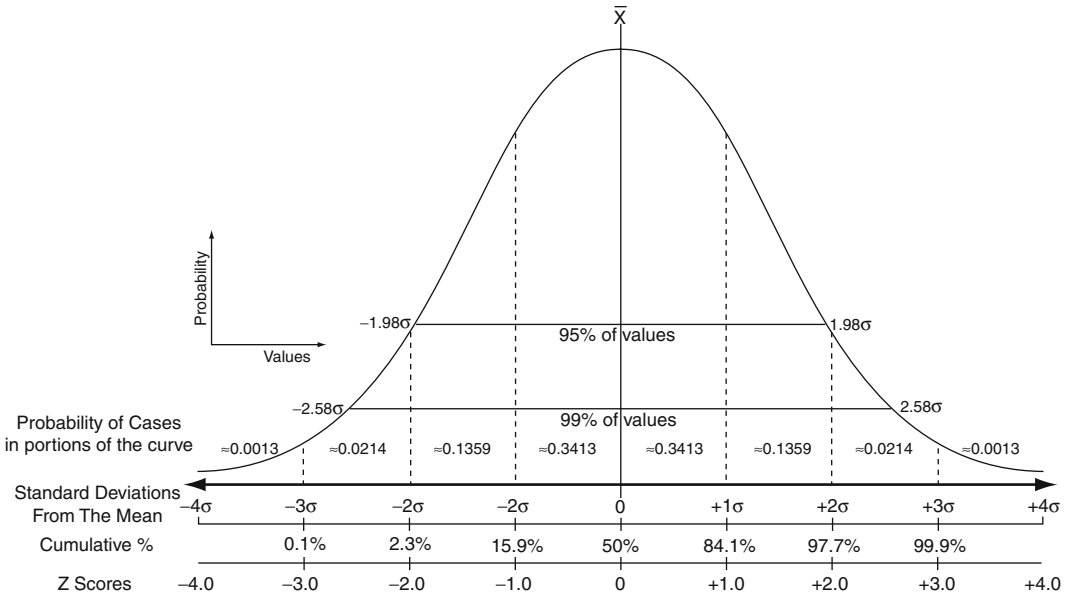

Fig. 1.3 The normal distribution. This plot illustrates standard results of the normal distribution including standard deviations from the means and the *Z*-scores

value of z, the probability that Z falls outside the interval $[-z; z]$: $P(z) = P(Z < -z \text{ or } Z > z) = 1 - P(-z < Z < z)$. Some standard normal values are commonly used: $P(1.64) = 0.10$ and $P(1.96) = 0.05$, that is, $P(-1.96 < Z < 1.96) = 95\%$. Thus, if a standard normal variable is randomly selected, there is a 95% chance that its value will fall within the interval [–1.96; 1.96]. Equivalently, the probability that a standard normal random variable $Z \sim N(0,1)$ falls outside the interval [–1.96; 1.96] is 5%. Given the symmetry of the normal distribution, $P(Z > 1.96) = P(Z < -1.96) = 2.5\%$. These standard results are illustrated in Fig. 1.3. The *Z*-values are usually referred to as the *Z*-scores and are commonly used in anthropometry. They are discussed in greater detail in a subsequent chapter.

The normal distribution is commonly used in anthropometry, in particular to construct reference ranges or intervals. This allows one to detect measurements which are extreme and possibly abnormal. A typical example is the construction of growth curves (WHO Child growth standards 2006). In practice, however, data can be skewed (i.e. not symmetric) and thus observations do not follow a normal distribution (Elveback et al. 1970). In such cases, a transformation of the observations, such as logarithmic, can remove or at least reduce the skewness of the data (Harris and Boyd 1995; Wright and Royston 1999).

1.3 Principles of Statistical Estimation

There are two estimation procedures: **point estimation** and **interval estimation**. Point estimation provides a value that we hope to be as close as possible to the true unknown parameter value. Interval estimation provides an interval that has a fixed a priori probability of containing the true parameter value.

1.3.1 Point Estimation

1.3.1.1 Point Estimator and Point Estimate

Point estimation is the process of assigning a value to a population parameter based on the observation of a sample drawn from this population. The resulting numerical value is called the **point estimate**; the mathematical formula/function used to obtain this value is called the **point estimator**. While the point estimator is identical whatever the sample, the point estimate varies across samples.

1.3.1.2 Point Estimation for a Proportion

The variable of interest is binary, such as the presence or absence of a specific health condition. We are interested in π, the true prevalence of this condition. Assume we randomly draw a sample of n subjects and denote the observed number of subjects with the condition of interest by k. The point estimator of π is given by $p = \frac{k}{n}$, while point estimates correspond to the numerical values $p_1, p_2, \ldots,$ obtained from distinct samples of n observations.

1.3.1.3 Point Estimation for a Mean and a Variance

X is a continuous variable with population mean and variance denoted respectively by μ and σ^2. If n subjects are randomly selected with subjects i=1 to n having respectively observed values x_1 to x_n, the mean μ, the variance σ^2 and the standard deviation SD are estimated respectively by $m = \sum_{i=1}^{n} \frac{x_i}{n}$, $s^2 = \sum_{i=1}^{n} \frac{(x_i - m)^2}{n-1}$ and $\mathrm{SD} = \sqrt{\sum_{i=1}^{n} \frac{(x_i - m)^2}{n-1}}$.

1.3.1.4 Point Estimation for a Reference Limit

Let $X_1, X_2, \ldots, X_n$ be the measurements for a random sample of n individuals. The $100p\%$ reference limit, where $0 < p < 1$, is the value below which $100p\%$ of the values fall. Reference limits may be estimated using nonparametric or parametric (i.e. distribution-based) approaches (Wright and Royston 1999).

The simplest approach is to find the empirical reference limit, based on the order statistics. The k^{th} order statistic, denoted as $X_{(k)}$, of a statistical sample is equal to its k$^{\text{th}}$-smallest value. Thus, given our initial sample $X_1, X_2, \ldots, X_n$, the order statistics are $X_{(1)}, X_{(2)}, \ldots, X_{(n)}$, and represent the observations with first, second, …, n^{th} smallest value, respectively. An empirical estimation of the $100p\%$ reference limit is given by the value which has rank $[p(n+1)]$, where [.] denotes the nearest integer. For example, for a sample of size $n = 199$ and $p = 0.025$, $[p(n+1)]$=5, and thus the value of the fifth order statistic, $X_{(5)}$, provides a point estimate of the 2.5% reference limit.

Reference limits can also be estimated based on parametric methods. Assume that the observations follow a normal distribution with mean μ and variance σ^2. For a random sample of size n, the sample mean and sample standard deviation are given by m and SD, respectively. The $100p\%$ reference limit is then estimated as $m + z_p \mathrm{SD}$, where z_p is the $100p\%$ standard normal deviate.

1.3.2 Interval Estimation

1.3.2.1 Principles

A single-value point estimate, without any indication of its variability, is of limited value. Because of sample variation, the value of the point estimate will vary across samples, and it will not provide any information regarding precision. One could provide an estimation of the variance of the point estimator. However, it is more common to provide a range of possible values. A **confidence interval** has a specified probability of containing the parameter value (Armitage et al. 2002). By definition, this probability, called the coverage probability, is $(1-\alpha)$, where $0<\alpha<1$. If one selects a sample of size n at random, using say a set of random numbers, then the sample that one gets to observe is just one sample from among a large number of possible samples one might have observed, had the play of chance been otherwise. A different set of n random numbers would lead to a different possible sample of the same size n and a different point estimate of the parameter of interest, along with its confidence interval. Of the many possible interval estimates, some $100(1-\alpha)\%$ of these intervals will capture the true value. This implies that we cannot be sure that the $100(1-\alpha)\%$ confidence interval calculated from the actual sample will capture the true value of the parameter of interest. The computed interval might be one of the possible intervals (with proportion $100\alpha\%$) that do not contain the true value. The most commonly used coverage probability is 0.95, that is $\alpha = 0.05 = 5\%$, in which case the interval is called a 95% confidence interval.

1.3.2.2 Interval Estimation for a Proportion

In this situation, the variable of interest is binary, such as the presence or absence of a specific health condition, and we are interested in π, the prevalence rate of this condition. Given a random sample of n subjects, a point estimator for the proportion π is given by $p = \frac{k}{n}$, where k is the observed number of subjects with the condition of interest in the sample. When n is large, the sampling distribution of p is approximately normal, with mean π and variance $\frac{\pi(1-\pi)}{n}$. Thus, a $100(1-\alpha)\%$ confidence interval for π is given by $\left[p \pm z_{1-\alpha/2}\sqrt{\frac{p(1-p)}{n}} \right]$. In smaller samples ($np < 5$ or $n(1-p)<5$), exact methods based on the binomial distribution should be applied rather than a normal approximation to it (Machin et al. 1997).

Example: Assume one is interested in estimating π, the proportion of overweight children. In a selected random sample of $n = 100$ children, the observed proportion of overweight children is $p = 40\%$.A 95% confidence interval $\left(z_{1-\alpha/2} = 1.96\right)$ for the true proportion π of overweight children is given by $\left[0.40 \pm 1.96\sqrt{\frac{0.40(0.60)}{100}} \right]$, that is [30%; 50%].

1.3.2.3 Interval Estimation for the Difference Between Two Proportions

The variables of interest are binary, and we are interested in π_1 and π_2, the prevalence rates of a specific condition in two independent samples of size n_1 and n_2. Let k_1 and k_2 denote the number of

observed subjects with the condition of interest in these two samples. A point estimator for the difference $\pi_1 - \pi_2$ is given by $p_1 - p_2 = \frac{k_1}{n_1} - \frac{k_2}{n_2}$, where p_1 and p_2 are the two sample proportions. When n_1 and n_2 are large, the sampling distribution of $p_1 - p_2$ is approximately normal with mean $\pi_1 - \pi_2$ and variance $\frac{\pi_1(1-\pi_1)}{n_1} + \frac{\pi_2(1-\pi_2)}{n_2}$. Thus, a 100(1 − α)% confidence interval for the true difference in proportions $(\pi_1 - \pi_2)$ is given by $\left[(p_1 - p_2) \pm z_{1-\alpha/2}\sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}\right]$. In case of smaller samples ($n_1 p_1 < 5$ or $n_1(1 - p_1) < 5$ or $n_2 p_2 < 5$ or $n_2(1 - p_2) < 5$), exact methods based on the binomial distribution should be applied rather than a normal approximation to it (Machin et al. 1997).

Example: Assume a randomized trial is conducted to compare two physical activity interventions for reducing waist circumference. A total of 110 and 100 subjects are assigned to receive intervention A or B, respectively. The observed success rate is 40% in group A and 20% in group B. A 95% confidence interval for the true difference in success rates is given by

$$\left[(0.40 - 0.20) \pm 1.96\sqrt{\frac{0.40 \times 0.60}{110} + \frac{0.20 \times 0.80}{100}}\right],$$ that is, [8%; 32%].

1.3.2.4 Interval Estimation for a Mean

The variable of interest is continuous with true mean μ and true variance σ^2. We are interested in estimating the true population mean μ. A total of n subjects have been randomly selected from this population of interest. When n is large ($n > 30$), the distribution of the sample mean m is approximately normal with mean μ and variance $\frac{\sigma^2}{n}$. A 100(1–α) confidence interval for μ is thus given by $\left[m \pm z_{1-\frac{\alpha}{2}}\sqrt{\frac{\sigma^2}{n}}\right]$. One can use s^2 as an estimate of the population variance, unless the variance σ^2 is known. If the sample size is small, and if the variable of interest is known to be normal, then a 100(1–α) confidence interval for μ is given by $\left[m \pm t_{n-1,\alpha}\sqrt{\frac{s^2}{n}}\right]$, where $t_{n-1,\alpha}$ corresponds to the α% tabulated point of the $t_{n-1,\alpha}$ distribution.

Example: One is interested in estimating the average weight of 15-year-old girls. After selecting a random sample of 100 girls, the observed average weight is 55 kg, and the standard deviation is 15 kg. A 95% confidence interval for the mean weight of 15-year-old girls is thus given by: $\left[55 \pm 1.96\sqrt{\frac{15^2}{100}}\right]$, that is [52; 58].

1.3.2.5 Interval Estimation for the Difference Between Two Means

Given two independent samples of size n_1 and n_2 with respective means μ_1 and μ_2, and variances σ_1^2 and σ_2^2, a point estimator for the difference $\mu_1 - \mu_2$ is given $m_1 - m_2$, where m_1 and m_2 correspond

to the two sample means. When n_1 and n_2 are large, the distribution of m_1–m_2 is approximately normal with mean μ_1–μ_2 and variance $\frac{\sigma_1^2}{n_1}+\frac{\sigma_2^2}{n_2}$. A 100(1–$\alpha$)% confidence interval for the true difference in means is then given by $\left[(m_1-m_2)\pm z_{1-\alpha/2}\sqrt{\frac{\sigma_1^2}{n_1}+\frac{\sigma_2^2}{n_2}}\right]$. Unless the variances σ_1^2 and σ_2^2 are known, one can use the sample variances s_1^2 and s_2^2 as their respective estimates: $\left[(m_1-m_2)\pm z_{1-\alpha/2}\sqrt{\frac{s_1^2}{n_1}+\frac{s_2^2}{n_2}}\right]$.

Example: One wishes to compare the diastolic blood pressure (DBP) between two populations of subjects A and B. In a sample of 50 randomly selected subjects from population A, the observed DBP mean is 110 mmHg, while the mean DBP in 60 patients randomly selected from population B is about 100 mmHg. The observed standard deviations are, respectively, 10 mmHg and 8 mmHg. A 95% confidence interval for the true difference in DBP means is thus $\left[(110-100)\pm 1.96\times\sqrt{\frac{10^2}{50}+\frac{8^2}{60}}\right]$, that is, [6.6; 13.4].

1.3.2.6 Interval Estimation for a Reference Limit

Using a nonparametric approach, a confidence interval for a reference limit can be expressed in terms of order statistics (Harris and Boyd 1995). An approximate 100(1–α)% confidence interval for the 100p% reference limit is given by the order statistics $x_{(r)}$ and $x_{(s)}$, where r is the largest integer less than or equal to $np+\frac{1}{2}-z_{\frac{\alpha}{2}}\sqrt{np(1-p)}$, and s is the smallest integer greater than or equal to $np+\frac{1}{2}+z_{\frac{\alpha}{2}}\sqrt{np(1-p)}$.

Example: In their example, Harris and Boyd are interested in the 90% confidence interval $\left(z_{1-\alpha/2}=1.645\right)$ for the 2.5% (p=0.025) reference limit based on a random sample of size n=240 (Harris and Boyd 1995). The lower bound of this interval corresponds to the value of the r^{th} order statistic, where r is the largest integer less than or equal to $np+\frac{1}{2}-z_{\frac{\alpha}{2}}\sqrt{np(1-p)}=240\times 0.025+\frac{1}{2}-1.645\sqrt{100\times 0.025\times 0.975}$, that is, 2. Similarly, the upper bound corresponds to the value of the s^{th} order statistic, where s is the smallest integer greater than or equal to $np+\frac{1}{2}+z_{\frac{\alpha}{2}}\sqrt{np(1-p)}$, that is, 11. Referring to the ordered observations, bounds of the 90% confidence interval for the 2.5% reference limit are thus provided by the values of the second and eleventh order statistics.

Confidence intervals can also be built using parametric methods. Assume that the observations follow a normal distribution with mean μ and variance σ^2. For a random sample of size n, the sample mean and sample standard deviation are given by m and SD, respectively. The parametric estimator of the $100p\%$ reference limit is $m+z_p\text{SD}$, where z_p is the $100p\%$ standard normal deviate. The variance of this estimator is given by $\frac{\sigma^2}{n}\left(1+\frac{z_p^2}{2}\right)$. A $100(1-\alpha)\%$ confidence interval for the $100p\%$ reference limit is thus $\left[m+z_p\text{SD}\pm z_{1-\frac{\alpha}{2}}\sqrt{\frac{\text{SD}^2}{n}\left(1+\frac{z_p^2}{2}\right)}\right]$. See Harris and Boyd for worked examples (Harris and Boyd 1995).

1.4 Precision-Based Sample Size Estimation

Sample size can be computed using either a precision-based or power-based approach. In anthropometry, however, there is greater emphasis on precision-driven estimation procedures (Gardner and Altman 1986, 1988).

For any given parameter, the length of the confidence interval is a function of the sample size. More specifically, the larger the sample, the narrower the confidence interval. Thus, the main purpose of confidence intervals is to indicate the (im)precision of the sample study estimates as population values (Gardner and Altman 1988). Conversely, one can fix the desired length of the interval and estimate the number of subjects needed accordingly. Formulae are available to estimate the sample size as a function of the precision, which can be expressed in two ways.

One can express the length of the interval in absolute terms based on the **absolute margin of error**, ME, which represents half the width of the confidence interval, and is the quantity often quoted as the "plus or minus" in lay reports of surveys. In such case, the confidence interval is expressed as "estimate ± ME". It is also possible to express the length of the interval in **relative** terms based on the **precision** usually denoted by ε. In such cases, the confidence interval is expressed as "estimate $\pm\varepsilon\times$ estimate". There is a direct relationship between the margin of error and the precision since ME $=\varepsilon\times$ estimate; sample size can thus be estimated as a function of either parameter.

Note that the term *error* is often a source of confusion when dealing with sample size and power calculations. Therefore, it is always very important to provide a precise definition of this term, that is, to clarify whether we are referring to an absolute or relative error.

Throughout this section, we consider that observations from the same sample are independent. In the case of two-sample problems, we consider that the two samples are independent.

1.4.1 Dichotomous Variables

1.4.1.1 Sample Size for Estimating a Single Proportion with a Given Precision

A $100(1-\alpha)\%$ confidence interval for the true proportion π given a sample size n and an anticipated value p is given by: $\left[p\pm z_{1-\frac{\alpha}{2}}\sqrt{\frac{p(1-p)}{n}}\right]$. The width of the confidence interval is thus given by

$2 \times z_{1-\frac{\alpha}{2}} \sqrt{\frac{p(1-p)}{n}}$ and depends on the number of subjects in the sample. Conversely, the number of subjects needed to estimate the proportion will depend on the degree of precision (indicated by the maximum width of the confidence interval) one is willing to accept. The margin of error, ME, is half the width of the confidence interval. If one wants the absolute margin of error to be at most ME, that is, one wants $z_{1-\frac{\alpha}{2}} \sqrt{\frac{p(1-p)}{n}} \leq \text{ME}$, then the number of subjects should be at least $n = \frac{z^2_{1-\frac{\alpha}{2}} p(1-p)}{\text{ME}^2}$.

This problem can also be expressed in terms of precision (or relative error). The confidence interval $\left[p \pm z_{1-\frac{\alpha}{2}} \sqrt{\frac{p(1-p)}{n}} \right]$ can be rewritten as $[p \pm \varepsilon p]$, implying that the estimation of π is provided to within $100\varepsilon\%$ of its anticipated value, where ε is the precision of the estimation. Since $\text{ME} = p\varepsilon$,the required sample size can thus be expressed as $n = \frac{z^2_{1-\frac{\alpha}{2}} (1-p)}{p\varepsilon^2}$. Note that the sample size is maximized for $p = 0.50$.

If either np or $n(1-p)$ are small (i.e. below 5), exact approximations based on the binomial distribution should be applied rather than a normal approximation to it (Machin et al. 1997).

Example: One is interested in estimating the prevalence of overweight children with an absolute margin of error smaller than 0.05 (ME = 0.05). If the prevalence, π, is expected to be around 50% ($p = 0.50$), and interest is in estimating a 95% confidence interval $\left(z_{1-\frac{\alpha}{2}} = 1.96 \right)$, the minimum number of subjects needed should be $\frac{1.96^2 0.5(1-0.5)}{0.05^2}$, that is, at least 384 subjects.

1.4.1.2 Sample Size for Estimating the Difference Between Two Proportions with a Given Precision

Given two proportions π_1 and π_2 for two independent samples of size n_1 and n_2, a $100(1-\alpha)\%$ confidence interval for the true difference in proportions $(\pi_1 - \pi_2)$ is estimated by $\left[(p_1 - p_2) \pm z_{1-\alpha/2} \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}} \right]$, where p_1 and p_2 are the observed sample proportions.

The width of the confidence interval is given by $2 \times z_{1-\alpha/2} \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}$. Assuming samples are of equal size $n = n_1 = n_2$ and an absolute margin of error ME, the number of subjects in each sample should be at least $n = \frac{z^2_{1-\alpha/2} \left(p_1(1-p_1) + p_2(1-p_2) \right)}{\text{ME}^2}$. In terms of precision ε or relative error, where $\text{ME} = \varepsilon(p_1 - p_2)$, the required sample size is expressed as $n = \frac{z^2_{1-\alpha/2} \left(p_1(1-p_1) + p_2(1-p_2) \right)}{\varepsilon^2 (p_1 - p_2)^2}$. Similar formulae have been derived for the case of unequal sample sizes (Machin et al. 1997).

***Example*:** A study is set up to compare a new physical activity intervention to a standard one for overweight subjects. The aim is to reduce the body mass index (BMI) down to 30 cm/kg^2 or lower. The anticipated success rates are expected to be approximately $p_1 = 10\%$ and $p_1 = 25\%$ for the new and standard interventions respectively. The investigator would like to recruit two groups of patients with equal sample sizes $n = n_1 = n_2$, and provide a 95% confidence interval for difference in success rates with an absolute margin of error ME = 10%. The minimum number of subjects per group should be at least $n = \dfrac{1.96^2\left(0.10 \times 0.90 + 0.25 \times 0.75\right)}{0.10^2}$, that is, 107 subjects per group.

1.4.2 Continuous Variables

1.4.2.1 Sample Size for Estimating a Single Mean with a Given Precision

A 100(1–α)% confidence interval for a mean μ given anticipated mean m and assuming a large sample is given by $\left[m \pm z_{1-\frac{\alpha}{2}} \dfrac{\sigma}{\sqrt{n}}\right]$. The width of the confidence interval is $2 \times z_{1-\frac{\alpha}{2}} \dfrac{\sigma}{\sqrt{n}}$. If we want the absolute margin of error to be at most ME, then the number of subjects has to be greater than $n = \dfrac{z^2_{1-\frac{\alpha}{2}} \sigma^2}{\mathrm{ME}^2}$. If one wishes to express the sample size in terms of precision ε, where ME = εm, the required sample size is expressed as $n = \dfrac{z^2_{1-\frac{\alpha}{2}} \sigma^2}{\varepsilon^2 m^2}$. Unless the variance σ^2 is known, one can use a literature-based or experience-based s^2 as an estimate of the population variance.

Example: An investigator is interested in estimating diastolic blood pressure (DBP) in a specific population. The mean DBP and standard deviation are anticipated to be about 105 mmHg ($m = 105$) and 20 mmHg (SD = 20). If the desired relative precision is 5% ($\varepsilon = 5\%$), the required sample size for estimating a 95% confidence interval for the mean DBP should be at least $n = \dfrac{1.96^2\, 20^2}{0.05^2 105^2}$, that is 56 subjects.

1.4.2.2 Sample Size for Estimating the Difference Between Two Means with a Given Precision

Assuming independent samples of size n_1 and n_2, with respective sample means m_1 and m_2 and common variance σ^2, a 100(1–α)% confidence interval for the true difference in means is given by $\left[(m_1 - m_2) \pm z_{1-\alpha/2}\sigma\sqrt{\dfrac{1}{n_1} + \dfrac{1}{n_2}}\right]$. The width of the confidence interval is thus given by $2 \times z_{1-\alpha/2}\sigma\sqrt{\dfrac{1}{n_1} + \dfrac{1}{n_2}}$. Assuming samples of equal size $n = n_1 = n_2$ and a margin of error ME, the number of subjects in each sample should be at least $n = \dfrac{2\, z^2_{1-\alpha/2} \sigma^2}{\mathrm{ME}^2}$. If one wishes to express the

sample size in terms of precision ε, where ME = $\varepsilon(m_1 - m_2)$, the required sample size is expressed as $n = \frac{2\, z^2_{1-\alpha/2}\, \sigma^2}{\varepsilon^2 (m_1 - m_2)^2}$. Unless the variance σ^2 is known, one can use a literature-based or experience-based s^2 as an estimate of the population variance. Similar formulae have been derived for the case of unequal sample sizes (Machin et al. 1997).

Example: An investigator is interested in evaluating two treatments (A and B) aimed at decreasing cholesterol level. The anticipated mean cholesterol levels following treatments A and B are, respectively, 200 and 250 mg/dL, with a 20 mg/dL common standard deviation. To obtain a 95% confidence interval for the difference in cholesterol levels after treatment with (relative) precision $\varepsilon = 10\%$, the sample size should be at least $n = \frac{2 \times 1.96^2 \times 20^2}{0.10^2 (200 - 250)^2}$, that is 123 subjects per group.

1.4.2.3 Sample Size for Estimating a Regression-Based Reference Limit with a Given Precision

In some cases, the variable of interest might be indexed by a secondary variable. Suppose we have a continuum of distributions indexed by a covariate. For example, assume that we are studying BMI in a group of children of different ages. Instead of the mean BMI, we might be interested in other parameters of the BMI distribution, more particularly in the 95% reference limit of the BMI distribution for various ages. How many children should we sample in order to have a precise estimate of this reference limit and for every possible value of age? This question can be answered by applying linear regression techniques to estimate the reference limit as a function of age. Methods have been developed to estimate sample sizes for regression-based reference limits under various situations (Bellera and Hanley 2007). We provide an overview of these approaches, and refer the interested reader to this literature for additional details.

It is assumed that the mean value of the response variable of interest (e.g., BMI) varies linearly with the covariate (e.g., age), and that the response values are approximately normally distributed around this mean. The response variable and the covariate of interest are denoted by Y and X, respectively. Assume that at any given value x_0 of age, the mean value of interest, such as BMI, is an approximate linear function of X and that individual BMI values are normally distributed around this mean (the latter eventually after a suitable transformation) with constant variance: $Y \,|\, x_0 \sim N\left(\beta_0 + \beta_1 x_0, \sigma^2\right)$. The 100$p$% reference limit for Y at this specific age point x_0 is given by: $Q_0 = \beta_0 + \beta_1 x_0 + z_p \sigma$, where z_p is the standard normal deviate corresponding to the 100p% reference limit of interest.

Given n selected individuals with data points $\left((x_i, y_i), i = 1, \ldots, n\right)$, a point estimator for the 100p% reference limit is given by: $\hat{Q}_0 = \hat{\beta}_0 + \hat{\beta}_1 x_0 + z_p s_{Y|X}$, where $\hat{\beta}_0$ and $\hat{\beta}_1$ are obtained by least-squares estimation of the regression coefficients β_0 and β_1, and $s_{Y|X}$ is the observed root mean square error.

Sample size estimation for regression-based reference limits requires defining the following parameters:

- The 100p% reference limit of interest, where $0 < p < 1$, and the corresponding one-sided standard normal deviate, z_p. For example, if we are interested in the 95% reference limit, the one-sided standard normal deviate is $z_{0.95} = 1.64$.

- The 100(1–α)% confidence interval for the reference limit of interest, and its corresponding two-sided standard normal deviate $z_{1-\frac{\alpha}{2}}$, where $0 < \alpha < 1$. For example, if we want the 95% confidence interval, then $\alpha = 0.05$ and $z_{1-\frac{\alpha}{2}} = 1.96$.
- The 100(1–β)% reference range, which encompasses 100(1–β)% of the values (e.g., BMI) as well as its corresponding two-sided standard normal deviate $z_{1-\frac{\beta}{2}}$, where $0 < \beta < 1$. For example, if we want the 95% reference range, then $\beta = 0.05$ and $z_{1-\frac{\beta}{2}} = 1.96$.
- The relative margin of error Δ, defined as the ratio of the width of the 100(1-α)% confidence interval for the reference limit to the width of the 100(1–β)% reference range. This means that we want a sample size large enough so that the width of the 100(1–α)% confidence interval for our reference limit is small when compared to the width of the 100(1–β)% reference range (we usually take $\alpha = \beta$).
- The design of the study, that is, the distribution of the covariate (e.g., age) in the sample investigated, which will influence the computation of the sample size.

Once the above parameters have been specified, we can estimate the sample size. Assume, first that we choose our sample so that the covariate (e.g., age) follows a uniform distribution. In such cases, the variance of the estimator $\hat{Q}$ of the reference limit is approximately equal to $\text{var}(\hat{Q}_0) = \frac{\sigma^2}{n}\left(4 + \frac{z_p^2}{2}\right)$. The width of the 100(1–α)% confidence interval for the 100p% reference limit at the *extreme* value of age is therefore $2z_{1-\frac{\alpha}{2}}\sigma\frac{\sqrt{4+\frac{z_p^2}{2}}}{\sqrt{n}}$. Assume we want a relative error of Δ, defined as the ratio of the width of the 100(1–α)% confidence interval for the reference limit to the width of the 100(1–β)% reference range. The width of the 100(1–α)% reference range is given by $2z_{1-\frac{\beta}{2}}\sigma$. Thus, if we want the ratio of the width of the 100(1–α)% confidence interval for the reference limit to the width of the 100(1–β)% reference range to be smaller than the relative error Δ, we require $\frac{z_{1-\frac{\alpha}{2}}\sqrt{4+\frac{z_p^2}{2}}}{z_{1-\frac{\beta}{2}}\sqrt{n}} \le \Delta$. That is, the minimum sample size, n, required to estimate the 100(1–α)% confidence interval for the 100p% reference limit, with a relative margin of error of Δ, when compared to the 100(1–β)% reference range, should be at least $n = \frac{z_{1-\frac{\alpha}{2}}^2\left(4+\frac{z_p^2}{2}\right)}{z_{1-\frac{\beta}{2}}^2\Delta^2}$. Similar formulae have been derived assuming other sampling strategies (Bellera and Hanley 2007). For example, instead of a uniform age distribution, one might take one-third of the sample at one age extreme, one-third at the midpoint, and one-third at the other age extreme. In this study design, the minimum

sample size requirement is then $\frac{z^2_{1-\frac{\alpha}{2}}\left(\frac{5}{2}+\frac{z_p^2}{2}\right)}{z^2_{1-\frac{\beta}{2}}\Delta^2}$. Similarly, we can also expect that the age distribution in the sample will follow a normal distribution. If we assume that the range of X is approximately 4 times the standard deviation of X, then we show that the sample size requirement becomes: $\frac{z^2_{1-\frac{\alpha}{2}}\left(5+\frac{z_p^2}{2}\right)}{z^2_{1-\frac{\beta}{2}}\Delta^2}$.

Notice that the previous formulae were derived under the "worst-case" scenario, that is, assuming that we are interested in estimating the reference limit at the extreme end of age, where the variability is highest, and thus the largest sample size is needed. If one is interested in the $100p\%$ reference limit at the average age value (where the variability is minimized), then the sample size is reduced to $\frac{z^2_{1-\frac{\alpha}{2}}\left(1+\frac{z_p^2}{2}\right)}{z^2_{1-\frac{\beta}{2}}\Delta^2}$, for any given age distribution (or similarly, assuming a homogeneous population not indexed by a covariate). Put simply, information from either side of the average age adds strength to the information at the average age. In contrast, information at the extremes of the age distribution can only gather "strength" from one side of the age distribution; on the other side, there is infinite uncertainty.

Several other factors can impact the sample size (Cole 2006), such as for example the range of the covariate of interest. If one is interested in the height of children, a larger sample will be needed when considering birth to 18 years than when considering 5–12 years. Non-constant variability can also affect the sample size, since the variance of the estimator, $\text{var}(\hat{Q}_0)$, is proportional to $\frac{\sigma^2}{n}$, where σ^2 varies with age. This ratio can be made constant across age groups by ensuring that the sample size n is proportional to σ^2. Thus, at the ages at which the variability is increased, for example during puberty, the sample size needs to be increased appropriately to compensate (Goldstein 1986; Cole 2006). Similarly, in case of heteroscedasticity of the variable of interest across the covariate, regression techniques can be used to model the standard deviation as a function of the mean, and previous formulae can still be used as a rough guide for sample size planning. Notice that the variation σ^2 to be used in planning includes both the true inter-individual variability and the variability of the measuring instruments used: measurement tools with differing precisions will provide different sample size estimates. Finally, the nature of the relation between the covariate and the variable of interest can also affect the sample size, as more subjects will be needed to capture "wiggles" in the relation compared to a simple linear relation. If there is some nonlinearity in the covariate, such as for example a quadratic relationship, the formulae can also be accommodated by adjusting the point estimator of the reference limit of interest.

Example: We are interested in estimating a specific BMI reference limit as a linear function of age. Specifically, we wish to produce a 95% confidence interval $\left(z_{1-\frac{\alpha}{2}}=1.96\right)$ for the 95% BMI reference

limit ($z_{0.95} = 1.64$), with a relative margin of error $\Delta = 10\%$, when compared with the 95% reference range $\left(z_{1-\frac{\beta}{2}} = 1.96 \right)$. If age is uniformly distributed in the sample, then the minimum required sample size is $n = \frac{1.96^2 \left(4 + 1.64^2\right)}{1.96^2 0.10^2}$, i.e., we would need at least 536 observations to obtain this precise an estimate of the 95% BMI reference limit at any place in the age range. If, on the other hand, one is interested in the 95% reference limit only at the average age value, or in a homogeneous population not indexed by a covariate, then we would need at least $n = \frac{1.96^2 \left(1 + 1.64^2\right)}{1.96^2 0.10^2}$, that is, 236 observations.

1.5 Principles of Hypothesis Testing

We have presented formulae for the estimation of the sample size required to estimate various parameters with a desired degree of precision. Similarly, one may want to ensure that a sufficient number of subjects are available to show a difference between two parameters. We discuss here some basic principles of hypothesis testing which can be found in introductory statistical textbooks, as well as works devoted to clinical trials or epidemiology (Lachin 1981; Friedman et al. 1998; Armitage et al. 2002).

One wishes to compare two groups, A and B, with true prevalence rates, π_A and π_B. From a statistical point of view, this comparison is expressed in terms of a **null hypothesis**, called H_0, which states that no difference exists between the two groups: H_0: $\pi_A - \pi_B = 0$. Hypothesis testing consist in testing whether or not H_0 is true, more specifically, whether or not it should be rejected. Thus, until otherwise proven, H_0 is considered to be true. The true prevalence rates, π_A and π_B are unknown. If two groups of subjects are properly sampled, one can obtain appropriate estimates P_A and P_B. Although π_A and π_B might not differ, it is possible that by chance alone, the observed proportions P_A and P_B are different. In such cases, one might falsely conclude that the two groups have different prevalence rates. Such a false-positive error is called **a type 1 error**, and the probability of making such an error corresponds to the **significance level** and is denoted by α. The probability of making a type 1 error should be minimized. However, decreasing the significance level increases the sample size. The probability of observing a difference as extreme as or more extreme than the difference actually observed, given that the null hypothesis is true, is called the ***p-value*** and is denoted by P. The null hypothesis H_0 will be rejected if $p < \alpha$.

If the null hypothesis is not correct, then an **alternative hypothesis**, denoted by H_A must be true, that is H_A:$\pi_A - \pi_B = \delta$, where $\delta \neq 0$. It is possible that by chance alone, the observed proportions P_A and P_B differ only by a small amount. As a result, the investigator may fail to reject the null hypothesis. This false-negative error is called **a type 2 error**, and the probability of making such error is denoted by β. The probability of correctly accepting H_0 is thus $1-\beta$ and is referred as the **power**. It defines the capability of a statistical test to reveal a given difference between two parameters, if this difference really exists. The power depends on the size of the difference we wish to detect, the type 1 error, and the number of subjects. That is, if the type 1 error and the sample size are held constant, a study will have a larger power if one wishes to detect a large difference compared to a small one.

1.6 Power-Based Sample Size Estimation

The number of subjects needed should be planned carefully in order to have sufficient power to detect significant differences between the groups considered. To provide a power-based (or test-based) estimation of sample size requires defining a priori the difference one wishes to detect, the desired significance level and the desired power of the test.

As will be discussed below, sample size formulae involve the ratio of the variance of the observations over the difference one wishes to detect, or more generically, a noise–signal ratio, where the signal corresponds to the difference one wishes to detect, and the noise (or uncertainty) is the sum of all the factors (sources of variation) that can affect the signal (Sackett 2001).

Note that we only discuss the case of independent observations. In clinical trials, for example, it may not always be possible to randomize individuals. For example, a physical activity intervention might be implemented by randomizing schools. Individuals are then grouped or clustered within schools. They cannot be considered as statistically independent, and the sample size needs to be adapted since standard formulae underestimate the total number of subjects (Donner et al. 1981; Friedman et al. 1998).

1.6.1 Dichotomous Variables

1.6.1.1 Sample Size for Comparing a Proportion to a Theoretical Value

The variable of interest is dichotomous. For example, one is interested in the prevalence of obese children π_1. Based on a random sample, the objective is to compare this proportion to a target (fixed) value p_0. The null and alternative hypotheses are given respectively by $H_0: \pi_1 = p_0$ and $H_A: \pi_1 \neq p_0$. The minimum number of subjects needed to perform this comparison assuming an observed prevalence rate p_1, a significance level α and power $1-\beta$ is $n = \dfrac{\left(z_{1-\frac{\alpha}{2}}\sqrt{p_0(1-p_0)} + z_{1-\beta}\sqrt{p_1(1-p_1)} \right)^2}{(p_1 - p_0)^2}$.

Example: One is interested in evaluating a specific diet aimed at reducing weight in obese subjects. A success is defined as reducing a BMI down to 25 or lower. One wishes to test whether this new diet has a better success rate than the standard diet for which the efficacy rate is known to be $p_0 = 20\%$. The anticipated efficacy rate of the new diet is $p_1 = 40\%$. The sample size needed to show a difference between the efficacy rate of the new diet and the target efficacy rate p_0 assuming a significance level $\alpha = 0.05$ $\left(z_{1-\frac{\alpha}{2}} = 1.96 \right)$, and power $1-\beta = 0.90$ ($z_{1-\beta} = 1.28$) is at least $n = \dfrac{\left(1.96\sqrt{0.20(1-0.20)} + 1.28\sqrt{0.40(1-0.40)}\right)^2}{(0.40-0.20)^2}$, i.e., 36 patients. If the anticipated efficacy rate is $p_1 = 30\%$, that is, one wishes to detect a smaller difference, then the sample size must be increased to at least $n = \dfrac{\left(1.96\sqrt{0.20(1-0.20)} + 1.28\sqrt{0.30(1-0.30)}\right)^2}{(0.30-0.20)^2}$, that is, 137 subjects.

Note that the calculated sample sizes are quite low. This is because we are comparing one sample to one historical (or literature-based) sample. In practice, one will usually be comparing two samples (next section), as in clinical trials. In this case, the resulting sample size is much higher as variability of the second sample has to be accounted for.

1.6.1.2 Sample Size for Comparing Two Proportions

The outcome of interest is dichotomous and two independent groups of equal size are being sampled and compared. The objective is to detect a difference between two proportions π_0 and π_1, that is, the null and alternative hypotheses are given respectively by H_0: $\pi_1-\pi_0=0$ and H_A: $\pi_1-\pi_0=\delta$, where $\delta\neq 0$. The size of each sample required to detect an anticipated difference p_1-p_0, assuming a significance level α, and power β is $n=\dfrac{\left(z_{1-\frac{\alpha}{2}}\sqrt{2\bar{p}(1-\bar{p})}+z_{1-\beta}\sqrt{p_0(1-p_0)+p_1(1-p_1)}\right)^2}{(p_1-p_0)^2}$, where $\bar{p}$ is the average of the two anticipated proportions p_0 and p_1. Similar formulae are available for the case of unequal sample sizes (Piantadosi 2005).

Example: A trial is set up to compare two physical activity interventions with anticipated success rates of 50% and 30%. The sample size per group needed to show a difference between the two interventions assuming a difference in success rates $\delta=50\%-30\%=20\%$, a significance level $\alpha=0.05$ $\left(z_{1-\frac{\alpha}{2}}=1.96\right)$, and power $1-\beta=0.90$ $\left(z_{1-\beta}=1.28\right)$ is $n=\dfrac{\left(1.96\sqrt{0.40(1-0.40)}+1.28\sqrt{0.30(1-0.30)+0.50(1-0.50)}\right)^2}{0.20^2}$ that is, 84 subjects per group.

1.6.2 Continuous Variables

1.6.2.1 Sample Size for Comparing a Mean to a Theoretical Value

The variable of interest is continuous. For example, one is interested in the mean waist circumference, μ_1, following a physical activity intervention. Based on a random sample of subjects, the objective is to compare this mean circumference to a target mean value m_0. The null and alternative hypotheses are thus given respectively by H_0: $\mu_1=m_0$ and H_A: $\mu_1\neq m_0$. For this one sample problem, the number of subjects needed to perform this comparison assuming an anticipated mean value m_1, a standard deviation σ, significance level α and power $1-\beta$ is $n=\dfrac{\sigma^2\left(z_{1-\frac{\alpha}{2}}+z_{1-\beta}\right)^2}{(m_1-m_0)^2}$. Unless the variance σ^2 is known, one can use a literature-based or experience-based s^2 as an estimate of the population variance.

Example: One wishes to test whether mean waist circumference in a given population following a new physical activity intervention is reduced compared to a standard intervention. Following the standard intervention, the mean waist circumference is known to be about $m_0 = 140$ cm. It is anticipated that the new intervention will reduce this circumference to $m_1 = 130$ cm. The sample size needed to show a difference between the mean waist circumference with the new intervention and a target value m_0, assuming a significance level $\alpha = 0.05$ $\left(z_{1-\frac{\alpha}{2}} = 1.96\right)$, a 90% power $\left(z_{1-\beta} = 1.28\right)$ and standard deviation SD = 20cm, is $n = \frac{20^2\left(1.96+1.28\right)^2}{\left(130-140\right)^2}$, that is, 42 patients.

1.6.2.2 Sample Size for Comparing Two Means

The variable of interest is continuous and two independent groups of equal size are being sampled and compared. The objective is to detect a difference between two means, that is, the null and alternative hypotheses are given respectively by $H_0: \mu_1 - \mu_0 = 0$ and $H_A: \mu_1 - \mu_0 = \delta$, where $\delta \neq 0$. The sample size of each group required to detect this difference assuming an anticipated difference $m_1 - m_0$, common variance σ^2, significance level α and power β is $n = \frac{2\sigma^2 \times \left(z_{1-\frac{\alpha}{2}} + z_{1-\beta}\right)^2}{(m_1 - m_0)^2}$. Unless the variance σ^2 is known, one can use a literature-based or experience-based s^2 as an estimate of the population variance.

Example: In their example, Armitage et al. are interested in comparing two groups of men using the forced expiratory volume (FEV) (Armitage et al. 2002). From previous work, the standard deviation of FEV is 0.5 L. A two-sided significance level of 0.05 $\left(z_{1-\frac{\alpha}{2}} = 1.96\right)$ is to be used with an 80% power ($z_{1-\beta} = 0.842$). In order to show a mean difference of 0.25 L between the groups, and assuming samples of equal sizes, the total number of men should be at least $n = \frac{2 \times 0.5^2 \times \left(1.96 + 0.842\right)^2}{0.25^2}$, that is, 63 men per group.

1.7 Other Parameters, Other Settings

Sample sizes can be estimated for various parameters and under various settings. As such, it is not possible to cover all possible situations into a single book chapter! We have reviewed formulae for the estimation of sample sizes for commonly used parameters such as means, proportions and reference limits. Other parameters such as time-to-event outcomes (Freedman 1982; Schoenfeld 1983; Dixon and Simon 1988), correlation coefficients (Bonett 2002), concordance coefficients (Donner 1998), or even multiple endpoints can be considered (Gong et al. 2000). Similarly, methods for calculating sample size assuming other designs have been investigated. Instead of detecting a specific difference, one might be interested in showing equivalence or noninferiority (Fleming 2008); observations may be clustered (Donner et al. 1981; Hsieh 1988), etc. Sample size estimation procedures have been developed for these settings and we refer the interested reader to specialized literature or general works on sample size (Friedman et al. 1998; Machin et al. 1997; Altman et al. 2000; Piantadosi 2005).

Finally, although they should be used with caution, several statistical software packages, such as nQuery® (nQuery Advisor ® 6.0), or East® (Cytel), are available to compute sample size and power for means, proportions, survival analysis, etc.

1.8 Application to Other Areas of Health and Disease

The methods presented in this chapter can be applied to many areas of research and study design, including anthropometry, but also fundamental biology, epidemiology, clinical trials, social sciences, demography, or economics.

Summary Points

- Before estimating a sample size, the nature and the distribution of the variable of interest must be defined. The parameter of interest (mean, proportion, reference limit) can then be identified.
- Before estimating a sample size, the type of sample has to be identified: one single sample? Two samples?
- Sample size estimation can be either precision-based or power-based.
- When performing precision-based sample size estimation, the anticipated value of the parameter as well as the level of significance and the precision (absolute or relative) must be defined a priori.
- When performing power-based sample size estimation, the anticipated value of the parameter as well as the level of significance and the power must be defined a priori.

Key Features of Sample Size Estimation

Table 1.3 Sample-size required for the estimation of a 100(1–α)% confidence interval for various parameters (*assuming an absolute margin of error* ME)

Parameter of interest	Sample size
Proportion (assuming an anticipated value P)	$n = \frac{z^2_{1-\frac{\alpha}{2}}\, p(1-p)}{\mathrm{ME}^2}$
Difference between 2 proportions (assuming independent samples with the same sample size and anticipated proportions p_1 and p_2)	$n\ (\text{per group}) = \frac{z^2_{1-\alpha/2}\left(p_1(1-p_1)+p_2(1-p_2)\right)}{\mathrm{ME}^2}$
Mean (assuming sample variance s^2)	$n = \frac{z^2_{1-\frac{\alpha}{2}}\, s^2}{\mathrm{ME}^2}$
Difference between 2 means (assuming independent samples with the same sample size and common sample variance s^2)	$n\ (\text{per group}) = \frac{2\, z^2_{1-\alpha/2}\, s^2}{\mathrm{ME}^2}$
Regression-based reference limit for the 100p% reference limit (assuming a uniform distribution for the covariate and a relative margin of error of Δ when compared to the 100(1–β)% reference range)	$n = \frac{z^2_{1-\frac{\alpha}{2}}\left(4+\frac{z_p^2}{2}\right)}{z^2_{1-\frac{\beta}{2}}\Delta^2}$

Table 1.4 Sample-size required for the comparison, via a test, of various parameters (assuming significance level α, and power $1-\beta$

Comparison of interest	Sample size
Single proportion π_1 (with anticipated value p_1) to a theoretical value p_0	$n = \dfrac{\left(z_{1-\frac{\alpha}{2}}\sqrt{p_0(1-p_0)} + z_{1-\beta}\sqrt{p_1(1-p_1)}\right)^2}{(p_1-p_0)^2}$
Two proportions (assuming independent samples of equal size, with anticipated proportions p_0 and p_1 and where $\bar{p} = (p_0+p_1)/2$)	n (per group) $= \dfrac{\left(z_{1-\frac{\alpha}{2}}\sqrt{2\bar{p}(1-\bar{p})} + z_{1-\beta}\sqrt{p_0(1-p_0)+p_1(1-p_1)}\right)^2}{(p_1-p_0)}$
Single proportion μ_1 (with anticipated value m_1) to a theoretical value m_0 (assuming sample variance s^2)	$n = \dfrac{s^2\left(z_{1-\frac{\alpha}{2}} + z_{1-\beta}\right)^2}{(m_1-m_0)^2}$
Two means (assuming independent samples of equal size with common sample variance s^2)	n (per group) $= \dfrac{2s^2 \times \left(z_{1-\frac{\alpha}{2}} + z_{1-\beta}\right)^2}{(m_1-m_0)^2}$

Chapter 2
Use of Percentiles and *Z*-Scores in Anthropometry

Youfa Wang and Hsin-Jen Chen

Abstract Percentiles and *Z*-scores are often used to assess anthropometric measures to help evaluate children's growth and nutritional status. In this chapter, we first compare the concepts and applications of percentiles and *Z*-scores and their strengths and limitations. Compared to percentiles, *Z*-scores have a number of advantages: first, they are calculated based on the distribution of the reference population (mean and standard deviation), and thus reflect the reference distribution; second, as standardized quantities, they are comparable across ages, sexes, and anthropometric measures; third, *Z*-scores can be analyzed as a continuous variable in studies. In addition, they can quantify extreme growth status at both ends of the distribution. However, *Z*-scores are not straightforward to explain to the public and are hard to use in clinical settings. In recent years, there has been growing support to the use of percentiles in some growth and obesity references. We also discuss the issues related to cut point selections and outline the fitting/smoothing techniques for developing reference curves. Finally, several important growth references and standards including the previous and new WHO growth reference/standards and the US 2000 CDC Growth Charts, are presented and compared. They have been developed based on different principles and data sets and have provided different cut points for the same anthropometric measures; they could, thus, provide different results. This chapter will guide readers to understand and use percentiles and *Z*-scores based on recent growth references and standards.

Abbreviations

BMI	Body mass index
CDC	Centers for Disease Control and Prevention
IOTF	International Obesity Task Force
HAZ	Height- or length-for-age *Z*-score
MGRS	Multicentre Growth Reference Study
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
SD	Standard deviation
WHO	World Health Organization
WHZ	Weight-for-age *Z*-score

2.1 Introduction

Anthropometric assessment for children and adolescents involves the use of growth standards and/or growth references for assessing their growth, nutritional status and well being (Wang et al. 2006; WHO 1995). A growth standard reflects optimal growth, suggesting that all children have the potential to achieve that level, while a growth reference is simply the distribution used for comparison (WHO MGRSG 2006a).

Percentiles and *Z*-scores in anthropometric measures have been widely used to help assess young people's nutritional status and growth, such as undernutrition (e.g., underweight, stunting and wasting) and overnutrition (i.e., overweight and obesity), see Tables 2.1 and 2.2. Often, percentiles (such as the 5th, 85th, 95th, 97th, 99th percentiles) and *Z*-scores (e.g., -2 and +2) are used to classify various health conditions, and sex-age-specific anthropometric measures cut-points (based on *Z*-scores or percentiles) are provided in tables and as smoothed curves on growth charts (see Figs. 2.1 and 2.2).

For the past four decades, the World Health Organization (WHO) has recommended the use of growth reference (or "growth chart"), mainly based on *Z*-scores of anthropometric measures, to assess children's nutritional status and growth. These growth charts were developed based on data

Table 2.1 Comparison of percentiles and *Z*-scores in anthropometry

	Percentiles	*Z*-scores
1. Definition	The percentage of observations (or population) falls below the value of a variable	The number of standard deviation (SD) away from the mean, when the distribution is normal
2. Scale	Rank scale	Continuous scale (from $-\infty$ to ∞)
3. Strengths	(a) Intuitively more understandable	(a) Allowing comparisons across ages and sexes
	(b) Indicating the expected prevalence	(b) Able to quantify the extreme values
		(c) Good for assessing the longitudinal changes in growth status
4. Limitations	(a) Not comparable across different anthropometries	Difficult to perceive than percentiles, especially for the public
	(b) Extreme values are lumped to the highest/lowest percentile	
	(c) Not suitable for assessing longitudinal growth status	

5. Under normal distribution, a percentile must correspond to a fixed *Z*-score.

Following is a list of usually used percentile-*Z*-score conversion values.

0.2nd	–3
2.3rd	–2
2.5th	–1.96
5th	–1.64
15th	–1.04
16th	–1
50th (median)	0
84th	+1
85th	+1.04
95th	+1.64
97.5th	+1.96
97.7th	+2
99.8th	+3

This table lists the key definitions and scales of percentiles and *Z*-scores, and compares their strengths and limitations. In practical setting, users would often face the task to convert *Z*-scores to percentiles or vice versa. Thus, this table also shows the corresponding values between percentiles and *Z*-scores

Table 2.2 The 1995 WHO growth reference: use of percentiles and *Z*-scores

Outcomes	Anthropometric measures and cut points	Indication of growth/nutrition problems
Infants and children (<10 years)		
Stunting	HAZ < –2 *Z* score, or <3rd percentile	Chronic malnutrition
Wasting/thinness	WHZ < –2 *Z* score, or <3rd percentile	Acute malnutrition, current malnutrition
Overweight	WHZ > 2 *Z* score	Overweight
Adolescents (> =10 years)		
Stunting	HAZ <–2, or <3rd percentile	Chronic malnutrition
Thinness	BMI-for-age < 5th percentile	Underweight
At risk of overweight	BMI-for-age > =85th percentile	Overweight
Obese	BMI-for-age > =85th percentile and triceps and subscapular skinfold thickness-for-age > =90th percentiles	Obesity

This table summarizes the cut-points of percentiles and *Z*-scores to define problematic growth status in children and adolescents when using anthropometric measures. These cut-points based on statistical distribution are often adopted by other growth references/standards including the recent new WHO growth standards and references
HAZ: Height- or length-for-age *Z*-score; *WHZ*: Weight-for-age *Z*-score; *BMI*: Body mass index (WHO 1995)

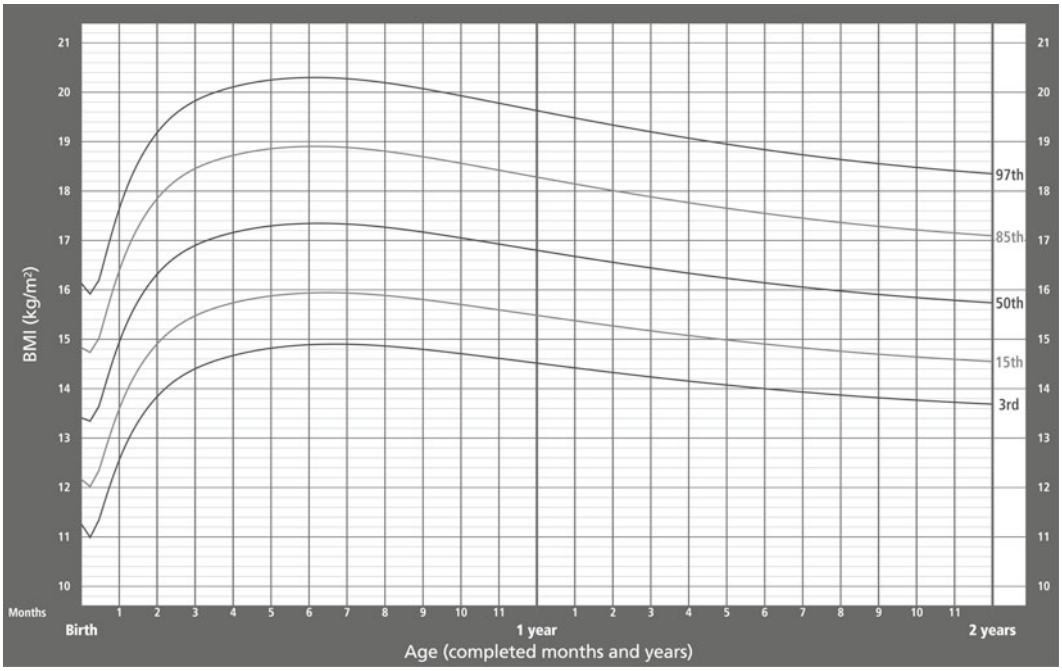

Fig. 2.1 The 2006 WHO growth standards: BMI-for-age percentiles for boys under 2-year-old. The curves for the 3rd, 15th, 50th, 85th, and 97th percentiles of 0–2 year-old boys' BMI-for-age are presented in this growth chart (Preprinted from WHO Growth Standards website, with permission)

collected in the United States (Wang et al. 2006). In 1995, WHO recommended the use of the sex-age-specific percentiles of some anthropometric measures for adolescents (WHO 1995). Historically, the WHO international growth references focused more on undernutrition problems, including wasting, stunting and underweight, even as the need to address a growing obesity problem in many countries has risen over the past two decades. The earlier versions of WHO growth

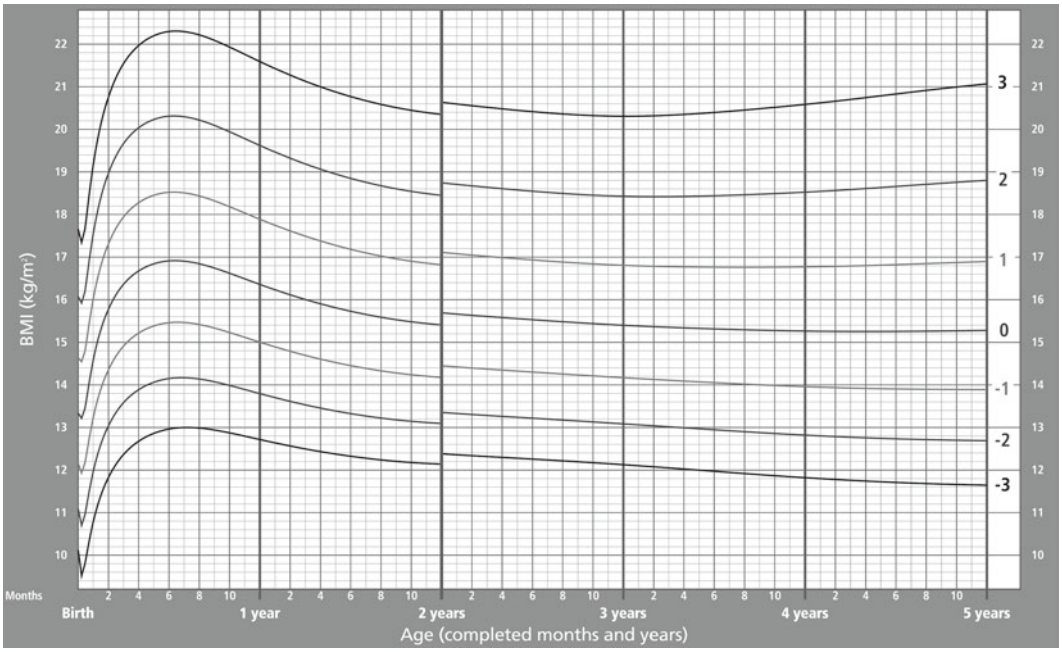

Fig. 2.2 The 2006 WHO growth standards: BMI *Z*-scores growth chart for preschool girls (0–5 years). This growth chart juxtaposes 0–2 year-old and 2–5 year-old girls' BMI-for-age *Z*-score curves. This chart provides curves for *Z*-scores of 0, ±1, ±2, and ±3. The disjunction at 2 years old addresses the issue of differential measurements between recumbent length and standing height. The length-for-age curves are averagely 0.7 cm larger than height-for age curves at 2-year-old (Reprinted from WHO Growth Standards website, with permission)

references were based on US data, whereas the new 2006 WHO Growth Standards for preschool age children have been developed based on data collected from several countries (see below).

Pediatric growth charts have been widely used globally by researchers, pediatricians, nurses and parents to assess the growth and nutritional status of children, but often users might not be aware of their limitations (Wang et al. 2006). For example, growth charts were not designated as a sole diagnostic instrument. Instead, they contribute to forming an overall clinical impression of the child being measured (CDC 2000). In addition, many users are not aware of the differences between "growth standard" and "growth reference" as these two terms are often used interchangeably.

In this chapter, we first describe the concepts and application of percentiles and *Z*-scores in anthropometry and compare their limitations and strengths. Next, we address two important issues: the selection of anthropometric measure cut points and the statistical methods and techniques for growth curve fitting and smoothing. Finally, we describe several international growth references including the 2006 WHO Growth Standards, growth references based on the US population, and an international reference for childhood obesity. In some of these references, anthropometric values corresponding to certain *Z*-scores and percentiles are provided.

2.2 The Use of *Z*-Scores

The use of *Z*-scores is recommended for several reasons (Table 2.1). First, *Z*-scores are calculated based on the distribution of the reference population (both the mean and the standard deviation [SD]); thus, they reflect the reference distribution. Second, as standardized measures, *Z*-scores are comparable

Fig. 2.3 *Z*-score and the corresponding cumulative probability and percentile (proportion). For normal distribution, the *Z*-score of 0 divides the total area into two equal halves. Thus, the *Z*-score of 1 corresponds to the 84th percentile (=0.5 + 0.34), i.e., 84% of the population are measured lower than *z*-score of 1. A *Z*-score is calculated as dividing the difference between measured value (x) and the mean (μ) by standard deviation (σ)

across age, sex and measure (as a measure of "dimensionless quantity"). Third, a group of *Z*-scores can be subject to summary statistics such as mean and SD and can be studied as a continuous variable. In addition, *Z*-score values can quantify the growth status of children outside of the percentile ranges (WHO 1995). However, the major limitation of *Z*-scores is that they are not straightforward to explain to the public and may be of limited use in clinical settings. The WHO and US Centers for Disease Control and Prevention (CDC) have ever developed a statistical software to help researchers to calculate *Z*-scores based on the 1978 WHO/NCHS (National Center for Health Statistics) references.

In statistical terms, *Z*-scores are a special application of transformation rules. The *Z*-score for a measure (e.g., height or BMI), indicates how far and in what direction (positive vs. negative) a measured value deviates from the population mean, expressed in units of the population SD. It is a dimensionless quantity derived from dividing the difference between individual value (x) and the population mean (μ) by the population SD (σ). The transformed *Z*-scores' distribution will have a mean of zero and a SD of one (i.e., mean = 0, SD = 1). This conversion process is called standardizing or normalizing.

$$Z = \frac{x - \mu}{\sigma}$$

Z-scores are sometimes called "standard scores". The *Z*-score transformation is especially useful when seeking to compare the relative standings of different measures (e.g., height vs. BMI, or the measures of boys' vs. girls') from distributions with different means and/or different SDs. *Z*-scores are especially informative when the distribution to which they refer is normal. In every normal distribution, the area under the curve between the mean and a given *Z*-score value corresponds to a fixed proportion of the total area (Fig. 2.3). Based on this characteristic, statisticians have created tables indicating the value of these proportions for various *Z*-scores.

2.3 The Use of Percentiles

A percentile is the value of a variable below which a certain percentage of observations (or population) falls, i.e., the percentile refers to the position of an individual on a given reference distribution. Percentiles are easier to understand and use in practice, both by health professionals and the public.

In addition, a percentile dictates the expected percentage of a population should be above (or below) it (see Table 2.1). Often age-sex-specific percentiles are recommended to assess children's growth and nutritional status based on anthropometric measures as well as other health conditions such as blood pressure. During recent years, there is a growing consensus on using sex- and age-specific BMI percentiles as cut-offs instead of weight-for-height *Z*-scores (WHZ) for assessing overweight and obesity as well as thinness/underweight in children over 2 years old (Kuczmarski et al. 2002; Wang et al. 2006; WHO 2006). The widely used percentiles include the 3rd, 5th, 50th (median), 85th, 95th, 97th, 99th.

In statistics, the term percentile and the related term percentile rank are often used in descriptive statistics as well as in the reporting of scores from norm-referenced tests. Percentiles are often represented graphically, using a normal curve (Fig. 2.3). A normal curve is always represented with some key features. The peak or the center of the bell-shaped curve stands the point of the mean of the distribution. The mean ($z = 0$) halves the normal distribution into two equal and symmetric areas. On both the right and left sides each, the graph can be shown as divided into three parts, according to *Z*-scores of 1, 2, and 3 SD to the right and -1, -2, -3 SD to the left, respectively. At each point of these SDs, the corresponding percentile (or cumulative probability) is fixed. In other words, as long as the distribution is normal, every SD unit on the *x*-axis has a specific percentile which is always paired with them. Therefore, on a normal curve, 34.13% of the data lies between 0 and -1 (or +1), 13.59% between -1 and -2 (or between +1 and +2), and 2.14% between -2 and -3 (or between +2 and +3). The remaining 0.14% of the data lies below -3 (or above +3).

A limitation of using percentiles is that the same interval of percentile values corresponds to different ranges in absolute values for different measurements. For instance, increments from 85th to 90th percentile correspond to different ranges in subscapular and in triceps skinfold thickness. Even within the distribution of one measurement, same increments at different percentile levels could correspond to different changes in both *Z*-scores and absolute measures. In addition, it does not allow for quantifying the change in percentile values near the extremes of the reference distribution (e.g., people in the uppermost 1st percentile can have very different absolute values). For these reasons, we suggest that percentiles should not be used to assess change in status over time, while change in *Z*-scores is a better measure. *Z*-scores are more useful in research while percentiles are easier for use in clinical settings and by the public.

Z-scores and percentiles can be converted to each other, but the commonly used cut points of each are not at exactly comparable levels. For example, *Z*-scores of 2 and -2 correspond to the 97.7th and 2.3rd percentiles, while the 85th and 5th percentiles correspond to *Z*-scores of 1.04 and -1.65, respectively.

2.4 Selection of Anthropometric Measure Cut Points

In growth references and standards based on international data or those from individual countries, *Z*-scores of +2 and -2, and/or certain percentiles (e.g., 5th, 85th, and 95th), have often been chosen as cut points to classify problematic growth/nutritional status such as malnutrition or obesity. These criteria are based on statistical distribution rather than on the risks of health outcomes (see Table 2.2). Ideally, the criteria should be established based on their associations with higher health risks, and cut points should be chosen for the particular purpose. The classification of "higher risk" individuals and population groups should be based on the evidence of increased risk for morbidity, mortality, or/and impaired function performance (WHO 1995).

However, to assess the relationship between different indicators and health outcomes is often more difficult in children than in adults. It is even harder to choose cut points for "higher risk". In children, two types of health outcomes need to be considered for studying the association with anthropometric measurement/indicators: (a) the short- and intermediate-term health outcomes during childhood and adolescence, and (b) long-term health outcomes in adulthood. Before well-designed long-term longitudinal studies provided sufficient information for these purposes, the International Obesity Task Force (IOTF) recommended sex-age-specific cut points for overweight and obese children and adolescents. These cut points are distinct from other statistical criteria based on growth reference/standards: they correspond to the overweight and obesity status in adulthood. (Cole et al. 2000, see below) Even with these unprecedented features, more solid evidence regarding the association between growth status and health outcomes are necessary.

In addition to connecting the deviations in anthropometric indicators and health/functional consequences, Pelletier suggested two more considerations for selecting cut points to assess growth and nutritional status: (1) Variation in age, maturation, gender, ethnicity, and other "technical" factors that affect anthropometry "independently" or in conjunction with health or social causes or consequences; and (2) The intended or potential applications of the anthropometric cut points, such as clinical diagnosis, policy formulation, social utility as well as advocacy for particular problems and solutions. (Pelletier 2006) He further argued that different indicators and cut points are needed for different application purposes. However, this notion may not be agreed upon by various user communities, including international expert groups, because universal cut points of simple indicators are considered easier to use and better for international comparisons.

Nevertheless, given the increasing understanding of the complexity of assessing children's growth and the new reality of a growing global obesity epidemic, as well as that many developing countries are facing a double burden of under- and over-nutrition problems, the international community and the public might take a new position if appropriate single cut points for simple indicators cannot be developed (Wang et al. 2006). For example, although the WHO has been recommending to use the BMI cut points of 25 and 30 for adults to classify overweight and obesity since the mid 1990s (WHO 1995), later research suggested that different BMI cut points may be more appropriate for specific populations and for different purposes, for example, lower BMI cut points of 23 and 25 for some Asian Pacific populations (Inoue et al. 2000; WHO Expert Consultation 2004).

2.5 Statistical Methods/Techniques Used for Curve-Fitting or Smoothing

Growth references/standards are used to compare an individual's measurements with that of the population. To develop sex-age-specific growth curves of critical percentile or *Z*-score cut points is important. Several different curve-fitting and smoothing techniques have been used in the development of existing growth references. When the 1978 WHO/NCHS growth curves were developed, a least-squares-cubic-spline technique was used (Hamill et al. 1979). The BMI and skinfold thickness percentiles being recommended by the WHO for international use were developed based on data collected in the US using the LOWESS method (LOcally WEighted regression Scatter-plot Smoothing) (Must et al. 1991). Several recent growth and obesity references, such as the 2000 CDC Growth Charts, the 2006 WHO Growth Standards, and the 2007 WHO Growth references (see below) used the LMS (lambda, mu, and sigma) estimation procedure or its modified approach to accommodate the distributions of different anthropometric measurements. The LMS method was introduced in the 1980s (Cole et al. 1992). For example, the CDC Growth Charts were carried out in

two stages: curve smoothing and transformation. The LMS method was modified for the transformation stage (Kuczmarski et al. 2002). In general, methods which summarize the centiles as an underlying distribution, such as the LMS method, "borrow strength" from neighboring ages and centiles and thus make better use of the data than the separate percentile-fitting methods used in the 1978 WHO/NCHS reference (Wang et al. 2006).

Based on the smoothed percentile curves over ages, the normalized distribution can be reconstructed and the *Z*-scores can be estimated. Theoretically, under normal distribution, each percentile should correspond to a *Z*-score (see below). Thus, the transformation procedure of the data is then carried out. For example, to develop the US 2000 CDC Growth Charts, Box-Cox transformation procedure and/or LMS (lambda, mu, and sigma) method were conducted for correcting the skewness of distribution at each age month, and then converting the percentile into *Z*-score. Given the LMS equation for specific indicator and the estimated parameters λ (L, the power in the Box-Cox transformation for "correcting" the skewness), μ (M, median), and σ (S, a coefficient of variation) for each age of month, child's anthropometric measurements can be converted to *Z*-scores and percentiles (see below).

These different methods may affect the final curves and cut points. For example, the BMI percentiles developed by Must et al. and Hammer et al. based on the First National Health and Nutrition Examination Survey (NHANES) data are not identical (Hammer et al. 1991; Must et al. 1991). Take the 5th percentile for 18-year-old white adolescents as an example, Must et al.'s figure vs. Hammer et al.'s was 17.5 vs. 18.3 for males and 16.9 vs. 17.2 for females, respectively. For the 95th percentile, the figures were 29.9 vs. 29.7 for males and 29.2 vs. 31.0 for females, respectively. Hence, different curve-fitting and smoothing techniques could lead to different results.

2.6 Practical Methods and Techniques: How to Use Growth References/Standards

To use a growth reference or standard to help assess individual or groups of children's growth and nutritional status, one will need to compare the subject(s)'s measure against the cut points provided in such growth references or standards, provided either in tables or growth charts (called growth curves). To use the growth charts, the users plot the observations on them. Since the growth charts were designated applicable to different sexes and age ranges, users need to choose the appropriate one.

Figure 2.4 is an example showing how to use the 2000 CDC Growth Charts to monitor a girl's growth in weight. This is a weight-for-age chart, and the girl's body weight measurements at 11 months after birth were plotted on the chart. The chart shows reference curves for the 5th, 10th, 25th, 50th, 75th, 90th and 95th percentiles from birth to 36 months old. These curves can be used to evaluate the position of a child's anthropometric measurement relative to the reference population. The girl's weight-for-age was first generally between the 50th and 75th percentile curves after birth, but faltered to below the 10th percentile after 15 months old. This indicated failure of growth and the need of more careful examination and care such as better nutrition and/or appropriate treatment to the underlying causes. Similarly, one can use the growth charts for different anthropometric indicators provided by other growth references and standards.

Another way to use the recent growth references and standards, in particular, for research, is to calculate exact percentile and *Z*-score values for the subjects' measured values, compared to the selected reference or standard. The WHO 2006 and 2007 growth standards and reference and the 2000 CDC Growth Charts utilized similar techniques of smoothing and transformation (the LMS method).

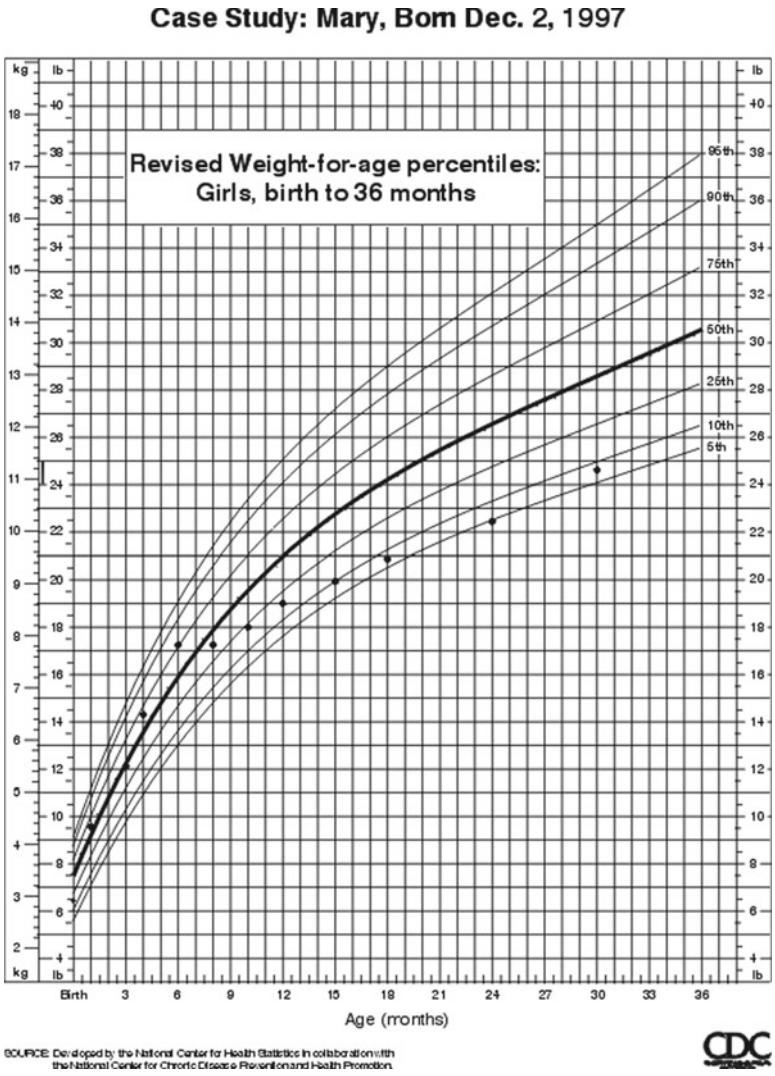

Fig. 2.4 An example from CDC of how to use growth chart to monitor individual child's growth (Adapted from http://www.cdc.gov/growthcharts/case_mary.htm). This figure uses a case to show how to apply a growth chart to assess a child's growth trajectory and health status. It shows a girl who had experienced growth faltering after age of 6 months. More details were provided in text (Reprinted from CDC website: http://www.cdc.gov/growthcharts/case_mary.htm)

They all provide the sex-age-specific LMS parameters that allow users to calculate the *Z*-score corresponding to each individual child's measured value. The formula for calculating *Z*-score is:

$$z = \frac{\left(y/M\right)^{L} - 1}{SL} \text{ when } L \neq 0; \quad z = \frac{\ln\left(y/M\right)}{S} \text{ when } L = 0;$$

where y is the individual observation, while the LMS parameters for the individual's age and sex need to be applied. For example, to calculate the WHZ for a 60-month-old (or 5 year-old) boy with a body weight of 15 kg based on the 2000 CDC Growth Reference, the reference table of weight-for-age

children of 2–20 years of age should be used. The estimated LMS parameters for boys aged 60.0–60.9 months old are listed on the reference table as -1.000453886 for *L*, 18.48592413 for *M*, and 0.129879257 for *S*. Thus, the boy's WHZ is -1.79 according to the formula.

As for percentile, it can be calculated after the *Z*-score is obtained, because the distributions of anthropometric measurements are close to normal under the Box-Cox transformation. In the above case, where the WHZ is -1.79, the corresponding percentile is the 3.7th. Namely, within the normal distribution with a mean of 0 and SD of 1, the cumulative probability below -1.79 SD from mean is 0.037. This can be calculated using a statistical software or by looking up the *Z*-table. This boy's body weight was below the lowest 5% compared to 60-month-old boys in the 2000 CDC reference. If the CDC's weight-for-age chart for children aged 2–20 was used, this boy's body weight would be plotted between the 3rd and 5th percentile curves.

Additional attention should be paid to including the 2006 WHO Growth Standard's formulas to adjust distorted extreme values and the 2000 CDC Growth Reference's formula for special occasions when *L* parameter equals to 0 (CDC 2000; WHO MGRSG 2006a). Furthermore, the formula for *Z*-scores of different anthropometric indicators may vary in the 2006 WHO Growth Standards (WHO MGRSG 2006a). Users should read the manuals carefully before applying these formulae. Furthermore, even though the recent growth charts from the CDC and the WHO since 2000 are developed using similar statistical techniques, the reference populations and data used to develop them are quite different (see below).

2.7 The WHO Growth References and Standards

Since the 1970s the WHO has published several versions of growth references, recommended for international use to help assess children's growth and nutritional status. Thus far, there are three widely known and used versions: the 1978 WHO/NCHS Growth References (for children up to age 10), the WHO Growth References (for children and adolescents up to age 19), and the 2006 WHO Growth Standards (for preschool children, under 6 years of age).

Most of the earlier versions are based on growth references developed and used in the US. The US CDC NCHS developed growth references based on national survey data collected in the 1960s and 1970s. These NCHS Growth Charts included anthropometric measurements such as weight-for-height, weight-for-age, height-for-age, and head circumference-for-age. They were developed based on several national surveys (namely NHES II, NHES III, and NHANES I) and a local study for infants (the Fels Longitudinal Study). More details about the history of the WHO growth references are provided elsewhere (WHO 1995; Wang et al. 2006; WHO MGRSG 2006a).

2.7.1 The 1978 WHO/NCHS Growth References

In 1978, the WHO/CDC produced a normalized version of the US CDC/NCHS growth curves, showing *Z*-scores instead of absolute anthropometric values. It was called the 1978 WHO/NCHS Growth References, and has been widely used all over the world since then. However, it has a number of limitations (Wang et al. 2006). For example, one of its main limitations is about representativeness, because the growth reference for infants was developed based on data collected from the Fels Longitudinal Study, which followed mainly formula-fed children in an area in Ohio State in mid-west of the USA. Moreover, these children were followed with large time intervals, which

Table 2.3 Key anthropometric measures and indicators provided in recent WHO and US CDC growth references/standards

	2000 CDC growth reference		2006 WHO growth standards		2007 WHO growth reference
Applicable age range (years)	0–3	2–20	0–2	2–5	5–19
Length/height/stature-for-age	v	v	v	v	v
Weight-for-age	v	v	v	–	v
Weight-for-length	v	–	v	–	–
Weight-for-height/stature	–	v	–	v	–
BMI-for-age	–	v	v	v	v
Head circumference-for-age	v	–	v	–	–
Arm circumference-for-age	–	–	v[a]	v	–
Subscapular skinfold-for-age	–	–	v[a]	v	–
Triceps skinfold-for-age	–	–	v[a]	v	–

This table lays out the anthropometric measures included in the three sets of recent growth references/standards. The first two are widely used by people in different countries

"v" indicates available measures

[a]From 3 months to 5 years (CDC 2000; de Onis et al. 2007; WHO 2006)

provided insufficient data to describe the rapid and changing rate of growth in early infancy (Kuczmarski et al. 2002). Recent studies have shown that the growth pattern of breast-fed infants differed from that of formula-fed infants (Victora et al. 1998; de Onis and Onyango 2003). To overcome these limitations, new growth references and standards have been developed in the US in 2000 and by the WHO in 2006, respectively (see below).

2.7.2 The 1995 WHO Growth References

In 1995, a WHO Expert Committee reviewed existing growth references and research findings, and then re-endorsed the use of the 1978 WHO/NCHS Growth Charts. In addition, for adolescents, the committee recommended use of the sex- and age-specific BMI ≥ the 85th percentile and both triceps and subscapular skinfold thickness ≥ the 90th percentile for classifying "at risk of overweight" and "overweight" (WHO 1995). These percentiles were developed based on the US data. Previously the WHO had not made specific recommendation for adolescents. The committee acknowledged the weaknesses of the NCHS infant growth charts, and some potential problems when using these US adolescent BMI percentiles in other populations. For example, their predictability to future health risk and generalizability for children from developing countries was unknown. The committee recommended the use of these references on a provisional basis, until better reference data became available (WHO 1995).

2.7.3 The 2006 WHO Growth Standards for Preschool Children

On April 27, 2006, the WHO released new growth standards for children from birth to the age of 60 months (5 years old, see Tables 2.3 and 2.4). In order to establish growth standards for different races/ethnicities, the Multicentre Growth Reference Study (MGRS) recruited affluent, breast-fed, and healthy infants/children whose mothers did not smoke during or after delivery from six cities in

Table 2.4 Estimated children/adolescents' percentiles and *Z*-scores corresponding to the recommended BMI cut points for adults for the classification of thinness grade 2 (BMI < =17), overweight (BMI > =25), and obesity (BMI > =30)

This table summarizes the corresponding percentiles and *Z*-scores which correspond to the specific BMI cut-points at the age (e.g., 18 or 19 years old) of transitioning to adulthood

[a]WHO (2007)2007 growth reference, BMI equal to these cut points at age 19 years old (de Onis et al. 2007)

[b]The IOTF reference, at age of 18 years on each country's data set (Cole et al. 2000, 2007)

Brazil, Ghana, India, Norway, Oman, and the USA. This study included a longitudinal sample followed from birth to 24-month-old and a cross-sectional sample recruiting 18- to 71-month-old children. The MGRS data showed great similarities in growth across all study centers, with only about 3% of the total variation in growth was contributed by race/country. Hence, the multicenter data were pooled for a more powerful sample (WHO MGRSG 2006a). The data demonstrate that preschool children in different regions of the world have the same growth potential to achieve similar levels of heights and weights when their nutrition and health care needs are met. However, this conclusion was based on children from birth to 6 years (72 months) of age. Genetic influence on inter-individual variation in the ultimate height in adulthood cannot be ruled out.

The WHO recommends these new standards in replace of the old versions for international use among preschool children, although some countries still use their own growth references/standards. The 2006 WHO Growth Standards include anthropometric indicators such as length/height-for-age, weight-for-age, weight-for-length/height, BMI-for-age, head circumference-for-age, arm circumference-for-age, subscapular skinfold-for-age, and triceps skinfold-for-age. Recumbent length-for-age was used for indicator of stature from birth to age of 24 months, while standing height-for-age from 2 to 5 years old. Due to the differential measurements of body length and body height, a 0.7 cm taller in length at 24-month-old was observed. Thus, to address this issue, weight-for-length for 0–2 year-old children and weight-for-height for 2–5 year-old children were presented on separate charts. Meanwhile, growth charts for all other indicators that involve length/height show a disjunction between the curves for 0–24 months-old and those for 24–60 month-old, like the BMI-for-age chart in Fig. 2.2. The WHO provides growth charts and tables of percentiles and *Z*-scores, separately for girls and boys. On the *Z*-score growth charts, the curves for 0, ±2, and ±3 SD from the age specific median of certain indicator were plotted. As for the percentile charts, five curves for the 3rd, 15th, 50th, 85th, and 97th percentiles were shown for each indicator. In the tables, the values of indicator at 0, ±1, ±2, and ±3 SD, and for percentiles of 1st, 3rd, 5th, 15th, 25th, 50th, 75th, 85th, 97th and 99th were provided for each age of month.

The 2006 WHO Growth Standards differ from the existing growth charts in many ways. They suggest "how children should grow", which is developed using a prescriptive approach, not just a descriptive one. They show that all children can attain similar levels of healthy height and weight as long as they have adequate feeding and health care. A key characteristic of the new standards is that it presumed breastfeeding as a biological norm. Furthermore, the pooled sample from the six participating countries creates better international standards, in contrast to the previous growth reference based on children from a single country. The standards can serve as tools for detecting both under-nutrition and obesity. The standards go beyond the previous references and include indicators like BMI and skinfolds. These charts are particularly useful in monitoring childhood obesity, which is relevant to public health in both developed and developing countries (WHO MGRSG 2006a; WHO 2006).

2.7.4 The 2007 WHO Growth Reference for School-Age Children and Adolescent

Based on recommendations made in 2006 by a group of international experts including the lead author, in particular, regarding the limitation of the previous growth references and the needs of better ones for assessing both overweight and undernutrition (Wang et al. 2006), the WHO released another set of growth reference for children and adolescents aged 5–19 years in 2007 (de Onis et al. 2007). To our knowledge, this reference has not been widely used yet. The references were derived based on the same US dataset as for the 1978 WHO/NCHS growth references but used different growth curve

smoothing techniques. The references include three indicators: BMI-for-age, weight-for-age, and height-for-age (Tables 2.3 and 2.4). For each indicator, charts and tables for percentiles and *Z*-scores were provided. The percentiles charts draw the 3rd, 15th, 50th, 85th, and 97th percentile curves, while the tables provided the values of anthropometric measures for more percentiles (1st, 3rd, 5th, 15th, 25th, 50th, 75th, 85th, 95th, 97th, and 99th). Regarding *Z*-scores of these three indicators, the curves for 0, ±1, ±2, ±3 *Z*-scores from median were shown on charts, and the values for these cut points were provided in tables.

The WHO recommended the cut points for overweight and obesity based on the BMI-for-age *Z*-scores. With the smoothing methods, it showed that the BMI-for-age *Z*-score = 1 at 19 year-old was 25.4 for boys and 25.0 for girls, which equals or is close to the WHO BMI cut point of 25 used in adults. Thus, the reference curve of *Z*-score = 1 was recommended to classify "overweight", while that of *Z*-score > 2 for classifying "obesity" based on the same idea. BMI-for-age *Z*-score < -2 and < -3 were set as the cut-points for thinness and severe thinness, respectively (WHO MGRSG 2006b).

2.8 The 2000 International Obesity Task Force (IOTF) Reference for Classification of Childhood Obesity

To define "overweight" and "obesity" among children aged 2–18 years, the IOTF endorsed a series of sex-age-specific BMI cut points. Based on data from multinational surveys, the cut points were developed from sex-specific BMI-age curves that pass through a BMI of 25 for overweight and 30 for obesity at age of 18 years old, respectively (Cole et al. 2000). Thus, these classifications of overweight and obesity in young people would be more biologically or pathologically meaningful compared to those references just based on distribution (i.e. percentiles or *Z*-scores). Given the concern for the differences among races/ethnicities, the reference was developed based on nationally representative data from six countries/regions: Brazil, Great Britain, Hong Kong, the Netherlands, Singapore, and the USA. The LMS methods with Box-Cox transformation was used to construct percentile curves. At age of 18 years, the BMI *Z*-score corresponding to 25kg/m^2 ranged from 0.91 to 1.68 across the six countries/regions, while the pooled data of the WHO MGRS data showed that this BMI for 19 year-old was about at the *Z*-score of 1 for boys and girls (Table 2.4). This IOTF reference used pooled data to calculate sex-age-specific BMI cut points for overweight and obesity.

The cut points were reported for children from 2 to 18 years old in every half year in age for clinical use. For epidemiological studies, Cole et al. recommended that the mid-year cut points could be used for the year group to obtain unbiased prevalence estimate (e.g., using the cut point at 7.5 years for the age group 7.0–7.9). However, these BMI cut points for obesity may be less precise than those for overweight because of the larger variations in the percentile curves for obesity among the 6 datasets.

The IOTF reference has been recommended for international use due to its unique strengths: First, it is based on large data sets from six countries or regions and covers different races/ethnicities. Second, the BMI cutoffs are linked to adult cutoffs for overweight and obesity, which are good indicators of risks for adverse health outcomes. On the other hand, there are also concerns about this reference (Wang 2004). There is great variation in the prevalence of overweight and obesity across the six countries/regions that the IOTF reference population was based on Cole et al. (2000).

Moreover, recently the same procedure was applied using the same data for generating the cut point curve for thinness in children and adolescents, using the WHO-recommended cut point for adults of BMI < 17 for grade 2 thinness (Cole et al. 2007). They intentionally used the term "thinness" rather than "underweight". Because these cut-points were only based on BMI-for-age, they want to make this distinct from wasting and stunting. The 2007 WHO Growth Reference also used the term thinness rather than underweight for BMI-Z < 2.

2.9 The US 2000 CDC Growth Charts

As mentioned above, the US CDC/NCHS has developed several versions of growth charts since the 1970s, and some of them had been recommended by the WHO for international use. In order to address the limitations of the previous growth charts, the CDC/NCHS released new growth charts in 2000, which were developed based on data of infants and children from birth to 5 years old in the Third National Health and Nutrition Examination Survey (NHANES III) to replace the Fels Longitudinal Study, and on the other data from earlier national surveys.

The growth charts consist of a series of percentile curves of selected anthropometric measures, including weight-for-age, length-for-age, weight-for-length, and head circumference-for-age from birth to 36 months of age. For children above 2 years old, there are weight-for-age, stature-for-age, BMI-for-age, and weight-for-stature charts for children taller than 77cm (Table 2.3) (CDC 2000; Kuczmarski et al. 2002). The charts are presented separately for 0–2 year-old and for 2–20 year-old children, thus, the issue of disjunction between length and height measurements at the age of 2 years is not observable on the charts.

Growth curves for these anthropometric measurements were laid out as two sets of charts, "Individual Growth Charts" and "Clinical Growth Charts." Each chart is printed on one page, namely "Individual Growth Charts." As for "Clinical Growth Charts", length/stature-for-age and weight-for-age were graphed on a same page, and so were the head circumference-for-age and weight-for-length charts displayed together. The growth charts and tables present the 3rd, 5th, 10th, 25th, 50th, 75th, 90th, 95th and 97th percentile curves. The 85th percentile curve is in addition provided, on the BMI-for-age and weight-for-stature growth charts for 2–20 year-old children because this is a recommended cut point for childhood overweight. Regarding the *Z*-score for the indicators, only tables provide the detailed corresponding values indicator-for-age at 0, ±0.5, ±1, ±1.5, and ±2.

2.10 Comparisons of Using Different International and Local Growth References/Standards

As many previous studies have used the earlier growth references and various recent and new growth references/standards will continue to be used in the future, it is important to know how comparable the results are if these references and standards are applied on the same study population. A number of studies have attempted to address this issue. Following highlighted some of the related findings (see Table 2.5 for a summary). Overall, they showed that the estimated unhealthy growth status can vary when different growth reference/standards are applied.

One recent study showed that the Bangladeshi, Dominican Republic, and North American/European children aged 0–12 months had higher prevalence of overweight and stunting but lower prevalence of underweight, when the 2006 WHO Growth Standards was used compared to the 2000 CDC Growth Charts. In addition, according to the 2000 CDC Growth Charts, these children's WHZ decreased as age increased but were relatively stable based on the 2006 WHO Growth standards (de Onis et al. 2006). The US children showed a higher prevalence in stunting but lower prevalence in wasting when using the WHO 2006 Growth Standards versus the 2000 CDC Growth Charts, but they used the percentiles as cut points (5th for undernutrition and 95th for overweight) (Mei et al. 2008). Schwarz et al., compared the prevalence of undernutrition among Gabonese children based on three growth references/standards, namely the 1978 WHO/NCHS, the 2000 CDC and the 2006 WHO ones. They found that the prevalence of wasting and stunting was significantly higher when applying the 2006 WHO Growth Standards among 3-month-old children, while for 15-month-old

Table 2.5 Comparisons of prevalence (%) of growth/nutritional status problems assessed based on The 1978 WHO/NCHS reference, The 2000 CDC Growth Charts and The 2006 WHO Growth Standards

Country/settings, data collection year, sample	WHO/NCHS (1978)	CDC (2000)	WHO (2006)	References
Bangladesh, 1996–1997 4,787 children aged 0–60 months	N/A	Stunting: 54.4% Wasting: 56.5%	Stunting: 60.1% Wasting: 52.9%	de Onis et al. (2006)
Gabon, 2002 (baseline) 289 children aged 3 months 289 children aged 15 months (at follow-up)	Stunting: 10–15% Wasting: 0.7% Stunting: ~30% Wasting: ~15%	Stunting: 10–15% Wasting: 1.0% Stunting: ~15% Wasting: ~20%	Stunting: 23.5% Wasting: 4.0% Stunting: ~30% Wasting: ~5%	Schwarz et al. (2008)
Madagascar, 2004 969 children aged 6–59 months	Stunting: 35.8% Wasting: 3.2%	Stunting: 30.0% Wasting: 12.2%	N/A	Roberfroid et al. (2006)
US, 1999–2004 (NHANES) 3,920 children aged 0–59 months	N/A	Stunting: 3.7% Wasting: 5.0% Overweight: 9.2%	Stunting: 7.0% Wasting: 2.8% Overweight: 12.9%	Mei et al. (2008)
Dominican Republic, 2004 10,381 children aged 0–60 months	N/A	Overweight: 6.4%	Overweight: 8.6%	de Onis et al. (2006)

This table shows selected studies that compared the results based on different growth references/standards, and they have revealed considerable differences. Except for the US study, stunting is defined as length/height-for-age z scores < –2, wasting as weight-for-age *z*-scores (WHZ) < –2, and overweight as weight-for-length/height *z*-scores >2. Findings in the US study were based on the 5th or 95th percentiles for weight-for-age, length-for-age, and weight-for-height, respectively

children, the prevalence of stunting was lowest based on the 2000 CDC reference (Schwarz et al. 2008). Comparing the 1978 WHO/NCHS Growth References and the 2000 CDC Growth Charts, Roberfroid et al. (2006) demonstrated that for children aged 6–59 months in Madagascar, the estimated prevalence of stunting and underweight were different. The prevalence of stunting was higher using the 1978 reference, while the prevalence of underweight was more salient when applying the 2000 CDC references.

These findings suggest that, when the CDC 2000 Growth Charts replaced the Fels Longitudinal Study with the NHANES III data, the reference was representative of a heavier preschool subpopulation. Thus, the prevalence of wasting became higher. It is important to consider the reference population and methods used for developing the references/standards when choosing a growth reference/standard for assessing problematic growth outcomes.

Table 2.6 summarizes the main references and classifications having been used to define overweight and obesity in children and adolescents. Table 2.7 shows that according to one of our recent studies, the obesity prevalence estimated for Chinese children aged 6–18 years old in Beijing could vary between 5.8% and 9.8%, but in relative term, by 69% (Shan et al. 2010). Prevalence of overweight in Dominican and the US children was lower when using the 2000 CDC Growth Charts than using the 2006 WHO Growth Standards, regardless of the cut points (de Onis et al. 2006; Mei et al. 2008; Table 2.5). These findings indicate considerable differences in the prevalence of overweight/obesity based on different references, and the need of more research in these areas to help understand and guide appropriate applications of such references in different populations and for various purposes (Wang 2004; Wang et al. 2006).

Table 2.6 Different classifications/references for child and adolescent overweight and obesity

Standards/references	Overweight	Obesity	Data and reference population	References
2006 WHO Growth Standards for preschool children[a]	BMI-for-age or weight-for-length/height *Z*-score > 2	BMI-for-age or weight-for-length/height *Z*-score>3	Multicenter Growth Reference Study	WHO Training Course (2006)
2007 WHO Growth Reference for school age children	BMI-for-age *Z*-score > 1	BMI-for-age *Z*-score > 2	Same data as the CDC growth charts	de Onis et al. (2007)
2000 IOTF Reference	≥BMI-for-age cutoffs derived from BMI-age curves passed BMI of 25 at age 18	≥BMI-for-age cutoffs derived from BMI-age curves passed BMI of 30 at age 18	Data from the US, Brazil, Britain, Hong Kong, the Netherlands, and Singapore	Cole et al. (2000)
US 2000 CDC Growth Chart	≥BMI 85th percentile	≥BMI 95th percentile	US NHANES data (1971–1994)	Kuczmarski et al. (2002)
Europe-French BMI reference	≥BMI 90th percentiles	≥BMI 97th percentiles	Data collected for the French population	Poskitt (1995); Rolland-Cachera et al. (1991)

This table compares the evolving definition for childhood problematic growth status in different growth references/standards. See Table 2.1 for the corresponding values between percentiles and *Z*-scores, e.g., a *Z*-score of 2 corresponds to the 97.7th percentile, and *Z*-score of 1, the 84th percentile

[a]The 2006 WHO Growth Standards for preschool children recommends using BMI-for-age or weight-for-length/height Z scores of 1–2 to classify "at risk of overweight"

Table 2.7 Prevalence (%) of overweight and obesity among Chinese children and adolescents aged 2–18 years old in Beijing based on four local and international BMI references (Shan et al. 2010)

Age group (years)	Overweight (not obese)				Obesity			
	IOTF	WHO	CDC	WGOC[a]	IOTF	WHO	CDC	WGOC[a]
2–5	7.6	3.7	8.0	No ref.	3.5	2.3	6.8	No ref.

All, 2–18	13.1	13.2	11.1	No ref.	5.6	8.2	9.0	No ref.

Data source: Shan et al. (2010)

This table demonstrates the different results in prevalence of childhood obesity when different growth references/standards were used. IOTF, the 2000 International Obesity Task Force reference; WHO, The 2006 and 2007 WHO standards/references; CDC, the 2000 CDC Growth Charts; WGOC, the local reference developed by the Working Group on Obesity in China, which corresponded to the BMI cut points of 24 and 28 at age 18, respectively. BMI cut points of 24 and 28 are used in China to define overweight and obesity in adults, respectively

[a]WGOC' BMI reference: BMI cut points were only provided for children at age of 7–18 years

In summary, key issues for consideration before one chooses and uses a growth reference/standard include: (a) Whether it is a reference population or optimal growth pattern that one wants to compare to? (b) Whether the plotting on the charts or calculating the exact percentiles/*z*-scores for individual children is more feasible and/or useful? (c) Whether percentile or *z*-score can serve the purpose of application? (d) What age-sex- and anthropometric indicator- specific references are provided? These issues also suggest the directions for future research, including validating the generalizability of existing reference/standards to different countries, and deciding the cut points for unhealthy growth status which associated with future health risk.

2.11 Applications to Other Areas of Health and Diseases

People can use the percentiles and *Z*-scores of anthropometric measures in various growth standards or references to assess children's growth and nutritional status problems including malnutrition (e.g., stunting, wasting, underweight) and overnutrition (e.g., overweight and obesity). In addition, percentiles of other health measures such as blood pressure has been used to help classify elevated blood pressure (or called "hypertension") in young people (National High Blood Pressure Education Program 1996). This means that blood pressure readings are ranked according to where they fall against the percentage of the reference population of all children, while taking into account variations in gender, height, age, and other developmental parameters. For example, in the USA, the updated blood pressure tables were developed based on the NHANES 1999–2000 data, and included the 50th, 90th, 95th, and 99th percentiles (NHLBI 2004). The 50th percentile indicates the midpoint of normal blood pressure range, and is additionally compared to earlier guidelines. "Prehypertension" is defined as average systolic and/or diastolic blood pressure (SBP/DBP) ≥ 90th and < 95th percentiles (previously defined as "high normal"). Hypertension is defined based on the 95th percentile, and the 99th percentile allows more precise staging of hypertension.

Summary Points

- Percentile and *Z*-score of anthropometry are statistical tools to help assess child growth and nutritional status, relative to a reference or standard population.
- Percentile and *Z*-score can be converted to each other when the distribution is normal.
- Percentile indicates the percentage of observations that fall below a certain value. It is easier to use and for the public to understand, but may not be a good quantitative tool.
- *Z*-score is the distance and direction of an observation away from the population mean. Although it is not very intuitively perceivable, this dimensionless quantity can be used for comparison across indicators and populations. Individual children's measurments can be transformed to *Z*-scores based on growth reference, and *Z*-scores can be used as a continuous variable in research.
- Usually a growth reference is developed based on data collected from a representative sample of a population and shows the growth pattern of the reference population, which may not be an optimal growth pattern.
- A growth standard derived from a healthy and affluent child population can be regarded as an optimal distribution of growth.
- Various statistical methods and techniques have been used for curve-fitting and smoothing to help derive the related cut points for anthropometric measures in existing growth references and standards. These methods/techniques can affect the derived cut points.
- The 2006 WHO Growth Standards for preschool children differ from the other existing references, and show "how children should grow." It is developed based on a prescriptive approach for evaluating children's growth rather than a descriptive one.
- The 2006 WHO Growth Standards provide a tool for detecting both under nutrition and obesity, and thus address the double burden of under- and over-nutrition problems. They are relevant to both developed and developing countries.
- The US 2000 CDC Growth Charts have a number of improvements when compared to earlier versions of CDC growth references, but may not be appropriate for use in other populations, in particular, developing countries.

- Prevalence of problematic growth or nutrition status patterns can be different when estimated based on different growth references/standards.
- More research is needed to assess and guide the appropriate application of international growth references and standards in different populations, in particular, in developing countries.

Acknowledgments This work was supported in part by research grants from the NIH/NIDDK (R01DK81335-01A1, 1R03HD058077-01A1, R03HD058077-01A1S1) and the Nestle Foundation. We also thank Irwin Shorr for his comments on an earlier draft of this chapter.

Chapter 3
Use of Bioelectrical Impedance: General Principles and Overview

Alexander Stahn, Elmarie Terblanche, and Hanns-Christian Gunga

Abstract The present chapter clarifies some of the basic concepts of bioimpedance and discusses its significance with regard to biophysical models and their limitations. The focus is on bioimpedance body composition models, which have become popular under the term Bioelectrical Impedance Analysis (BIA) and Bioelectrical Impedance Spectroscopy (BIS). The intention is to provide the novice reader who is unfamiliar with biophysics, electromagnetics, and circuit theory with a comprehensive, easy-to-follow, and interdisciplinary introduction to the technical and biophysical concepts underlying current BIA and BIS techniques. Such knowledge is considered important to carefully perform and interpret bioimpedance results in clinical and research settings. The main sections of the chapter build on each other in a logical order, but can also be used independently as future reference by the experienced reader. In brief, the present chapter starts with an explanation of the raw data obtained from bioimpedance measurements. This serves as a basis for reviewing the passive electrical properties of human cells and tissue and for showing how these properties can be represented by electrical equivalent circuits. This goes on to explain the frequency-dependent nature of the electrical properties of biological tissue and clarify the differences between single-frequency, multi-frequency BIA, and BIS. Subsequently, safety considerations and general measurement principles such as electrode arrangements are also addressed in order to highlight how deep-tissue measurements can be obtained non-invasively without the use of needle electrodes. This is followed by a detailed outline of the fundamental biophysical model underlying most bioimpedance body composition applications. The weak points of present biophysical models are identified by comparing conventional whole-body BIA approaches to alternative techniques such as proximal electrode configurations or segmental measurements. Examples are used to show how to improve segmental measurements by performing multiple measurements along the limbs, thus "slicing" the limbs in various cross-sections such as during MRI scanning. Finally, the chapter assesses the reliability of bioimpedance measurements by discussing several endogenous and exogenous sources of error, and concludes with a guideline for standardizing bioimpedance measurement procedures. This serves as the basis for a discussion of selected applications in the following chapters on bioelectrical impedance and is therefore intended to complement each other.

X	Reactance [Ω]
X_c	Capacitive reactance [Ω]
Z	General impedance (magnitude) [Ω]

Greek letters

ρ	Resistivity [Ω·m]
ε	Permittivity [$F \cdot m^{-1}$]
σ	Conductivity in general [$S \cdot m^{-1}$]
τ	Time constant [s]
φ	Phase angle [°]
ω	Angular frequency ($2\pi f$) [Hz]
Ω	Ohm

3.1 Introduction

Presently, the term bioimpedance measurements refer to all methods based on the characterization of the passive electrical properties of biological tissue. Some biological tissues show active electrical properties, as they are capable of generating electrical potentials, the passive electrical properties of biological tissues relate to their response to the injection of external electrical energy. Different measurement techniques and various bioelectrical properties form a collection of methods that are now employed for multiple applications. Generally, these methods can be classified according to the following four groups: transimpedance, transmission line, microwave, inductive, and finally a combination of the preceding. Furthermore, all methods can be based on either single- or multiple-channel measurements. The latter have also been associated with the term tomography as they focus on characterizing the spatial distribution of the passive electrical properties. Presently, single-channel transimpedance methods are most widespread due to their extensive research history and ease of application, and have become popular under the term bioelectrical impedance analysis (BIA). They reconstruct the passive electrical properties of biological tissue by injecting alternating currents into

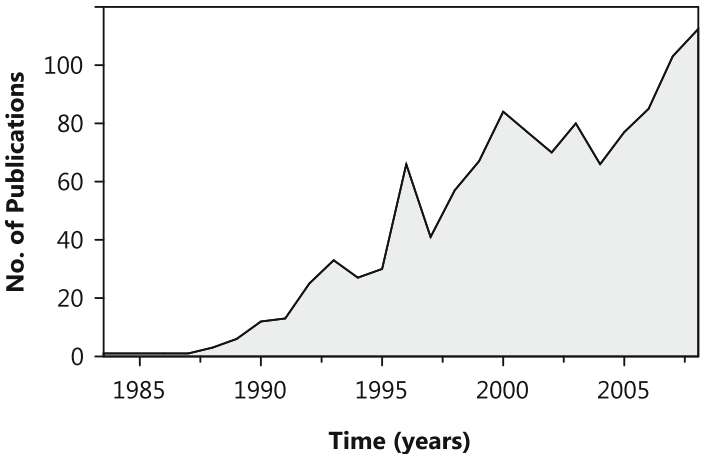

Fig. 3.1 Number of annual peer-reviewed publications on BIA since 1980. Results based on PubMed search using the following citation: (bioelectrical impedance analysis [Title/Abstract]) AND ("Year/MM/DD"[PDAT]: " Year/MM/DD "[PDAT])

an object via electrodes and measuring the potential differences between select points of interest. Because of the different passive electric properties of biological tissue and their frequency-dependent response to an alternating current, impedance magnitude and phase can provide diagnostic information about physiological properties and events of the body or body segment under consideration. While the basic idea of this approach can be generally adopted for cellular measurements (i.e. Coulter counter principle), volume changes (transthoraic impedance cardiography for stroke volume measurements), tissue classification and tissue monitoring (i.e. ischemia detection), most research and developments have focused on body composition applications. The significant impact of this technology can be traced to its main advantages:

- It is non-invasive.
- It is relatively inexpensive.
- It can be easily operated.
- It enables continuous (online) monitoring.
- It is rapid.
- It is portable.

These benefits are important characteristics in designing new medical instrumentation and are still a major reason for the permanent refinement of existing techniques and the investigation of new applications. A survey of publications on BIA, retrieved using Boolean methods through the internet database 'PubMed' revealed that the number of papers per annum between 1990 and 2000 increased seven-fold, and continues to rise gradually at a growth rate of nearly 22% (Fig. 3.1).

The need for further research on BIA has also been confirmed by various expert panels stating that a vast number of questions about BIA still remain unanswered today and the full range of applications of the technique has yet to be investigated.

3.2 Impedance, Phase Angle, Resistance, and Reactance

In spite of the growing accessibility and use of BIA, there are still a lot of misconceptions concerning the appropriate analysis of BIA results. The basic concept of in-vivo bioimpedance monitoring is the injection of an alternating current between two specific points of the human body (usually the wrist and ipsilateral ankle for body composition assessments) and the measurement of the resulting voltage

Table 3.1 Key concepts of bioelectrical impedance

Concept	Definition	Equation	Unit
Impedance (Z)	Electrical impedance is a measure of the total opposition of a conductor against an alternating current. This opposition is directly proportional to voltage across the two points and inversely proportional to the current between them. Given that the human body can be electrically modeled as an array of resistors and capacitors, the electrical impedance of the human body comprises both a real part (resistance R) and an imaginary part (reactance X). Since in an alternating-current circuit voltage and current change as a function of frequency, impedance comprises both information about both the direction (phase) as well as the magnitude of impedance. Consequently, it is expressed as a complex number which can be graphically depicted as a vector.	$Z = R + jX$	[Ω]
Magnitude of impedance (Z)	The magnitude of impedance is a scalar quantity as it only refers to the distance of the impedance vector. It can be calculated as the vector sum of resistance and reactance.	$Z = \sqrt{R^2 + X_c^2}$	[Ω]
Phase (φ)	Phase reflects the delay between voltage and current. Hence, it indicates to the direction of complex impedance. Graphically, it is represented as the angle between impedance and the x-axis.	$\varphi = tan^{-1}\left(\frac{X_c}{R}\right)$	[°]
Resistance (R)	Resistance refers to the real part of complex impedance. It is the opposition offered by a resistor to the flow of electrons due to friction. It is limited by the area and length of the conductor as well as its specific resistivity, the temperature-dependent intrinsic property of material to conduct a current.	$R = \rho\frac{l}{A}$	[Ω]
Reactance (X_c)	Reactance refers to the imaginary part of complex impedance. It is the opposition generated by the storage and release of charges by a capacitor in an alternating current-circuit. Given that reactance is inversely proportional to frequency it decreases with increasing frequency.	$X_c = \frac{1}{2\pi fC}$	[Ω]
Extracellular resistance (R_e)	At very low frequencies or rather zero frequency obtained from extrapolation by bioimpedance spectroscopy, an alternating current will be able to penetrate the cell membrane. Accordingly, a measurement of resistance is only a reflection of the extracellular space and therefore termed extracellular resistance.	$R_0 = R_e$	[Ω]
Intracellular resistance (R_i)	Intracellular resistance refers to the resistance of the intracellular space only. It cannot be measured, but computed from extracellular and infinite resistance using Kichhoff's laws.	$R_i = \frac{R_0 R_\infty}{R_0 - R_\infty}$	[Ω]
Infinite resistance (R_∞)	At very high frequencies or rather infinite frequency, cell membranes are continuously charged and recharged, so that virtually a current is also "conducted" in the intracellular space. Accordingly, resistance is a reflection of the extracellular and intracellular resistance. Infinite resistance can be extrapolated by bioimpedance spectroscopy and is related to intra- and extracellular resistance by Kichhoff's laws.	$\frac{1}{R_\infty} = \frac{1}{R_e} + \frac{1}{R_e}$	[Ω][Ω]

The table above summarizes important key concepts underlying bioimpedance measurements, starting with the most important key point, impedance. Phase-sensitive analyzers additionally allow the differentiation between reactance and resistance. Extracellular resistance and intracellular resistance require performance of a bioimpedance spectroscopy, where measurements are performed between a range of frequencies (15–500) between 5 kHz and 1 MHz

drop between these points. The data obtained from this measurement are impedance, phase angle, resistance, and reactance. To effectively interpret BIA results, a basic physical understanding of these concepts and their implications for physiologic processes is mandatory. To provide a simple and clear introduction to these concepts, they are first addressed in a general context from a physical perspective. In the following subsection they will then be linked to biological cells and tissues. The key concepts underlying these two subsections are summarized in Table 3.1.

3.2.1 Ohm's Law

Electrical impedance is a measure of the total opposition of a conductor against an alternating current. It is defined by Ohm's law, stating that the opposition of a conductor against an alternating current is directly proportional to voltage across the two points and inversely proportional to the current between them. Hence, if a known current is applied to a subject and voltage is measured, the underlying impedance can be calculated. Since in an alternating-current circuit voltage and current change as a function of frequency, impedance comprises information about both the direction (phase) as well as the magnitude of impedance. Whereas for direct currents resistance is simply defined as the ratio of voltage to current, the mathematical expression for impedance takes into account the dependence of voltage and current on frequency. This is summarized in the following equation:

$$Z = \frac{v(t)}{i(t)} = \frac{V_{\max}\sin(\omega t + \varphi_v)}{I_{\max}\sin(\omega t + \varphi_i)}[\Omega]. \tag{3.1}$$

where Z is impedance, $v(t)$, $i(t)$, $V_{\max}$, and $I_{\max}$ denote instantaneous voltage, instantaneous current, maximum voltage, and maximum current, respectively. t is the time since the waveform started, ω is angular frequency, and φ_v and φ_i are the phase angle of voltage and current, respectively.

While pure resistors offer resistance to a flow of current due to friction against the motion of electrons, electrical circuits can also comprise reactance, which can be understood as inertia against the motion of electrons. Taken together, resistance and reactance determine the direction and magnitude of impedance.

3.2.2 Resistance

Resistance is referred to as the real part of impedance and expressed in Ohm. Assuming uniform current density, resistance (R) can be defined by the physical geometry and resistivity of the conductor. Specific resistivity is commonly denoted by ρ (Ω·m).·It·is a measure of the material's ability to transmit electrical current that is independent of the geometrical constraints. The geometrical constraints are given by the cross-sectional area A (m^2) of the conductor and its length l (m) as indicated in

$$R = \rho\frac{l}{A}[\Omega]. \tag{3.2}$$

3.2.3 Reactance

The imaginary part of impedance is termed reactance and also measured in Ohm. Reactance can be traced to capacitive and inductive sources. The latter, however, do presently not play a significant role in most bioimpedance models, and will therefore not be considered in the following (Ward et al. 1999; Gluskin 2003; Riu 2004).

Capacitors are able to store and release charges, but do not permit a direct, physical flow of charges. However, by changing the polarization, they can virtually "conduct" current in proportion to the rate of voltage change. Hence, they will pass more current for faster-changing voltages (as they charge and discharge to the same voltage peaks in less time), and less current for slower-changing voltages. This frequency-dependent opposition is termed capacitive reactance (X_c) and defined as

$$X_c = \frac{1}{2\pi fC}[\Omega]. \tag{3.3}$$

where f is frequency (Hz), and C is capacitance (F). Capacitance depends on the dimensions of the capacitor as well as the composition between the capacitor plates. For simple structures (i.e. parallel-plate capacitors), capacitance can be defined as

$$C = \varepsilon_0 \varepsilon_r \frac{A}{d} [F]. \tag{3.4}$$

where A (m^2) is the cross-sectional area of the plates, d (m) is the distance between the plates, ε_0 is permittivity of free space (8.854 e−12 $F \cdot m^{-1}$), and ε_r is the relative permittivity of the permittivity of the material between the plates, i.e. the dielectric (dimensionless). The latter indicates the ease with which localized electrical charge can be polarized by the application of an electrical field, thus affecting C.

3.2.4 Impedance and Phase

Electrical impedance comprises both the opposition to current related to resistance and reactance.

In Cartesian form, electrical impedance can be defined as

$$Z = R + jX \, [\Omega]. \tag{3.5}$$

where Z denotes impedance, j is an imaginary unit ($\sqrt{-1}$) and is used instead of i to avoid confusion with the current symbol. Since, in alternating-current circuits, voltage and current change as a function of frequency, impedance is also dynamic because it changes in direction and amplitude. Consequently, impedance cannot be represented by a scalar quantity, which only reflects a single dimension. To represent both direction (i.e. phase shift) and amplitude (i.e. distance or magnitude) complex numbers are used to denote impedance. For these reasons complex impedance is sometimes written in bold to distinguish it from the magnitude of impedance. For simplification, Z is used to denote complex impedance as well as general impedance (magnitude) throughout in this text. Graphically, complex impedance can be depicted as a vector. It has a definite direction and a definite length. Thus, it comprises the information of both dimensions. The relationships between Z, R and X_c can also be graphically depicted in a complex plane. Figure 3.2 shows an example of such as plane for a resistor-capacitor (RC) circuit.

Due to the representation of R and X_c as vectors, the magnitude of Z can be calculated as the vector sum of its individual components. The geometrical relationship between R and X_c is also characterized by the phase angle (φ), which varies between 0 degree and −90 degrees. φ represents the delay between voltage and current, and is caused by the ability of the capacitor to store and release charges. For an ideal capacitor, φ is −90 degrees and Z is purely reactive. In contrast, if an alternating-current circuit is purely resistive, i.e. it consists of resistors only, the phase shift between the voltage and current is zero, and hence, Z is equal to R. As a result,

$$Z = \frac{v(t)}{i(t)} = \frac{V_{max} \sin(\omega t + \varphi_v)}{I_{max} \sin(\omega t + \varphi_i)} = \frac{V_{max}}{I_{max}} \angle 0 = \frac{V_{max}}{I_{max}} [\Omega]. \tag{3.6}$$

The frequency-dependent response of X_c is also reflected in φ. An example for a simple resistor-capacitor (RC) circuit in series is given in Fig. 3.3.

The behavior of the transfer functions can be explained straightforwardly. In a direct current circuit, once the applied voltage reaches a maximum, no more charges can accumulate on the plates of the

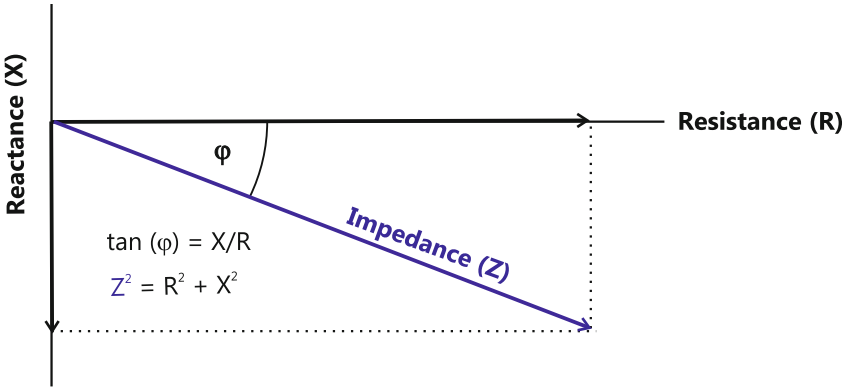

Fig. 3.2 Complex impedance plane of an RC circuit. Complex impedance can be graphically visualized as a vector. The vector indicates both magnitude (or distance) and direction (or phase) of impedance. The magnitude can be computed as the sum of the vectors of resistance (*R*) and reactance (*X*). The phase angle is expressed in degrees and can be calculated as the inverse tangent of *X* and *R*. Presently, except for a few exceptions *X* is expected to be purely attributed is to capacitive sources in human body composition models. Reactance is therefore also commonly denoted by the subscript c for capacitance (X_c)

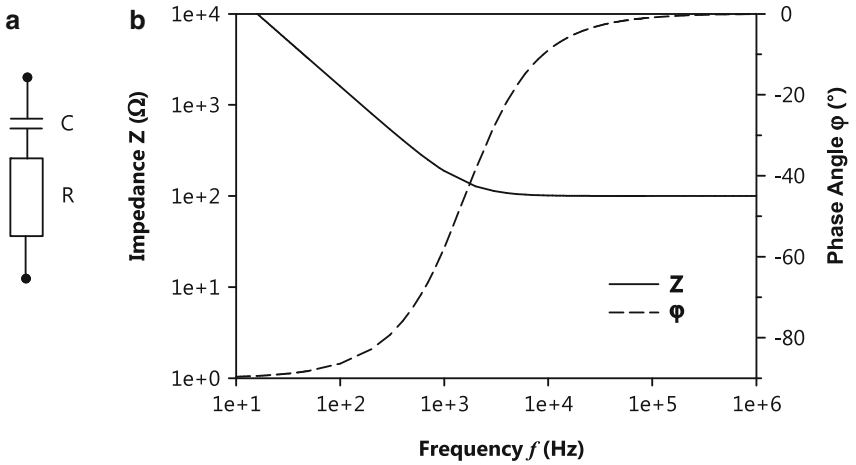

Fig. 3.3 Schematic presentation of serial RC circuit and its corresponding Bode plot. (**a**) Serial RC circuit (**b**) Bode plot for a serial RC circuit with $C = 1$ μF and $R = 100$ Ω, depicting magnitude and phase as a function of frequency. Abscissa and ordinate are both expressed in logarithm to base 10 for magnitude. Bode plot Magnitude *Z* (*solid line*), phase *φ* (*dashed line*)

capacitor. Hence, no further current will pass through the circuit. For these reasons, it is commonly said that capacitors block direct current. Similarly, in an alternating-current circuit, at very low frequencies, capacitors nearly block the current, as the periodic accumulation of charges on the plates of the capacitor occurs at a low rate. Hence, as frequency decreases and converges towards 0, the opposition of the capacitor to the flow of current increases. In contrast, at high frequencies, the capacitor is continuously charged and discharged with regard to frequency, creating a continuous flow of electrons. Thus, it is said that alternating current "passes" capacitors as a function of frequency. Finally, for frequencies converging towards infinity, the capacitor is short-circuited and the opposition of the capacitor diminishes. Consequently, as indicated in Fig. 3.3b the magnitude of impedance is equal to 100 Ω and the phase converges to zero.

3.3 Cells and Tissue and Their Electrical Equivalent Circuits

3.3.1 The Passive Electrical Properties of Biological tissue and Cells

Biological tissue can be defined as a group of similar cells and associated intercellular matter acting together to perform specific functions in an organism. Each cell is surrounded by a semipermeable phospholipid bilayer, called the cell membrane, which physically separates the intracellular components from the extracellular environment. It consists of two layers of phospholipid molecules, each having a hydrophobic tail pointing toward the inside of the membrane and a hydrophilic head forming the inner and outer surfaces of the membrane (Fig. 3.4).

Since the lipid bilayer is immiscible with the extra- and intracellular fluid, it has a static separation effect for water-soluble substances such as ions. Due to its thickness of ≈5–10 nm (Pocock et al. 1999), the cell membrane can therefore electrically be modeled as a capacitor.

On the other hand, both intra- and extracellular liquids contain ions that are free to migrate, and can therefore be considered as electrolytes. By far the most important ions for extracellular conductance are sodium (Na^+) and chloride (Cl^-). In the cytoplasm potassium (K^+), negatively charged proteins, hydrogen phosphate $\left(HPO_4^{2-}\right)$, sulfate $\left(SO_4^{2-}\right)$ and organic acids constitute the dominant charge carriers. The contribution of bicarbonate $\left(HCO_3^-\right)$ is marginal compared to overall conductivity. Indirect effects of $\left(HCO_3^-\right)$ on the conductivity of body fluids are, however, possible by influencing the ionic exchange across the cell membrane. For small changes in ion concentrations, a linear relationship with the changes in conductivity can be assumed (Scharfetter et al. 1997a).

In summary, due to the composition of the cell membrane and extra- and intracellular fluids, biological tissue would be expected to exhibit both reactive and resistive properties, when an alternating current is applied. If tissue impedance is measured over a broad frequency range between a few kHz and several GHz, such a frequency-dependent response can be observed. In addition, the passive electrical properties of biological tissue are not only highly frequency-dependent, but also vary significantly with the type of tissue. This is summarized for selected tissues at 5, 50 and 500 kHz in Fig. 3.5. It should be noted that conductivity is the inverse of resistivity.

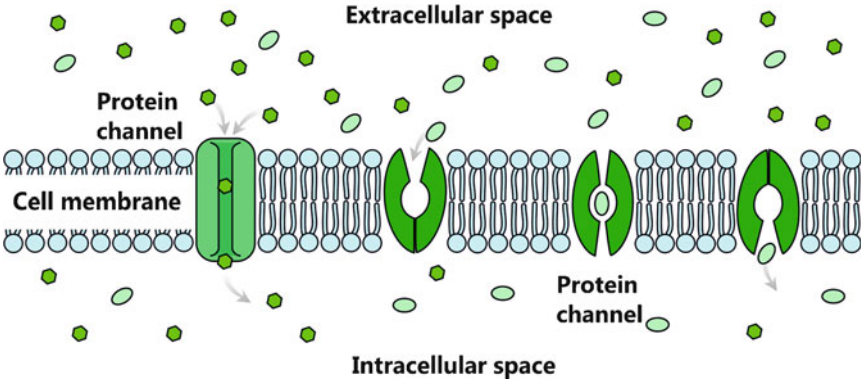

Fig. 3.4 Two-dimensional structure of the cell membrane. The basic structure of the cell membrane consists of two layers of phospholipid molecules. As a result, the cell membrane has a static separation effect for water-soluble substances such as ions. Exchange of ions is therefore facilitated via specialized proteins channels. The proteins embedded in the lipid bilayer may be peripheral (situated on either side of the membrane) or extend from one end to the other (transmembrane or integral proteins)

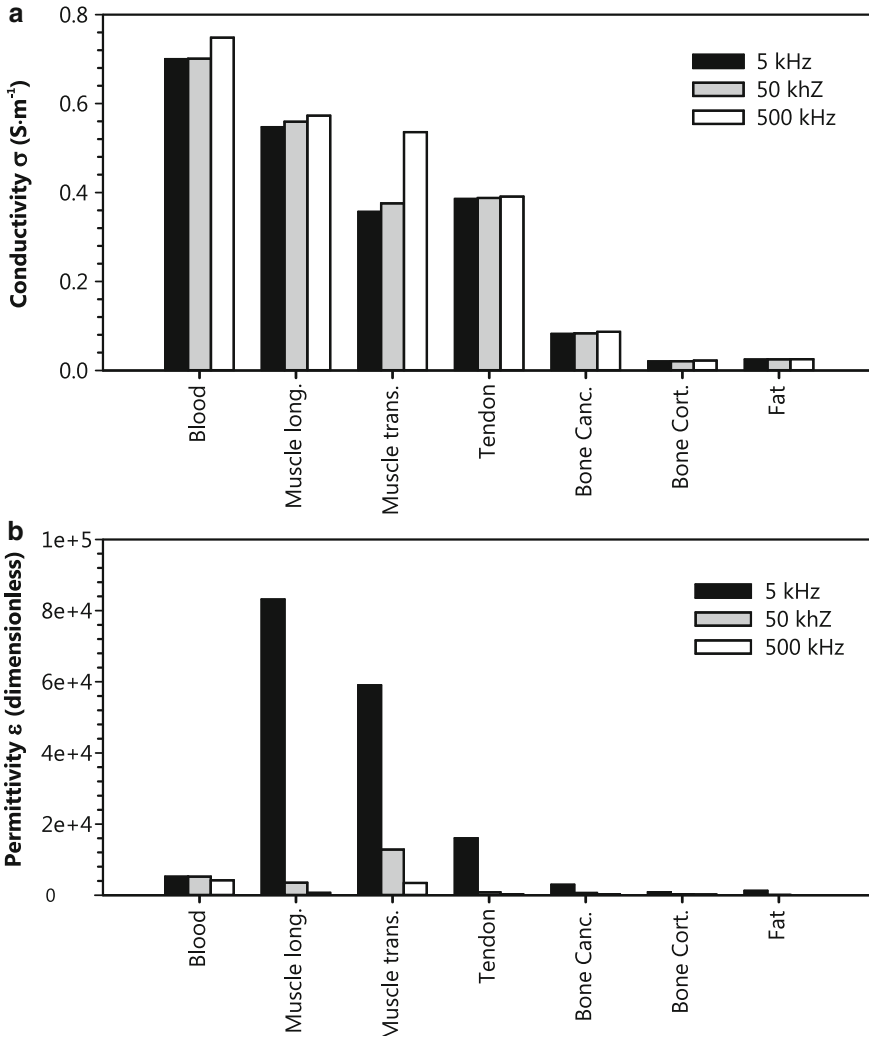

Fig. 3.5 Conductivity and permittivity at low and high frequencies for selected tissue samples. (**a**) Conductivity (inverse of resistivity) and (**b**) permittivity of selected tissue samples at 5, 50, and 500 kHz. Conductivity increases as a function of frequency. This effect is most pronounced for highly anisotropic tissue such as muscle fibers. In addition, the frequency-dependence for muscle tissue is also clearly observable for permittivity. As frequency increases, permittivity decreases. Data based on Gabriel et al. (1996). Muscle long., skeletal muscle tissue measured in longitudinal direction; Muscle trans., skeletal muscle tissue measured in transverse direction; Bone canc., cancellous bone; Bone cort., cortical bone tissue

As frequency increases, permittivity decreases while conductivity increases. The individual quantities, however, vary significantly. Due to their high content of electrolytes, blood and muscle have very high conductivity compared to fat and bone. Furthermore, it is clearly shown that some tissues exhibit strong anisotropic effects. For instance, the conductivity for muscle in longitudinal direction at 5 and 50 kHz is ≈1.5 times higher than conductivity for muscle in the transverse direction. This discrepancy can be explained by the alignment of muscle fibers and muscle cell membranes which exhibit high capacitive effects and therefore increase reactance when arranged perpendicular to the applied current. This is in accordance with the observation that at high frequencies (500 kHz) the difference in conductivity diminishes.

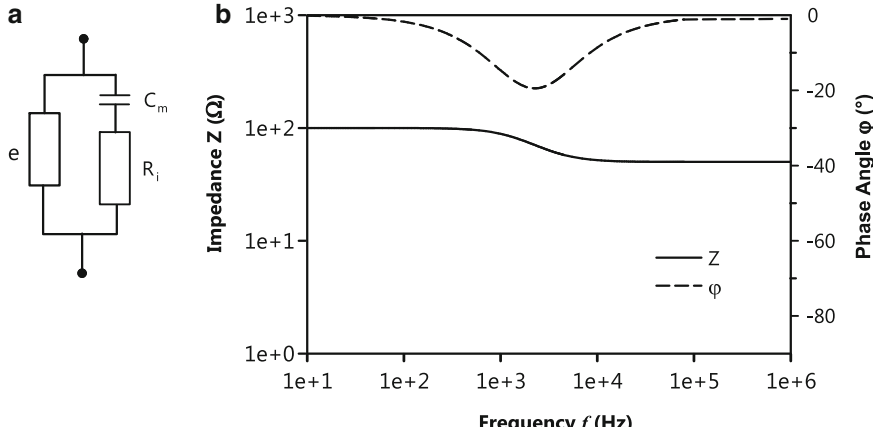

Fig. 3.6 Equivalent electrical circuit analogous to the Fricke and Morse model and its corresponding Bode plot. (**a**) Schematic presentation of equivalent electrical circuit analogous to the Fricke and Morse model. The extracellular compartment is represented by a resistor, and the intracellular compartment is represented by a resistor and capacitor in series. (**b**) Bode plot for a resistor (R_e = 100 Ω) in parallel with a series combination of a resistor (R_i = 100 Ω) and a capacitor (C_m = 1 μF). It should be noted that the electrical system depicted could also be represented by two resistors in series with a capacitor in parallel because it is possible to obtain the same immittance (impedance or admittance) values for both arrangements. In fact, the electrical properties of a system as a whole unit can be described by 'lumping' all its capacitive and resistive properties into a single equivalent capacitance and resistance component, respectively. The arrangement of these components in parallel or series depends on the investigator's choice. Though the parallel version is best characterized by admittance, the use of impedance is frequently employed in the present work for consistency and simplicity, in spite of the parallel electrical circuit depicted here. The impact of circuit choice is, however, important with regard to the imaginary and real part since their parallel and series equivalents are not identical. The quantities measured by bioimpedance analyzers yield components corresponding to their series equivalent (Neves and Souza 2000). R_e, extracellular resistance, R_i, intracellular resistance; C_m, membrane capacitance; Z, impedance; φ, phase

3.3.2 Electrical Equivalent Circuits of Biological Tissue

3.3.2.1 Fricke and Morse Model

In 1925, Fricke proposed a theoretical model for the passive electrical properties of living tissues. Fricke and Morse (1925) found that their measurements on suspensions of red blood cells could be explained by a circuit consisting of a resistor in parallel with the series combination of a resistor and capacitor (Fig. 3.6a).

Due to the phospholipid bilayer, Fricke and Morse assumed that the cell membrane could be modeled by a capacitor (C_m). Furthermore, they represented the intracellular and extracellular electrolytic medium each with a pure resistor (R_i and R_e respectively). This means that when a potential difference is applied across a cell suspension, C_m is charged by ions moving under the influence of the electric field. Consequently, at low frequencies, the membranes have high X_c so the cells behave as non-conductors in a conducting medium. Thus, most of the current is considered to flow around the cells, resulting in a relatively high Z and equal to R_e (Fig. 3.7). At high frequencies, however, X_c is low and an increasing amount of current can penetrate the membranes and flow through the relatively highly conducting cytoplasm of the cells. Thus, the current is able to flow through both extra- and intracellular spaces and Z is limited by the combined resistance of R_i and R_e in parallel.

An example of the resulting Bode plots for such an equivalent circuit is given in Fig. 3.6b with R_i = 100 Ω, R_e = 100 Ω, and C_m = 1 μF. As stated above, at very low frequencies or direct current

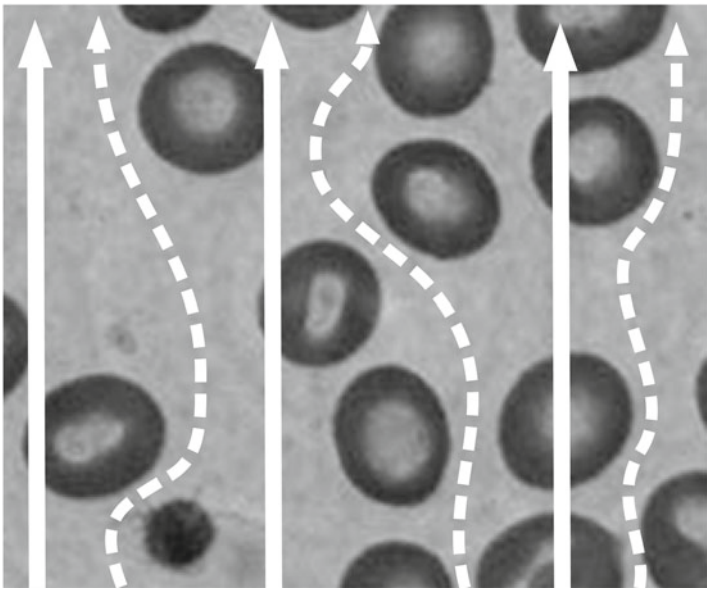

Fig. 3.7 Current flow at low and high frequencies. At low frequencies or direct current (*dashed line*) capacitance obstructs the current from penetrating the cells. At high frequencies (*solid line*), capacitance is short-circuited and the current can flow through both extra- and intracellular compartments

sources the current is blocked by the capacitive properties of the cell membrane and is only able to flow through R_e. Thus, for frequency converging towards zero, the phase is zero degree and Z is purely resistive. Hence, at zero frequency Z is equal to R and termed R_0. Accordingly, for the equivalent electrical circuit in Fig. 3.6a, it can be stated that

$$R_0 = R_e\ [\Omega]. \tag{3.7}$$

In the above example R_e is therefore equal to 1 kΩ. With increasing frequency, the cell membrane is gradually short-circuited until finally Z equals R_e and R_i in parallel. Thus, Z at infinite frequency is also purely resistive and termed R_∞. It can be calculated as

$$\frac{1}{R_\infty} = \frac{1}{R_e} + \frac{1}{R_i}\ [\Omega]. \tag{3.8}$$

3.3.2.2 Bode Plot Versus Cole Plot

The same information revealed by Bode plots can be displayed by plotting X_c vs. R on a complex plane. Such a plot's impedance, at least for the equivalent circuit in Fig. 3.6a, is given by

$$Z = R_\infty + \frac{R_0 - R_\infty}{1 + (j\omega\tau)}\ [\Omega]. \tag{3.9}$$

where τ is the relaxation time of the system. It is a constant, which takes into account that polarization, the field-induced disturbance of the charge distribution in a region, does not occur instantaneously. Instead, there is a momentary delay in polarization after the application of an electric field. If the frequency is low enough that all charges are given the required time to change their position, polarization is maximal. In contrast, at a higher frequency there will be less time for the charges to

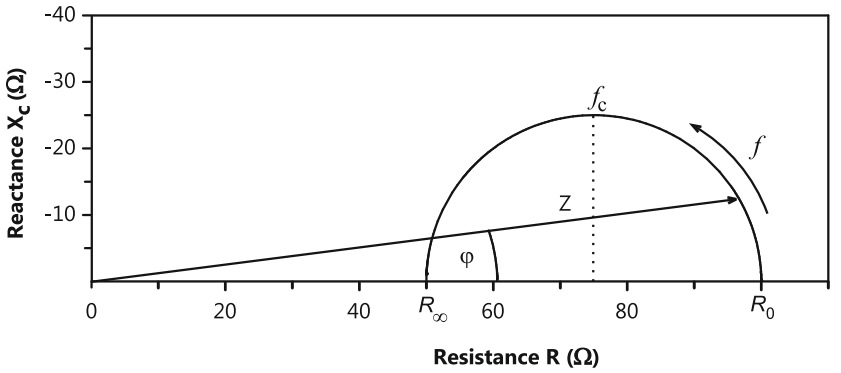

Fig. 3.8 Complex impedance plot for R-RC circuit indicated in Fig. 3.6. Reactance (X_c) is plotted vs. resistance (R) as a function of frequency. R_0 indicates resistance at 0 frequency and is expected to represent the extracellular space only. R_∞ is a measure of the total resistance offered by the extracellular and intracellular space. At very low frequencies, the impedance of cell membranes is high and thus blocks the conduction through the intracellular space. Hence, the measured impedance is purely resistive (R_0). As frequency increases, the current penetrates the cell membranes and X_c also increases. Once frequency has reached a certain threshold, i.e. the characteristic frequency (f_c), where X_c is at a maximum, X_c decreases when frequency is further increased as cell membranes "lose" their capacitive characteristics. As a result, at high frequencies Z is again purely resistive (R_∞). Furthermore, because the conducting volume increases with higher frequencies (an increasing amount of intracellular fluid is conducting the current) Z decreases. The impedance locus corresponds to data of the R-RC circuit indicated in Fig. 3.6 (R_e = 100 Ω; R_i = 100 Ω and C_m = 1 μF). Z, impedance; R_0, resistance at zero frequency; R_∞, resistance at infinite frequency; f_c, characteristic frequency

orient themselves. Hence, as frequency increases polarization and permittivity will decrease. The time period till the system relaxes toward a new equilibrium is characterized by the time constant τ. Generally, it is defined as:

$$\tau = RC\,[\mathrm{s}]. \tag{3.10}$$

and for the circuit in Fig. 3.6a it is given by:

$$\tau = \left(R_i + R_e\right)C_m\,[\mathrm{s}]. \tag{3.11}$$

To plot X_c vs. R, they need to be rationalized as follows:

$$R = R_\infty + \frac{R_0 - R_\infty}{1+\omega^2\tau^2}\,[\Omega]. \tag{3.12}$$

$$X_c = -\frac{\omega\tau\left(R_0 - R_\infty\right)}{1+\omega^2\tau^2}\,[\Omega]. \tag{3.13}$$

Plotting X_c vs. R yields a locus corresponding to a semi-circle with a center on the real axis at $(R_0 + R_\infty)/2$, and with a radius of $(R_0 - R_\infty)/2$, a high-frequency intercept at R_∞ and a low-frequency intercept at R_0 (Fig. 3.8). φ can be expressed mathematically as the inverse tangent of the quotient of X_c and R.

For convenience, it has been commonly adopted that the diagram is plotted in the first quadrant of the complex plane. Complex impedance plots have been referred to by a variety of names, such as 'Argand diagram', 'Wessel diagram', 'Nyquist plot' or 'Cole plot'. Though there is some criticism about the appropriateness (McAdams and Jossinet 1995), the terms 'Nyquist plot' and 'Cole plot' are now frequently used to refer to complex impedance plots in the field of bioimpedance research. The circle of the impedance plot indicates Z for frequencies between zero and infinity. As frequency increases, the tip of the impedance vector moves anti-clockwise around the locus and indicates the decrease of Z. Furthermore, at any given frequency, phase can be expressed by the angle between the

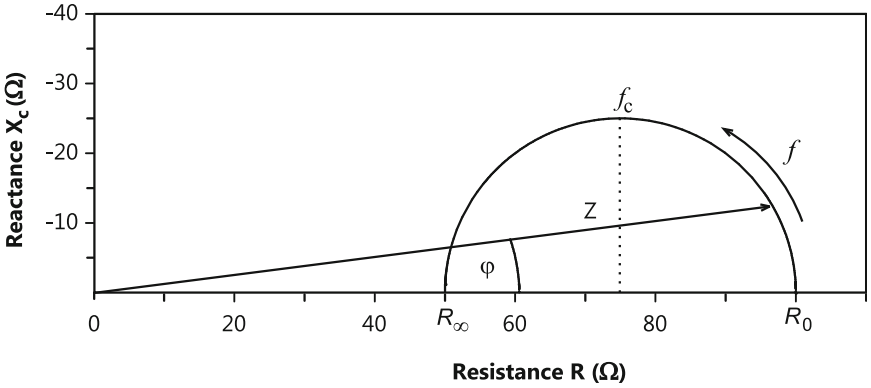

Fig. 3.9 Complex impedance plot of real whole-body measurement of a human subject (*white circles*) and its and its equivalent R-RC circuit (*continuous line*). X_c is plotted versus R for a range of frequencies between 4 and 1,024 kHz of a sample of an adult, healthy man (*white circles*). The *dotted line* shows the corresponding curve fit and extrapolation of R_0 and R_∞. R_e = 652 Ω, R_i = 1,164 Ω, R_Ω = 418 Ω, and C_m = 2.67 nF. The *solid line* indicates the impedance locus, which would have been expected according to the Fricke model with its center at 535 Ω (=$(R_0 + R_\infty)/2$ = (652 + 418)/2 = 535) and a radius of 117 Ω (= $(R_0 - R_\infty)/2$ = (652 − 418)/2 = 117). In comparison to the locus expected from the equivalent circuit corresponding to the Fricke and Morse model, the center of the locus obtained for experimental data is suppressed below the *x*-axis. The angle to the suppressed center is given by φ. *Z*, impedance; R_0, resistance at zero frequency (= extracellular resistance R_e); R_∞, resistance at infinite frequency (= sum of extracellular and intracellular resistance, i.e. $1/R_\infty = 1/R_e + 1/R_i$); f_c, characteristic frequency

impedance vector and the real axis, and R and X_c are obtained by the coordinates of the locus. Finally, f_c is termed the characteristic frequency ($f_c = 1/(2\pi\tau)$) and indicates the frequency at the peak of the locus, where X_c is at a maximum. Thus, the same information given by two Bode plots can be visualized in a single graph. The biggest advantage of complex impedance plots in bioimpedance research and applications is to mathematically derive R_0 and R_∞. They are two quantities providing important diagnostic information, but they cannot be measured directly because of practical constraints and the occurrence of multiple dispersions. For these reasons, a number of bioimpedance applications employ fitting algorithms to measured data between a few kHz and 1 MHz and extrapolate R_0 and R_∞.

3.3.2.3 Drawbacks of the Fricke and Morse Model

Though the Fricke-Morse model had been shown to be useful for describing the electrical properties of suspensions of red blood cells and some homogeneous tissues, it was also apparent from the first studies that the model was not accurately representing the complex behavior of other living tissues (Cole 1972). When experimental data for living tissue is plotted in a complex impedance plane, it can be observed that the center of the semi-circle is located below the real axis. A typical example for a complex impedance plot of real living tissue and its electrical equivalent R-RC circuit is given in Fig. 3.9.

Measurements were taken at 496 logarithmically spaced frequencies between 4 and 1,024 kHz. The dotted line indicates fitted data for *Z*. R_e was assumed to equal R_0, whereas R_i was calculated as:

$$R_i = \frac{R_0 R_\infty}{R_0 - R_\infty} [\Omega]. \tag{3.14}$$

Whereas the center of the equivalent R-RC circuit is located on the real axis at 535 Ω and a radius of 117 Ω, experimental data yields an arc with a corresponding semicircle that has a suppressed center and increased radius compared to its equivalent R-RC circuit. It could be speculated that the

equivalent circuit model proposed by Fricke and Morse has blatant simplifications. For instance, that the intracellular medium is usually treated as a pure ionic conductor. However, a number of additional cellular structures such as mitochondria, the nucleus, the endoplasmatic reticulum, lyosomes, and the Golgi apparatus actually confine the idea of the intracellular compartment as a purely conductive medium. Accordingly, the cytoplasm is actually a mixture of capacitive and conductive properties and it is only for reasons of simplicity that it is treated as pure electrolyte. Similarly, it should also be noted that a number of transmembrane protein complexes protrude through the lipid bilayer (see also Fig. 3.4). Electrically, these structural channels (or pores) represent shunt pathways in parallel with the lipid bilayer. Though important for the subject of bioelectricity, the membrane conductance is usually very low, and can be ignored in bioimpedance measurements.

Instead, the theoretical explanation of the discrepancy between the expected and observed impedance locus often includes the concept of a distribution of relaxation times. For an ideal dielectric, the real part of complex permittivity is assumed to be constant and the imaginary part equal to zero. A biological system, which could be characterized by a single relaxation time should be composed of identical structural elements, which do not exhibit any interactive effects. Real biological tissue is, however, structurally diverse, and individual elements such as particles in a concentrated suspension can also lead to a distribution of relaxation times in the bulk properties, even though the dilute suspensions of the same material might exhibit a single time constant (Foster and Schwan 1989).

3.3.2.4 Cole-Cole Model

In order to account mathematically for the 'depressed semicircle' observed for biological tissue, Cole and Cole (1941) extended the expression for describing bioimpedance data in the complex impedance plane according to the Fricke-Morse model (Eq. 3.9) by the parameter α.

$$Z = R_{\infty} + \frac{R_0 - R_{\infty}}{1 + \left(j\omega\tau_0\right)^{\alpha}} [\Omega] \tag{3.15}$$

where τ_0 is the mean or characteristic time constant and α is a dimensionless numerical distribution parameter related to the width of the particular distribution, having a value between 0 and 1. Geometrically, the effect of the parameter α is that the locus appears as an arc with its center below the real axis.

Since the Cole model is a mathematical model, it cannot be correctly represented by an equivalent electrical circuit. An analogue representation that is nonetheless used to symbolize the distribution of time constants is given in Fig. 3.10.

As stated above, one of the most commonly cited reasons for the α parameter is the heterogeneity of cell sizes and shapes in biological tissue (Ackmann and Seitz 1984; Foster and Schwan 1989). In this regard, it should be noted that α is empirically derived and a clear explanation of its physical meaning is still lacking today. Cole and Cole (1941) already emphasized the descriptive nature of α by stating that in the absence of any satisfactory explanation, the distribution function implied by α is nothing more than a means of expressing the experimental results. Due to the lack of a clear physical meaning for α, the Cole model has also been criticized for being a descriptive rather than an explanatory model (Moissl et al. 2006). Descriptive models characterize tissue electrically by means of both known and electric components and algorithms. These models primarily describe the observed phenomena without providing sound explanations related to the underlying anatomical structures. In contrast, explanatory models try to employ basic concepts of electrical theory to mimic similar properties in biological materials. However, the major drawback of explanatory models is their simplification of the material under study, jeopardizing a correct representation of the true tissue properties.

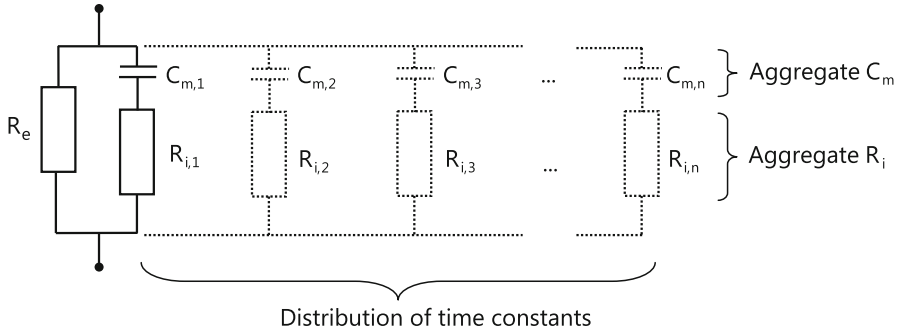

Fig. 3.10 Equivalent electrical circuit analogous to Cole model. The Cole-Cole model is a mathematical model and its electrical properties cannot be correctly represented by common electrical equivalent circuits. The distribution of time constants is therefore indicated by an infinite number of RC branches in parallel. An alternative way to physically realize the frequency-dependent capacitance is a so-called constant phase element. C_m, membrane capacitance; R_i, intracellular resistance of a single branch; R_e, extracellular resistance

Finally, various authors also noted characteristic deviations in actual whole-body impedance spectra from the theoretically expected arc at frequencies higher than 500 kHz (Van Marken Lichtenbelt et al. 1994; Stroud et al. 1995; Scharfetter et al. 1997b). Predominantly, this effect can be attributed to stray capacitance in the environment due to the presence of other electronic equipment as well as the interaction between electrode impedance and lead positioning or it might also have physiological meaning (Bolton et al. 1998). Accordingly, while the discrepancy of observed data from the expected Cole-Cole model might be simply due to a phase shift associated with the propagation delay of the signal along the measurement site, Scharfetter et al. 1997b) also suggested that the deviation might be explained by a difference in beta-dispersion center frequencies between blood and muscle. Given that muscle tissue and blood can be assumed to lie in parallel, two impedance spectra might be detected that do not fit a single Cole-Cole arc Scharfetter et al. 1997b). Irrespective of the underlying mechanism of the deviation, in settings where various electrical equipment are used, such as in intensive care units, artifactual instrument errors might be erroneously interpreted as abnormal fluid balances. In addition to improvements regarding instrument design such as active screening of the voltage sensing leads with preamplifiers at the electrode ends (Bolton et al. 1998), it has also been suggested to extend the classical Cole model (Eq. 3.15) by a correction factor (De Lorenzo et al. 1997; Bolton et al. 1998; Scharfetter et al. 1998). In addition, given that the frequency range up to 500 kHz seems to be high enough for most applications such as volume rendering, it has been recommended that data obtained in the high-frequency domain and/or limit bioimpedance measurements to frequencies lower than 500 kHz for these purposes be interpreted carefully (Scharfetter et al. 1998).

3.4 Principles of Bioimpedance Measurements

3.4.1 Terminology

The applied current lies between 200 and 800 μA, depending on the instrumentation employed. The frequency of the current varies according to the underlying biophysical principle between a few kHz and 1 MHz. Using phase-sensitive devices Z can be separated into its real and imaginary parts, i.e. R and X_c. For these types of analyses, the terms single and multi-frequency BIA as well as bioimpedance spectroscopy (BIS) are commonly used. Single-frequency BIA refers to the measurement technology

of performing measurements at a single frequency. In accordance, multi-frequency BIA implies a technique employing data collection at more than one frequency. Finally, in order to clearly distinguish multi-frequency BIA from BIA based on Cole plots or other models for fitting impedance data over the entire frequency range (between 1 kHz and 1 MHz), the term BIS has also been frequently used to refer to the latter. For reasons of clarity, this terminology is also followed in the present work.

3.4.2 Safety

Geddes and Baker (1989) provide a summary of the impact of alternating current sources on biological tissue. Alternating currents at power line frequencies (50–60 Hz) stimulate nerve and muscle cells with a threshold of perception of a few mA. Higher currents induce pain and involuntary muscle contractions. Yet, at substantially higher frequencies the large tissue capacitance raises the threshold of perception. Using tactile electrodes, the threshold of perception increases from 100 μA at 10 Hz to 2 mA at 1 kHz, to over 10 mA at 10 kHz (Settle et al. 1980). Consequently, the currents in the microampere range employed in bioimpedance monitoring present no hazard to the subject. Though no interference is anticipated for patients with cardiac pacemakers or defibrillators, the possibility cannot be categorically eliminated and for these reasons patients with implanted cardiac pacemakers or catheters filled with conductive fluid leading into the heart are usually excluded from bioimpedance measurements. In addition, according to the *NHANES Body Composition Procedures Manual* (2000) subjects with artificial joints, pins, plates, or other types of metal objects in their body should also be excluded from the measurement. Similarly, the effects of bioimpedance measurements in pregnancy have not been well researched and some manufacturers have recommended excluding pregnant women.

3.4.3 The Four-Terminal Technique

3.4.3.1 Electrical Properties of the Skin

The measurement of bioimpedance requires an interface between instrumentation and the human body or segment under study. The transfer between the ion-related transport of electric charges in the human body and the electron-based transport in the measurement equipment is achieved by the application of electrodes to the skin surface. In order to obtain a measurement of deep-tissue impedance the upper layers of the skin (epidermis and dermis) need to be bridged. Due to its multi-layered structure, skin demonstrates capacitive effects. Since skin is also penetrated by channels formed by sweat pores and hair follicles there is also a direct conductive connection between the upper layer of the skin (stratum corneum) and the subcutaneous tissue layers. The electrical properties of the skin can therefore be modeled by a capacitor in parallel with a resistor.

3.4.3.2 Needle Electrodes Versus Surface Electrodes

To minimize the effects of skin impedance on deep-tissue impedance measurements needle electrodes penetrating the upper layers of the skin were frequently used in the past. Due to subject discomfort and poor reliability this technique failed to gain large-scale acceptance. In order to minimize the effect of contact impedance related to surface electrodes, the following procedures can be taken into account. First of all, the respective skin areas are cleaned with alcohol to remove oil and dead tissue particles

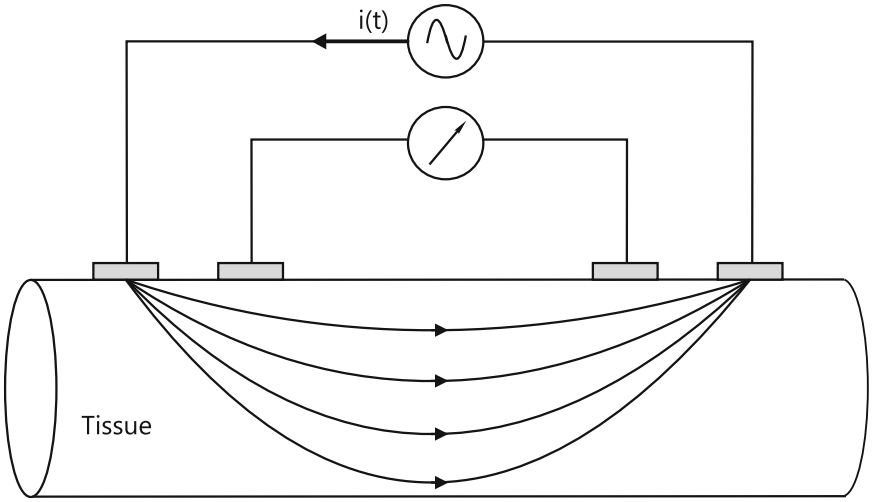

Fig. 3.11 Schematic presentation of tetrapolar electrode configuration and non-uniformity of current lines distribution for spot electrodes. Present bioimpedance technology usually employs a tetrapolar electrode arrangement. The current is introduced via the outer (distal) electrodes, while the voltage is picked up by the inner (proximal) electrodes. Using spot electrodes the current distribution is not uniform with current lines being most densely distributed in close proximity to the current injecting electrodes

which may negatively affect the conductive properties of the skin. Extensive alcohol treatment of the skin could, however, cause dehydration of the upper skin layers and induce contraindicative effects. Consequently, cleaning of the electrode sites should be restricted to a few seconds and given enough time to dry. Additionally, silver/silver-chloride (Ag/Ag-Cl) electrodes coated with an electrolytic gel reduce the polarization of the electrode to a minimum. The electrolyte fills the pores and wrinkles of the skin, and produces an optimal surface contact. The electrolyte also diffuses through the outer layers of the skin and improves their conduction, thus lowering the skin-electrode contact impedance. Since human electrolytes correspond approximately to a 0.9% sodium chloride solution, this would also be expected to be the ideal electrolyte for bridging the skin-electrode interface. Yet, in order to achieve lower contact impedances, gels containing 4% sodium chloride are commonly used for bioimpedance measurements (Fercher 1992). In spite of these measures, contact impedance remains relatively unstable. It depends on additional factors such as the pressure employed to apply the electrodes, skin thickness and skin secretions. For these reasons, the standard for performing bioimpedance measurements is the use of a four-terminal electrode set up, commonly referred to as a tetrapolar electrode arrangement. With this electrode configuration the current enters into the skin via two outer injecting electrodes (current electrodes), while the voltage signal is picked up by a second pair of two inner electrodes (voltage electrodes). Because of a high input impedance of the voltmeter, the voltage-sensing electrodes draw no or negligible current. Accordingly, polarization effects as well as the skin-electrode contact impedance are minimized and a measurement of deep-tissue impedance can be obtained. This electrode configuration is almost immune to movement artifacts or to changes in the interface impedance. For instance, Cornish et al. (1998) found that changes in skin temperature and hydration have no significant effect on bioimpedance measurements employing the four-terminal technique. Finally, it should be noted that the spacing between the two electrode pairs should theoretically be as large as possible. If the current electrodes are located further away from the voltage-sensing electrodes, the latter detect a signal in a region with a more uniform current distribution. In contrast, if the inner electrode pair is closely placed to the outer electrode pair, the current distribution will be less uniform since the current density is higher near the outer electrodes (Fig. 3.11).

3.4.3.3 The Human Body: An Isotropic Conductor?

It should be noted that the current flow may be constricted near the electrodes if the electrodes are small, yielding an additional constrictional resistance. Furthermore, the distribution of current lines depicted in Fig. 3.11 represents a simplified ideal, which is only true for isotropic conductors. An isotropic conductor exhibits the same electrical properties regardless of the measurement direction. However, human tissue and body fluids can be highly anisotropic. Figure 3.5 indicates that skeletal muscle can exhibit a 1.5-fold increase in conductivity when measured in transverse compared to longitudinal direction. The assumption of a unidirectional array of muscle fibers might roughly be acceptable for the limbs. Hence, they might be approximated by the cylindrical model of the human body with the different tissue compartments arranged in parallel. In the trunk, however, muscles lie perpendicular to the current distribution and conductivity is altered. Additionally, organs and adipose tissue depots are diversely arranged. They limit the development of homogeneous electric fields, which can be highly variable between and within subjects. This has been empirically confirmed by studies reporting a two- to fourfold difference between trunk and limb resistivity and a three- to four times higher coefficient of variation of trunk resistivity compared to limb resistivity (Baumgartner et al. 1990; Chumlea and Baumgartner 1990). Thus, the individual composition and distribution of intra-abdominal adipose fat depots and the dielectric properties of organs such as the lung as well as the orientation of muscle fibers jeopardize the assumption of a homogeneous current distribution. This problem has not been solved satisfactorily. Though the use of band electrodes would improve the development of uniform current distribution, the viability of the approach in terms of economic attractiveness, subject comfort, and simplicity of use would be lowered besides introducing other technical difficulties such as the reliability of electrode positioning. For these reasons the determination of trunk impedances should be interpreted with care when a parallel resistance lumped parameter model is used to represent the human body.

3.4.4 The Basic Biophysical Model

The total impedance of the human body against an alternating current is composed of several partial impedances related to different tissue types and fluid compartments. Assuming that the different types of tissue are aligned in parallel, that these tissues are an electrical source-free region, that they are mainly isotropic and conductive in character and that any magnetic fields can be neglected, the human body can be regarded as a complex conductor consisting of discrete conductive paths arranged in parallel. These parallel paths might include skeletal muscle, bone, fat, blood, neural, connective, skin and other tissues. The total resistance of the body can then be assumed to be the sum of the resistances of each of these discrete conductive paths. Figure 3.12 provides a simplified model describing the relation of the cross-sectional area A (m^2) and resistivities ρ ($\Omega \cdot m$) of these individual tissue components to their length l (m) and total resistance R_{tot} (Ω). Based on a rearrangement of Eq. 3.2, the term l/R_{tot} is directly related to the sum of the quotients of each discrete cross-sectional and its resistivity. Accordingly, total resistivity ρ_{tot} can also be expressed as the ratio of total cross-sectional area A_{tot} of the conductor and the sum of the quotients of the individual areas A and their respective resistivities ρ.

Given that an applied current always follows the path of the least resistance, R_{tot} is mainly a reflection of the extracellular fluid, blood, muscle and other highly conductive tissues since fat and cortical bone have a conductivity which is more than 20 times higher than that of muscle in longitudinal direction (see also Fig. 3.5). The measurement of R_{tot} can therefore provide structural information about body fluids and fat-free mass. Basically, the determination of conducting volume is based on

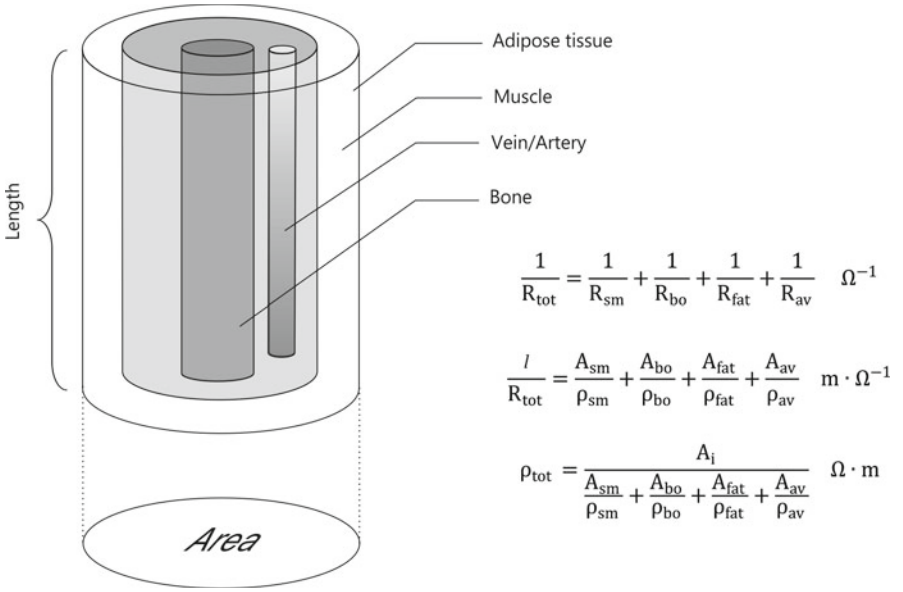

Fig. 3.12 A parallel resistance lumped parameter model of a body segment. The model assumes body segments to correspond to concentric cylinders of different tissues arranged in parallel when exposed to an electric current. Total resistance (R_{tot}) can be expressed as the sum of individual resistors arranged in parallel. Furthermore, R_{tot} is inversely related to the sum of the quotients of each discrete cross-sectional and its resistivity, whereas the latter is also directly proportional to length. Consequently, the total resistivity (ρ_{tot}) can also be expressed as the ratio of total cross-sectional area (A_{tot}) of the conductor and the sum of the quotients of the individual areas and their respective resistivities. l, conductor length; R, resistance; A, cross-sectional area; ρ, resistivity; the subscripts tot, sm, bo, fat, bl, neu, con, sk denote total tissue, skeletal muscle, bone, fat, blood, neural, connective, and skin tissue, respectively

the physical and geometrical constraints of resistance (Eq. 3.2) and the relationship between volume, length and cross-sectional area. Since volume V (m^3) is the product of length l (m) and cross-sectional area A (m^2), the latter can be defined as:

$$A = \frac{V}{l}\,[\mathrm{m}^2]. \tag{3.16}$$

Substituting Eq. 3.16 into Eq. 3.2 and simple algebraic rearrangement gives:

$$V = \rho\frac{l^2}{R}\,[\mathrm{m}^3]. \tag{3.17}$$

where the quotient of l^2 and R is frequently termed the resistance index (l^2/R) and can be considered as the fundamental quantity of structural bioimpedance applications (note that the dimensions are frequently expressed in centimeter instead of meter). Alternatively, R is sometimes used instead of Z, yielding the impedance index l^2/Z. Hence, if ρ is known, l and R (or Z) can be measured and subsequently used for the determination of conducting volume, i.e. the human body or body segment. These relationships, however, assume that the human body is an isotropic conductor (equivalent electrical properties regardless of the measurement direction) with homogeneous length and cross-sectional area and that the proportion of a specific tissue area is consistent along the limb. Since these assumptions are a grave simplification of the human body, alternative bioimpedance models have been proposed. These models include restricting measurements to body segments or even cross-sectional areas, modeling the limbs as truncated cones, or taking into account that

tissues other than intracellular and extracellular fluid also draw some of the current (Brown et al. 1988; Van Kreel et al. 1998; Fuller et al. 1999; Biggs et al. 2001; Stahn et al. 2007).

3.4.4.1 Descriptive Versus Explanatory Models

Most applications rarely derive ρ in the laboratory in vitro or empirically in vivo. Instead, ρ is usually determined by regression analysis, first using an established gold standard as a reference for the quantity of interest, which is then correlated to l^2/R (for a comparison of regression-based techniques and biophysical approaches based on causal relationships see Stahn et al. 2007). Frequently, the final prediction algorithms also include additional predictors such as age, body mass or gender to compensate for the violation of assumptions underlying the above-mentioned model. Some approaches have also employed artificial neural networks to relate the impedance index to the target quantity (Mohamed et al. 2003).

A number of terms have been used to indicate the distinction between these two approaches: empirical vs. structural models, statistical vs. causal relationships, indirect vs. doubly indirect, or descriptive vs. explanatory models. Irrespective of terminology, the major difference between descriptive and explanatory approaches is that the latter are based on well-established assumptions that do not require further development by statistical modeling. This distinction also highlights the major drawback of the use of regression analysis to derive prediction formulas. The relationships underlying a statistical model may be highly sample-specific. Consequently, the prediction equation becomes less stable in subjects differing from the sample underlying the original validation study. This drawback can be most problematic in multiple regression analysis. Certainly, it may seem quite tempting to include additional covariates to compensate for some of the violations underlying the respective biophysical model. However, though prediction accuracy might be improved, the resulting equations tend to become less generalizable since the underpinning relation between the dependent variable and the additional predictors may be highly sample-specific. Examples of bioimpedance applications based on either approach are provided and discussed in detail in the following chapters on bioimpedance of this book.

3.4.5 Whole-Body Versus Segmental Measurements

3.4.5.1 Distal Electrode Arrangement

Most BIA models employ a so-called whole-body approach in which the body is modeled as a single cylinder and electrodes are placed at the wrist and ankle of one side of the body (Figs. 3.13 and 3.14). This electrode configuration is referred to as distal bioimpedance measurement.

Based on the fundamental biophysical model underlying BIA (Eq. 3.17), impedance can be used to obtain an estimate of total body fluid volumes. Usually, conductive length is replaced by height because it is easier to obtain than the actual length of the conductor (sum of arm, trunk and leg length), and has been shown to only marginally lower the predictive potential of the index (Chumlea et al. 1988). The side of the body being measured does not have a significant effect on impedance in healthy adults (Baumgartner 1996). Contralateral electrode placement between the right wrist and left ankle or vice versa affect results only minimally (< 1.7%, Lukaski et al. 1985). For reasons of consistency and standardization, measurements at the right side of the body are usually considered as the norm (US Department of Health and Human Services. National Center for Health

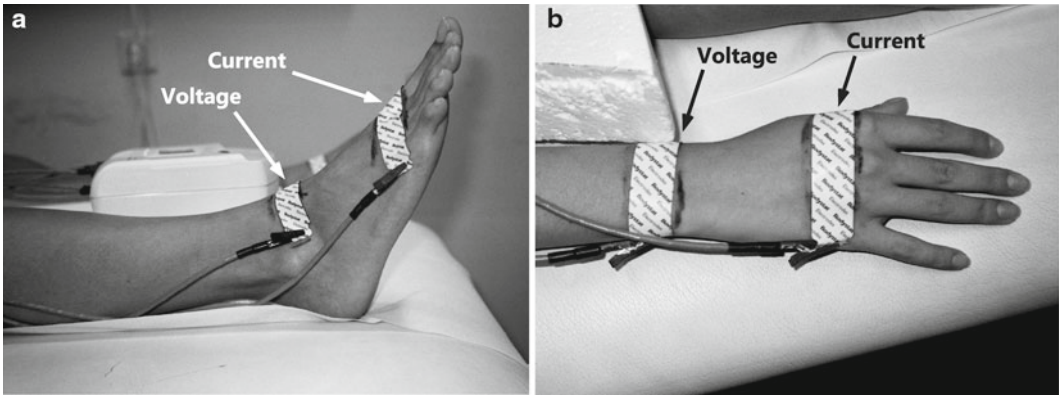

Fig. 3.13 Typical electrode arrangement. The figure displays a typical electrode configuration for a whole-body measurement. The outer (current or source) electrodes introduce the current, while the inner (voltage or sensing) electrode pair picks up the voltage. The source electrodes are placed in the middle on the dorsal surface of the right hand and foot just below the metacarpal-phalangeal and metatarsal joints, respectively. The sensing electrodes are positioned midline between the styloid processes of the ulna and radius on the dorsal surface of the wrist and midline between the medial and lateral malleoli on the dorsal surface of the right ankle. Further details of electrode configurations are given by Stahn et al. (2006) and Stahn et al. (2008)

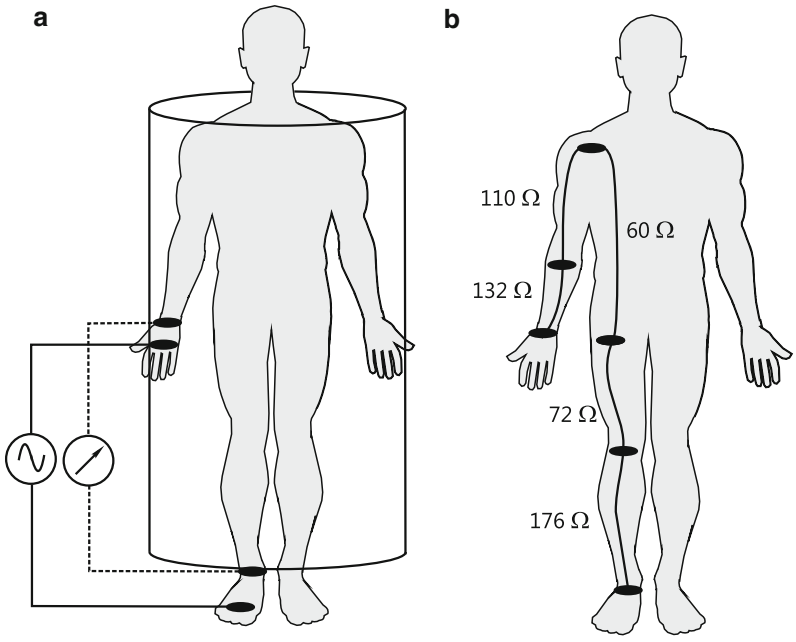

Fig. 3.14 (**a**) Whole-body bioimpedance measurement modeling the body as a single cylinder. Schematically illustrates that the conventional whole-body measurement configuration assumes that the human body can be modeled as a single isotropic cylinder with a homogeneous cross-sectional area. Consequently, assuming that bone, fat, connective tissue and skin draw negligible current, the resistance index (I^2/R) can be used to provide an estimate of different fluid volume compartments. (**b**) Body segment resistance distribution. Reveals the discrepancy between segment mass and segment resistance. Although the trunk contributes ≈50% of total body mass, due to its large area it only contributes marginally to total resistance (≈15%)

Statistics 2000). Yet, it should be noted that patients having experienced stroke, trauma or other conditions concomitant with atrophy of a single body side might exhibit significant discrepancies between body sides.

Limitations of Whole-Body (Distal) Measurements

As outlined in subsection 4.4, the distal measurement configuration is based on the assumption that the human body is an isotropic (equivalent electrical properties regardless of the measurement direction) conductor with homogeneous length and cross-sectional area. Obviously this assumption is incorrect since the human body is a complex of truncated cones, cylinders and ellipsoids. In particular, the cross-sectional area of the trunk is ≈5–10 times larger than those of the arm and leg (Organ et al. 1994). Given that the cross-sectional area of a conductor is inversely related to R, the trunk contributes ≈ 15% of distal whole-body resistance (R_{wb}), although it contains ≈ 50% of the body mass (Clarys and Marfell Jones 1986). The discrepancy between the relations of body segment masses to total body mass and segment resistances to R_{wb} are illustrated in Fig. 3.14b. Due to this disparity even large variations of trunk resistance might not be reflected in R_{wb}. Additionally, the change of electrode positions at the foot and hand can cause a change in R_{wb} exceeding that of the trunk. The trunk-limb relationship might therefore explain why some studies could not confirm the diagnostic potential of l^2/R (Diaz et al. 1989; Eckerson et al. 1992).

3.4.5.2 Proximal Electrode Arrangement

One approach to circumvent the strong influence of limb resistance on whole-body measurements is to employ a proximal electrode arrangement as suggested by Scheltinga et al. (1991). This configuration places the electrode pairs at the level of the elbow and knee, respectively, and is therefore referred to as proximal compared to a distal electrode positioning at the ankle and wrist. The current source electrodes can also alternatively remain in their distal position to avoid artifacts related to constrictional resistance (Deurenberg et al. 1995). Thus, the relative impact of the limbs on whole-body values is reduced. Scheltinga et al. (1991) found that the proximal approach accounted for 50% of the whole-body technique and that changes in fluid status were more accurately reflected by the proximal electrode arrangement. A clear superiority of the proximal compared to distal electrode placement is, however, questionable. Whereas some investigators could substantiate the advantage of the technique (Lukaski 1993; Gudivaka et al. 1994), other researchers did not confirm a significant improvement (Danford et al. 1992; Deurenberg et al. 1995; Turner and Bouffard 1998).

3.4.5.3 Segmental Electrode Arrangement

A more sophisticated approach to eliminating the disparity between body segments is to model the human body as five cylinders, i.e. two arms, two legs and a trunk with varying cross-sectional areas. Total conductive volume (V_{tot}) can then be expressed as

$$V_{tot} = 2\rho_{arm}\frac{l_{arm}^2}{R_{arm}} + 2\rho_{leg}\frac{l_{leg}^2}{R_{leg}} + \rho_{trunk}\frac{l_{trunk}^2}{R_{trunk}}\,[\mathrm{m}^3]. \tag{3.18}$$

where ρ_{arm}, ρ_{leg}, ρ_{trunk}, l_{arm}, l_{leg}, l_{trunk}, R_{arm}, R_{leg} and R_{trunk} refer to resistivity (Ω·m), length (m) and resistance (Ω) of arm, leg and trunk segments, respectively. Certainly, further refinement of this approach is possible. For instance, the limbs could be further differentiated in their lower and upper

parts, respectively. Some of such developments are therefore further discussed in subsection 4.5.3.5. There are several ways to relate segmental data to total conductive volume. Basically, resistivity of the three sections can be assumed to be either constant or different. Hence, in structural bioimpedance modeling some models either rely on a single resistivity for all body segments or assume resistivity to be segment-specific. Similarly, in empirically derived segmental bioimpedance models the sum of the (weighed) resistance indices can be regressed against a dependent variable that is used as a reference. Alternatively, multiple regression analysis can also be used to predict a dependent variable from the three respective body segments.

The Role of Uniform Current Distribution for Segmental Measurements

The potential of segmental measurements was first mentioned by Settle and his coworkers in 1980 and it was almost a decade later that Chumlea et al. (1988) first published a segmental approach for determining fat mass and fat-free mass. For this purpose, current source and voltage-sensing electrodes were placed at the shoulder and wrist, ankle and hip, and hip and sterna notch for determining R_{arm}, R_{leg} and R_{trunk}, respectively. Theoretically, the sum of ipsilateral R_{arm}, R_{leg} and R_{trunk} should be equal to R_{wb} measured between the ankle and wrist. Data by Chumlea et al. (1988) however exceeded R_{wb} by roughly 16%. Such a discrepancy was too large to be purely attributed to experimental error. Organ et al. (1994) showed that this phenomenon could be explained by the fact that data from dissimilar measurement configurations were compared. They further explained that the sum of R_{arm}, R_{leg} and R_{trunk} would only be equal to R_{wb} when the same current source and magnitude are achieved. The placement of the current source electrodes next to the voltage-sensing electrodes caused a larger potential difference of each segment, respectively. Similarly, as already suggested for the proximal electrode placement, current injection should therefore be maintained via the ankle and wrist. Nonetheless, such segmental measurements still suffer from two major drawbacks. Firstly, subject comfort is reduced since at least partial undressing is necessary for correct electrode placement. More importantly, however, reliability is put at risk since at least for less experienced personnel the correct location of specific landmarks at the shoulder, hip and chest is likely to be more prone to errors than the positioning of electrodes at the wrist and ankle.

Effective and Reliable Electrode Placement for Segmental Measurements

In order to avoid difficulties underlying segmental measurements requiring electrode placements at the limbs and trunk, first Patterson et al. (1988) and Patterson (1989), and later Organ et al. (1994), as well as Cornish et al. (1999, 2000) presented a segmental measurement technique which only requires the application of two additional electrodes at the equivalent positions of the hand and foot at the contralateral side of the body. This technique will now be explained in detail.

Assuming that the current between the ipsilateral wrist and ankle flows in a longitudinal direction, the equipotential lines should be perpendicular to the current distribution lines in narrow sections.[1] For this reason, it should be possible to obtain the same voltage signal at any specific anterior, posterior and lateral level. That means that there is a virtual connection between the left wrist and the right shoulder, allowing the determination of the segmental resistance of the right arm by measuring the voltage between the right and left wrist (Fig. 3.15).

[1] Equipotential lines indicate points with identical potentials. If an electrical charge is moved along an equipotential line, it experiences no electric force and hence no work is performed. Since there is no force driving the charges, there is no current flow between two points with the same potential.

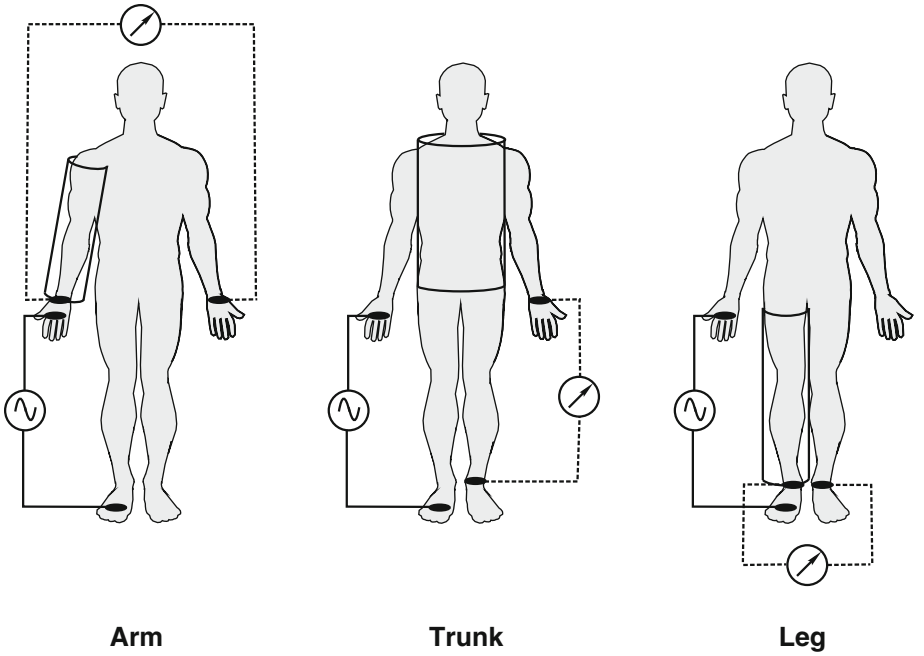

Fig. 3.15 Segmental bioimpedance measurements for right arm, trunk and right leg. This is an electrode configuration for segmental measurements that is based on the conventional whole-body measurement with two electrodes attached to the right hand and foot, respectively. In addition, only two extra detector electrodes are needed. These electrodes are placed at the equivalent positions (with regard to the detector electrodes of the right side of the body) of the left side of the body to determine segmental resistance of the arms, legs, and trunk, respectively. This measurement configuration neither requires the current injection electrodes to be moved nor to locate additional electrode sites other than those for the whole-body approach. To obtain separate resistance measurements of the right arm, leg and trunk the crocodile clips for measuring the potential difference are connected to the electrodes of the left and right wrists and ankles as indicated

In accordance, R_{leg} (right side) can be measured by sensing the voltage potential between the right and left ankle. R_{trunk} then only requires the determination of the voltage between the left wrist and left foot. Alternatively, the suggestion of Cornish et al. (2000) was to sense voltage between the contralateral wrist and ankle to first obtain the sum of R_{trunk} and R_{arm} (R_{trunk} and R_{leg}) and then compute R_{trunk} by subtracting R_{arm} (i.e. R_{leg}) from the sum of R_{trunk} and R_{arm} (i.e. R_{trunk} and R_{leg}). The ideal assumption of a current flowing only in a longitudinal direction is certainly not entirely valid. In regions where the electric field is not aligned in parallel with the longitudinal body axis, the equipotential lines are not linear and complex to determine. This difficulty increases in regions where the current has to pass regions with marked changes in cross-sectional area and where the poorly conducting tissues such as bone (e.g., shoulder and hip joints) complicate the development of a homogeneous electrical field. Despite these constraints, Cornish et al. (1999) empirically showed that the distal extremity of both the upper and lower limb is at the same equipotential as all parts of the upper and lower limb respectively. The variation in Z relative to the standard electrode site along the proposed equipotential lines was less than 1% and the standard deviation of relative Z did not exceed 2%. It should be noted that this deviation comprises both a technical measurement error as well as biological variations. Due to orthostatic effects substantial fluid shifts occur while lying supine, which might have confounded constant measurement conditions during that study. Thus, the observed discrepancies of 2% might simply be caused by a technical and biological variation.

Potential and Limitations of Segmental Measurements

The largest uncertainty underpinning the segmental approach can be traced to the volume estimation of the trunk. Given the anatomical complexity of the trunk, the assumption of isotropy is far from being fulfilled. Furthermore, given the disparity between segmental resistances and masses, small errors in R_{trunk} can lead to substantial artifacts in volume estimations of the trunk. In addition, the full potential of segmental measurements can only be achieved when the corresponding segmental lengths are also determined. This introduces additional measurement error, and if the electrode setup as suggested by Organ et al. (1994) is employed, the reference points for segmental lengths need to be determined without knowledge of the true conductive length.

Nonetheless, the segmental approach seems to be promising. Similar to the proximal electrode arrangement, it seems to be less prone to errors related to fluid shifts within body segments. For instance, Zhu et al. (1998a) demonstrated that in contrast to the whole-body approach the segmental technique is independent of the body position. In a study by Thomas et al. (2003) 13 impedance measurements were performed over a 60-min period while lying supine. While the whole-body impedance index linearly and significantly decreased by 6.6% after termination of testing, no significant changes were observed for the segmental approach. Some authors also suggested that the poorer performance of BIA in obese subjects might be related to the single-cylinder assumption underpinning the whole-body approach (Swan and McConnell 1999). Furthermore, a segmental approach would also be useful in the monitoring of body fat distribution and for classifying different types of obesity (gynoid vs. android obesity). In summary, a number of studies monitoring different fluid compartments during surgery and hemodialysis found the segmental technique to be a promising extension of the whole-body approach (Patterson et al. 1988; Patterson 1989; Bracco et al. 1996, 1998, 2000; Tatara and Tsuzaki 1998; Zhu et al. 1998b, 2000; Biggs et al. 2001).

Commercially Available Segmental Bioimpedance Systems

It is worth noting that the segmental approach also led to the commercial availability of a number of instruments, which combine a scale with a bioimpedance monitor. These instruments use tactile electrodes at the feet and allow bioimpedance measurements of the lower extremities. Similarly, some manufacturers also introduced hand-held devices to measure the bioimpedance of the upper extremities. As long as these two types of devices are not combined, the techniques are generally prone to errors associated with body fluid and tissue distribution since they both assume the upper or lower body to be representative of the total body. For instance, leg-to-leg instruments will hardly detect any changes in upper-body composition or reflect fat mass in android obesity, whereas hand-to-hand devices might not accurately measure fat in subjects with gynoid obesity. Thus, unless such approaches consider differences in fat mass distribution or limit the analysis of the target quantity to the segments measured, these methods should be carefully applied to assess individual body composition levels. A refinement of the technique that overcomes these drawbacks is a segmental eight-tactile electrode system, which is based on the segmental principle suggested by Organ et al. (1994), allowing the separate determination of the trunk and limbs, respectively. Recent validation studies have confirmed the validity of the approach, at least in healthy populations (Jaffrin and Morel 2009). Given its speed and ease of use it might promote the acceptability of BIA in the clinical, research and particularly epidemiological settings.

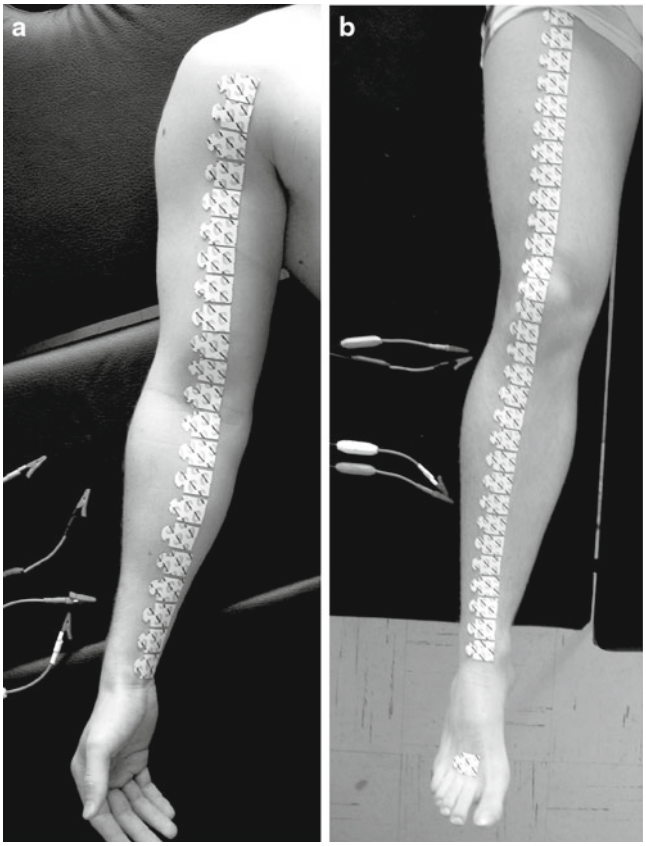

Fig. 3.16 Electrode configuration for the determination of limb resistance profiles. This figure displays the electrode configurations for the determination of limb resistance profiles of the arm (**a**) and leg (**b**), respectively

Directions for Future Research

Finally, ongoing research is trying to improve the segmental approach. For instance, Van Kreel et al. (1998) postulated that modeling the body segments as a combination of truncated cones and cylinders would more strictly reflect the geometrical properties of the human body. Though promising, this approach failed to improve the prediction of total body water as compared to whole-body measurements. A field of emerging interest is to restrict body composition analysis by bioimpedance measurements to specific body segments instead of using various segmental measurements to model whole-body composition. Limiting analyses to the extremities apparently avoids difficulties associated with assuming isotropy in the trunk. Furthermore, if measurements are reduced to small limb segments the assumption of representing the conducting volumes as cylinders will apparently gain significance. A further step is to perform local bioimpedance measurements to estimate skeletal muscle cross-sectional area. This type of measurement configuration has also been employed to provide diagnostic information on neuromuscular diseases (Tarulli et al. 2005), on induced muscle damage after prolonged physical exercise (Elleby et al. 1990) as well as on subcutaneous fat layers (Elia and Ward 1999; Scharfetter et al. 2001). Another approach combining the determination of individual measurements to cross-sectional areas and full segmental limb measurements is based on multiple measurements along the limbs (Fig. 3.16).

The basic idea of this approach is obtain a resistance profile of the limb, and approximate these data by a fitting algorithm so that it is possible to derive the resistance at any possible site along the limb (Fig. 3.17).

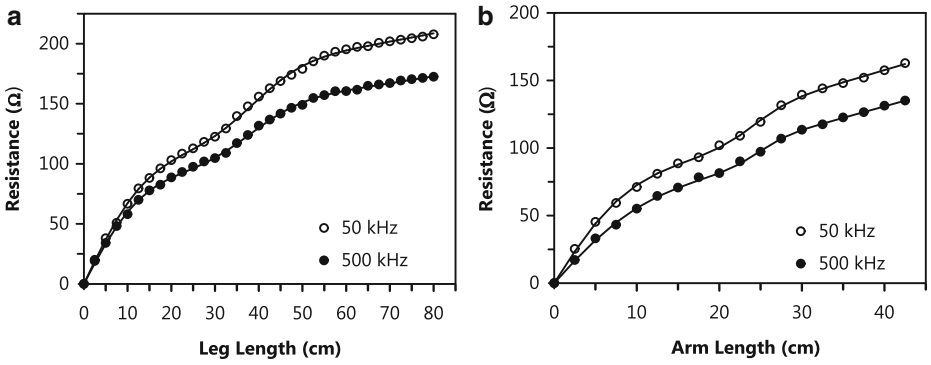

Fig. 3.17 Measured (*circles*) and curve-fitted (*continuous lines*) resistance profile of limbs. This figure illustrates typical resistance profiles of the leg (**a**) and arm (**b**) determined at 50 kHz (*white circles*) and 500 kHz (*black circles*) of a single subject. *Continuous lines* indicate curve-fitted data by two cumulative Gaussian functions plus a *straight line*. The goodness of fit for the model as determined by the coefficient of determination is 0.999 based on data published in Stahn et al. (2007)

Accordingly, assuming that the injected current is flowing in longitudinal direction only and that the resistivity of the tissue of interest is much smaller than that of other tissues, an estimate of the cross-sectional area (A) at a specific site (x) can be obtained from:

$$A(x) = \frac{\rho}{dR/dx}\,[\mathrm{cm}^2]. \tag{3.19}$$

where ρ (Ω·cm) is resistivity, and R (Ω) is the resistance of any specific site. Finally, the total limb volume can be computed as the integral over x of the estimated cross-sectional area. An example for an individual subject where skeletal muscle volume was determined for the leg and arm using this approach is given in Fig. 3.18.

The agreement between MRI-measured skeletal muscle mass and BIA is excellent in healthy populations. Furthermore, at least for the leg this approach is clearly superior to conventional segmental BIA for estimating skeletal muscle mass. The total error can be reduced by as much as 50% when compared to conventional segmental measurements. Furthermore, irrespective of the prediction accuracy the approach is promising as it does not imply the need of sample-specific regression equations. Yet, further validation of the technique is required to assess its accuracy in a variety of populations and to quantify the variability of specific resistivity and its impact on the estimation of skeletal muscle volume. Though the approach could also become more efficient by employing measurements at fewer electrode sites, it should be noted that measurement and its analysis are more sophisticated and time-consuming than conventional segmental BIA. Thus, in spite of the fact that the approach might serve several promising clinical applications and provide useful research opportunities, the trade-off between the gain in accuracy and the setback in efficiency should be carefully considered prior to the implementation of the technique.

3.5 Potential Errors in Bioimpedance Measurements

Consideration of Eq. 3.2 presents some of the major interferences on bioimpedance measurements: the length of the conductor, its volume and temperature-dependent resistivity, which is primarily determined by protein and ion concentrations (see also subsection 3.1). Moreover, since tissue is

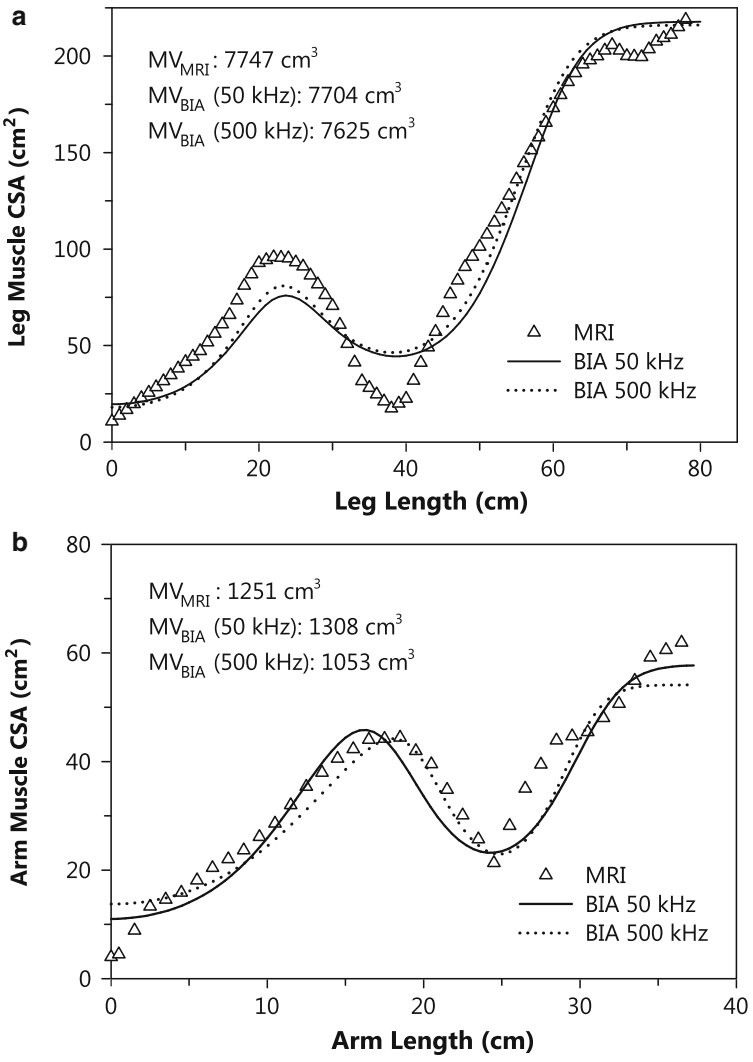

Fig. 3.18 MRI-measured (*triangles*) and BIA-estimated (*continuous and dotted lines*) muscle volume derived from limb resistance profiles. This figure shows the agreement between MRI-measured and BIA-estimated muscle volume derived from resistance profiles of the leg (**a**) and arm (**b**) of a single subject. MRI data is represented by *triangles*. *Continuous and dotted lines* refer to estimates of muscle volume based on bioimpedance measurements at 50 and 500 kHz, respectively. Leg muscle volume was 7,747, 7,404 and 7,625 cm^3 as determined by MRI, BIA at 50 kHz and BIA at 500 kHz, respectively. Arm muscle volume was 1,251, 1,308 and 1,053 cm^3 as determined by MRI, BIA at 50 kHz and BIA at 500 kHz, respectively (Based on data published in Stahn et al. (2007))

characterized by both capacitive and resistive properties, measurements are also dependent on the dielectric constants of the respective tissues. Any changes in one or more of these variables can therefore yield a change in bioimpedance.

3.5.1 Resistance Versus Impedance

It should be noted that some bioimpedance monitors do not allow distinguishing of the real and imaginary parts. Consequently, they consider the imaginary part of bioimpedance to be negligible and substitute Z for R. Though some authors report the fraction of X_c to be as low as $< 4\%$, individual

proportion can exceed 15% in young trained subjects (own unpublished observations). At either zero frequency (or very low) or infinite (or very high) frequencies, this difference is negligible since in this case Z converges toward R_0 and R_∞, respectively. At frequencies near the characteristic frequency f_c (30–100 kHz), however, a substantial amount of Z can be related to the capacitive properties of the tissue and results obtained by phase-insensitive instrumentation should therefore be interpreted with care. Consequently, the choice of Z or R should always be in accordance with the requirements of the regression equations employed.

3.5.2 Conductor Length

The length of the conductor is determined by the distance between the voltage-sensing electrodes or simply standing height, when a conventional whole-body approach is employed. Based on our own unpublished observations in 182 (96 men and 86 women) subjects, aged between 17 and 70 years with a body mass index ranging between 17 and 44 $kg \cdot m^{-2}$, height approximates about 94% of actual conductive length (sum of arm, leg, and trunk length). For the Reference Man (170 cm, 70 kg), and assuming R_e and R_i to be 500 and 100 Ω, respectively, this leads to an underestimation of 1.63 and 2.17 L for extra- and intracellular water by Hanai's mixture theory. Similarly, using a regression equation for total body water derived in representative sample (Sun et al. 2003) introduces an error of 3.18 L. These errors are, however, rather theoretical as such systematic bias can be corrected for by regression weights and/or resistivity values. Nonetheless, if the ratio of standing height to conductive length varies markedly between individuals, the conventional resistance index l^2/R can be prone to significant artifact error.

In accordance with that, measurement errors pertaining to height or body segments can confound the computation of l^2/R. Measurements of body lengths should therefore be performed by an experienced anthropometrist to the nearest millimeter. Moreover, due to the small diameter of the wrists and ankles in comparison to the remaining body parts, a deviation of the voltage-sensing electrodes of one centimeter can already induce changes in Z of nearly up to 5%, with distal electrode shifts causing substantially larger errors than proximal shifts (Elsen et al. 1987; Gualdi-Russo and Toselli 2002). While such a variation might still be acceptable for whole-body measurements, it should be noted that for segmental measurements (e.g., upper arm or thigh), this error can be inflated to 10% as a result of the shorter conductive length. This underlines the importance of choosing easily accessible and reproducible electrode sites, particularly when several measurements are performed such as during segmental analyses.

3.5.3 Spatial Geometry and Postural Changes

The subject's position during the performance of the measurement is a further important factor, which deserves clarification. Though a number of commercially available instruments combing a scale with a bioimpedance monitor employ lower-limb measurements in a standing position, the typical measurement procedure in most health or laboratory settings is characterized by having the subject lie in a supine position. On the one hand, this methodology is related to clinical conditions. On the other hand, this practice can be traced to the advantage of allowing subjects to remain in a comfortable, relaxed position. The major differences between whole-body impedance

while lying in a supine position and remaining in a standing position are related to local fluid shifts due to orthostatic effects. While a continuous increase in whole-body impedance can be observed for supine measurements (Roos et al. 1992; Shirreffs and Maughan 1994; Scharfetter et al. 1997b; Evans et al. 1998; Zhu et al. 1998a), whole-body impedance decreases while standing (Zhu et al. 1998a). Postural changes from standing to supine position result in rapid transfer of ≈0.5 L of blood from the extremities to the trunk (Kirsch et al. 1979). This fluid shift is most pronounced within the first 20–30 s after postural changes, after which it gradually slows down and nearly reaches a plateau after 30 min (Linnarsson et al. 1985; Shirreffs and Maughan 1994). Concomitant with this fluid shift is a reduction of filtration pressure in the extremities, causing plasma volume to increase, which, in turn, is compensated by changes in heart rate, blood pressure, and stroke volume. Treating the human body as a single cylinder with homogeneous cross-sectional area, measurements of whole-body impedance are insensitive to any fluid volumes changes. Consequently, decreases in extracellular water of up to 4.9% have been reported after 30 min of lying in a supine position (Zhu et al. 1998a). Since postural effects on bioimpedance measurements are most pronounced during the initial minutes after changing from standing to supine position (Scharfetter et al. 1997b; Shirreffs and Maughan 1994; Zhu et al. 1998a), a 10-min resting period prior to determination of bioimpedance measurements has been recommended. This period can be understood as a compromise between maintaining the efficiency of the technique and considering some primary physiological interference. Though an extended resting period would physiologically be favorable, this would undermine the quick character of the technique. However, as long as testing conditions remain identical, any fluid shifts associated with postural changes might not actually put the accuracy of the outcome variable at risk since the underlying model was derived exactly under these conditions. With regard to the effect of orthostatic fluid shifts on bioimpedance measurements it is worth noting that various prediction equations might suffer from systematic bias when applied in the clinical setting. Given that most regression equations have been developed in subjects who were measured within 10 min after lying down, these equations might cause substantial error when applied to persons who are restricted to bedrest for several hours or days (Kyle et al. 2004). At least theoretically though, a rather sound remedy for avoiding measurement artifacts due to peripheral fluid volume shifts induced by postural changes is to employ a segmental measurement technique (Zhu et al. 1998a) or placing the voltage sensing electrodes at more proximal positions such as at the elbow and knee (Scheltinga et al. 1991). A final aspect that needs to be taken into consideration with regard to body positioning is the placement of the limbs in relation to the trunk. A flexion in the elbow and knee joints as well as a change in the arm-trunk and leg-trunk angle can alter whole-body impedance by up to 10%. The smallest bias for arm-trunk angles is found at 10 ± 5 degrees, and for leg-trunk angles at 15 ± 5 degrees (Lozano et al. 1995). The cause for this phenomenon is not well understood. It can be speculated that any alteration of the joint angle induces a change in the electrical field as limb joints change shape. While it may seem obvious that limb extension should be limited, it is equally important that the limbs are not too closely positioned to the body to avoid capacitive couplings.

3.5.4 Ion Concentration

Given that conductivity is predominantly determined by the amount of ions (see subsection 3.1), any changes in ion concentrations can affect measurements of bioimpedance and the derived estimates of body composition. According to Scharfetter et al. (1995) a 5-mmol change in ion

concentration is associated with changes in extracellular water and intracellular water by about 2% and 5%, respectively. Consequently, assuming an extracellular and intracellular compartment of 17 and 25 L for the Reference Man, these changes correspond to errors of 0.34 and 1.2 L, respectively. While for the extracellular space such deviations might be tolerated, it should be noted that the relative error for estimations of intracellular water reaches 4.8%. The larger error for intracellular water is not unexpected. On the one hand, intracellular water can be derived as the difference of total body water and extracellular water, thus propagating the errors of extracellular and total body water measurements. On the other hand, if the volume calculations are based on Hanai's mixture theory (see Chap. 23, Selected Applications of Bioelectrical Impedance Analysis: Body Fluids, Blood Volume, Body Cell Mass and Fat Mass) both intra- and extracellular resistivities are required for the calculation, again propagating the errors underlying each parameter. Thus, the uncertainty of the volume estimations for intracellular water are generally higher than for extracellular water.

3.5.5 Tissue Temperature

Another major interference on bioimpedance measurements can be attributed to temperature. As temperature increases the viscosity of a solvent decreases. In turn, ion mobility increases, also causing conductivity to increase. According to Pethig (1979) the temperature coefficient of biological tissue is similar to that of electrolyte solutions and is about $-2\%\cdot°C^{-1}$ for conductivity and +0.5%/°C for permittivity at frequencies up to 50 kHz. These measurements, however, pertain to in-vitro measurements, and in-vivo studies employing skin temperature measurements have shown that impedance changes by $-0.39\%\cdot°C^{-1}$ to $-1.0\%\cdot°C^{-1}$ (Scharfetter 1999). The exact causes for the temperature dependence are still unclear. Increased perfusion, higher sweat gland activities, increased ion activities in the electrode coating, an increase of conductive volume (vasodilatation) and extra- and intracellular fluid shifts are some aspects that are discussed with regard to the increase of conductivity with increasing tissue and body fluid temperature (Caton et al. 1988; Gudivaka et al. 1996; Liang et al. 2000; Buono et al. 2004).

3.5.6 Sigman Effect and Hematocrit

The relationship between hematocrit (*Hct*) and conductivity has been well researched. Generally, it has been found that with increasing *Hct*, conductivity decreases. (Fricke and Morse 1925). Another aspect also related to the temperature dependence pertains to the Sigman effect. Basically the Sigman effect refers to the observation that conductivity changes as a function of blood velocity. Due to the observation that the Sigman effect is less prominent at lower *Hct* values (Valentinuzzi et al. 1996), it can be speculated that the increase of conductivity with increasing blood velocity is also related to blood cells. Though a full explanation of the Sigman effect has not been provided, it is assumed that with increased blood flow velocity erythrocytes orient themselves in parallel with the direction of the blood flow and present a reduced obstruction to the current flow compared to resting conditions. However, modification of the arterial lumen as well as cell clustering around the axial region of vessels might also play a role and the clear distinction of the separate contributions of these three events still needs to be investigated.

3.5.7 Ventilation

Since inspiration and expiration inflate and deflate lung volume, altering its dielectric properties, even changes in ventilation might theoretically affect bioimpedance. In fact, some researchers have suggested using transthoracic bioimpedance measurements for lung function monitoring (Valentinuzzi et al. 1996). In practice, the interference can be neglected as the reported dependence of *Z* on ventilation during conventional bioimpedance modeling seems to be negligible (Elsen et al. 1987; Baumgartner et al. 1988; Evans et al. 1998). Only for maximal inspiration and expiration does *Z* seem to be significantly affected by ventilation (Baumgartner et al. 1988; Gualdi-Russo and Toselli 2002).

3.5.8 Daily Activities, Nutrition and Menstrual Cycle

Besides the above-mentioned aspects, a number of investigators have reported additional significant exogenous factors influencing bioimpedance related to individual subject characteristics. Generally, any physiological change pertaining to one of the above-mentioned aspects can lead to variations in bioimpedance. Physical exercise, for instance, can substantially alter fluid volumes and electrolytes, thus also affecting *Z* (for review, see Stahn et al. 2006). Additionally, even the concomitant reduction in glycogen might influence the measurement. The numerous effects may also counteract and offset each other, causing *Z* to remain unchanged. Due to different adaptation processes following regular physical activity, the mechanisms involved in acute bouts of physical exercise may further contribute to within- and between-subject variability. Though small bouts of physical activity at a low intensity might not considerably alter bioimpedance monitoring, potential influences cannot be discounted. To reduce potential bias, physical activity should therefore be avoided at least 24 h prior to measurements.

Likewise, nutrition can play a role in bioimpedance monitoring. Its effect seems to be less prominent though. While electrolytic fluids have shown to both increase and decrease *Z* as a function of their ion concentrations (Roos et al. 1992; Asselin et al. 1998; Gudivaka et al. 1999), the effects related to the consumption of water seem to be less clear. Minimal changes in *R* or *Z* have been reported after consumption of 0.5–1 L of water or an electrolyte/carbohydrate drink (Rising et al. 1991; Evans et al. 1988; Dixon et al. 2006). However, Gomez et al. (1993) found a significant increase in resistance of 10 Ω after a period of four hours. Similarly, Gualdi-Russo and Toselli (2002) observed a significant increase of up to 17 Ω in Z 30 min after ingestion of 100 mL of Gatorade. Fogelholm et al. (1993) studied the effects of meals, high and low in electrolytes, on *Z*. Though average changes in *Z* were relatively marginal (+3 Ω to −5 Ω compared to median *Z* of 482 Ω), some individuals showed marked changes as compared to the fasting state (up to 20 Ω). These results were confirmed by Slinde and Rossander-Hulthén (2001), Gallagher et al. (1998) and Deurenberg (1988). However, some investigators did not detect a substantial influence of meals on bioimpedance (e.g., Chumlea et al. 1987). These contrasting results are likely to be explained by different methods and protocols and do not alleviate the impact of meal as a potential source of error in individuals. Certainly, the acute effects of nutrition on bioimpedance and their statistical significance occur to be a matter of sample size, study protocol, and methods (e.g., high/low electrolyte meal, total calories consumed, body size and composition, and time point of measurement). Thus, in individuals, nutrition, and particularly meals high in electrolyte content remain a potential source of error. For these reasons, it has recommended to perform bioimpedance measurements in a fasting state and to control hydration by limiting the amount and type of fluid consumption prior to the measurement (Fogelholm et al. 1993; Gallagher et al. 1998).

Table 3.2 Key features for standardization of bioelectrical impedance measurements

1.	Performance of repeated measurements at same time of the day.
2.	No large meals 2–4 h prior to testing.
3.	No coffee consumption >8 h prior to testing.
4.	No alcohol consumption >8 h (>24–48 h) prior to testing.
5.	Consumption of liquids limited to 1% of body mass 2 h prior to testing.
6.	No heavy physical activity >8 h (>12 h) prior to testing.
7.	No diuretic medications seven days prior to testing.
8.	Voiding immediately prior to testing.
9.	Removal of metallic jewelry prior to measurement.
10.	Fixed resting period (usually 5–10 min) in supine position prior to testing. Exact procedures should follow the manufacturer's specifications and/or the instructions provided by the literature underlying the prediction model employed.
11.	Constant body segment flexion (arm-trunk angles: 10° ± 5°; leg-trunk angles: 15° ± 5°). Supporting material (e.g., styrofoam blocks) can be used to maintain this body position. A piece of thin acrylic may be needed to be placed between the legs and/or the arm and trunk if be separated, respectively.
12.	Standard preparation of electrode skin surface (hair removal, cleaning with alcohol solution). No skin lesion at the site of electrodes.
13.	Use of electrodes that meet the manufacturer's requirements. Store electrodes appropriately (heat protection to maintain gel integrity).
14.	Position electrodes according to manufacturer's specifications or the instructions provided by the literature underlying the prediction model employed. Separation of current source and voltage-sensing electrodes by at least 5 cm.
15.	Maintaining thermoneutral conditions (constant ambient temperature and humidity).
16.	Calibration check of technical instrumentation prior to testing.
17.	Isolation of metallic objects and other electronic devices by a distance of at least 50 cm.
18.	Measurement of height or body segment length at least to the nearest 0.5 cm.
19.	Measurement of weight at least to the nearest 0.1 kg.
20.	Use only prediction models (equations) that have also been validated for the bioimpedance analyzer used or calibrate the instrument appropriately.

This table provides a list of general recommendations that should be considered for standardizing bioimpedance measurements in the clinical as well as the research setting. Further details regarding the standardization under specific clinical and disease conditions are provided by Kyle et al. (2004)

Finally, in female subjects total body water tends to increase after ovulation due to increased plasma progesterone levels. In spite of some contradicting results, neither the time of measurement during the menstrual cycle nor the administration of oral contraceptive seems to substantially confound bioimpedance measurements (Chumlea et al. 1987; Deurenberg et al. 1988; Gleichauf and Roe 1989; McKee and Cameron 1996; Gualdi-Russo and Toselli 2002). Nonetheless, in women experiencing large weight gains (2–4 kg) during the menstrual cycle, careful interpretation of bioimpedance data is necessary since a substantial amount of the increase in body mass can be related to total body water (Bunt et al. 1989).

In summary, measurement conditions (ambient temperature and posture), physiological state (physical activity or other events altering core and skin temperature, blood flow, ventilation, fluid distribution within different compartments and between different body segments), prandial and hydration state, and technical reliability of the operator (electrode placement and anthropometric measurements) may affect the reproducibility of in-vivo bioimpedance measurements. It is therefore imperative to perform bioimpedance measurements under highly standardized conditions, which are summarized in Table 3.2.

3.6 Reliability

One of the biggest challenges of bioimpedance monitoring is to distinctly relate changes in Z to physiological events. As outlined in the previous section any change in Z can be related to changes in tissue resistivity, changes in tissue geometry, or a combination of both. In many practical settings both parameters change simultaneously making it difficult to associate changes in Z with its underlying physiological phenomena (Lozano-Nieto 2000). This difficulty is a constant of the reliability and validity of bioimpedance applications. Validity will be discussed in detail with regard to specific applications in the following chapters on applications of bioelectrical impedance analysis. The following section will therefore exclusively focus on the reliability of bioimpedance measurements.

For the determination of the overall reliability of bioimpedance measurements, it needs to be taken into account that the latter are also dependent on technical measurement error. Depending on the test circuit (simple or complex impedance measurements), reliability of single-frequency bioimpedance measurements have measurement errors in the range of 1% to 2% (Segal et al. 1985; Roche et al. 1986; Van Loan and Mayclin 1987; Steijart et al. 1994) and reliability coefficients for repeated measurements exceeding 0.99 (Graves et al. 1989). Ward et al. (1997) studied the reliability of multi-frequency measurements. The relative differences between measured and expected Z were small (average between 0.7% and 1.3% for different machines from the same manufacturer) and somewhat larger for phase angle (average between 2.4% and 7.2%). Extrapolated R_0 was within 3% of theoretical values over a range of 50 Ω to 800 Ω. Extrapolated R_∞ was fitted equally well between 100 Ω and 530 Ω. For lower Z, particularly below 50 Ω, measurement accuracy decreased remarkably. However, usually values obtained for whole-body Z in vivo are of the order of several hundred ohms. Similar technical errors were reported by Oldham (1996) when he tested six bioimpedance analyzers. Yet, he also noted that in some instruments errors can get as large as 20% for values similar to those normally encountered in the human body and concluded that the state-of-the-art error for bioimpedance measurements appears to be within ±1% and ±2%. Substantial differences between the technical accuracy of commercially available bioimpedance systems were also reported by other investigators (Deurenberg et al. 1989; Graves et al. 1989; Smye et al. 1993; Bolton et al. 1998).The overall reliability of bioimpedance measurements is therefore a combination of the electronic precision and accuracy of instrumentation used, the technical operator reliability, the standardization of measurement conditions and individual subject characteristics. A number of studies confirmed that bioimpedance measurements can be performed with high within-day and between-day reliability when experienced investigators employ strictly standardized measurement protocols. Table 3.3 provides a summary of different reliability studies of bioimpedance. The average coefficient of variation for within-day and between-day variability is approximately 1–2% and 2–3%, respectively, and underlines the acceptable reproducibility of the method under standardized conditions. Nonetheless, it should be noted that the statistics reported rely on averages and the repeatability for individual measurements can be substantially lower. This pertains in particular to measurements at very low frequencies (1–5 kHz), to segmental measurements of the trunk as well to measurements of X_c. There is a clear need for future studies to investigate the reliability of segmental bioimpedance measurements as well as to provide data for R and X_c at a range of frequencies, including extrapolation of R_∞ and R_0. In addition to reporting average statistics, such studies should include the documentation of the range of deviations for individual measurements. This could be achieved by using Bland-Altman plots and reporting limits of agreement.

Table 3.3 Summary of reliability of in-vivo whole-body bioimpedance measurements (M, men; W, women)

Authors	Instrumentation	Variables	Methods	Reliability Statistics	Reliability
Deurenberg et al. (1988)	RJL BIA 101	R (50 kHz)	Four different days within a period of 3–4 weeks	Coefficient of variation	2.8%
Elsen et al. (1987)	RJL BIA 103	R (50 kHz)	Consecutive duplicate measurements with and without marked electrode sites	Correlation coefficient	0.998 (with) 0.989 (without)
			Four 5-min intervals with and without blanket	Mean relative changes	–0.02% to –0.6% (with) 0.4–2% (without)
Fornetti et al. (1999)	RJL BIA-101 A	R, X_c (50 kHz)	Consecutive duplicate measurements (replacement of electrodes not indicated)	Intraclass correlation coefficient form repeated measures ANOVA	0.957–0.980
Graves et al. (1989)	Valhalla Scientific model 1990-A, RJL BIA-101, Med-Fitness model 1000, Bioelectrical Sciences model 200Z	R (50 kHz)	Consecutive duplicate measurements with electrodes kept in place	Reliability coefficient (not further specified)	>0.99
Jackson et al. (1988)	RJL BIA 103B	R (50 kHz)	Two different testers on two different days within a 7-day period	Generalizability coefficient for all conditions	0.957 (M) 0.967 (W)
Kushner and Schoeller (1986)	RJL BIA 101	R (50 kHz)	Six 20-min intervals[a] Six 1-week intervals[b]	Coefficient of variation	1.3% (0.3–1.9%)[a]
Kyle et al (2003)	Xitron 4000B	R (50 kHz)	1 week 1 month	Not indicated	0.999 (1 week) 0.997 (1 month)
Lukaski et al. (1985)	RJL system	R (50 kHz)	Five consecutive days	Coefficient of variation	2%
Monnier et al. (1997)	Human IM-Scan	Z (1, 5, 10, 50, 100 kHz)	Single 10-min interval	Coefficient of variation	0.8–4.2% (0.6–7.6%)
Schell and Gross (1987)	RJL BIA 103	R (50 kHz)	Ten consecutive days	Coefficient of variation	2.0%
Stahn et al. (2006)	Bodystat Quadscan 4000	Z (5, 50, 100, 200 kHz)	Two 60-min intervals	Intraclass correlation coefficient form 2-way mixed ANOVA	0.998–0.999 for wb 0.997–0.999 for arm 0.942–0.981 for trunk 0.997–0.998 for leg

(continued)

Table 3.3 (continued)

Authors	Instrumentation	Variables	Methods	Reliability Statistics	Reliability
Turner and Bouffard (1998)	RJL Spectrum lightweight Instrument	R^e, X_c^f (50 kHz)	Two consecutive days (24 h) on two different occasions and three trials	Generalizability coefficients	0.87–0.98 for R (M) 0.67–0.91 for X_c (M) 0.84–0.96 for R (W) 0.54–0.98 for X_c (W)
Van Loan and Mayclin (1987)	RJL BIA 101	R (50 kHz)	Eight consecutive days	Coefficient of variation	2.9% (1.31–6.95%)

This table provides a summary of various reliability studies on bioimpedance measurements. The studies included measurement intervals as low as a few minutes and as long as 6 weeks. Reported data covered a range of reliability statistics including correlation coefficients, mean relative changes, coefficient of variations, intraclass correlation coefficients, as well as generalizability coefficients. It is noteworthy that most studies were conducted at a frequency of 50 kHz and report only data for whole-body measurements. Data for segmental measurements are provided by Stahn et al. (2006). As indicated in the table measurements of the trunk seem to be less reliable than measurements of the arm and leg. Furthermore, measurements at low frequencies (≤5 kHz) are less reliable than measurements at higher frequencies (≥50 kHz). This seems to be particularly important for measurements at 1 kHz, for which Monnier et al. (1997) reported a coefficient of variation of 4.2% for repeated measurements after 10 min, with a confidence interval ranging between 2.9% and 7.6%. This also highlights that in spite of excellent reliability statistics for average data, individual deviations can be much higher

Summary Points

- Bioimpedance measurements refer to all methods based on the characterization of the passive electrical properties of biological tissue. This is achieved by the introduction of a constant, alternating current below the threshold of perception, and the measurement of the resulting voltage potential.
- The technique has unique advantages in so far as it is non-invasive, it is inexpensive, it can be operated at low costs, it only needs minimal operator training, it enables continuous online monitoring, it is quick, and is easily portable.
- Most applications of bioimpedance monitoring have focused on body composition analysis and have become popular under the term bioelectrical impedance analysis (BIA).
- The fundamental parameters obtained from this measurement are impedance, phase, resistance, and reactance. All can be used to provide diagnostic information about the physiologic properties and events of the human body.
- A basic understanding of impedance, phase, reactance, and resistance is recommended to correctly understand and interpret bioimpedance measurements. Dependent on whether the bioimpedance monitor is phase-sensitive or not, resistance and reactance can be differentiated from impedance. Hence, resistance and impedance should not be used interchangeably.
- Human cells can be modeled by a resistor in parallel with a capacitor and resistor in series. The intra- and extracellular fluid compartments are expected to be pure electrolytes and modeled by resistors, whereas the cell membrane is represented by a capacitor. Hence, the passive electrical passive properties of tissue exhibit a frequency-dependent response.
- Low-frequency currents are more or less blocked by the cell membrane, and bioimpedance measurements are therefore a reflection of the extracellular fluid compartment only. In contrast, high-frequency currents increasingly short-circuit the cell membrane, and bioimpedance are indicative of both extra- and intracellular fluid.
- The upper and lower limits of the frequencies employed are biophysically limited. Even the lowest (i.e. highest) possible frequencies can only be considered approximates of the extracellular (i.e. the combination of the extra- and intracellular) space.
- Bioimpedance spectroscopy (BIS) is technique to estimate resistance at zero and infinite frequency. Employing a phase-sensitive device, resistance and reactance are obtained at several frequencies (15–500) between a few kHz and 1 MHz. Using Cole-Cole modeling, these data can be used to extrapolate resistance at 0 kHz and at infinite frequency.
- The passive electrical passive properties of tissue are also highly tissue-specific, with fat and bone having a high resistance per unit length and area, and muscles, and the vascular compartments having a relatively low resistance.
- To obtain a deep-tissue bioimpedance measurement, the upper layers of the skin need to be bridged. Presently, a tetrapolar electrode arrangement is used for this purpose. Two outer electrodes introduce the current, while two inner electrodes pick up the voltage using a high input impedance voltmeter.
- Assuming that fat draws negligible current, and the human body or body parts can be geometrically approximated by cylinders, the basic biophysical model is based on the fact that resistance is proportional to length and inversely proportional to area.
- Conventional BIA involves whole-body measurements between the right wrist and right ankle. For convenience, conductive body length is usually replaced by height.
- The use of the basic biophysical model for this measurement is based on the assumption that the human body is an isotropic conductor with homogenous cross-sectional area. Importantly, given

the geometrical and electrical complexity of the human body, the limbs make up most of whole-body bioimpedance measurements.
- To minimize the impact of the distal limbs, a proximal electrode configuration between the elbow and knee has been proposed. Alternatively, the body can be separated in segments such as arms, legs, and trunk, for which bioimpedances are determined separately.
- More recent developments also focus on local measurements to determine abdominal adipose tissue, muscle cross-sectional area at various points along the limbs, or even skinfold thickness.
- Given the anatomical complexity of the trunk, the assumption of isotropy is far from fulfilled, and segmental measurements of the limbs seem at present to be most promising.
- The reliability of bioimpedance measurements is excellent. However, there are a number of endogenous and exogenous factors that can substantially bias data collection. Electrode placement, body position and posture, temperature, blood chemistry, ovulation, nutrition, hydration, physical activities can substantially impact the reliability of bioimpedance measurements. Each measurement should therefore closely follow specific standardization procedures.

Chapter 4
An Anthropometric Analysis of Seated and Standing People

Antonino Nucara, Matilde Pietrafesa, Gianfranco Rizzo, and Gianluca Scaccianoce

Abstract Thermal radiative exchanges of the human body with surrounding surfaces play an essential role in describing the thermal conditions of people in a given environment. Moreover, they could be induced by, among other causes, the presence of high intensity radiant sources, like lighting spots or infrared heating panels. This implies that a suitable set of radiation data related to human body anthropometry is required. This set of data mainly comprises the body surface area, the clothing area factor, the effective radiation area factor, and projected area factors. Several analytical or experimental methods may be utilized in order to compute these parameters. A detailed description of the most common of these will be illustrated in this study, pointing out their main features and their ease of application or otherwise. Thereafter, with reference to a field experiment conducted by means of purpose-built experimental apparatus, a detailed analysis concerning the determination of the values of clothing area factor, effective radiation area factor and projected area factors of a sample of standing and seated, and male and female subjects of the population of southern Italy will be described. In addition, the results of a study to determine differences in anthropometric parameters with regard to different gender and nationalities will be reported. The study will conclude by analyzing a specific case-study.

Abbreviations

Mathematical symbol	Description	Unit of measurement
A_b	Total surface area of naked person	m^2
A_{cl}	External surface area of clothed person	m^2
A_p	Projected area of body	m^2
$A_{p,cl}$	Projected area of clothed person	m^2
$A_{p,n}$	Projected area of naked body	m^2
A_r	Effective radiating area of body	m^2
$A_{r,cl}$	Effective radiating area of clothed person	m^2
$A_{r,n}$	Effective radiating area of naked body	m^2
C	Convective heat loss	W
C_{res}	Respiratory convective heat loss	W

4.1 Introduction

The thermal sensation of a subject in a confined environment is related to the need of a human organism to realize a homeothermic state at body core level by means of physiological mechanisms, thus maintaining the balance between internal heat production and dispersion toward the environment. This variation, in units of time, ΔS of internal energy for a subject placed in a confined environment is equal to the difference between metabolic heat production, M, (excluding

Table 4.1 Dependence parameters appearing in the thermal balance equation

Diffusion heat loss	E_d		✓					✓	
Evaporation of sweat heat loss	E_{sw}								✓

This table reports the relation between terms appearing in the thermal balance and some physical physiological independent parameters

the so-called mechanical power, W) and thermal loss due to respiration, Q_{res}, and through the skin surface, Q_{sk}:

$$\Delta S = (M - W) - (Q_{res} + Q_{sk}) \tag{4.1}$$

Metabolic heat production depends on the activity performed by the subject and, in turn, part of metabolic heat production is converted into mechanical power. Respiration heat losses occur during respiration, when the subject inhales a certain amount of air. Since this air generally has a different temperature and humidity level compared with that of the body core, a portion of the body's internal heat is transferred to the external environment by means of convective (C_{res}) and evaporative (E_{res}) exchanges. Respiration heat losses depend on metabolic heat production, M, temperature, t_a, and air humidity in the environment; the latter is normally expressed by means of water vapor partial pressure, p_a.

Heat exchanges through the external surface of the human body occur because the thermo-hygrometric conditions of the skin are generally different from those of the surrounding environment. This induces thermal exchanges between the subject and the environment, which are termed *dry heat loss* (that is, by convection, C, radiation, R, and conduction, K) and *latent heat loss* (due to vapor diffusion through the skin, E_d, and evaporation of the sweat, E_{sw}).

Convective heat exchanges depend on the relative air velocity, v_{ar}, the clothed surface temperature, t_{cl} (defined as the mean temperature of the clothed surface, including uncovered parts), and the air temperature, t_a. Radiation heat exchanges depend on the clothed surface temperature, t_{cl}, and the mean radiant temperature of the surrounding environment, $\overline{t}_r$ (defined as "the uniform temperature of an imaginary black enclosure in which an occupant would exchange the same amount of radiant heat as in the actual non-uniform enclosure," as reported in the ISO Standard 13731) (ISO 2001). Both these heat exchanges depend on the thermal insulation of clothing, I_{cl}. In addition, the clothed surface temperature, t_{cl}, is a dependent variable that can be expressed as a function of the other parameters. Conductive heat exchange, caused by contact with objects, is usually ignored due to its low value.

Latent heat loss due to vapor diffusion through the skin is caused by migration of the vapor through the surface layer of the skin; it depends on the skin temperature, t_{sk}, and the evaporative thermal insulation of clothing. Latent heat loss due to evaporation of the sweat, E_{sw}, is assumed to be an independent parameter. Accordingly, the thermal balance equation will be:

$$\Delta S = (M - W) - (C_{res} + E_{res} + C + R + E_d + E_{sw}) \tag{4.2}$$

where each term may be expressed as a function of some physical and physiological independent parameters, as reported in Table 4.1.

Table 4.2 Typical contributions (absolute and percentual) of the components of a thermal balance equation

	Winter		Summer	
Heat loss	W/m^2	%	W/m^2	%
Respiratory convective	0.7	1	1.3	2
Respiratory evaporative	4.6	8	5.2	8
Convective	19.6	32	22.8	33
Radiation	22.2	36	24.4	35
Diffusion	11.0	18	12.5	18
Evaporation of the sweat	2.9	5	2.9	4
Total	61.0	100	69.2	100

This table reports contributions of each terms appearing in the thermal balance equation (excluding metabolic and mechanical powers) in a typical thermo-hygrometric condition of a subject performing a sedentary activity inside a thermal uniform environment and normally clothed for the time of year (i.e., air velocity of 0.1 m/s, humidity ratio 50%, air temperature of 20°C in winter and 26°C in summer). It highlights that the heat exchanged by radiation represents one of the major factors of the human body thermal balance

Appling balance (4.2) to a typical thermo-hygrometric condition of a subject performing a sedentary activity inside a thermal-uniform environment and normally clothed for the time of year (i.e., air velocity of 0.1 m/s, humidity ratio 50%, air temperature of 20°C in winter and 26°C in summer), the results in Table 4.2 are generated. They highlight that, of the main contributions of the human body thermal balance, heat exchange by radiation represents one of the major factors meriting further research.

4.2 Dry Heat Exchanges Between a Confined Environment and the Human Body

Many human activities take place in a confined environment in which the temperature of the surrounding surfaces and air are normally different from the temperature of the external surfaces of the human body. This involves convective and radiative thermal exchanges between the external surface of the clothed body, the air, and the surrounding surfaces of the environment.

4.2.1 Convective Exchanges

The convective heat exchange occurring within a confined environment, due to a difference between the air temperature and the temperature of the external part of the clothed body, may be expressed by the following equation:

$$C = A_{cl} h_c \left(t_{cl} - t_a \right) \tag{4.3}$$

where A_{cl} is the external surface area of a clothed person, h_c the convective heat exchange coefficient, t_{cl} and t_a the clothed surface temperature and air temperature, respectively. The external surface area of a clothed person in (4.3), i.e., the external surface area of the clothed body including unclothed parts (IS0 2001), may be calculated as:

$$A_{cl} = f_{cl} A_b \tag{4.4}$$

where f_{cl} is the clothing area factor and A_b the total surface area of a naked person.

4.2.2 Radiative Exchanges

The radiation heat exchange occurring from the subject to the environment may be evaluated by means of the following equation (considering the human subject as a small body in a large cavity):

$$R = \sigma \varepsilon A_r \left[(t_{cl} + 273)^4 - (\overline{t}_r + 273)^4 \right] \tag{4.5}$$

where A_r is the effective radiating area of the body, $\sigma = 5.67 \times 10^{-8}$ Wm^{-2} K^{-4} (the Stefan–Boltzmann constant), ε the emissivity of the human body (usually equal to 0.97, that is, a mean value between the emissivity of the most common type of clothing 0.95 and the human skin 1.00) (Fanger 1970), t_{cl} the clothed surface temperature and $\overline{t}_r$ the mean radiant temperature.

Equation 4.5 may be utilized in moderate environments, in which surface temperatures of walls are quite low and generally close to that of the air. Therefore, the presence of high intensity heat sources, characterized by a small area, high temperature, and a high directional radiant emission, causes a further radiative exchange toward the human body. It can be evaluated by:

$$R_{hi} = \alpha_{ir} A_p q_{ir} \tag{4.6}$$

where α_{ir} is the relative absorptance of the skin, A_p the projected area of the body, and q_{ir} the intensity of the radiation emitted by the source that directly hits the subject. Thus, the total thermal radiation leaving the body can be expressed as:

$$R = R_{lt} - R_{hi} = \sigma \varepsilon A_r \left[(t_{cl} + 273)^4 - (\overline{t}_r + 273)^4 \right] - \alpha_{ir} A_p q_{ir} \tag{4.7}$$

In (4.7), the effective radiating area of the body takes into account that the human body is not totally convex: the surface of a body that exchanges radiant energy with the environment through a solid angle of 4π is smaller than the actual surface area of the body if the body is not everywhere convex, e.g., the human body (ISO 2001). The effective radiating area of the body can be calculated by means of the following expression:

$$A_r = f_r f_{cl} A_b \tag{4.8}$$

where f_r is the effective radiating area factor, f_{cl} the clothing area factor, and A_b the total surface area of a naked person. However, the projected area of the body, A_p, is the surface of the profile of the human body projected onto a plane perpendicular to the direction of the radiant source. It may be determined, once the projected area factor f_p and the effective radiating area of the body A_r are known, by:

$$A_p = f_p A_r \tag{4.9}$$

or

$$A_p = f_p f_r f_{cl} A_b \tag{4.10}$$

Equation 4.7 may also be written as:

$$R = \sigma \varepsilon A_r \left[(t_{cl} + 273)^4 - (\overline{t}_{r,I} + 273)^4 \right] \tag{4.11}$$

where $\overline{t}_{r,I}$ represents the mean radiant temperature of an irradiated subject. It is expressed by:

$$\overline{t}_{r,I} = \sqrt[4]{\left(\overline{t}_r + 273\right)^4 + \frac{\alpha_{ir} q_{ir} A_p}{\varepsilon \sigma A_r}} - 273 \tag{4.12}$$

$\overline{t}_r$ being the mean radiant temperature of an non-irradiated subject, exposed only to a low temperature thermal exchange with the internal surface of the environment. Thus, the mean radiant temperature may be calculated as a function of the temperatures of the N surrounding surfaces of the enclosure, t_i, and the view factors (or *angle factors*) between the subject and the same surfaces, $F_{p \to i}$:

$$\overline{t}_r = \sqrt[4]{\sum_{i=1}^{N} \left(t_i + 273\right)^4 F_{p \to i}} - 273 \tag{4.13}$$

The view factors are defined as the fraction of the diffuse radiant energy emitted by a surface, which is received directly by another surface. They can be evaluated using diagrams where they are reported as a function of the relative position of people with surrounding surfaces (Fanger 1970; ISO 1998).

Excluding the use of these diagrams, the angle factor can be computed by means of a relationship, depending on the projected area factor:

$$F_{P \to i} = \frac{1}{\pi} \int_{x/y=0}^{x/y=a/c} \int_{z/y=0}^{z/y=b/c} \frac{f_p}{\sqrt{\left[1 + \left(x/y\right)^2 + \left(z/y\right)^2\right]^3}} d\left(x/y\right) d\left(z/y\right) \tag{4.14}$$

where a, b, and c are geometrical parameters singling out the position of the subject with respect to the internal surfaces of the envelope (Fanger 1970) and f_p is the projected area factor.

4.3 Methodologies for the Determination of Various Relevant Anthropometric Parameters

In order to determine the comfort conditions of people living in a confined moderate environment, the methods currently available in the literature require the use of various anthropometric parameters. Some of these parameters have been assessed using field and laboratory measurements, and the values obtained have been subsequently applied to mathematical models. However, other parameters seem to depend strongly on the specific anthropometric features of people, like gender, ethnic group, age, and so on. Now follows a discussion relating to the most important parameters involved in the evaluation of the thermal comfort conditions of people. We will deal in greater detail with the total surface area of a naked person, the clothing area factor, the effective radiating area factor, and the projected area factors by describing a field experiment conducted by the authors of this chapter.

4.3.1 Determining the Body Surface Area of a Naked Person

Since the heat production of a subject is proportional to the surface area of the human body, it is necessary to determine this anthropometric parameter, using a mathematical equation to determine surface area, in order to avoid the direct complex measurement of the shape of the human body. Early publications on this subject include the Meeh (1879) and Howland and Dana (1913) equations,

based only on the weight of the subject, and the Miwa and Stolzer (1898) equation, founded on several anthropometric parameters. Further equations can be found in literature that only depends on height and weight of the subject, easily measurable parameters.

Of these relationships, the most frequently used is that proposed by D. DuBois and E.F. DuBois (1916):

$$A_b = 0.20247\left(\frac{h}{100}\right)^{0.725} w^{0.425} \tag{4.15}$$

where h (cm) is the height and w (kg) the weight of the subject.

This procedure for determining human body surface, utilized by D. DuBois and E.F. DuBois, is based on the use of sheets of gummed hemp, which wrapped onto the subjects and subsequently cut out in pieces and placed onto a horizontal plane. The hemp pieces were then photographed, cut out again, weighed and converted into square meters, as the known value of the photographic paper weight.

Following the publication of the DuBois formula, other expressions have been published, including the following:

– Boyd's formula (1935):

$$A_b = 0.0003207\, h^{0.3} \left(1000w\right)^{0.7285 - 0.0188 \log_{10}(1000w)} \tag{4.16}$$

– Gehan and George's formula (1970):

$$A_b = 0.0235\, h^{0.42246} w^{0.51456} \tag{4.17}$$

– Haycock et al.'s formula (1978):

$$A_b = 0.024265\, h^{0.3964} w^{0.5378} \tag{4.18}$$

– and Mosteller's formula (1987):

$$A_b = \sqrt{\frac{hw}{3600}} \tag{4.19}$$

Comparing the results obtained by these different formulas reveals a similarity among them (Calvino et al. 2006), with a standard deviation lower than 6%. The DuBois formula is currently adopted in anthropometric evaluation.

4.3.2 Determining the Clothing Area Factor

The clothing area factor is the ratio between the external surface area of a clothed person and the surface area of a naked body:

$$f_{cl} = \frac{A_{cl}}{A_b} \tag{4.20}$$

Since the outer surface of a clothed person is always greater than the surface of a naked body, the clothing area factor is always greater than unity. It may be computed by one of three methods: (1) starting with the values of the effective radiating area of the clothed and naked person; (2) by means of a limited number of values of the projected area of the clothed and naked body; and (3) as a function of the thermal resistance of the clothing.

With reference to (1), the clothing area factor is determined thus:

$$f_{\mathrm{cl}} = \frac{A_{r,\mathrm{cl}}}{A_{r,n}} \tag{4.21}$$

where $A_{\mathrm{r,cl}}$ is the effective radiating area of the clothed body and $A_{\mathrm{r,n}}$ the effective radiating area of the naked body.

Method (2) compares the projected area of a clothed subject with the projected area of the same naked subject, as measured for six directions: altitude angles of 0° and 60°, and, for each altitude, azimuth angles of 0°, 45°, and 90°. Then the clothing area factor for the *i*-th direction is determined according to the equation:

$$f_{\mathrm{cl},i} = \frac{A_{\mathrm{p,cl},i}}{A_{\mathrm{p,n},i}} \tag{4.22}$$

and the clothing area factor is estimated as:

$$f_{\mathrm{cl}} = \frac{\sum_{i=1}^{6} f_{\mathrm{cl},i}}{6} \tag{4.23}$$

Referring to method (3) and given that the surface area of the clothing increases with the clothing thickness (usually related to its insulation), the clothing area factor is estimated by means of the following equation (ISO 1995):

$$f_{\mathrm{cl}} = 1.00 + 1.97 I_{\mathrm{cl}} \tag{4.24}$$

in which I_{cl}, expressed in $\mathrm{m^2{}^{\circ}C/W}$, is the clothing insulation of the person.

4.3.3 Determining the Effective Radiating Area Factor

The ratio between the effective radiating area of a clothed body, $A_{r,\mathrm{cl}}$, and the external surface area of a clothed body, A_{cl}, is defined as the effective radiating area factor:

$$f_{\mathrm{r}} = \frac{A_{\mathrm{r,cl}}}{A_{\mathrm{cl}}} \tag{4.25}$$

Using (4.20) and (4.21), we can express:

$$f_{\mathrm{r}} = \frac{A_{\mathrm{r},n}}{A_{\mathrm{b}}} \tag{4.26}$$

The computation of the effective radiating area of the human body (clothed or naked) was originally provided by Underwood and Ward (1966). By means of a method involving the use of photographs, they measured the projected areas of 25 male and female subjects. They then utilized these values of the projected areas with which to propose an empirical equation for the calculation of the effective area for a naked subject in a seated posture. Thereafter, an experimental method was proposed by Fanger (1970), the aim of which was to evaluate the projected area of seated and standing people. This photographic method involved 20 subjects (10 male and 10 female), naked and clothed, in seated and standing postures.

Other authors have also proposed different methods for assessing data concerning the radiative parameters of the human body. For example, Rizzo et al. (1991) have proposed two algorithms for the automatic computation of projected area factors for seated and standing persons by utilizing the original experimental data provided by Fanger. Jones and Ogawa (1992) have subsequently elaborated values of the projected area for the whole body and for single bodies.

The dependence of the projected area on the effective area is given by the following equation:

$$A_{\mathrm{r}} = \frac{4}{\pi} \int_{\alpha=0}^{\pi} \int_{\beta=0}^{\pi/2} A_{\mathrm{p}} \cos\beta d\alpha d\beta \tag{4.27}$$

where α and β are the azimuth and the zenith angles of the beam projected by the radiant source onto the barycenter of the human body respectively (Fanger 1970).

A numerical solution has been proposed by Alfano et al. (1997):

$$A_{\mathrm{r}} = \frac{4}{\pi} \Delta\alpha\Delta\beta \sum_{i=1}^{N+1} \sum_{j=1}^{M+1} A_{\mathrm{p},ij} \cos\beta_j \tag{4.28}$$

where N and M are the number of steps adopted for the azimuth and zenith angles respectively.

Unfortunately, this relationship is not viable when the discrete steps Δα and Δβ are too wide (Calvino et al. 2001), as is the case of several experimental works found in the literature. The application of the trapezoid rule for the solution of (4.27) leads to a more accurate result (Scheid 1968):

$$\int_{X_o}^{X_N} y(x)dx \cong \frac{1}{2}\Delta X \left(y_0 + 2\sum_{i=1}^{N-1} y_i + y_N \right) \tag{4.29}$$

When applied to the calculation of the effective radiating area, this equation provides the following expression, which is a function of the measured values of the projected areas, $A_{\mathrm{p},ij}$:

$$A_r = \frac{\Delta\alpha\Delta\beta}{\pi} \left\{ A_{p,0,0} + A_{p,N,0} + 2\sum_{i=1}^{N-1} A_{p,i,0} + 2\sum_{j=1}^{M-1} \left[\left(A_{p,0,j} + A_{p,N,j} + 2\sum_{i=1}^{N-1} A_{p,i,j} \right) \cos\beta_j \right] \right\} \tag{4.30}$$

Moreover, referring to (4.20), the external surface area of the same clothed person may be obtained as a function of the naked body surface area and the clothing area factor:

$$A_{\mathrm{cl}} = f_{\mathrm{cl}} A_{\mathrm{b}} \tag{4.31}$$

The terms used in (4.25) are absolutely determinate, given the evaluation of the f_{r} parameter.

4.3.4 Practical Methods and Techniques for the Projected Area Factors

The projected area factor in a given direction is defined as the ratio between the area of a human body projected onto a plane perpendicular to the direction, A_{p}, and the effective radiating area of the body, A_{r}:

$$f_{\mathrm{p}} = \frac{A_{\mathrm{p}}}{A_{\mathrm{r}}} \tag{4.32}$$

Regarding its determination, two kinds of methods are currently available: experimental methods, based on actual measured values of the project area of the human body, and numerical simulation methods, based on the reconstruction of the 3D human body numerical model.

4.3.4.1 Experimental Methods

Several experimental methods have been assessed over recent years in an attempt to measure the projected areas of standing and seated people, by means of photographic methods (Guibert and Taylor 1952; Underwood and Ward 1966; Fanger 1970; Calvino et al. 2005; Calvino et al. 2009). These consist of photographing the subject from many directions, with each photograph providing the project area of the body for a given viewing angle. When the project area of the body is known for an adequately large number of angles, all radiation data for the body can be calculated (Fanger 1970). Fanger applied this method to a Scandinavian panel of ten men and ten women. The apparatus employed six mirrors in fixed positions, at steps of 15°, and a movable mirror (see Fig. 4.1). The body (subject) is placed on a platform that can be pivoted around a vertical axis and elevated. By turning the movable mirror, the subject can be photographed with a fixed camera from six different angles (altitude β) on a vertical plane (six mirrors). By rotating the platform 15° at a time, a total of 13 horizontal angles (azimuth α) can be investigated. In total, 78 exposures (i.e., 13 × 6) within a quarter sphere are obtained, the measurement of which is sufficient due to the right/left symmetry of the body, and because the projected area from any two opposite directions is the same. Projected areas, $A_p(\alpha, \beta)$, were then obtained by means of double planimeter.

Once the values of the projected areas, A_p, are obtained, it is possible to deduce the effective radiating area, A_r, and the projected area factor, $f_p(\alpha,\beta)$, as a function of the azimuth and zenith angles. The last parameter is defined as the ratio between the projected area, $A_p(\alpha,\beta)$, and the effective radiating area of the human body, as described in (4.32).

The data of the projected area factor provided by Fanger are reported in Fig. 4.2 (Fanger 1970), for standing and seated postures; these data are currently used in ergonomic evaluations.

In order to take more pictures of subjects at smaller angle steps and verify Fanger's original data for non-Scandinavian people, we have designed and constructed a photographic platform at the Dipartimento dell'Energia of the Università degli Studi di Palermo (Calvino et al. 2005). A procedure for managing the digital images of the human body has been assessed, taking into account the measurement of people's projected areas in standing and seated postures at various azimuth and zenith angles.

This experimental apparatus can be classified as a *single viewpoint method* (Roebuck et al. 1975). It is composed (see Fig. 4.3) of an anthropometer, scales, mechanical equipment, optical apparatus, and a system for producing images.

The optical apparatus comprises a digital camera which is linked to a PC, the aim of which is to generate images and process them with appropriate software. The camera has been selected due to its compatibility with the computer, its graphical resolution, and is capacity to be remotely controlled. The digital camera comprises the camera's objective and the optical sensor; the former is required to reach a compromise between the minimization of the optical distortion of the image and the length of the jib (Calvino et al. 2005). After the images are produced, they are suitably edited to remove objects unrelated with the shape of people being measured. In order to remove any undesired color intensity, which could lower the contrast level of the image, the images are subjected to a filtering process. They are then converted into a gray scale to enhance the manageability of the elaboration process. Finally, the images are converted from the gray to a black and white scale, as shown in Fig. 4.4.

The final step is the computation of the projected area of the subject and this is accomplished by simply counting the black pixels. To convert the values of these data from the number of pixels to surface area (m^2), they are multiplied by the proper conversion factor obtained by the measurement of a sample image, which refers to an object of known dimensions. Starting from the statistical analysis of the anthropometric characteristics of a given group of people, it is now possible to address measurements of projected areas pertaining to subjects statistically representative of this group.

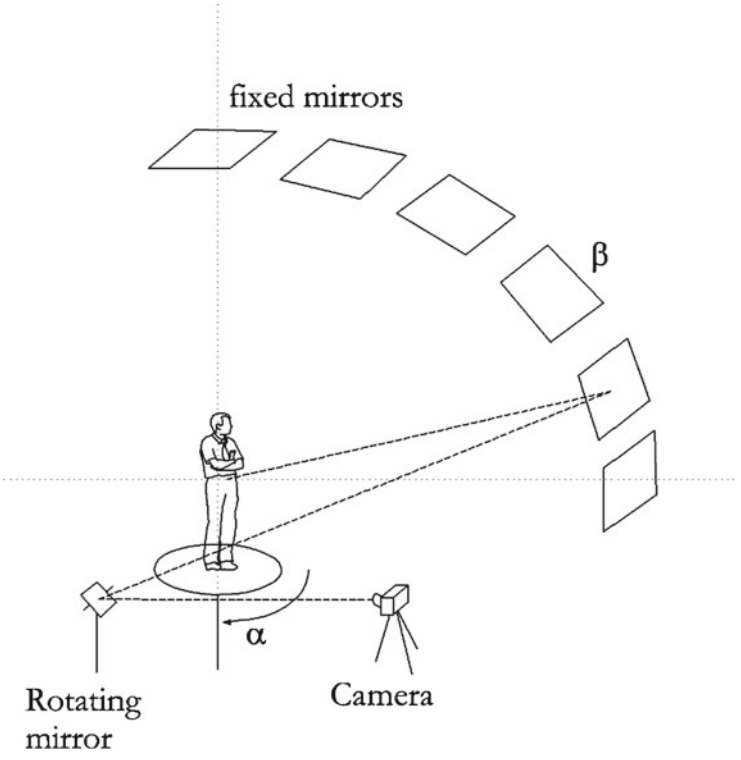

Fig. 4.1 Description of the photographic method utilized by Fanger. The experimental method assessed by Fanger consists of photographing the subject from several directions; the apparatus employed six mirrors in fixed positions, at steps of 15°, and a movable mirror. The subject is placed onto a platform, which can be pivoted around a vertical axis as well as being elevated

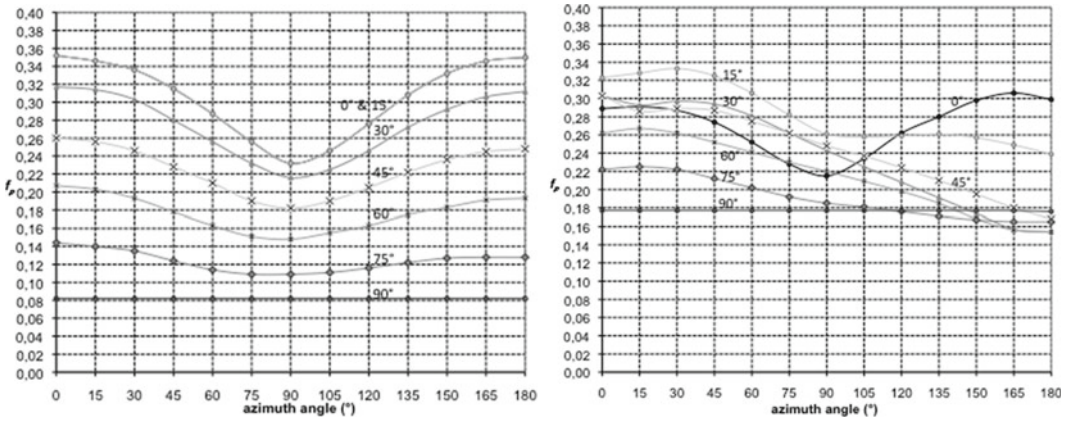

Fig. 4.2 Projected area factors for standing (*left*) and seated (*right*) people. By the values of the projected areas, obtained with experimental methods, it is possible to deduce the projected area factor. The results reported, provided by Fanger for standing and seated postures, are currently used in ergonomic evaluations

Calvino et al. (2009) have selected the subjects whose weight and height values fall within the 10th and the 90th percentiles, with respect to statistical data for the southern Italian population. Table 4.3 shows these limit values for male and female subjects.

The mean values of the projected area factors, f_p, for standing and seated people have been evaluated; they are shown in Fig. 4.5.

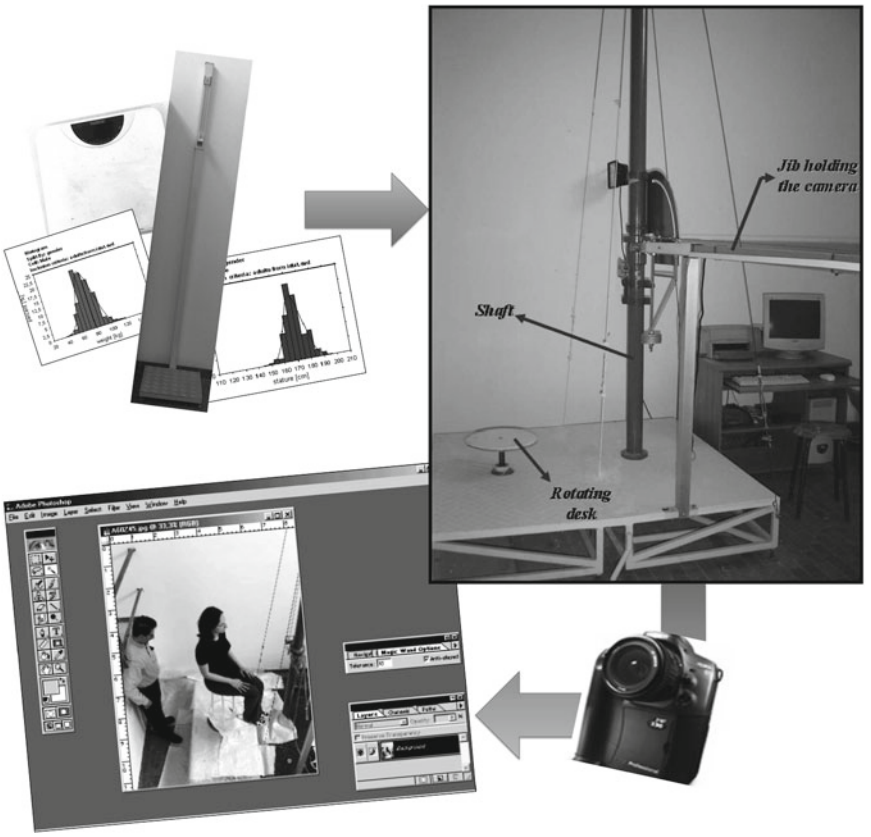

Fig. 4.3 Experimental apparatus. The experimental apparatus realized at the Dipartimento dell'Energia of the Palermo University is composed of an anthropometer, scales, mechanical equipment, optical apparatus, and a system for producing images

4.3.4.2 Numerical Simulation Methods

One of the first researchers to propose a new numerical simulation method for predicting the effective radiating area and the project area of the human body for any posture was Tanabe (Tanabe et al. 2000). This method is based on the solar gain simulation, as proposed by Ozeki et al. (1992, 1997), according to which body shape was obtained by means of commercially available software and divided into 4,396 quadrilateral surface elements, for both standing and seated postures. To derive the project area of the human body, they utilized the parallel ray method introduced by Fanger (1970): "this project area is equal to the surface area of the human body where parallel rays reach directly and which is projected onto a plane perpendicular to the parallel rays" (Tanabe et al. 2000). The projected area is evaluated by utilizing both surface elements A_i and incident angles θ_i of the parallel rays to the surface elements. Thus, the projected area A_p of the human body is obtained by means of the following equation:

$$A_p = \sum_i \gamma_i A_i \cos\theta_i \tag{4.33}$$

where γ_i indicates whether a parallel ray reaches the surface element ($\gamma_i = 1$) or not ($\gamma_i = 0$). The algorithm utilized for calculating the project area of a human body is shown in Fig. 4.6.

Tanabe et al. (2000) applied the algorithm, in Fig. 4.6, to 91 directions of the ray (13 × 7), 13 values of the azimuth angle and seven values of the zenith angle. They utilized (4.27) to evaluate the

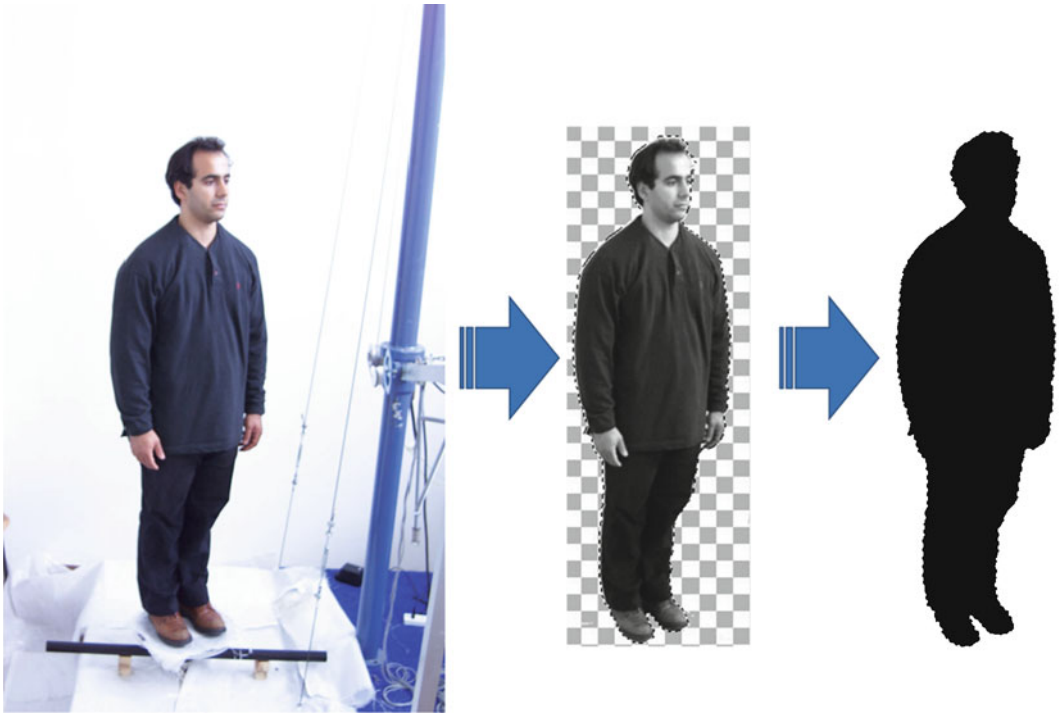

Fig. 4.4 Starting from the actual image, the *gray* and *black-and-white* scales. The images are suitably edited to remove objects unrelated and any undesired color intensity; then they are converted into a *grey* scale and finally to a *black and white* scale

Table 4.3 Weight and height values, corresponding to 10th and 90th percentiles for male (subscript M) and female (subscript F) subjects of the southern Italian population

Percentiles (%)	$Weight_M$ (kg)	$Weight_F$ (kg)	$Height_M$ (cm)	$Height_F$ (cm)
10	62	50	161	153
90	90	79	180	169

This table reports the limit values (10th and 90th percentiles) of weight and height for male and female subjects, with respect to statistical data for the southern Italian population, within which Calvino et al. (2009) have selected the subjects

effective radiation area. Finally, they divided the obtained projected area by the effective radiating area to evaluate the project area factor (see Fig. 4.7).

Another study that utilized a numerical simulation method is that of Lo Curcio (2009), who also utilized commercially available software (Poser®) to obtain a body-shape digital model and to photograph it from several viewing angles with a virtual camera; he thus simulated the photographic method utilized by Fanger. The algorithm utilized for calculating the projected area of a human body is shown in Fig. 4.8.

Lo Curcio applied this algorithm to 12 body shape models (six male and six female) from Italy, Australia and Britain, China, Japan, Germany, and the United States (see Fig. 4.9).

The main anthropometric characteristics of these body shape models are reported in Table 4.4.

Figure 4.10 shows the projected area factors of standing (left) and seated (right) people, referring to the Italian male sample, obtained by Lo Curcio (2009).

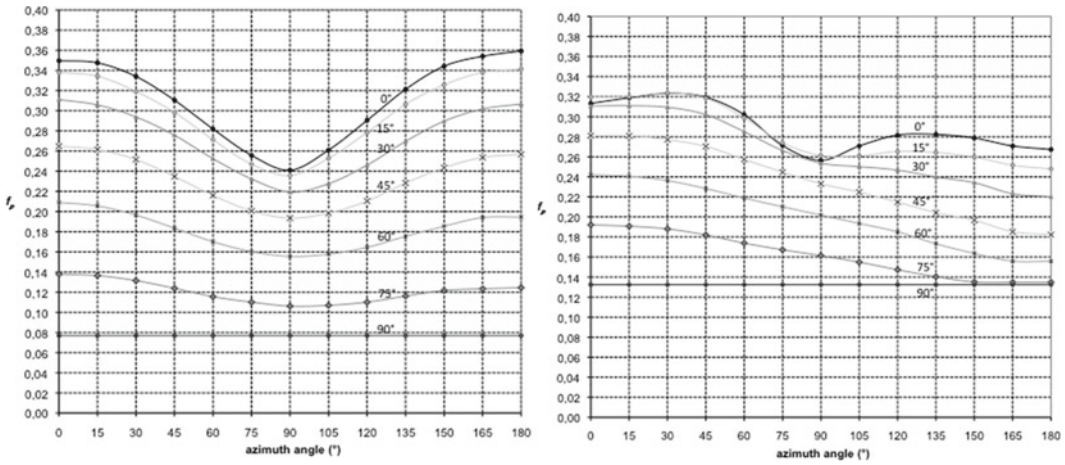

Fig. 4.5 Projected area factors of standing (*left*) and seated (*right*) people referring to the southern Italian population (Calvino et al. 2009). Calvino and his co-workers, have evaluated the mean values of the projected area factors, for standing and seated people, selecting the subjects whose weight and height values fall within the 10th and the 90th percentiles, with respect to statistical data for the southern Italian population

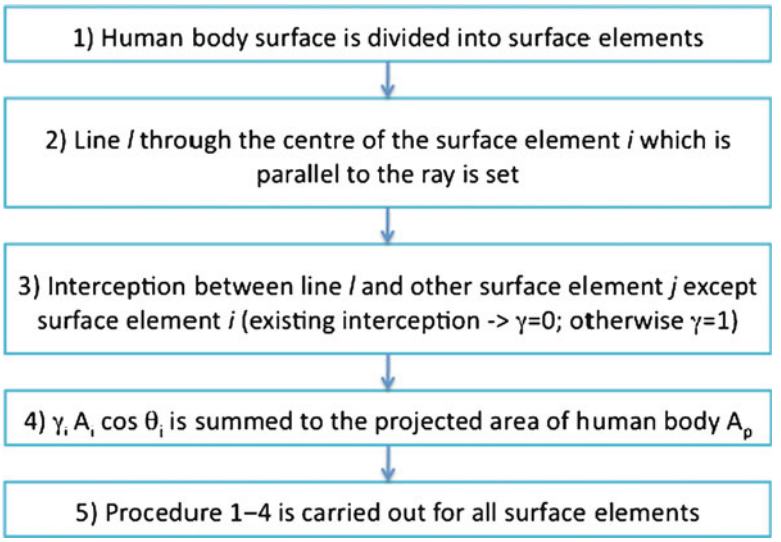

Fig. 4.6 Algorithm for calculating project area of the human body (Tanabe et al. 2000). The Tanabe numerical simulation method for predicting the effective radiating area and the project area of the human body (Tanabe et al. 2000) is based on the solar gain simulation, according to which body shape, obtained by means of commercially available software, is divided into quadrilateral surface elements

4.4 Anthropometric Parameters in the Literature

A comparison of the results of the studies considered in this chapter (Fanger 1970; Tanabe et al. 2000; Calvino et al. 2009; Lo Curcio 2009) reveals a high agreement of the data of the projected area factor in a standing posture; the same cannot be said of data relating to the projected area factor in a

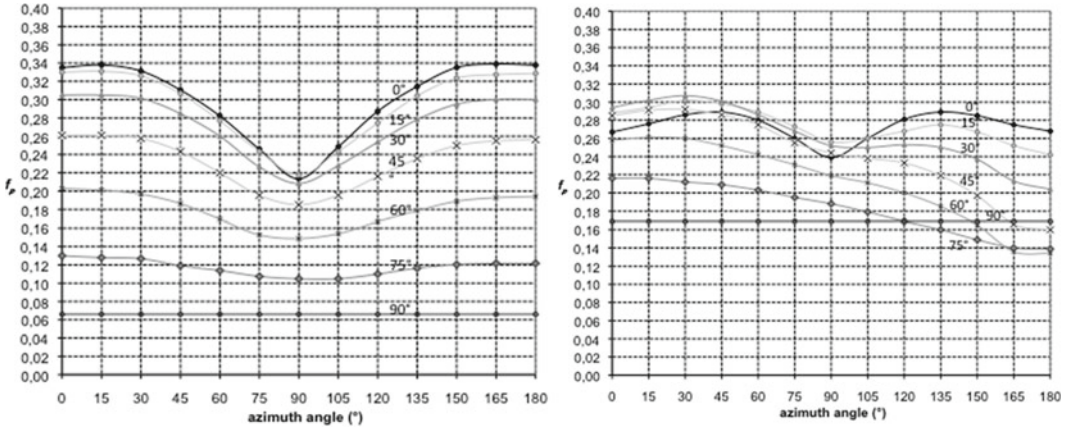

Fig. 4.7 Projected area factors of standing (*left*) and seated (*right*) people, referring to the Tanabe's samples (Tanabe et al. 2000). Tanabe and his co-workers applied their numerical simulation method to 91 directions of the ray, obtaining the mean values of the projected area factors, for standing and seated people

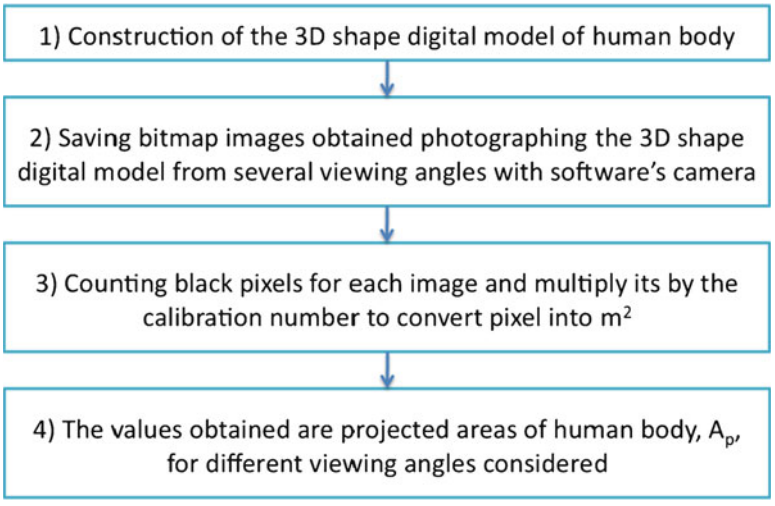

Fig. 4.8 Algorithm for calculating project area of the human body (Lo Curcio 2009). The Lo Curcio numerical simulation method utilizes commercially available software (Poser®) to obtain a body-shape digital model and to photograph it from several viewing angles with a virtual camera; the images are then processed to deduce the projected areas

seated posture. Data for the projected area factors (Fig. 4.2) are available in graphical form (Fanger 1970); nevertheless we can also recall a polynomial algorithm, proposed by Rizzo et al. (1991), for an easy computation of the mean projected area factors for standing and seated people:

$$f_p(\alpha,\beta) = \sum_{i=0}^{4}\sum_{j=0}^{3} A_{ij}\alpha^i\beta^j \tag{4.34}$$

where α and β are azimuth and zenith angles respectively, and A_{ij} are proper coefficients depending on the posture of those involved (see Table 4.5).

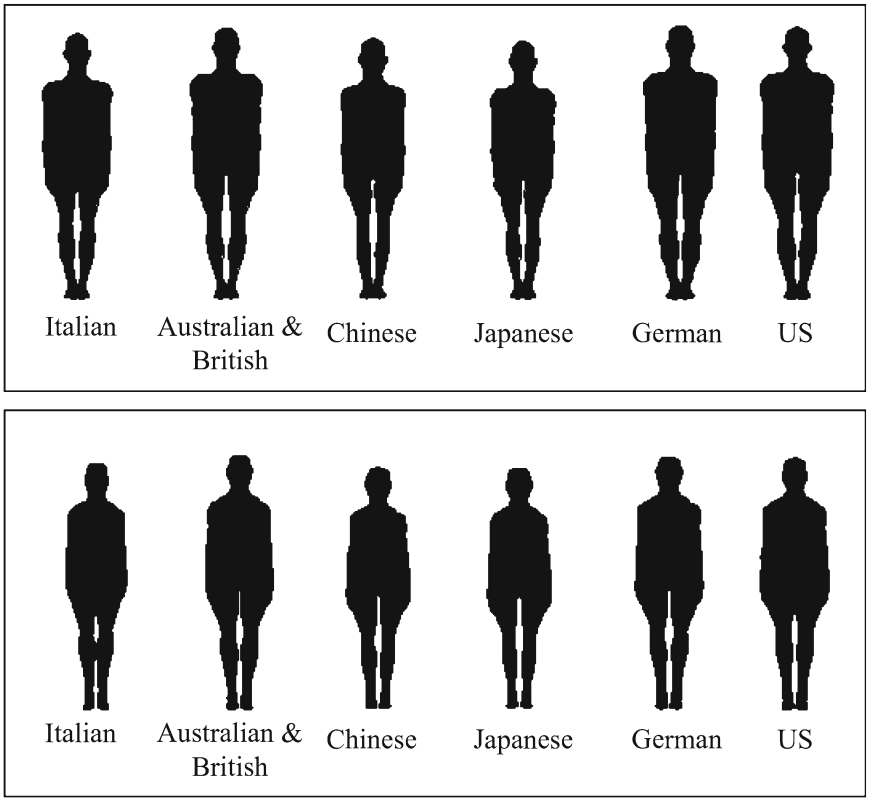

Fig. 4.9 Digital shape model of human body in standing posture of male (*up*) and female (*down*) samples. Lo Curcio applied his algorithm to six male and six female digital body shape models, representative of Italian, Australian and British, Chinese, Japanese, German, and United States ethnic groups

Table 4.4 The main anthropometric characteristics of the body shape of models analyzed by the Lo Curcio's study

	ISO 7250 (1995)	Anthropometric measurements	Italian	Australian & British	Chinese	Japanese	German	US
Male subjects	4.01.02	Stature (mm)	1,714	1,759	1,686	1,685	1,771	1,769

This table reports the main anthropometric characteristics of the Lo Curcio's body shape models utilized to evaluated the influence of gender and nationality on the projected area factors and the effective radiating area

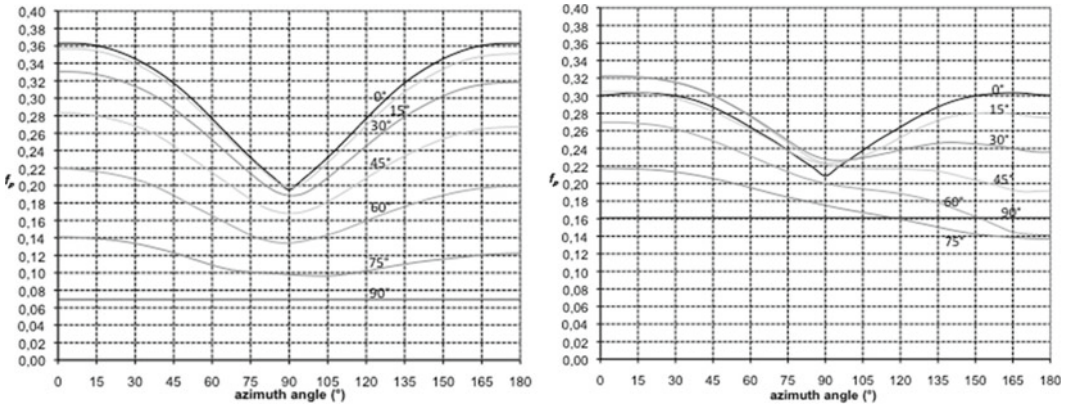

Fig. 4.10 Projected area factors of standing (*left*) and seated (*right*) people, referring to the Italian male sample (Lo Curcio 2009). Lo Curcio has evaluated the mean values of the projected area factors, for standing and seated subjects, male and female, starting from the statistical analysis of the anthropometric characteristics of several ethnic groups; in the figure are reported the results obtained for the Italian, male sample

Table 4.5 Coefficients *Aij* for standing and seated subjects

			i-th index				
	A_{ij}		0	1	2	3	4
Seated posture	*j*th index	0	+2.884 E-01	+2.225 E-03	−9.292 E-05	+9.027 E-07	−2.517 E-09
		1	+2.225 E-03	−7.653 E-05	+4.021 E-06	−4.632 E-08	+1.380 E-10
		2	−5.472 E-05	+7.286 E-07	−6.215 E-08	+7.690 E-10	−2.341 E-12
		3	+1.802 E-07	−1.457 E-09	+3.152 E-10	−4.015 E-12	+1.231 E-14
Standing posture	*j*th index	0	+3.453 E-01	+1.945 E-03	−1.023 E-04	+1.003 E-06	−2.747 E-09
		1	+6.930 E-04	+1.122 E-05	−1.502 E-07	+4.040 E-10	+8.461 E-13
		2	−7.319 E-05	−1.288 E-06	+3.676 E-08	−3.036 E-10	+7.489 E-13
		3	+3.675 E-07	+1.030 E-08	−2.517 E-10	+1.969 E-12	−4.715 E-15

This table reports coefficients A_{ij} of a polynomial algorithm, proposed by Rizzo et al. (1991), for an easy computation of the mean projected area factors for standing and seated people ($f_p(\alpha,\beta)=\sum_{i=0}^{4}\sum_{j=0}^{3}A_{ij}\alpha^i\beta^j$ where α and β are azimuth and zenith angles respectively)

4.4.1 Comparison with Fanger's Data of Projected Area Factors

In this section, we will compare the trends for the projected area factor relating to the standing and seated postures of Lo Curcio's (2009) study with those of Fanger (1970). The analysis reveals that there is a strong agreement between the data of the two studies as regards the standing posture. In particular, the mean excursion of differences is contained in the range (−0.020, +0.020), for male and female subjects, with the exception of the 90° azimuth angle, for which the differences reach values equal to −0.040 for female subjects and −0.030 for male subjects. This consideration highlights an underestimation of the projected area factors in Lo Curcio's study with respect to Fanger's study for positions close to the azimuth angle of 90°. This is probably due to the absence of hair in Lo Curcio's digital model study. However, the analysis of data relating to the seated posture reveals a significant agreement between the two studies, with the exception of the 30° zenith angle, for which the difference reaches a value of 0.080 (for an azimuth angle of 180°). This latter observation indicates a significant disagreement only for a zenith angle of 30° for the seated posture, which has also been demonstrated by the studies of Tanabe et al. (2000) and Calvino et al. (2009).

Table 4.6 The effective radiating area and the effective radiating area factor for standing and seated postures

		Literature reference				
Posture	Parameters	Rizzo et al.	Tanabe et al.	Fanger et al.	Horikoshi et al.	Miyazaki et al.
Standing	A_r (m^2)	1.424	1.276	1.262	1.312	1.317
	f_r (–)	0.806	0.744	0.725 ± 0.013	0.803 ± 0.005	0.834
Seated	A_r (m^2)	1.300	1.176	1.211	1.214	1.224
	f_r (–)	0.735	0.691	0.696 ± 0.017	0.740 ± 0.012	0.775

This table reports the effective radiating area and effective radiating area factor for standing and seated postures, as available in the current literature

Table 4.7 The effective radiating area and effective radiating area factor for standing and seated postures (male subjects) (Lo Curcio 2009)

		Australian					
Posture	Parameters	British	Italian	Chinese	Japanese	German	US
Standing	A_r (m^2)	1.388	1.253	1.210	1.197	1.449	1.460
	f_r (–)	0.771	0.784	0.790	0.788	0.777	0.774
Seated	A_r (m^2)	1.326	1.196	1.153	1.145	1.361	1.381
	f_r (–)	0.737	0.748	0.752	0.753	0.730	0.732

This table reports the effective radiating area and effective radiating area factor for standing and seated postures for male subjects as a function of posture and nationality, obtained by Lo Curcio (2009). This results regard subject characterized by the main anthropometric characteristics reported in Table 4.4

4.4.2 Influence of Gender and Nationality on Projected Area Factors

A comparison of the available data relating to project area factors pertaining to people of different gender and nationality reveals a high level of agreement. Indeed, the observed excursions of differences of project area factors are very low; the mean ranges of excursions are:

- (–0.017, +0.017) varying the nationality, for standing posture (reference: Italian sample);
- (–0.018, +0.014) varying the nationality, for seated posture (reference: Italian sample);
- (–0.011, +0.017) varying the gender, for standing posture;
- (–0.023, +0.028) varying the gender, for seated posture.

The projected area factor thus does not depend significantly on the different anthropometric characteristics existing between the various ethnic groups worldwide. Furthermore, passing from standing to seated posture, the range of excursion of the projected area factor remains almost unvaried with changing nationality, while it shows a slight increase with varying gender. As a general consideration, these changes are mainly highlighted in the sitting posture and are probably due to the geometric differences between male and female subjects.

4.4.3 Comparison of Available Effective Radiating Area Values

We will proceed in this section, to compare values of effective radiating area, as available in the current literature. A comparative summary of the effective radiating area and effective radiating area factor for standing and seated postures are reported in Tables 4.6–4.8.

Table 4.8 The effective radiating area and effective radiating area factor for standing and seated postures (female subject) (Lo Curcio 2009)

Posture	Parameters	Australian British	Italian	Chinese	Japanese	German	US
Standing	A_r (m^2)	1.254	1.107	1.074	1.082	1.263	1.261
	f_r (–)	0.802	0.810	0.824	0.822	0.809	0.794
Seated	A_r (m^2)	1.181	1.020	0.991	1.013	1.168	1.182
	f_r (–)	0.756	0.747	0.760	0.769	0.748	0.744

This table reports the effective radiating area and effective radiating area factor for standing and seated postures for female subjects as a function of posture and nationality, obtained by Lo Curcio (2009). This results regard subject characterized by the main anthropometric features reported in Table 4.4

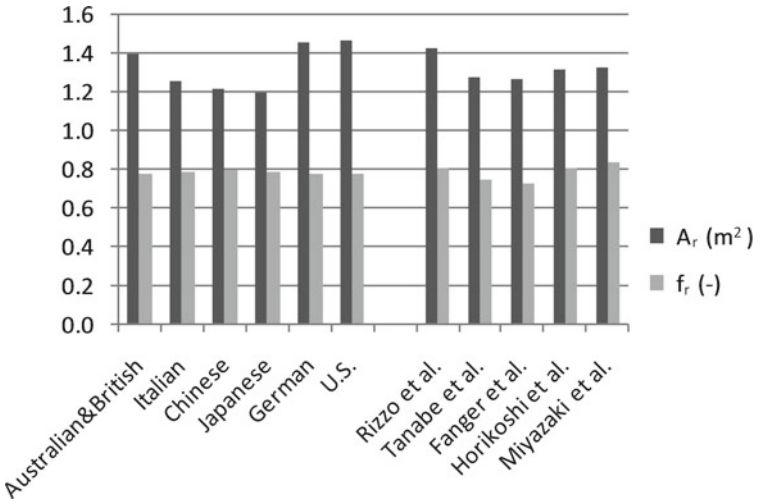

Fig. 4.11 The effective radiating area and the effective radiating area factor versus nationality (only male subjects) and literature studies (standing posture). The graph of the effective radiating area and the effective radiating area factor for male subjects in standing posture shows a correlation of the data from Lo Curcio's study and data currently available in literature

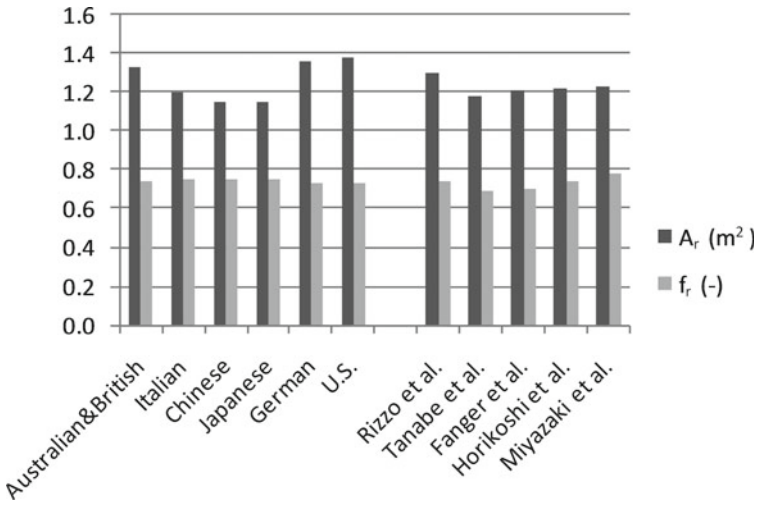

Fig. 4.12 The effective radiating area and the effective radiating area factor versus nationality (only male subjects) and literature studies (seated posture). The graph of the effective radiating area and the effective radiating area factor for male subjects in seated posture shows a correlation of the data from Lo Curcio's study and data currently available in literature

In order to enhance data comparison, we report only graphs of the effective radiating area and the effective radiating area factor as a function of gender, posture and nationality (see Figs. 4.11–4.14).

These graphs show a correlation of the data from Lo Curcio's study, for male subjects, using data currently available in literature.

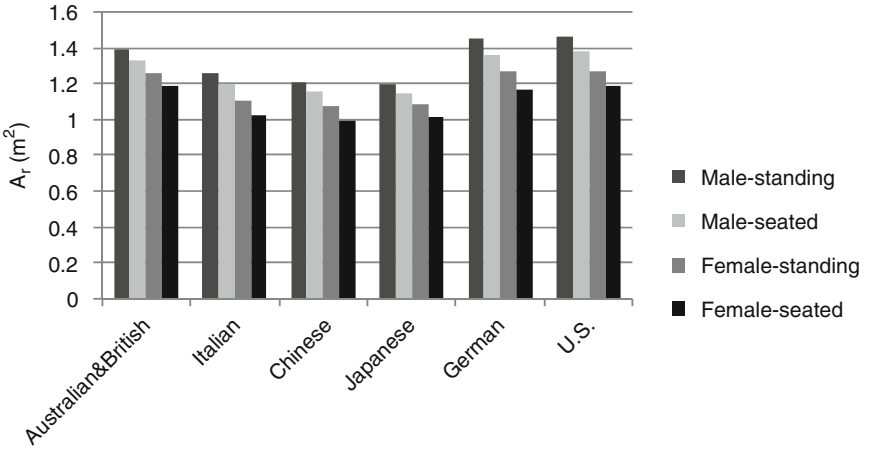

Fig. 4.13 The effective radiating area versus gender, posture, and nationality. The graph of the effective radiating area for male and female subjects, in seated or standing posture, shows a correlation of the data from the different people analyzed in the Lo Curcio's study

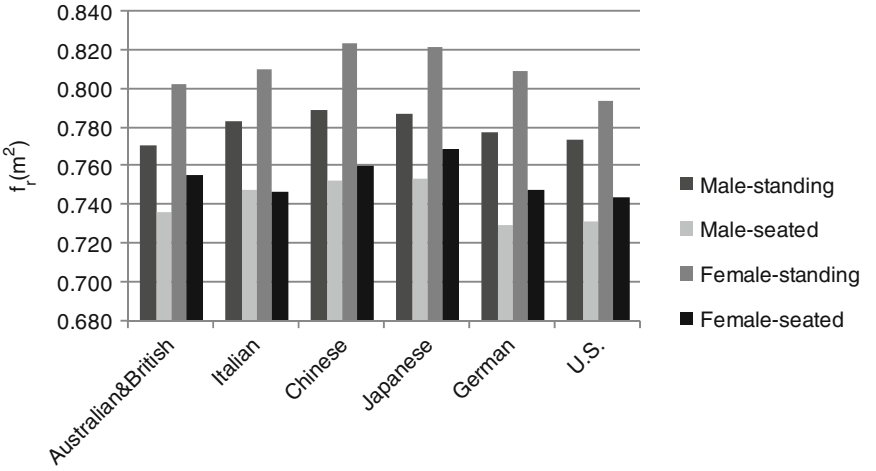

Fig. 4.14 The effective radiating area factor versus gender, posture and nationality. The graph of the effective radiating area factors for male and female subjects, in seated or standing posture, shows a correlation of the data from the different people analyzed in the Lo Curcio's study

4.5 Applications to Other Areas of Health and Disease

Although the previous description refers to standing and seated postures, the analysis of the anthropometric parameters can be extended to other situations, where people are mainly in a lying posture, as in hospitals. The utility of the relationship for the calculation of the radiative exchanges of an irradiated subject placed in a given enclosure and the importance of the knowledge of anthropometric parameters will now be illustrated by means of a numerical example.

Consider a naked resting subject, lying on the back, placed in a moderate thermal uniform environment with air temperature and mean radiant temperature of 26°C and a low speed of air

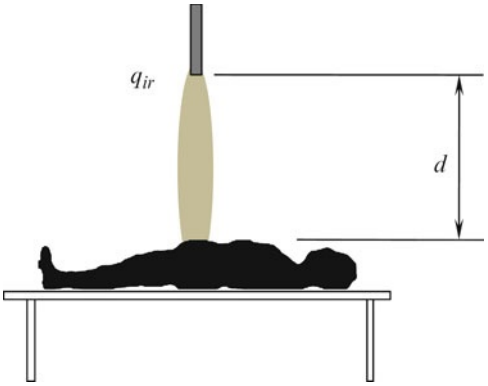

Fig. 4.15 Sketch of subject about to undergo surgery. The case for a patient about to undergo surgery may be considered as a naked resting subject, lying on his back, placed in a moderate thermal uniform environment, with a lamp placed in front of him

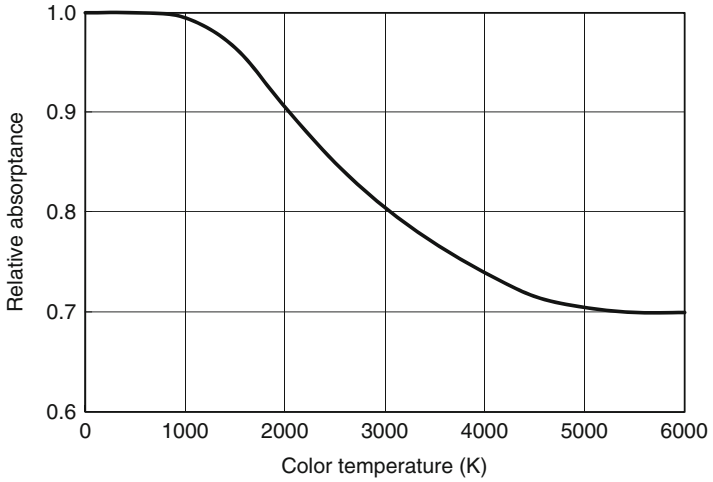

Fig. 4.16 Relative absorptance of skin at various color temperatures (ASHRAE 1989). The relative absorptance of skin depends on the color temperature of the emitting source

(i.e., less than 0.15 m/s). A lamp with a color temperature of 3,000 K is positioned in this environment whose intensity of the emitted radiation at the distance of 1 m, $q_{ir,1m}$, is equal to 150 W/m^2. The lamp, a high intensity heat source, is placed in front of the subject at a distance varying from 1 to 4 m; this may be the case for a patient about to undergo surgery (see, e.g., Fig. 4.15).

The positions of the human body and the lamp enable us to adopt the view factor values for standing people and, consequently, the pertinent equation for the radiative human body thermal balance.

In order to evaluate the total thermal radiation leaving the body for unit of body area, (4.35) is used, dividing (4.7) by the naked body surface area:

$$\frac{R}{A_b} = \sigma \varepsilon f_r \left[\left(t_{cl} + 273 \right)^4 - \left(\overline{t}_r + 273 \right)^4 \right] - \alpha_{ir} f_p q_{ir} \tag{4.35}$$

In (4.34), the clothed surface temperature, t_{cl}, may be obtained by means of a balance of the dry component of the energy exchanged between the external surface of the body and the environment (Fanger 1970). Emissivity, ε, and the effective radiating area factor, f_r, have been assumed equal to 0.97 and 0.696, respectively; the projected area factor, f_p, has been set at the value of 0.35 (valid for a standing subject with altitude and azimuth angles of 0°); and the relative absorptance of skin, α_{ir}, has been assumed to be equal to 0.8, with reference to Fig. 4.16.

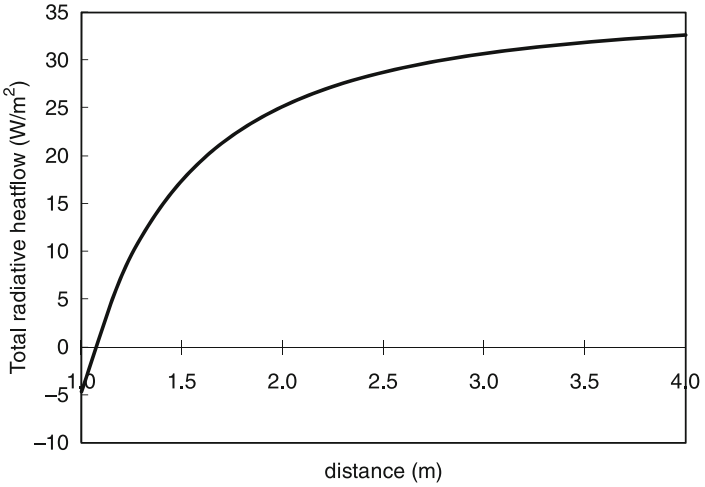

Fig. 4.17 Total thermal radiation as a function of the distance between the body and the high intensity heat source. The figure shows as, when a lamp is near to the subject, the total radiative heat flow is a gain, whereas, when a lamp is further away, the radiative heat flow is a dispersion

Moreover, the dependence of the radiant flow on the distance of the lamp has been evaluated by the following equation:

$$q_{\mathrm{ir}}(d) = \frac{q_{\mathrm{ir},1m}}{d^2} \tag{4.36}$$

Finally, the behavior of the radiative heat flow leaving the body of the irradiated subject is reported in Fig. 4.17, as a function of the distance between the subject and the lamp.

In Fig. 4.17, the total radiative heat flow by the subject toward the environment is assumed as positive, while the total radiative heat flow reaching the human body from the environment is assumed as negative. When the lamp is near the subject, the total radiative heat flow is a gain; when the lamp is further away, this radiative heat flow is considered dispersion.

These considerations definitely confirm the crucial importance of the knowledge of human body radiative parameters (particularly, the projected and the effective radiating area factor) in order to evaluate radiative heat flows and the thermal sensation of a subject. Similar considerations can be made for clothed persons by taking into account the importance of other human body radiative parameters, which the clothing area factor will markedly increase.

Summary Points

- The thermal sensation of a subject in a confined environment is related to the need of the human body to arrive at a homeothermic state at body core level.
- In order to evaluate the thermal condition of a subject in a confined environment, a suitable set of radiation data referring to the human body anthropometry is required.
- The main parameters facilitating the evaluation of the convective and radiative exchanges between the human body and the environment are:
  - The body surface area;
  - The clothing area factors;
  - The effective radiation area factor;
  - The projected area factors.

- A detailed description of the practical methods and techniques for determining the relevant human body anthropometry parameters has been described by pointing out the main features and the ease or otherwise of their suitable application.
- The results of a new study concerning the determination of the differences of peoples of various gender and nationalities on the radiation anthropometric parameters has been outlined.

Key Points of Homeothermic State

- The thermal comfort of people in confined, thermally moderated environments is considered to be of paramount importance today in order to guarantee optimal working and living conditions to the occupants of any given building. The conditions for ensuring indoor comfort involve a relevant consumption of energy, required by HVAC systems in winter (heating) and summer (cooling). Thus, suitably addressing the thermal conditions of buildings could result in a significant primary energy saving.
- In order to evaluate the thermal body (thermo-hygrometry) comfort conditions at a design level, specific algorithms, which obtain human body thermal balance in a given indoor environment, are required. This calls for knowledge of various important anthropometric parameters, particularly in relation to the radiative heat exchange of the human body, which represents one of major factors in the thermal balance of human body.
- Algorithms, practical methods and techniques for obtaining such parameters (the body surface area, the clothing area factor, the effective radiating area factor and the project area factors) have been reported in this chapter.
- The potential of these parameters to address new areas of health and disease, particularly in hospitals and buildings where people assume predominantly supine postures, has also been analyzed.

Chapter 5
Optical and Electromagnetic Shape-Capturing Systems for Limb Anthropometrics

Mark D. Geil

Abstract The allied health disciplines of prosthetics and orthotics require specialized knowledge of anthropometrics and have consequently developed instrumentation and systems to capture shapes of specific body segments. This instrumentation has found application for digital shape capture and subsequent model modification for intact and residual limbs as well as for the head and torso. Two primary technologies have emerged. Optical scanners are largely non-contact and use combinations of digital cameras, lasers, and lights to capture the surface geometry of a limb. Electromagnetic field-based systems are contact scanners that require the entire surface of the limb segment to be traced using a stylus. The accuracy of both systems has been established versus known measures and conventional hand-tool anthropometrics. Furthermore, the use of systems for routine collection of anthropometrics for all patients has been proposed even in cases when the instrumentation is not used as part of the process of fabrication of a prosthesis or an orthosis. Additional utility is possible with the use of the digital caliper function of magnetic field scanners. In particular, the collection of body segment parameters that is a necessary part of clinical gait analysis is significantly more efficient with the digitizer. An additional practical application of the systems is centralized fabrication of prosthetic and orthotic components. In conclusion, specialized equipment for limb digitization has benefitted the disciplines of prosthetics and orthotics and could have ancillary benefits in other fields as well.

5.1 Introduction

While anthropometry is already important in health care disciplines that monitor growth or changes in limb shape and size, its importance increases when a device must be fabricated to provide a customized, intimate fit with the limb. In particular, the allied health disciplines of prosthetics and orthotics require detailed information about human extremities, including residual limbs following amputation and congenitally malformed limbs (Table 5.1). Such information must contain three-dimensional data including not only overall limb volume, contours, and dimensions, but also the location of certain skeletal and soft-tissue landmarks. In addition, specific conditions require anthropometric data for the head and torso.

Historically, prosthetists and orthotists have found ways to capture anatomical shapes using simple tools and a minimum of measurements. Casting has been and still is used to produce a three-dimensional negative impression of an anatomical segment, from which a positive plaster model can be produced, modified, and used for the fabrication of an orthosis or a prosthetic socket (Fig. 5.1).

Table 5.1 Key features of prosthetics and orthotics

Prosthetics	Orthotics
Prostheses are devices that replace a missing body part	Orthoses, or braces, are devices that augment an existing body part
Prostheses are fabricated and fit by a prosthetist	Orthoses are fabricated and fit by an orthotist
Limb prostheses replace arms or legs, and may include joints including knees or elbow	Limb orthoses may be used to control range of motion, modify shape, or transfer forces
Limb loss may occur as a result of congenital deformity or dysfunction, trauma, or disease	Limb orthoses may be necessary when muscle function is compromised, resulting in either too much or too little tone

These key facts provide an introduction to the related allied health care disciplines of prosthetics and orthotics

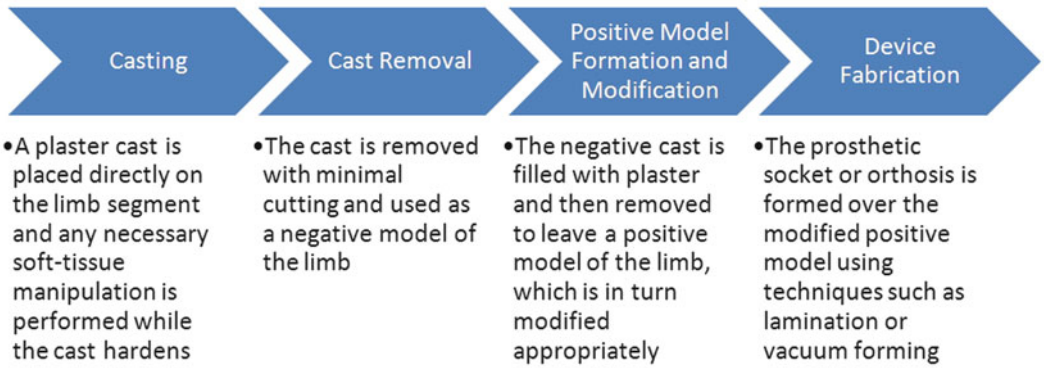

Fig. 5.1 Fabrication flow chart. Fabrication process in prosthetics and orthotics using traditional limb capture techniques

In the process of seeking enhancements to this traditional process, technologies in computer aided design and manufacturing (CAD/CAM) were modified for clinical use in prosthetics and orthotics (Boone and Burgess 1989; Houston et al. 1992). CAD/CAM rectification is intended to accomplish several tasks: capturing the three-dimensional anatomical shape, allowing software-based modification of that shape, and producing output data suitable for automated manufacture. Ancillary benefits of the process are related to anthropometrics research; most notably, the process generates a digital model of the shape from which any required anthropometric dimension can be obtained.

Although development continues in all aspects of CAD/CAM in prosthetics and orthotics, technologies for digital capture of anatomical shapes have outpaced technologies for automated fabrication of orthoses or prosthetic sockets. Consequently, practical application of CAD/CAM often entails automated manufacture of a positive model upon which the final step in Fig. 5.1 must still be performed, as opposed to direct automated manufacture of a finished socket or orthosis (Smith and Burgess 2001).

This chapter will focus on technologies and techniques for digital shape capture of the human extremities, with a focus on digitization of the residual lower limb of an individual with limb loss for the purpose of prosthetic socket fabrication.

5.2 Limb Anthropometrics

Specific anthropometric measurements are important in prosthetics and orthotics because of the clinical needs of individual patients. Very specific limb dimensions might be important for needs as diverse as increased force application for skeletal control or pressure relief for comfort. Common clinical needs necessitating specific anthropometric measurements are detailed in Table 5.2.

These clinical needs require detailed and accurate understanding of measures associated with the complete limb, such as residual limb volume, alongside specific measures of one anatomical aspect with respect to another, such as the linear distance from the distal end of the residual limb to the center of the patella.

With a goal of clinical efficiency, prosthetists and orthotists have developed means to fabricate devices that meet the varied clinical needs of patients without quantifying specific anthropometric data. Before digitization was available, techniques were developed to transfer anatomical landmarks to the positive model and then modify the model to add or reduce volume based on clinical experience. These techniques persist such that a large percentage of facilities do not routinely record a wide array of anthropometric measurements. This practice impedes post-hoc research in prosthetics and orthotics, and CAD/CAM techniques have been proposed for routine data collection, even when conventional fabrication techniques are used (Geil 2007).

Table 5.2 Anthropometric examples

Category	Clinical need	Example of required anthropometrics
Prosthetic socket	Comfort, pressure relief over skeletal prominences	Height of fibular head over cross-sectional limb circumference
Prosthetic socket	Suspension and weightbearing control	Location of patellar tendon relative to patella and distal aspect of the residual limb
Spinal Orthosis	Prevention of curve progression in scoliosis	Spinal curvature and height of specific vertebrae

Examples of anthropometric requirements that might be required to address specific clinical needs in prosthetics and orthotics

5.3 Technologies for Digital Shape Capture

Technologies designed specifically for use in prosthetics and orthotics have developed into two primary platforms: magnetic field and optical. Electromagnetic field-based digitization involves tracing the contour of the limb, while optical digitization requires little to no contact with the limb. Each approach has advantages and disadvantages in terms of ease of use, accuracy, repeatability and clinical utility. Both arrive at similar sets of anthropometric outcomes.

5.3.1 Magnetic Field-Based Digitization

Magnetic-field based systems for the digital capture of human limb shapes typically use three components: a magnetic field emitter, a stylus, and a reference field sensor (Fig. 5.2). The reference sensor is attached to the limb to provide a local coordinate system. Limb anthropometrics are initially defined with respect to this limb coordinate system to allow for the possibility of limb movement. The stylus is then used to identify overall limb space and orientation (anterior, posterior, medial, and lateral aspects). To capture limb volume and contours, the limb surface is traced with the stylus. Finally, anatomical landmarks of interest are identified with the stylus.

5.3.2 Optical Digitization

Optical scanners use different combinations of cameras, light-emitting diodes, and eye-safe lasers to capture the shape of the limb (Fig. 5.3). These systems usually perform the shape capture process in less time than magnetic field contact scanners. Digital camera-based optical scanners usually involve the application of a material to the limb. In some cases, a white sleeve is placed over the limb,

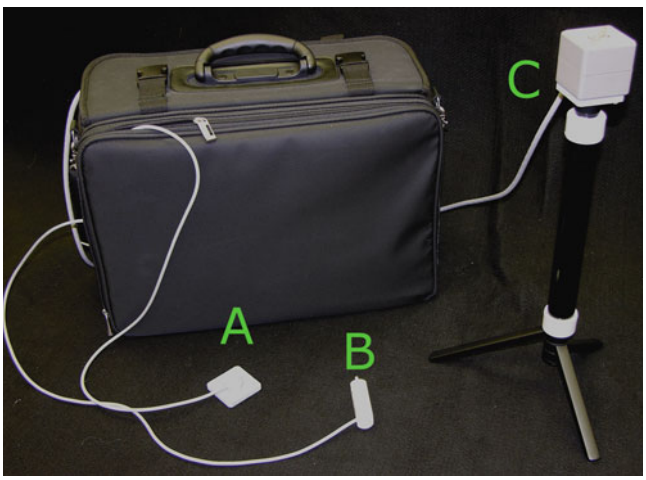

Fig. 5.2 Magnetic field-based instrumentation. Instrumentation for digital shape capture based on magnetic field-based sensors. Components are labeled as follows: (**a**) reference field sensor; (**b**) stylus; (**c**) magnetic field emitter

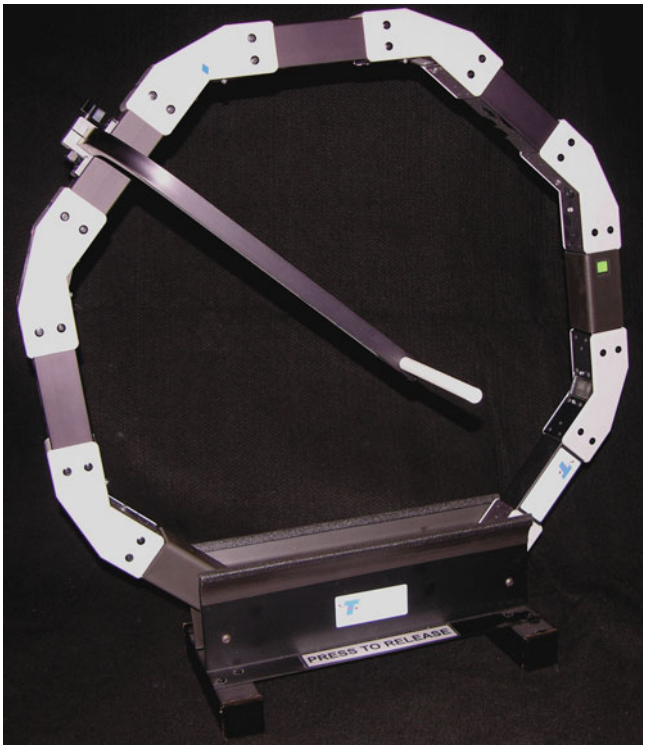

Fig. 5.3 Optical instrumentation. Optical instrumentation for limb anthropometry. The ring shown emits parallel bands of light on a limb and cameras record the distance between lines

and the scanner system uses lasers or light emitting diodes to project a fixed array of stripes or a grid onto the sleeve. In some cases, reflective markers placed on the surface identify contours.

In both scenarios, human limbs are most often mathematically modeled as closed cylinders, and the same software can be used to observe or modify models obtained through either method. Clinically, an important distinction between the methods is that non-contact methods are usually faster, but they do not allow the clinician the opportunity to manipulate soft tissue during the shape capture process.

5.4 Anthropometric Outcomes

Completed digital models of the limbs enable the collection of multiple anthropometric measures. Digital models are produced in file formats appropriate for computer numerical control (CNC) milling machines or rapid prototyping machines, and these files afford the measurement of linear dimensions, circumferences, and volume in any direction. Discipline-specific front–end software used for model modification displays a limited set of measurements; nonetheless, readily available outcomes are still vast. Standard measurements include (Fig. 5.4):

- Circumference at any level perpendicular to the long axis of the limb
- Anterior–Posterior diameter at any level perpendicular to the long axis
- Medial–Lateral diameter at any level perpendicular to the long axis
- Linear distance from any point on the model surface to the distal end parallel to the long axis

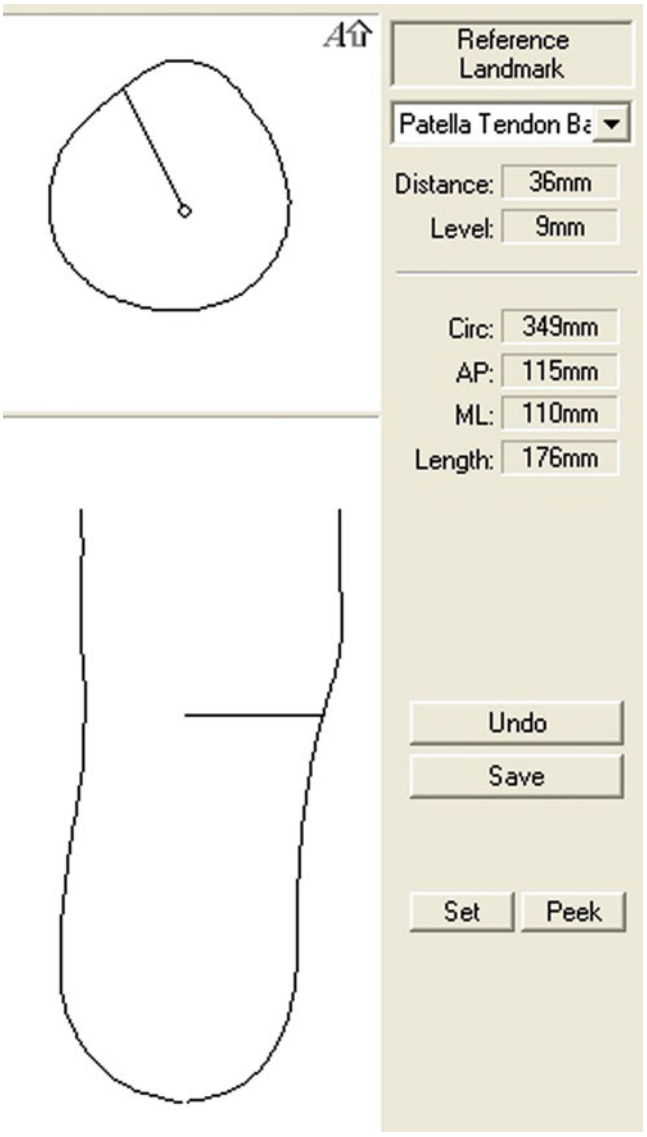

Fig. 5.4 Measurements within software. Basic anthropometric measurements reported for a model of the residual limb of an individual with transtibial amputation on Omega Tracer software (version 11.0, Ohio Willow Wood, Mt. Sterling, Ohio, USA)

Another important clinical outcome is limb volume, since closeness of fit is essential for component function. While clinicians do not routinely quantify volume, temporal fluctuations in volume for a given patient are important. In prosthetics, socks are used to fill space between the prosthetic socket and the residual limb, and the number of sock ply has developed as an indirect measure of volume.

Perhaps one reason that volume has not been routinely measured is the difficulty in measurement and the equipment required. Magnetic resonance imaging and related medical imaging techniques can be used to assess volume, but the process and equipment are expensive. Water displacement has been used as a primary tool and to validate other tools (Fernie and Holliday 1982; Smith et al. 1995),

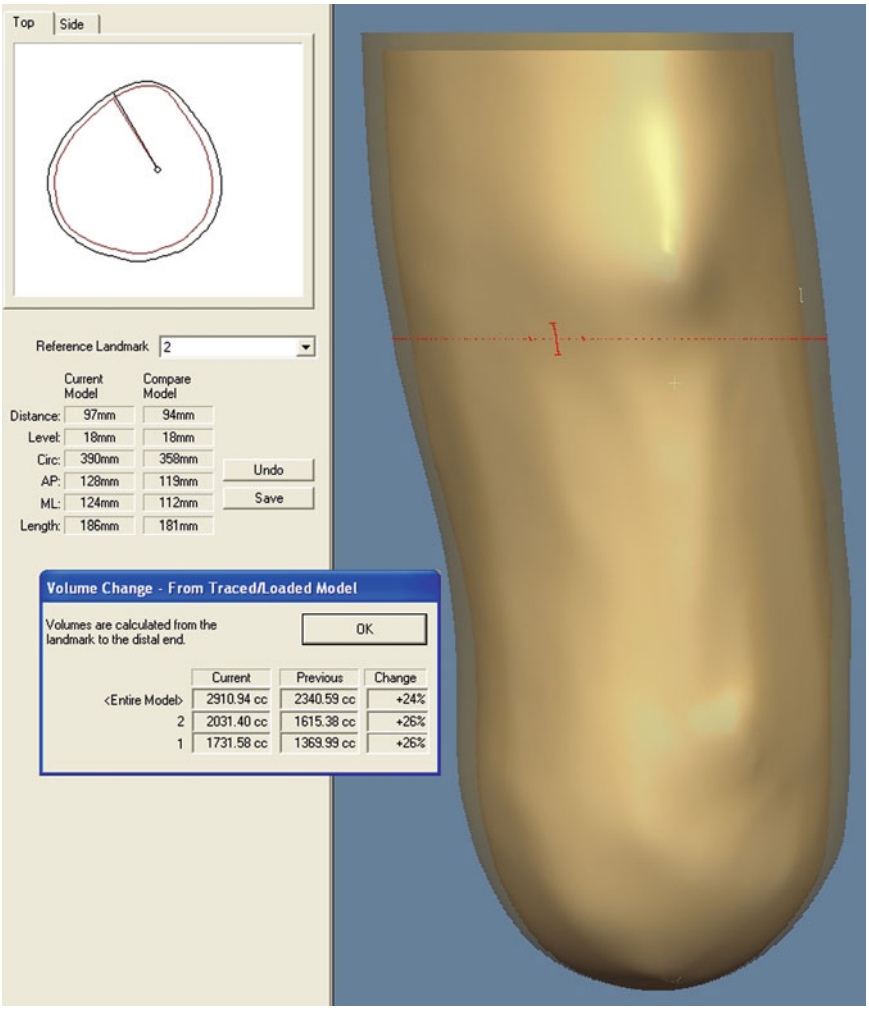

Fig. 5.5 Volume comparison in software. Comparison of volume for two residual limb scans on Omega Tracer software (version 11.0, Ohio Willow Wood, Mt. Sterling, Ohio, USA). Volume difference is displayed visually and reported numerically

but it is cumbersome. Electrical bioimpedance has been used to assess residual limb volume within the prosthetic socket in individuals with amputation (Sanders et al. 2007); like all of these techniques, it requires specialized equipment.

Because limb volume fluctuation within an individual is of such importance, a useful feature of software customized for digital shape capture in prosthetics and orthotics is the ability to visualize volume fluctuation and to add or remove volume in a model (Fig. 5.5).

In some cases, the volume measurement is not the most essential outcome, but it is related to the essential outcome. Prosthetic sockets must employ some type of suspension to remain affixed to the residual limb. Designs have evolved through history, and newer sockets have been developed with a different suspension philosophy than their predecessors. Socket designs that originally reduced volume at certain anatomical landmarks to apply active pressure have been augmented or replaced by total surface bearing sockets that employ an additional gel liner interface, hydrostatic sockets intended to equalize pressure over the entire residual limb, and sub-atmospheric pressure suspension

systems which employ vacuum to maintain suspension. With these approaches, accurate measure of the contours and shape of the limb are paramount. The fact that digitized limb models permit the calculation of the curvature of the surface of the limb at any point (Vannah et al. 2000) may become more important as socket designs continue to necessitate very close fit.

5.5 Accuracy of Digital Shape Capture

The accuracy of models that result from digital shape capture can be assessed using anthropometry. Comparisons must be made between the model and a known standard. For the sake of simplicity, Lilja et al. measured accuracy using a cylinder (Lilja and Oberg 1995). For measures of volume using a Swedish Computer-Aided-Prosthetic and Orthotic-Design (CAPOD) System, a consistent systematic error of 2.5% was identified. Because general volume modifications are easily accomplished within software, such a general error is not a major clinical concern. The same study identified random error of 0.5%, which is comfortably small for most clinical applications. Johansson and Oberg compared two CAD systems for precision and accuracy and found results similar to Lilja et al. for the CAPOD system and larger random errors for the ShapeMaker system, but still less than 1.3% (Johansson and Oberg 1998).

Geil focused on common clinical anthropometric measurements to assess the precision, accuracy, and reliability of two types of systems: a contact and non-contact scanner (Geil 2007). This research also investigated operator experience, comparing a group of experienced practitioners to a group of prosthetics students. In general, measurement results were consistent across systems and operators, and the mean difference in measurement between the systems was less than 1 cm. A specific source of error was identified in the use of the optical non-contact scanner to determine limb diameter. If the scanner was held at an angle to the line perpendicular to the long axis of the limb, and this deviation was not corrected in the model, diameters were overestimated as the hypotenuse of a triangle formed based on the angle of deviation (Fig. 5.6).

Geil's work suggests that modern CAD/CAM systems can be of clinical value for the purpose of routine collection of anthropometrics, even if they are not used for limb modeling, rectification, or device fabrication.

5.6 Applications to Other Areas of Health and Disease

Clinical gait analysis is an important procedure that provides insight into movement disorders that is not otherwise available through observation. Human walking is dynamic and complex, and specialized equipment is required to record human motion, model the segments of the human body, and reconstruct the motion paths in three dimensions for subsequent analysis (Perry 1992).

In its relatively young history, a reasonably standard approach to modeling of the human body has emerged. In general, three-dimensional kinematics are recorded with a minimum of three markers per segment. The lower extremities are modeled by rigid segments for the foot, lower leg or shank, upper leg or thigh, and pelvis. Shared markers near joint axes of rotation minimize the total number of markers required. These markers must be combined with information about the geometry of each segment in order to accurately model joint centers, segment centers of mass, segment lengths, and segment moments of inertia. Specific anthropometric data called body segment parameters (BSPs) provide this geometric information (Vaughan et al. 1992).

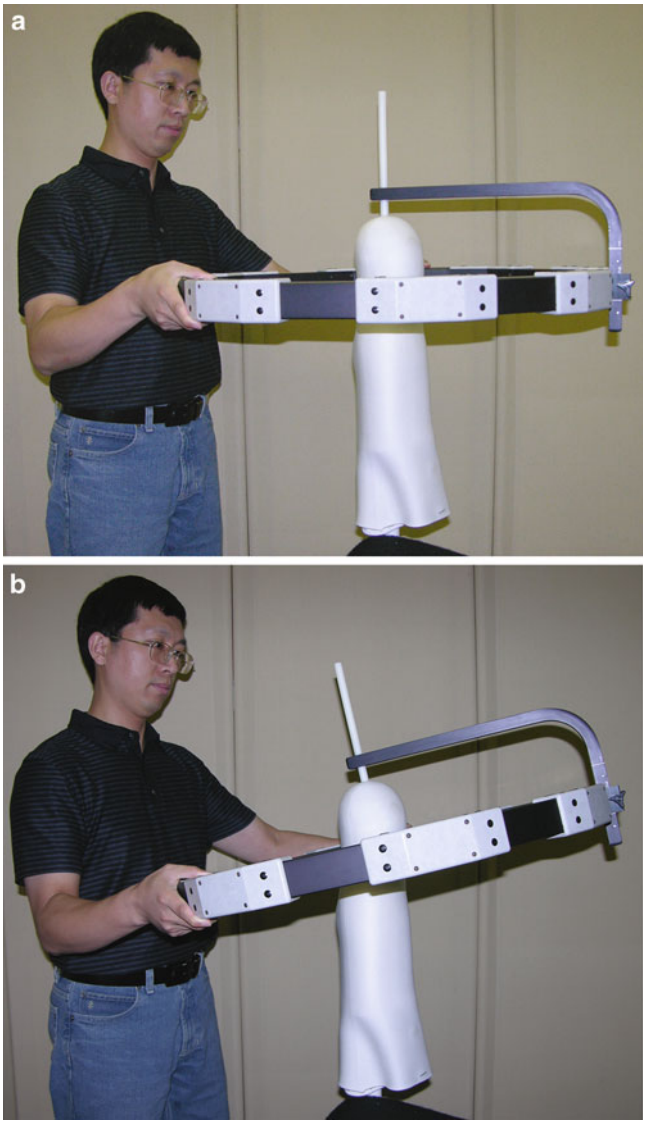

Fig. 5.6 Source of error in shape capture. Optical scanner positioned on a model of a residual limb, illustrating alignment of scanner perpendicular to the long axis of limb (**a**) and oblique to the long axis of limb (**b**). If not subsequently corrected in software, the angle in (**b**) will introduce errors in limb diameter and circumference measurements

In practice, BSPs are collected at the beginning of a gait analysis session. The number of measurements required depends on the model used and can be fairly large. A largely untapped utility present in contact scanners for digital shape capture in prosthetics and orthotics has application in clinical gait analysis. Because magnetic field-based systems employ two independent sensors in the same magnetic field (one to establish the limb coordinate system and one for contact scanning), the linear distance between the two sensors can be readily determined. In this technique, the two sensors function as ends of digital calipers (Fig. 5.7). In our laboratory, we have utilized the digital caliper mode to streamline collection of BSPs in clinical gait analysis.

This approach provides significant time savings, in particular due to the fact that once the calipers are in place for a given measurement, the operator simply pushes a button on one of the sensors and

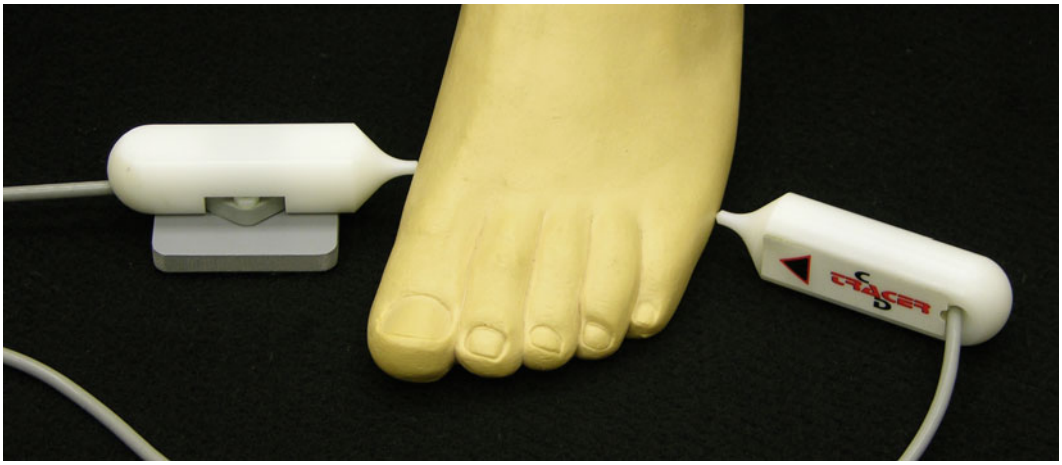

Fig. 5.7 Digital calipers. Configuration of a magnetic field contact scanner as digital calipers. The model reference sensor is used as an additional stylus. The system provides real-time feedback of the distance between the two sensors, and the dimension can be recorded by the system (following software modification) by clicking the button marked with the black triangle on the stylus

the measurement is recorded. This avoids problems associated with standard calipers, including inadequate throat size, the need to remove the caliper from the limb to read the gauge, and the possibility of misreading the gauge.

When the digital caliper technique was used in our laboratory by two investigators to measure a standard set of ten lower limb BSPs and compared to measurement using traditional calipers and tape measures for ten subjects, the digital caliper technique was more efficient. The mean time to complete the measurements using digital calipers was 1 min, 30 s. The mean time to complete the measurements using traditional measurement tools was 4 min, 5 s. The difference is statistically significant ($p < 0.0001$). Research to compare the accuracy of the two techniques is ongoing.

5.7 Practical Methods and Techniques

One of the advantages of digital shape capture of limb anthropometrics is the portability of digital files. With the traditional method described in Fig. 5.1, the only complete record of limb shape and volume is the physical positive model. If the limb shape has been digitized, complete shape information is contained in a single computer file.

This portability has expanded the practicality of central fabrication in prosthetics and orthotics (Smith and Burgess 2001). In this model, practitioners see patients at a different facility from the one in which components are fabricated. There are multiple potential benefits to a central fabrication approach. Facility overhead is reduced, enabling the establishment of smaller offices in more locations, possibly reducing expense. However, the model does require close communication between practitioner and fabricator. In particular, anthropometric definitions must be clearly defined. A variable such as “residual limb length” is highly dependent on measurement technique. Even if the proximal location from which length is measured is clearly specified, results can vary widely. If the length is measured on the limb or on a positive model, one practitioner might align the caliper parallel to the long axis of the limb. Another might keep the caliper close to the surface

of the limb. Still another might use a tape measure. If the same measurement is determined from a digitized model using anthropometric software, it is important to understand the technique employed by the software.

The portability of shape capture equipment has also found application in the developing world, where patient care is challenged by distance. With fewer fabrication facilities and increased difficulty for patients to reach those facilities, portable anthropometric measurement can be the only feasible patient care solution. Because digital shape capture devices can be carried by the practitioner to remote locations and because they produce computer files that can be easily transferred to distant fabrication facilities, they provide a practical solution to challenging patient care.

Summary Points

- Tools for digital capture of limb shapes have developed specifically for clinical use in prosthetics and orthotics
- Prosthetists and orthotists have need for measurements of limb length, circumferences at certain levels, and anterior–posterior and medial–lateral limb diameters
- Limb volume is important but not routinely quantified
- Two primary technologies are used for digital shape capture: optical scanners and electromagnetic field scanners
- Accuracy of these devices has been independently assessed in the literature
- Magnetic field-based systems have a potential application in clinical gait analysis for the routine recording of body segment parameters
- Digitization of the limbs has advanced the concept of centralized fabrication of prosthetic and orthotic components

Table 5.3 Key features of limb digitzation systems

Time for capture	Digitization occurs in real time. Optical systems can capture a limb shape in less than 1 s. Contact scanners require contact with the entire limb surface area, which can take 2–3 min.
Landmarks and modification	Optical systems automatically identify landmarks, which are in some cases special marks affixed to the limb prior to digitization. Contact systems allow marker identification using the stylus. Modification can occur on the limb with contact scanners and in post-processing with both systems.
Patient involvement	The limb must be held relatively still and extended with both technologies. A reference sensor in magnetic field systems permits some patient movement within the magnetic field. Most systems can be used with the limb in a variety of orientations.
Portability	Both systems are portable enough to take to remote locations and can be carried by one person along with a laptop computer. This portability has permitted the use of limb digitizers in developing countries to treat patients who do not have local facilities and cannot travel.

This table lists the key features of limb digitization systems, including their practical use in the clinic

Chapter 6
The Composite Index of Anthropometric Failure (CIAF): An Alternative Indicator for Malnutrition in Young Children

Shailen Nandy and Peter Svedberg

Abstract Malnutrition is a serious problem in many developing countries. It is one of the main causes of child morbidity and contributes significantly to premature mortality. This chapter discusses the design and use of an alternative indicator of malnutrition – the composite index of anthropometric failure (CIAF). It argues the three most commonly used anthropometric indicators of stunting, wasting and underweight, while providing valuable information about distinct biological processes, are individually unable to provide a comprehensive picture of the overall burden of malnutrition among young children in a population. They are frequently used to predict health and mortality risk, but provide quite limited information on the relationship between malnutrition and disease. The CIAF, however, can also be used to predict morbidity risk, and in its disaggregated form provides a more useful picture of the relationship between ill health and malnutrition. It can also be used to examine the relationship between different forms of malnutrition and poverty.

Using the new World Health Organization (WHO) reference population norms and recent anthropometric data on 45,377 Indian children aged under 5 years, the prevalence of stunting, wasting and underweight are calculated and compared to prevalence estimates by the CIAF. Age adjusted logistic regression is used to see how well different indicators predict morbidity risk. Analysis of variance is used to see the relationship between groups of anthropometric failure and poverty. This chapter also provides information on how reliable, nationally representative anthropometric data from household surveys can be freely accessed by researchers to pursue their own study.

6.1 Introduction

Other chapters in this Handbook detail the use of assorted anthropometric indicators to reflect malnutrition in young children, and set out how new, more appropriate, international growth norms for children have been developed by the WHO. This short chapter aims to:

1. Present the CIAF as a policy-relevant alternative means of assessing the prevalence of child malnutrition
2. Demonstrate how and why the CIAF is a more comprehensive indicator of malnutrition *than conventional indicators*
3. Show how the CIAF can be used to reflect the relationship between malnutrition, morbidity and poverty; and
4. Provide guidance on how to obtain reliable, nationally representative, anthropometric data on children and adults collected in household surveys around the world can be accessed at no cost and used in research

6.2 What Is the Composite Index of Anthropometric Failure (CIAF)?

The CIAF was first proposed by Swedish development economist, Professor Peter Svedberg (Svedberg 2000). The conventional indicators of malnutrition reflect different aspects of anthropometric failure. Stunting (low height for age (HTA)), which reflects retarded skeletal growth, is used as an indicator of chronic malnutrition. Wasting (low weight for height (WTHT)), which means loss of fat and lean tissue, is a measure of more acute malnutrition. Underweight (low weight for age (WTA)), finally, can be caused by stunting or wasting, or combinations thereof. Each indicator provides valuable information about quite distinct biological processes (World Health Organization 1995), which in turn require different clinical responses.

Malnutrition is a function both of food deprivation and disease. Both are often consequences of poverty, and as such, all anthropometric indicators only serve as proxies for evaluating the prevalence of malnutrition among children. As proxies, they may over- and underestimate malnutrition in different dimensions. They miss, for example, the possibility that children can be malnourished by being too physically inactive for a healthy life, even if they are not stunted or underweight. In addition, anthropometric failure can sometimes be the outcome of disease unrelated to nutrition (e.g. Crohn's disease, Celiac disease). Hence, while anthropometric failure is most often caused by a combination of ill health and inadequate diet, anthropometric indicators alone cannot tell us what the main cause is at the level of individuals.

The three conventional indicators cannot provide a single figure of the overall estimate of malnutrition among children in a population; although such information should be useful to policy makers

and planners, whose task it often is to allocate resources and design programmes and interventions to reduce malnutrition in a given region or country (Nandy and Miranda 2008).

Svedberg argues that stunting, wasting and underweight are not independent entities, and that while underweight is often used to reflect the extent of both chronic and acute malnutrition, it cannot distinguish between them. Underweight is also limited by the fact that it does not identify the sum of those children who are stunted and/or wasted, and so provides an underestimate of the extent of anthropometric failure in a population. What is needed instead is a means of identifying all undernourished children, be they stunted and/or wasted and/or underweight. The solution is the CIAF.

6.3 Constructing the CIAF

Svedberg modelled the distribution of different combinations of anthropometric failure in a population using Fig. 6.1. The vertical axis shows the deviation from the WTA norm, the horizontal axis shows deviation from the HTA norm and the diagonal line gives the combinations of weights for heights, which comply with the norm.

Thus, underweight (i.e. low WTA) would include children in sections (Groups) C, D and E, but misses those children in Groups B and F; stunting (i.e. low HTA) would include children in sections (Groups) D, E and F, but misses those children in Groups B and C; and wasting (i.e. low WTHT) would include children in sections (Groups) B, C and D, but misses those in Groups E and F. Svedberg (2000: 196) reasoned

> If one considers a child who is either stunted, wasted, or underweight… to be in a non−acceptable state, the only anthropometric indicator capable of giving an all−inclusive estimate is: CIAF=(1−a)/(a+b+c+d+e+f)=(1−a)/1=1−a, which we call the Composite Index of Anthropometric Failure.

Table 6.1 shows the groups of anthropometric failure in more detail.

The overall prevalence of malnutrition is then ascertained by summing all of the groups together, but excluding the children in Group A (i.e. those not experiencing any form of anthropometric failure). In operationalising the CIAF for the first time, an additional group, Group Y, containing children who are only underweight, was identified and added to Svedberg's model (Nandy et al. 2005).

Fig. 6.1 The total prevalence of anthropometric failure (Svedberg 2000. By permission of Oxford University Press, Inc.)

Table 6.1 Groups of anthropometric failure among children[a]

Group	Description	Wasting	Stunting	Underweight
A	**No failure**: Children whose height and weight are above the age-specific norm and who do not suffer from any anthropometric failure	No	No	No
B	**Wasting only**: Children with acceptable weight and height for their age, but who have subnormal weight for height (WTHT)	Yes	No	No
C	**Wasting and underweight**: Children with above-norm heights, but whose weight for age (WTA) and WTHT are too low	Yes	No	Yes
D	**Wasting, stunting and underweight**: Children who suffer from anthropometric failure on all three measures	Yes	Yes	Yes
E	**Stunting and underweight**: Children with low WTA and low height for age (HTA), but who have acceptable weight for their height	No	Yes	Yes
F	**Stunting only**: Children with low HTA but who have acceptable weight, both for their age and for their short height	No	Yes	No
Y	**Underweight only**: Children who are only underweight – whose WTA is acceptable	No	No	Yes

[a]Another theoretical combination would be the children who were "wasted and stunted" but not underweight. This combination is not physically possible since a child cannot have a low WTHT and low HTA and not be underweight

Table 6.2 Malnutrition among Indian children under 5, NFHS 2005 ($N = 45{,}377$) (Calculated from NFHS-3)

Indicator of malnutrition	Prevalence rate (%) (with 95% CIs)	Estimated number of Indian children under 5
Stunting	**48.3** (47.5–49.1)	61,739,475
Wasting	**20.1** (19.5–20.7)	25,692,825
Underweight	**42.8** (42.0–43.7)	54,709,100
CIAF	**61.8** (60.9–62.6)	78,995,850

Let us now provide an illustration of how the prevalence of malnutrition as estimated by the CIAF classification differs from estimates based on the three conventional indicators. Using anthropometric data on 45,377 Indian children aged under 5 years collected in the 2005 National Family Health Survey (NFHS-3) (IIPS and Macro International 2007), the prevalence of stunting, wasting and underweight were calculated. Estimates of malnutrition were made based on the new WHO international reference population (World Health Organization Multicentre Growth Reference Study Group 2006). Table 6.2 shows the rates of stunting, wasting and underweight obtained and the estimated number of children affected. It also shows the prevalence of malnutrition when the CIAF is used as an aggregate indicator of malnutrition.

Among the children for whom valid anthropometric data were collected, 48% were stunted, 43% were underweight and 20% experienced wasting. The CIAF provides a much higher prevalence of malnutrition, of 62%. This difference is considerable in terms of the numbers of children affected. According to the United Nations estimates, there were around 127,825,000 children aged under 5 in India in 2005 (UNPOP 2008). This means, applying the percentages in Table 6.2, 62 million children were stunted, 26 million were wasted, and 55 million were underweight. However, according to the CIAF, there were closer to 80 million children in one or more states of anthropometric failure. This difference of nearly 18 million children has clear cost and policy implications for planners and for international targets like the Millennium Development Goals (MDGs). Table 6.3 provides estimates of malnutrition for several other countries based on conventional measures as well as the CIAF,

Table 6.3 Prevalence rates of malnutrition among children under 5 in seven countries (Calculated from National Demographic and Health Surveys)

Country and year of DHS	Underweight (%)	Stunting (%)	Wasting (%)	CIAF (%)
Bangladesh (2008)	**41.1**	43.4	17.6	**56.1**
Nepal (2006)	**38.8**	49.6	12.9	**57.9**
Nigeria (2008)	**23.4**	40.8	14.0	**51.6**
Liberia (2007)	**18.4**	38.1	7.6	**44.0**
Ghana (2008)	**14.0**	27.5	9.0	**35.6**
Egypt (2008)	**6.1**	29.0	7.4	**36.0**
Dominican Republic (2007)	**3.2**	10.0	2.3	**12.5**

using the new WHO reference population norms. It shows clearly the magnitude of difference when underweight is used to estimate the overall prevalence of malnutrition (chronic=stunting and acute=wasting) as compared to the CIAF. In populous countries like Bangladesh, Egypt and Nigeria, these differences can amount to many millions of children.

6.4 Using the CIAF as a Disaggregated Measure

Given the known relationship between malnutrition and morbidity and mortality (Eveleth and Tanner 1990; Schroeder and Brown 1994; Rice et al. 2000; Caulfield et al. 2004), the conventional indicators are often used as predictors of risk. However, Svedberg reasoned that a more disaggregated classification of malnutrition, which set out specific failures as well as combinations of failures, might have greater predictive power than the conventional indicators. He suggested that the children who were simultaneously stunted, wasted and underweight were likely to be at a greatest risk of mortality. This theory can be tested, when suitable data become available. In the present case, the NFHS 2005 data only allow for the theory to be tested with regards to morbidity.

Table 6.4 shows the distribution of children in the sample across distinct groups of anthropometric failure. Over one third of children (38%) experience no failures at all. Around one quarter of all children are both stunted and wasted (Group E), and around one in seven (15%) were only stunted. One in eleven children (9%) experienced a triple failure (Group D), around 11.4 million children. These are the children predicted to be at a greatest risk of ill health.

6.5 Indicators of Morbidity

Three health conditions are used here to gauge the relationship between the various CIAF classes and morbidity: the prevalence of diarrhoea, dysentery and acute respiratory infection (ARI) (WHO/CDR 1994). Each condition, either alone or associated with malnutrition, is a common cause of death among children under 5 in developing countries (Tomkins and Watson 1989; Smith et al. 1991; Cunha 2000). Information about children's health is ascertained in the NFHS 2005/2006 from the mother or main caregiver. Respondents are asked if, during the previous 24 h or 2 weeks, the child has had diarrhoea, and if so, was there any blood in the stool. Children with diarrhoea were then classed as having diarrhoea and those who had had blood in the stool were classed as having dysentery.

Table 6.4 Groups of anthropometric failure among Indian children, under 5, NFHS 2005 (N = 45,377) (Calculated from NFHS-3)

Group	%
A – No failure	38.2
B – Wasting only	4.3
C – Wasting and underweight	6.9
D – Wasting, stunting and underweight	8.9
E – Stunting and underweight	24.8
F – Stunting only	14.6
Y – Underweight only	2.3
Total	**100.0**

Children who were reported to have a cough with/without a fever and who had breathing difficulties (short, rapid breaths) and who showed symptoms of a chest infection were considered to have an ARI.

6.6 Predicting Risk

According to the NFHS 2005, around 9% of children under 5 experienced diarrhoea in the 2 weeks preceding the survey, of whom about 11% had symptoms of dysentery (i.e. just under 1% of all children sampled). The prevalence of ARI among children under 5 years was 6%.

Table 6.5 shows how the CIAF and groups of anthropometric failure can be used alongside conventional indicators of malnutrition to assess morbidity risk. In this instance, age-adjusted logistic regressions have been used to show the different risks associated with different forms of malnutrition, as well as with the disaggregated CIAF.

If the relationship between malnutrition and diarrhoea is considered first, it is clear that the odds ratios for children experiencing stunting, wasting and underweight are all roughly equal, with no statistically significant difference between them. The aggregate CIAF performs as well as each of the individual measures. With regards to dysentery, stunting and underweight provide similar indications of risk, as does the CIAF. Wasting, however, as a single indicator, appears to be a relatively poor predictor of dysentery.

The value of the CIAF is in the way it can be used as a disaggregated measure. When children with no failures (i.e. Group A) are set as the referent, against which each of the other groups are compared, a more nuanced pattern can be observed. As Svedberg predicted, children who experience a triple failure (i.e. those who are stunted, wasted and underweight, in Group D) are at greatest risk of suffering from diarrhoea and dysentery – around 50% and 80%, respectively, more likely than children with no failures. As one might expect, the risks of diarrhoea and dysentery are greater for children with multiple anthropometric failures (i.e. in Groups D and E), and especially so when stunting is among the failures (Group F).

The picture with regards ARI is less clear. In this instance, underweight is the only statistically significant (but weak) predictor among the single indicators. The disaggregated CIAF groups of anthropometric failure show there to be no strong predictors, in contrast to the findings of a study, which conducted an identical analysis on an earlier round of the NFHS (Nandy et al. 2005). In 2005, there were only marginal differences in the prevalence of ARI for children of different background characteristics (e.g. maternal education, standard of living, etc.). This lack of variation suggests that in India, respiratory infections affect children irrespective of their socioeconomic background (IIPS and Macro International 2007), which in turn may explain the low predictive power of the indicators.

Table 6.5 Predicting morbidity risk Indian children, under 5, NFHS 2005 ($N = 45{,}377$)

	Diarrhoea[a]		Dysentery		Acute respiratory infection	
	Odds ratio	95% CI	Odds ratio	95% CI	Odds ratio	95% CI
Indicator						
Stunting	**1.18**[b]	(1.10–1.26)	**1.56**[b]	(1.28–1.90)	1.04	(0.96–1.12)
Wasting	**1.23**[b]	(1.14–1.32)	1.12	(0.89–1.41)	1.00	(0.91–1.10)
Underweight	**1.24**[b]	(1.16–1.32)	**1.52**[b]	(1.25–1.84)	**1.12**[c]	(1.03–1.21)
Composite Index of Anthropometric Failure (CIAF)	**1.19**[b]	(1.11–1.27)	**1.56**[b]	(1.26–1.92)	1.01	(0.93–1.09)
Groups of anthropometric failure						
A – No failure (referent)	1.00		1.00		1.00	
B – Wasting only	1.12	(0.96–1.29)	0.97	(0.56–1.68)	**0.81**[c]	(0.66–1.00)
C – Wasting and underweight	**1.22**[c]	(1.08–1.38)	1.33	(0.89–1.99)	1.02	(0.87–1.19)
D – Wasting, stunting and underweight	**1.48**[b]	(1.34–1.65)	**1.80**[b]	(1.30–2.51)	1.10	(0.96–1.26)
E – Stunting and underweight	**1.24**[b]	(1.13–1.35)	**1.76**[b]	(1.36–2.26)	1.08	(0.98–1.19)
F – Stunting only	1.02	(0.92–1.13)	**1.42**[c]	(1.05–1.93)	0.90	(0.79–1.02)
Y – Underweight only	0.84	(0.66–1.06)	1.49	(0.80–2.78)	1.06	(0.82–1.37)

[a]Includes children with dysentery
[b]$P < 0.001$
[c]$P < 0.05$

Further work on data from other countries, or a pooled analysis, might provide more conclusive answer as to the relationship between ARI and malnutrition.

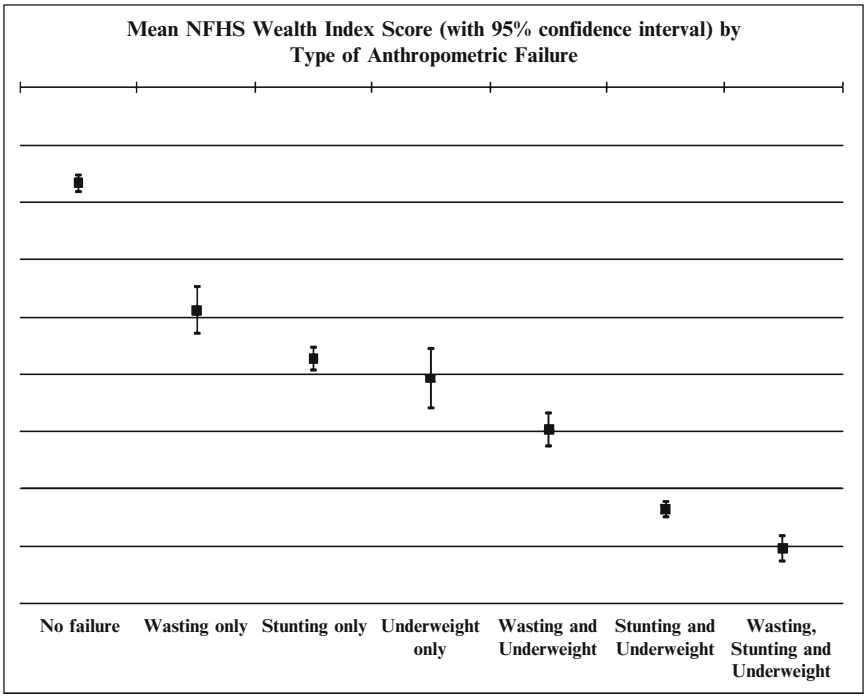
6.7 Anthropometric Failure and Poverty

The NFHS 2005 contains a wealth index based on household ownership of different assets (e.g. land, type of house) and durable goods (e.g. car, television, radio), which can be used to reflect socioeconomic disadvantage, deprivation and poverty. Such asset indices commonly serve as proxies for household wealth and economic status (Montgomery et al. 2000; Filmer and Pritchett 2001; Falkingham and Namazie 2002; Howe et al. 2008) in the absence of data on income or expenditure.

Svedberg reasoned correctly that children experiencing multiple anthropometric failures would be at greatest risk of ill health. Can a similar conclusion be reached with regards to poverty? Figure 6.2 shows the results of an analysis of variance (ANOVA) of the mean wealth index scores for each subgroup of anthropometric failure. Children with no failure have significantly higher (i.e. better) wealth scores than children with any form of anthropometric failure.

Two other things are apparent: first, children with a single failure (i.e. who experience wasting only, stunting only or underweight only) have significantly higher scores than children who experience multiple failures, and second, children who experience a triple failure are on average likely to live in the poorest households. These findings confirm similar analyses of the previous round of the NFHS (Nandy et al. 2005) and support those of other studies on malnutrition and poverty (ACC/SCN 1997; Wagstaff and Watanabe 2000).

Svedberg has in recent work built on his model of anthropometric failure, to include overweight and obesity (Svedberg 2007). Recent survey data from Mexico has revealed the existence of sizeable



Source: Calculated from NFHS-3

Fig. 6.2 Malnutrition and poverty in India (Calculated from NFHS-3)

proportions of children (5–10%) who are stunted *and* overweight/obese (Fernald and Neufeld 2007), whose distribution is similar to those identified above (i.e. greater prevalence among poorer socio-economic groups). The simultaneous prevalence of overweight/obesity and stunting has also been observed in other countries undergoing nutritional transition, such as Russia, Brazil and South Africa. There are genuine concerns about the potential negative impacts on health of obesity, and how these might manifest when combined with chronic malnutrition, for example, increased risk of chronic disease in later life.

6.8 Sources of Anthropometric Data

There is now an unprecedented amount of household survey data available to researchers. International organisations like the WHO, World Bank and UNICEF conduct surveys using standardised questionnaires and sampling methodologies, many of which can be accessed for free, or at low cost, over the Internet (Box 6.1). These surveys provide information used by international agencies to monitor international development targets, such as the MDGs, and summarised in many of their flagship reports (e.g. UNICEF's *State of the World's Children Reports*, the UN Development Programme's *Human Development Reports*, etc.). Researchers interested in conducting their own analyses can access most of these data at little or no cost.

One of the best sources of primary household-survey data are the demographic and health surveys (DHS) (Vaessen 1996). Survey data are provided for free and are available online to those who want them. Surveys were first conducted during the 1980s, and by mid 2009 about 270 DHS surveys have

Box 6.1 Household survey data available on the Internet

been published, providing a unique data base for cross-country investigations. Many countries have been surveyed repeatedly, allowing for analyses of changes of time. The DHS also provides access to useful tools like the STATCOMPILER, which can be used to make comparisons between countries of a range of different nutrition-related indicators.

UNICEF used the DHS format to develop its own survey programme, the Multiple Indicator Cluster Surveys (MICS). Three rounds of MICS have been conducted, the most recent in 2005/2006. Similar to the MICS and DHS are the surveys conducted by the Pan Arab Project for Family Health (PAPFAM), which cover the countries of North Africa and the Middle East. Two rounds of surveys have been conducted, with a third ongoing. The World Bank, as part of its Living Standards Measurement Study (LSMS), has conducted surveys in more than 30 countries. As well as collecting data on health and nutritional status, detailed information about household expenditure and consumption are recorded. The WHO runs its own survey programme, the World Health Surveys, in over 70 countries. Many of these surveys, and also some recent DHS, include detailed information about respondent location (GPS co-ordinates), making it possible to map malnutrition, morbidity and mortality more precisely. Another source of anthropometric data for researchers is the China Health and Nutrition Survey, a collaborative project between the Carolina Population Centre at the University of North Carolina at Chapel Hill and the National Institute of Nutrition and Food Safety at the Chinese Centre for Disease Control and Prevention. This is a longitudinal survey of 4,400 households in nine of China's provinces. Data from seven rounds can be accessed from the website shown in Box 6.1.

The World Health Organization Database on Child Growth and Malnutrition provides a standardised compilation of child growth and malnutrition data from nutrition surveys conducted around the world since 1960. Data on children's nutritional status are provided using both the "old" NCHS and the new, WHO multi-country reference population data.

6.9 Conclusions

This chapter has shown how and why the CIAF is an important new policy-relevant anthropometric indicator of malnutrition. It showed how conventional indicators "miss" large numbers of malnourished children, and that the CIAF is the only indicator to provide a single figure, aggregate estimate

of the overall burden of malnutrition among children in a population. The disaggregated CIAF allows for more nuanced assessments of the relationship between malnutrition, morbidity and poverty, and is increasingly being used in the assessments of child poverty and malnutrition (Gordon et al. 2003; Baschieri and Falkingham 2007; Seetharaman et al. 2007). Given the ready availability of anthropometric data from household surveys, it is likely to be used much more frequently in future research.

Efforts to reduce malnutrition will depend heavily on reducing poverty and raising people's living standards. This will require improving the quality of their homes, and their access to basic services, such as clean water and effective sanitation, as well as food of sufficient quality and quantity. Access to affordable qualified health care to prevent the debilitating effects of diseases like dysentery and pneumonia are essential if children's nutritional status is to improve. The CIAF provides researchers and planners with another tool to assess change and see if progress is being made.

Summary Points

- The conventional indicators of malnutrition – stunting, wasting and underweight – each individually "miss" large numbers of malnourished children.
- The CIAF provides an aggregate measure to estimate the overall burden of malnutrition among young children.
- In its disaggregated form, the CIAF can be used to predict the varying risks of morbidity for different types of anthropometric failure.
- The CIAF can be used to show the relationship between poverty and multiple anthropometric failures.
- Anthropometric data from hundreds of household surveys are available on the Internet and can be downloaded and used by independent researchers.

Key Features

- The CIAF can provide policy-relevant information on the pattern of child malnutrition in any country.
- The CIAF can be used to illustrate the complex relationship between morbidity risk and malnutrition.
- The CIAF can be easily computed using freely available, individual-level household survey data from over 70 countries.

Chapter 7
The Human Body Shape Index (HBSI): An Anthropometric Measure Based on an Age-Related Model of Human Growth

Maria K. Lebiedowska and Steven J. Stanhope

Abstract Body shape during age-related human growth is customarily described using either the body mass index (BMI) or the Ponderal Index (PI). These indices describe the human body shape (HBS) with different proportions between body mass (M) and body height (H). Both indices are affected by age during childhood. The establishment and maintenance of age- and sex-specific databases is time consuming and an expensive process. The lack of a general model for abnormal HBS makes the comparison of different populations (both in respect to time and location) very difficult. Efforts to evaluate the epidemic status of childhood obesity would benefit from the development of new tools and the refining of existing simple, reliable tools to evaluate and monitor HBS. An age invariant, sex-specific human body shape index (HBSI) has been recently introduced as an alternative to age-specific BMI and PI models. The HBSI was based on a mathematical model of human growth of Polish children (5–18 year old) between years 1985 and 1990. The sample was characterized by ideal fat composition (judged by 95th percentile of BMI values). To model growth, the best fit between individual body height (h) and body mass (m) was calculated separately between sexes with the function $M = c_p H^{\chi}$. The models of growth were $M = 13.11\ H^{2.84}$ ($R^2 = 0.9$) and $M = 13.64\ H^{2.68}$ ($R^2 = 0.91$) in girls and boys respectively. The HBSIs were calculated as ($HBSI_p = M/H^{\chi}$), where $HBSI_B = 13.74 \pm 1.72$ (in boys), $HBSI_G = 13.21 \pm 1.73$ (in girls) and $HBSI = 13.47 \pm 1.74$ (for both sexes). While the sensitivity and specificity of HBSI in the classification of the pathological changes in human body shape has not been explored, HBSI may be beneficial over other age-specific indices in the comparative analysis of HBS in children originating from different populations (location, diversity, and time periods) over long periods of growth.

Abbreviations

HBS	Human body shape
M_G, M_B, M	Body mass in girls, boys and pooled together treated as a physical variable (respectively)
H_G, H_B, H	Body height in girls, boys and pooled together treated as a physical variable (respectively)

7.1 Introduction

7.1.1 The Shape of the Living Organisms and the Environment

One of the basic features of life is an active interaction of an organism with the environment. From the systemic point of view, in order to survive in the environment living organisms (systems) need to maintain a state of the homeostasis. Homeostasis is an ability of a system to effectively act within the domain of environmental changes. The wider the range of the adaptation to environmental changes, the larger the chances the system will survive. An ability of a system to control position in space and time is determined by the system's structure and biomechanical interaction between the living organism and the environment. In humans, gravity and body structure combine to limit some activities but facilitate others. For example: walking and not floating is possible in the earth's gravitational field. However the reverse is true in the space. Any activity in a gravitational field requires more energy expenditure with increasing mass of an object. Potential energy is used to maintain the body in a certain position in relation to the gravitational field and kinetic energy moves the body in that field. The organisms living on earth exhibit very large variation in body size (for example elephant vs. ant) with a comparatively small variation in the body density (1–2 g/cm^3), because water is the substantial component of any earthly body. Body mass is usually associated with the size of the body. While the body density varies little, shapes vary greatly. The shapes of earthly organisms usually exhibit some form of symmetry (axial or rotational). The proportions between the dimensions in a three-dimensional space are an estimate of a body's distribution. In humans, mass is non-uniform and distributed mainly along the long axis of the body. The distribution of human body mass is the elementary determinant homeostasis. It affects all aspects of interaction with the environment which are necessary for basic human functions.

7.1.2 The Human Body Shape

Human body size and shape change during ontogenetic and phylogenetic development. Throughout a lifespan, the human body also undergoes physiological and pathological processes that affect its size and shape. Human body shape (HBS), mass distribution and its changes are subjects of interest in various scientific disciplines such as anthropometry, biomechanics, nutrition, and ergonomics. The monitoring and prediction of changes in mass and its distribution is important in an individual subject and in monitoring population trends. For the sake of this chapter, growth is defined as an age-related increase in body height and mass.

Prenatal development is characterized by the most dramatic and qualitative changes in HBS. During the first year of a child's life, rapid growth and change in mass distribution take place. Body proportions undergo rapid change, especially in the areas of the head and trunk. The body proportions continue to

change until a relatively robust adult-like body structure emerges by the age of 5–7 years. The next stage (7–18 years) is characterized mainly by quantitative changes, with an almost proportional increase in body size and mass in three dimensions (except for a short time of puberty). When the final body height is achieved (18–21 years) increases in body size and mass may occur only in two dimensions. Body height usually remains unchanged until the later stages of aging. Other factors such as demographics and life style also affect HBS. Changes in HBS other than due to age-related growth may be early signs of development or acceleration of disease. In the face of an epidemic of childhood obesity (Wang et al. 2008) and associated obesity-related health problems, monitoring of changes in HBS that are not related to age-related growth continues to be an important medical and social challenge.

This chapter addresses the challenge of developing an age invariant, sex-specific human body shape index (HBSI) as an alternative to indices based on age grouping body mass. Algorithms to establish a mathematical model of growth in children (5–18 years old) and the application of the growth model to establish an age-independent body mass index (HBSI) will also be introduced. A primary goal of this work is to model changes in HBS due to age-related growth as a means for enhanced monitoring of the incidence of overweight and obesity in children.

The chapter is broadening the previously published paper (Lebiedowska et al. 2008).

7.2 Quantitative Evaluation of Human Body Shape (HBS)

7.2.1 Standard Methods of Evaluation of HBS

There are different ways to quantify HBS, the most basic being to monitor indices based on commonly accessible data: body mass (m) and body height (h).These two anthropometric measures are very important in routine clinical practice; they are widely accessible and routinely monitored during clinical examination. The most popular body mass index (BMI), or Quételet's index, is defined in adults as BMI = m/h^2 (Ricardo and Araujo 2002). BMI has become an accepted tool to quantify obesity with established ranges for obesity (www.cdc.gov). Its associations with other measures of obesity in adults had been confirmed (Dahlström et al. 1985). BMI is fully justified in adults because of the matured stature, and an increase in body mass, and therefore dimensions, can occur only in the horizontal plane. However in children, growth occurs in three dimensions. Ponderal (PI) or Rohrer index (RI) index, (PI = m/h^3) accounts for three-dimensional growth of the human body (Sheldon et al. 1940). PI, or its inverse, has often been used to quantify obesity in young children 0–3 years old (Davies and Beverley 1979), but it is seldom used in older children (Alley et al. 1968; Agarwal et al. 2001; Ricardo and Araujo 2002; Mei et al. 2002).

In children, the applications of BMI and PI are more complex than in adults. BMI increases and PI decreases during growth, with much more substantial changes in BMI than PI (Alley et al. 1968; Rolland-Cachera et al. 1982; Garn et al. 1986; Cole et al. 1995; Agarwal et al. 2001; Ricardo and Araujo 2002). In children the changes of BMI and PI with body height require the application of age charts and the application of percentile or z-score analysis. Standardized, smoothed (Flegal 1999) percentile growth charts are routinely generated from data obtained from samples of population of children in different age groups (Alley et al. 1968; Pietrobelli et al. 1998; Cole et al. 2000; Ricardo and Araujo 2002). Percentiles describe what percentage of the sampled population exhibits the same value of the index as an individual. A z-score is calculated as the ratio between the difference of a data point obtained in an individual and the mean value in an age group, divided by the standard deviation (S.D.) of the age group. Both a z-score and percentile analysis relate the individual HBS to

the data obtained from a control/non-disabled population. The growth charts require data collection in the age groups and neither *z*-scores nor percentile calculations allow for a direct comparison of different populations (Cole et al. 2000). Neither percentile nor *z*-score analyses define absolute physiological thresholds for classification of abnormal HBS including obesity. As a result the application of BMI growth charts may lead to an underestimation of obesity in children and a more precise classification criteria of obesity is necessary (de Onis 2004; Wang 2004).

7.2.2 Mathematical Modeling of Human Growth

Until human growth is completed and final body height is reached (18–21 age), a monotonic increase in body height is related to a three-dimensional increase in body dimensions and mass distribution. Since human growth consists of the different periods during which the body shape undergoes qualitative and quantitative changes we focus on age-related human growth between 5–18 years. In children 5–18 years old, growth appears to follow the rule of allometry (or geometrically similar growth) (Günter 1975), because the proportions between body part dimensions may be considered somewhat invariant.

7.3 Practical Methods and Techniques

7.3.1 The Mathematical Model of the Human Growth

To establish mathematical models of human growth we identified body height as the primary age-related growth factor. Body height increases monotonically during growth as opposed to body mass, which fluctuates. To model growth, the best fit between individual body height (h) and body mass (m) was calculated separately in boys (B) and girls (G) with the function $M_p = c\ H^{\chi}$, where: p = <B,G>, c, χ = sex-specific constant, H and M = body height and mass treated as physical variables (Benn 1971). The body height is expressed in meters (m) and body mass in kilograms (kg). There are several ways to obtain the approximation.

1. The exponent χ can be identified by calculation of the best mathematical fit of the function between body mass, and body height $M = c\ H^{\chi}$.
2. Due to the mathematical properties of the logarithmic function the exponent χ can also be calculated as a slope of the linear regression function between the $\log(M) = a + \chi \log(H)$. Any statistical package or Excel or curve fitting software can be used to calculate one of the above mathematical approximations.

7.3.2 Establishing an Age-Related Growth Model

Sex-specific growth models have been developed based on a set of data collected in 847 Polish children (444 girls and 403 boys, aged 5–18 years) obtained between 1985 and 1990 (Lebiedowska et al. 2008) (Table 7.1). The sample of Polish children contained a homogeneous sample of children with generally ideal body fat composition, as judged by 95th percentile of BMI (<24.4 in girls and <23.5 in the boys). No obesity/overweight or underweight was reported in the sample.

Table 7.1 Demographics of the sample Polish children 5–18 years old (between 1985 and 1990)

	Girls (N = 444)			Boys (N = 403)		
		m (kg)	h (m)		m (kg)	h (m)
Age (years)	N	Mean ± S.D.	Mean ± S.D.	N	Mean ± S.D.	Mean ± S.D.
5	26	18.88 ± 2.19	1.12 ± 0.04	29	20.81 ± 2.75	1.14 ± 0.05
6	43	22.57 ± 4.64	1.19 ± 0.06	30	22.37 ± 3.48	1.2 ± 0.06
7	37	24.78 ± 3.55	1.25 ± 0.05	33	25.15 ± 3.6	1.26 ± 0.06
8	23	26.79 ± 5.13	1.28 ± 0.06	34	29.96 ± 6.83	1.33 ± 0.07
9	42	28.68 ± 4.97	1.34 ± 0.06	35	30.23 ± 4.73	1.35 ± 0.05

This table lists the demographics of the children included into the study. N: number of subjects, m: body mass, h: body height, S.D.: standard deviation

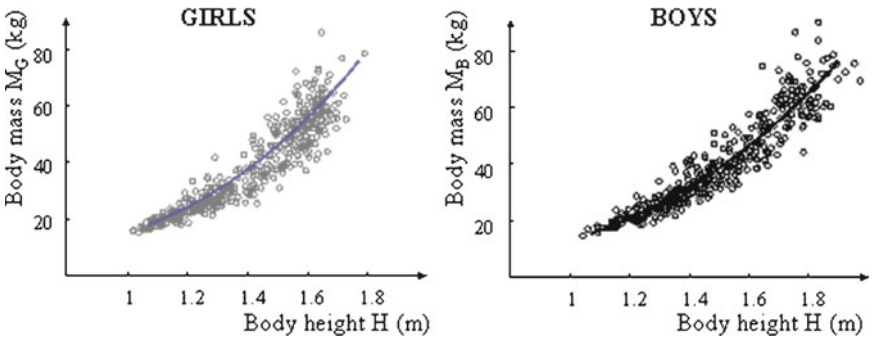

Fig. 7.1 Mathematical models of growth based on the exponential fit between body mass (M) and body height (H) in 847 (444 girls, and 403 boys) Polish children 5–18 years old. The growth models in girls $M_G = 13.11\ H^{2.84}$ ($R^2 = 0.9$) (*left*) and in boys $M_B = 13.64\ H^{2.64}$ ($R^2 = 0.91$) (*right*) (Modified from Lebiedowska et al. (2008). With permission)

1. The mathematical approximations of the body mass (m) against body height (h) obtained from individual subjects were calculated separately for boys and girls with the function $M_p = c\ H^{\chi}$ (Fig. 7.1).
2. The same model was calculated using a logarithmic function where the exponent χ was equal to the slope of the linear regression function between the log (M) = $a + \chi \log(H)$ (Fig. 7.2).

Both mathematical methods generated the following models of growth: $M_G = 13.1\ H^{2.84}$ ($R^2 = 0.9$) for girls and $M_B = 13.1\ H^{2.84}$ ($R^2 = 0.91$) for boys and $M = 13.1\ H^{2.76}$ ($R^2 = 0.89$) for both sexes.

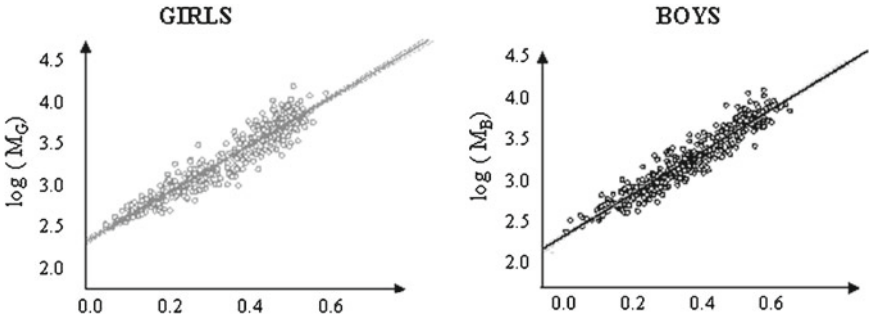

Fig. 7.2 Mathematical models of growth based on the linear fit of log(*H*)-log(*M*) function in 847 (444 girls, and 403 boys) Polish children 5–18 years old. The linear regression line in girls (*left*) $\log(M_G) = 2.57 + \mathbf{2.84} \log(H_G)$; $r = 0.95$) and in boys (*right*) $\log(M_B) = 2.61 + \mathbf{2.68} \log(H_B)$; $r = 0.95$ (*right*)

7.3.3 Physical and Physiological Interpretation of Age-Related Growth Models

Assuming that body density does not change, human growth follows the rule of allometry or geometrically similar growth, if the proportions between the sizes of body parts are invariant. In prefect geometrical similar growth, an increase in body mass according to the third power of body height would be expected. In other words, if $\chi \rightarrow 3$ the assumption about the geometrically similar growth is more reliable. The difference between the exponent χ and number 3 describes the discrepancy between the experimental and geometrically similar model of growth. Growth in Polish children 5–18 years old followed the geometrical model with 10.6% accuracy in boys and 5.3% accuracy in girls (as judged from the differences between the experimentally obtained value of χ and number 3). The larger exponents obtained in girls, in part, reflects the fact that the final average body height reached by males is larger than in females (http://www.cdc.gov). However, gender-specific changes in body proportions may play a role. The group of Polish children contained a homogeneous sample of children with generally ideal body fat composition, as judged by 95th percentile of BMI (<24.4 in girls and <23.5 in the boys). Similar exponents reported in a population of English children (Rosenthal et al. 1994) suggest similar growth in English and Polish children between years 1985 and 1992. Due to the lack of the generally accepted "golden standards" for human growth at this time, we treat these experimentally established models of growth as a reflection of ideal age-related growth. It is important to model age-related growth in order to separate healthy age-related growth from changes in HBS related to changes in percentage body fat.

It should be emphasized that the described growth models may be beneficial to the description of HBS growth-related changes over a longer period of time, when body height is the most important factor affecting growth. To analyze the shorter periods of growth, or to characterize the diverse populations other models may be more suitable.

7.3.4 General Guidelines for the Establishment of Age-Independent Indices Based on Growth Models

To calculate an individual HBSI, the following procedure should be followed:

1. Body mass data obtained from individual subjects should be divided by the body height to the sex-specific exponent χ ($\chi = 2.84$ for girls and $\chi = 2.64$ for boys).

2. Correlations between HBSI and body height should be calculated. If there are no statistically significant correlations, the correlation between the index and the calendar age should be calculated. If the correlation with the calendar age is not statistically significant the mean and S.D. of the index may be considered as HBSI of the population from which the sample comes.
3. To determine if it is necessary to introduce age corrections, the data should be divided into age groups and the mean of HBSI of the age groups should be calculated. A one-factor ANOVA test can be used to determine the effect of age on the HBSI. If the groups' mean is significantly different, an age correction for each group should be introduced as the ratio between the mean of each group and the first age group.

7.3.5 Application of Normalization Algorithms in the Establishment of Age-Independent, Sex-Specific, Human Body Shape Indices

The sex-specific human body shape indices ($HBSI_p$) were calculated using a sample population of Polish children using body mass and body height of individual subjects as $HBSI_p = m/h^x$. Polled HBSI for girls and boys were calculated using the mean power of body height across sexes. Mean and S.D.s, correlations and the slopes of linear regression lines between HBSI and H are displayed in Table 7.2.

The HBSI were compared for 4 age categories (5–9, 9–12, 12–15 and 15–18 years old). To determine the degree to which the mean indices were affected by age, indices for each age were compared using ANOVA test with Bonferroni adjustment. The HBSI were statistically different in girls (Table 7.3) but not in boys (Table 7.4).

The largest difference occurred between age groups 9–12 and 15–18 years (1.28 or 0.75 S.D.s, $p = 0.003$). Based on the analysis, appropriate age corrections had been introduced in girls (Table 7.4).

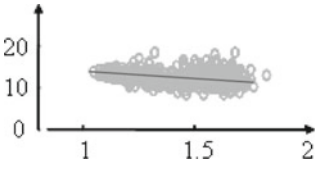
7.3.6 The Physical and Physiological Interpretation of the HBSI

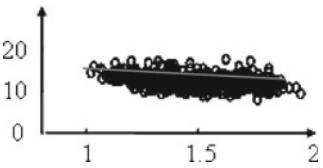
HBSI exhibited very low and statistically not significant correlations between indices and body height and next calendar age with the slopes of the regression lines approaching 0. The fact that HBSI could be considered independent of body height sanctions the characterization of a population of children 5–18 years old with one mean and one S.D. The Polish data model is designed to reflect the normal age-related changes in HBS. It seems that at least in some applications, BMI in children 5–18 years old may be replaced as a HBS measure with the HBSI which is coherent with the biomechanics of human growth. The HBSI may also replace multiple indices with two sex-specific, age-invariant indices.

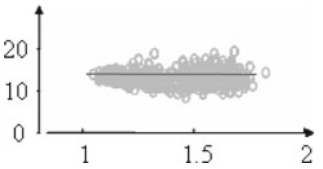
HBSI may be very useful in some applications requiring comparison of HBS changes over time, coming from different populations. In the case of one sex or single subject analysis the application of gender-specific HBSI should be considered. In the case of a single population of children of both genders, the pooled HBSI could be beneficial to healthcare professionals.

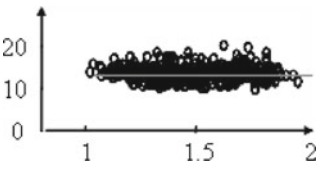
PI based on the ideally geometrically similar growth ($\chi = 3$) decreases slightly with the body height and age, introducing more variability over the age groups (Lebiedowska et al. 2008). Due to larger variability of PI over HBSI, PI may introduce a slightly larger error over HBSI in the classification of

Table 7.2 PI, HBSI of Polish children (5–18 years old; between years 1985 and 1990) as a function of body height (horizontal line)

	Girls $N = 444$		Boys $N = 403$	
	Regression equation	Mean ± S.D.	Regression equation	Mean ± S.D.
PI = m/h^3 (kg/m^3)	15.81–2.28 H $r = -0.15$, $p = 0.002$	12.47 ± 1.64	17.32–3.46 H $r = 0–0.34$, $p < 0.001$	12.21 ± 1.62
				




$HBSI_G$ (kg/m$^{2.84}$)	12.93 + 0.19 H $r = 0.02$, $p = 0.66$	13.21 ± 1.73	–	
				


$HBSI_B$(kg/m$^{2.68}$)	–		13.51 + 0.15 H $r = 0.02$, $p = 0.7$	13.74 ± 1.72
				


HBSI (kg/m$^{2.76}$)	12.18 + 0.98 H $r = 0.1$, $p = 0.03$	13.6 ± 1.79	14.2– 0.59 H $r = 0–0.08$, $p = 0.13$	13.34 ± 1.67

This table illustrates that *HBSI*: Human Body shape Index, but not *PI*: Ponderal Index can be considered as independent on the body height (*H*) (horizontal line in all graphs)

abnormal HBS. PI may still be useful, especially in the analysis of different populations, irrespective of location and time (Seltzer 1966; Nahum 1966; Huber 1969; Hattori and Hirohara 2002; Rolland-Cachera et al. 1982; Ricardo and Araujo 2002).

As the HBSI described above were based on growth models treated as the "gold standard" of human growth, they carry over the advantages and the limitations already mentioned. HBSI may be useful to describe HBS growth-related changes over a larger period of time, when increase in body height is the most important factor affecting growth. To analyze shorter periods of growth (for example during puberty) other indices, may be more suitable.

Table 7.3 $HBSI_B$ in age groups in boys

Age group (years old)	*N*	Mean ± STD
5–9	124	13.80 ± 1.55
9–12	103	13.51 ± 1.65
12–15	107	13.69 ± 1.93
15–8	69	14.03 ± 1.75

[a]5–9 and 9–12 years old, $p = 0.003$
[b]5–9 and 15–18 years old, $p = 0.006$
[c]9–12 and 15–18 years old, $p = 0.001$
[d]12–15 and 15–18 years old, $p = 0.001$
The appropriate age corrections for girls have been calculated (last column)

7.3.7 Application of HBSI for the Establishment of Standard Thresholds for Detection of Overweight and Obesity in Children

Out of the full spectrum of the HBS two extremes are especially important from the humanitarian, social and economic point of view. Malnutrition causes 53% of all deaths in children younger than 5 years (Bryce et al. 2005), whereas obesity has been announced as a major public health crisis in the USA (Cole et al. 2000; Wang et al. 2008). The limitation of BMI to detect obesity in children based on the growth charts was reported by Piers et al. 2000 and de Onis, 2004. The differences in the estimates of the prevalence of obesity in children and adolescents vary from 11–24%, despite using the same set of the data (Troiano and Flegal 1999). The lack of uniform, absolute thresholds for obesity classification in children must play a role in the diffusion of the estimates. Future studies should compare the sensitivity and specificity of HBSI versus other indices in the classification of the obesity/malnutrition in children (Field et al. 2003). The model of growth which was used to establish the HBSI was based on the sample of population of Polish children (5–18 years old; between years 1985 and 1990), characterized by ideal fat composition as judged by 95th percentile of BMI values. In addition, a similar model of growth (during a comparable period of time) was reported in English children (Rosenthal et al. 1994). The lack of any other "golden standard" suggests that the model based on the population of Polish children may serve as a model of natural growth. The absolute thresholds for HBS based on the model are displayed in Table 7.5.

The thresholds are based on the sex- and age-specific percentiles values: "underweight" (<5th percentiles), "normal" (5th–85th percentiles), "at risk of overweight" (85th–95th percentiles) and "overweight" (≥95th percentiles). Since these thresholds for overweight and obesity were established

Table 7.5 Thresholds for overweight and obesity based on a model of growth of Polish children (5–18 years old) between years 1985 and 1990.

Sex		Ranges of indices in Polish children population	
		Girls ($N = 444$)	Boys ($N = 403$)
$HBSI_G$ (kg/m$^{2.84}$)	Underweight	<10.67	–
	Normal	10.67–14.97	
	At risk of overweight	14.97–16.4	
	Overweight	≥16.4	
$HBSI_B$ (kg/m$^{2.68}$)	Underweight	–	>11.27
	Normal		11.27–15.36
	At risk of overweight		15.36–17.19
	Overweight		≥17.19
HBSI (kg/m$^{2.76}$)	Underweight	>10.96	>10.97
	Normal	10.96–15.39	10.97–14.93
	At risk of overweight	15.39 – 16.85	14.93–16.57
	Overweight	≥16.85	≥16.57

Modified from Lebiedowska et al. (2008). With permission
This table displays the ranges of sex-independent (HBSI) and sex-specific ($HBSI_B$, $HBSI_G$) body shape indices for: underweight (<5th percentiles), normal (5th percentiles–85th percentiles), at risk of overweight (≥85th percentiles and ≥95th percentiles) and overweight (≥95th percentiles) conditions
N: number of children, *B*,*G*: boys and girls respectively

Table 7.6 The key features of Human Body Shape Index (HBSI)

Human BODY Shape Index HBSI	Girls	Boys	Girls and boys
HBSI	$HBSI_G = m/h^{2.84}$	$HBSI_B = m/h^{2.68}$	$HBSI_G = m/h^{2.76}$
Mean (±S.D.)	13.21 ± 1.73	13.74 ± 1.72	13.47 ± 1.74
Units	kg m$^{-2.84}$	kg m$^{-2.68}$	kg m$^{-2.76}$

This table lists equations to calculate HBSI: Human Body Shape Index from body mass, m (kg) and body height $h(m)$ (first row). The reference values (mean and standard deviations: S.D.) of HBSI of Polish children (5–18 years old; between years 1985 and 1990) are listed in the second row, and the appropriate units in the third row

using sample distributions, the development of physiologically based thresholds for overweight and obesity should be explored. There exists a discrepancy between the definitions for abnormal HBS in children and adults. It is well established that increased BMIs in adults (for overweight BMI ≥ 25 and for obesity BMI ≥ 30) are associated with the changes in other anthropometric, biochemical and instrumental measure of obesity (Dahlström et al. 1985; Wang et al. 2004). The projection of well established adult thresholds into the pediatric population may lead to the development of physiologically based thresholds. It seems however, that the thresholds may be sex specific.

7.4 Application of the Growth Models to Other Areas

The algorithms presented for the development of growth models and the establishment of age-independent HBSI were originally developed to separate the influence of growth and rehabilitation treatment in children. The normalization techniques has been successfully applied to children aged

5–18 years and the age independent, normalized databases of various biomechanical parameters (maximum knee extension and flexion isometric movement of force, lower-leg moment of inertia, passive stiffness and damping of the knee joint (Lebiedowska et al. 1996). The approach presented in this chapter can be easily applied in ergonomics (Lebiedowska 2006), sport and other research disciplines where human growth affects the outcome measures.

Summary Points

- The growth of Polish children 1985–1990 was close to the geometrically similar growth (10.6% accuracy in boys and 5.3% accuracy in girls).
- The lack of any other "golden standard" suggests that the model based on the population of Polish children 1985–1990 may serve as a model of natural growth.
- The age independent, sex-specific index (HBSI) was based on the mathematical model of Polish children's growth.
- HBSI characterizes the shape of children 5–18 years old with one sex specific, age-independent mean and one standard deviation.
- HBSI allows for comparison of the changes in the human body shape during growth in individuals and between different populations (time, location).
- Comparison of sensitivity and specificity of HBSI and standard BMI to detect overweight and obesity in children should be explored.

Chapter 8
Reproducibility of DXA Measurements of Bone Mineral and Body Composition: Application to Routine Clinical Measurements

Colin E. Webber

Abstract Measurements of bone mass and body composition using X-ray based dual photon absorptiometry (DXA) are used extensively to investigate patients suspected to be suffering from conditions that affect the skeleton or soft tissues. Commonly, such measurements seek to establish whether or not a change has occurred since a previous measurement. The ability to detect change is determined by perhaps the most important characteristic of a DXA system; that is the precision of the measurement. In this chapter, the results of precision assessments made in various groups of subjects using equipment housed in a routine, diagnostic Department of Nuclear Medicine are reviewed and compared to published values.

In phantoms, the precision or reproducibility of a bone mineral density (BMD) measurement is better than 0.005 g cm^{-2} even if the number of measurements from which the precision is derived is accumulated over an extended time period. In children, same-day precision for spine BMD, whole body BMD and proximal femur BMD worsens to values of 0.007, 0.009, and 0.011 g cm^{-2}, respectively. For adults, the same-day precision of spine BMD decreases further to 0.010 g cm^{-2} while femur BMD precision is virtually unchanged. Long-term precision for spine BMD and femur BMD decreases again to 0.029 and 0.023 g cm^{-2} while for the radius, long-term precision is 0.012 g cm^{-2}. The precision attained by routine clinical laboratories for the measurement of BMD can be comparable to that obtained by research laboratories.

The same-day precision of DXA measurements of body composition in children is about 20 g for whole body bone mineral content (WBBMC), 250 g for lean tissue mass (LBM) and 190 g for fat mass (FM). In adults, same-day precision for WBBMC is similar to that measured in children while for LBM and FM, same-day precision worsens to about 350 and 280 g, respectively. Extending the time interval between pairs of measurements to more than 1 day makes the reproducibility of soft tissue composition assessments much worse as the effect of daily fluctuations in dietary balances will be included in the reproducibility evaluation. The presence of obesity means that the precision of measurements in all body composition compartments deteriorates.

8.1 Introduction

When several measurements are made of a given variable, the extent of dispersion of the results about a mean value is determined by the reproducibility or precision of the technique. In turn, precision determines the magnitude of the smallest difference that can be detected reliably between successive measurements of the same variable. If the difference between repeat measurements of the same variable for a range of subjects is small and shows little variation, then the reproducibility, or precision, is good. The better the reproducibility, the greater is the chance of correctly identifying the extent and direction of a change between two measurements.

DXA is an X-ray based technique that can be used to measure the mass of each constituent in an object that consists of two radiologically distinct materials. Since people can be considered as a mixture of bone mineral and soft tissues, DXA can be applied to the measurement of bone mineral and body composition. The technique depends upon differences in the relative attenuation of X-rays by the two materials at two different energies. The key features of DXA are listed in Table 8.1.

When DXA measurements are used for the assessment of fracture risk in patients suspected of suffering from osteoporosis, scans are performed at fracture-prone sites such as the spine or hip. DXA measurements of body composition require a scan of the whole body. Typical examples of a lumbar spine scan and a whole body scan are shown in Figs. 8.1 and 8.2. Figure 8.2 clearly demonstrates the discrimination between fat and lean constituents of soft tissues.

The reproducibility of a bone mass or body composition measurement technique is important since it establishes the time interval that must elapse before a likely change in response to disease progression or in response to a putative treatment intervention can be detected. Precision for a technique such as DXA depends, in part, upon the measurement context. For example, it is to be expected that the reproducibility of BMD measured for an inanimate object such as a model spine embedded in a plastic block will be better than when reproducibility is measured for a living subject. In turn, the reproducibility derived from measurements repeated on the same day in a person will be expected to be better than that derived from measurements repeated over an extended period of time in the same person. These different reproducibilities are termed phantom in vitro precision, same-day in vivo precision and long-term in vivo precision, respectively. The term “short-term precision” should be applied to reproducibility measurements separated by a period of a few months while the term “long-term precision” should be applied to reproducibility measurements separated

Table 8.1 Key features of X-ray based dual energy absorptiometry (DXA or DEXA)

Bone mineral attenuates low-energy X-rays to a much greater extent than soft tissues.
Bone mineral and soft tissues attenuate medium-energy X-rays to a similar extent.
Attenuation measurements for low- and medium-energy X-rays transmitted through people allow an evaluation of the mass of mineral and soft tissue in the path of the X-rays.
DXA measurements of bone mineral can be applied to fracture-prone sites such as the spine and hip in patients suspected to be suffering from osteoporosis.
A DXA scan of the whole body allows the evaluation of total mineral mass in the skeleton and total soft tissue mass in the body.
The differences in density and composition between lean and fat mean that the relative attenuation of low and medium energy X-rays, when measured at locations where no bone mineral is present, is dependent on soft tissue composition.
DXA allows non-invasive, in vivo measurements of bone mass and body composition.

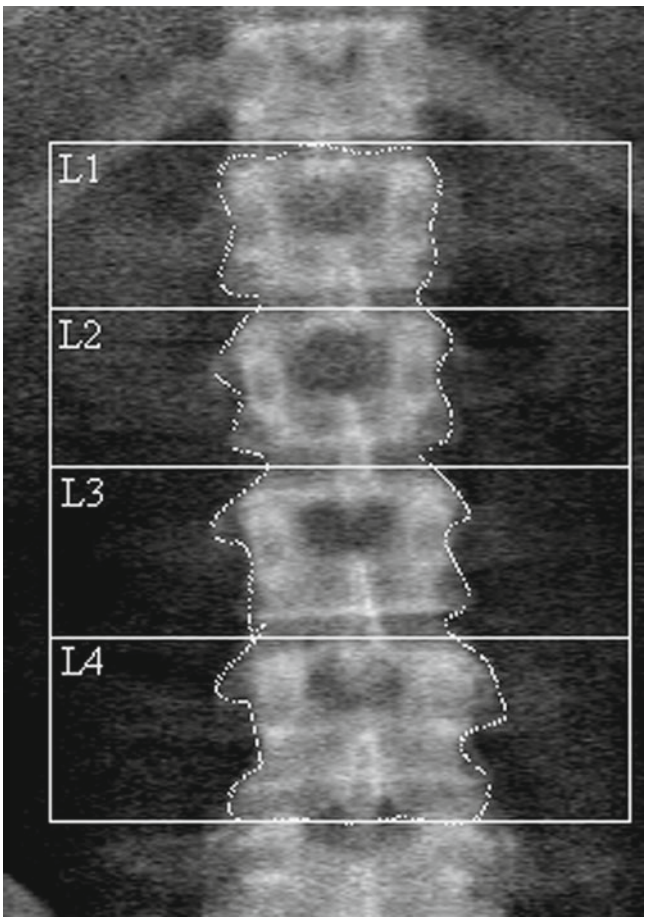

Fig. 8.1 A typical DXA scan of the lumbar spine. Analysis software places regions of interest over the projected vertebrae from L1 to L4. The result is expressed as an areal density (g cm^{-2}); that is, the mass of bone mineral detected (BMD) within the region of interest divided by the area of bone mineral measured

by a period of a year or more. The first purpose of this chapter is to review the mathematical means of assessment and expression of reproducibility for DXA measurements of bone mass and body composition. This is followed by the reporting of results of same-day and long-term reproducibility for in vitro phantom BMD measurements. Same-day in vivo precision is then established for children who are either above or below age 10. Next, same-day and long-term in vivo precision is

Fig. 8.2 A whole body DXA scan. The primary software analysis divides the body mass into contributions from bone mineral and soft tissue. A secondary analysis separates the soft tissue into lean and fat components

evaluated in adults. Finally, same-day in vivo precision is also measured for WBBMC, LBM, and FM. Most of these precision assessments are made using equipment within a routine, clinical Department of Nuclear Medicine.

The second purpose of this chapter is to compare the reproducibility attainable during routine clinical DXA measurements of bone and body composition with values of precision reported in the literature. While there are many reported bone mass precision measurements, considerably less information is available concerning the reproducibility of DXA-based body composition measurements. If the precision measured in a routine clinical service setting is similar to accepted published values then equipment and personnel normally dedicated to clinical practice should be able to participate in research protocols. Clinical trials that are designed to search for small changes in bone mass or body composition frequently require the participation of multiple sites to recruit sufficient subjects to detect an anticipated change with a given statistical confidence. If the precision of routine clinical DXA systems is equivalent to that of research DXA systems, then the opportunities for trial recruitment may be expanded.

8.2 Definitions of Precision

8.2.1 Phantom Precision

The reference article that defines BMD reproducibility and describes methods for precision assessment was published by Glüer et al. (1995). If numerous (n) measurements of BMD (x) are made for a phantom without repositioning between measurements, the precision of the measurement will be reflected in the *standard deviation* (SD) of the frequency distribution given by the familiar expression:

$$\text{Phantom Precision} = \left(\sum \frac{(x-\mu)^2}{(n-1)} \right)^{0.5} \tag{8.1}$$

where μ is the mean of the BMD measurements.

When the BMD for the same phantom is measured numerous times over a period of about 1 year with repositioning between each measurement, it is to be expected that the frequency distribution will broaden and the SD will increase reflecting the additional variance introduced from time-dependent changes in machine performance and phantom positioning.

8.2.2 In Vivo Same-Day Precision

When an additional source of variance, such as that originating from a patient, is introduced, the SD increases further. The SD derived from multiple in vivo measurements in a single subject would be greater than that established for a phantom. However, it is unreasonable to collect multiple measurements from a single subject because even though the radiation dose from a DXA measurement of bone mineral or body composition is acceptably low, good radiation safety practice demands that individual exposures are minimized. In addition, reproducibility is likely to differ between subjects and it is preferable to establish precision in a representative group of volunteers. A solution that satisfies both requirements is to replace many measurements in one person with a pair of measurements in many subjects. If two measurements are made in one subject the SD will be according to (8.1),

$$\left\{ \frac{\left[x_1 - \left(\frac{x_1 + x_2}{2} \right) \right]^2}{2-1} + \frac{\left[x_2 - \left(\frac{x_1 + x_2}{2} \right) \right]^2}{2-1} \right\}^{0.5} \tag{8.2}$$

which, provided sufficient care is taken with the algebra, reduces to

$$\text{Subject Same} - \text{Day Precision} = \left\{ \frac{(x_1 - x_2)}{2^{0.5}} \right\} \tag{8.3}$$

This expression shows that when two measurements are taken in one subject, the SD for that subject depends upon the difference between the two measurements. The reproducibility for the

BMD measurement technique is then obtained from an appropriate combination of the individual subject precisions obtained from a representative sample of volunteers (m subjects). That is:

$$\text{Technique Same} - \text{Day Precision} = \left\{ \frac{\sum (x_1 - x_2)^2}{2m} \right\}^{0.5} \tag{8.4}$$

Equation (8.4) is equivalent to expression 4b in the formulation by Glüer et al. (1995).

8.2.3 In Vivo Long-Term Precision

The difference between two BMD measurements separated by a considerable length of time will include contributions from both measurement uncertainty and bone mass change due to aging or disease. The measurement uncertainty not only reflects those factors that contribute to same-day uncertainty but also includes the influence of time-dependent changes in both patient and instrument such as, changes in body weight and soft tissue composition and modifications to measurement procedures or protocols, respectively. In addition there may be a contribution when different technologists perform the first and second measurements, a scenario that is likely in a clinical department offering routine diagnostic measurements of bone mass and body composition.

The assumption can be made that age-dependent changes in bone mass within a particular patient can be described accurately by fitting the measured BMD values to a mathematical expression that adequately represents the time-dependent changes for that patient. The measurement precision is then related to the extent of the deviations of the observed BMD values from the derived equation and is represented by the standard error of the estimate. The change required from (8.3) for the estimation of precision is that the differences between paired measurements are replaced by the differences between the measured and a predicted BMD, $\hat{\mathbf{x}}$, at each time point. The expression for subject long-term precision also has to be modified to account for the parameters estimated from the fitting process. If a linear change of bone mass is assumed then precision will be given by:

$$\text{Subject Long} - \text{Term Precision} = \left(\sum \frac{(x - \hat{\mathbf{x}})^2}{(n-2)} \right)^{0.5} \tag{8.5}$$

where the summation is performed across all n BMD measurements. The number of degrees of freedom (DOF) has been reduced by 2 because the slope and intercept of the fitted line has been calculated from the measured BMD values. If a more complicated expression, such as a second-order polynomial, is used to fit the measured BMD data, then the denominator of (8.5) may have to be modified accordingly. The intercept and the coefficients of the linear and quadratic terms would have to be fitted so that the denominator of (8.5) would become (n–3).

Once precision has been established in a sufficient number of representative subjects, long-term precision for the technique can be calculated using (8.6).

$$\text{Technique Long} - \text{Term Precision} = \left\{ \sum \frac{(x - \hat{\mathbf{x}})^2}{(\text{DOF} - 2)} \right\}^{0.5} \tag{8.6}$$

where the summation is performed across all subjects. Equation (8.6) is equivalent to expression 12 in the formulation by Glüer et al. (1995). If the time interval over which measurements are obtained for a subject is relatively short (<5 years) then the expected changes in BMD will likely be well represented by a linear expression. Longer time intervals may require fitting the observed

BMD values with a second-order polynomial expression that assumes no specific mechanism of age-dependent BMD decline.

When a variable is normally distributed, such as lumbar spine BMD at a given age in normal adults, the 95% confidence range extends from 1.96 SDs below the mean expected-for-age value to 1.96 SDs above the mean expected-for-age value. This range closely corresponds to a *Z*-score range from −2 to +2. When a variable such as the absolute difference between two successive, individual BMD measurements is considered, the difference always has to be finite and cannot take on a negative value. The normal distribution is inappropriate when describing differences between pairs of BMD measurements and is replaced by the Chi Square distribution. The upper and lower 95% confidence intervals are selected from tables depending on the total number of DOF involved.

8.2.4 Derived Terms

Despite the simplicity of using the SD as the expression of precision, other mathematical constructs have been devised. For example, the SD is often expressed as a *coefficient of variation* (CV) which is simply the SD expressed as a percentage of the mean value. The CV is not recommended as a means of expression of bone mass or body composition reproducibility. This is because the CV will increase in populations such as children or subjects with disease who will have low mean values for the measured variable. However, the increased CV does not necessarily indicate a poorer precision.

Another form of expression for reproducibility is the *intra-class correlation coefficient* (ICC). The ICC is applicable when reproducibility is measured in groups of samples extracted from a single population and measures the proportion of the total variance that can be attributed to the population rather than to the measurement technique. As technique reproducibility improves, the value of the ICC approaches 1.

There are a number of terms that are derived from the precision measured in a group of subjects. The uncertainty in the BMD difference between two groups of subjects is $(SD^2 + SD^2)^{½}$. The upper limit of the 95% confidence interval for this uncertainty is $1.96 \times 2^{½} \times SD$. It is argued that if the difference between two successive measurements exceeds this value, then a statistically significant change has taken place. This upper limit is termed the *least significant change* (LSC). The LSC is also referred to as the *smallest detectable difference* (SDD).

8.3 BMD Precision

In this section, the results of precision measurements that have been derived from a densitometer operating in a busy, routine, clinical environment will be presented. This machine is located within a Department of Nuclear Medicine in an acute care hospital and provides DXA measurements of bone mass and body composition for referred inpatients and outpatients. The densitometer is operated typically by a number (~8) of experienced staff and, commonly, one or two trainees participating in a rigorous in-house DXA training program. It is essential for such a DXA service to know the reproducibility that is achievable by staff in representative groups of patients attending for diagnostic tests. In Sects. 8.3.1–8.3.4, precision results are presented for phantoms, children and for same-day and long-term precision in adults. In Sect. 8.3.5, the measured precision is compared with published values.

Table 8.2 In vitro precision for DXA measurements of spine BMD in a phantom

Phantom	Precision (g cm^{-2})
L1–L4 spine, same-day	0.0024
L1–L4 spine, long-term	0.0038

Precision deteriorates when the time scale is extended

Table 8.3 Same-day, in vivo precision for DXA measurements of BMD in children

Children	Same-day precision (g cm^{-2})
L1–L4 spine	0.0068
Total femur (left hip)	0.0110
Whole body	0.0087

Precision in children differs between sites and is considerably worse than precision measured in a phantom

8.3.1 Phantom BMD Precision

When a standard lumbar spine phantom was measured without repositioning on 33 occasions over a period of 75 min using a Hologic Discovery A densitometer, the mean and SD was 1.0224 ± 0.0024 g cm^{-2}. When the same quality control phantom was measured on 156 occasions over a period of 236 days with no more than a single measurement performed on any 1 day, the mean and SD was 1.0230 ± 0.0038 g cm^{-2}. The mean BMD values are not statistically different from each other but the SD for the extended phantom measurements is greater by a factor of 1.6. These values for the phantom reproducibility are shown in Table 8.2.

8.3.2 In Vivo Same-Day BMD Precision in Children

The densitometer responsible for the results shown in Table 8.2 has also been used to determine same-day precision in a number of groups of patients. Since many referrals involve children from McMaster Children's Hospital, we established reproducibility of bone mass and body composition measurements in children (Leonard et al. 2009). Thirty-two children were allocated to either a group aged less than ten (nine girls and six boys) or a group aged ten and above (nine girls and eight boys). Repeat BMD measurements for the lumbar spine (L1–L4), for the total region of the proximal femur and for the whole body were made with repositioning between the two studies.

Table 8.3 shows the results of precision measurements in children. There was a marginally poorer precision for lumbar spine BMD measurements in younger children (0.0083 vs. 0.0052 g cm^{-2}) with no significant differences between the groups for proximal femur BMD (0.0126 vs. 0.0094 g cm^{-2}) or for whole body BMD (0.0087 vs. 0.0086 g cm^{-2}). The results that are shown in Table 8.3 represent averages for the whole group of 32 children. It might be expected that reproducibility would be worse in younger children because of a poorer ability to co-operate during positioning for the DXA scan. On the other hand, reproducibility might be expected to be better in younger children since the number of transmitted X-rays will be greater than in older children so that statistical uncertainties of measured count rates will be less. It is clear that short-term in vivo precision in children is worse than both short-term and long-term precision in a phantom.

Table 8.4 Same-day, in vivo precision for DXA measurements of BMD in adults

Adults	
L1–L4 spine	0.0103
Total femur (left hip)	0.0117
Total femur (both hips)	0.0077

Precision for spine BMD is poorer in adults than children. Precision for hip BMD is the same for children and adults

8.3.3 In Vivo Same-Day BMD Precision in Adults

Same-day precision was measured for groups of 30 adults recruited from routine referrals by each of eight experienced technologists again using the same densitometer as in Sect. 8.3.1 (Nelson et al. 2009). Each technologist performed repeat scans of the lumbar spine and the proximal femur with repositioning between each scan. The results averaged over all 8 technologists are shown in Table 8.4. Same-day precision for lumbar spine BMD was better in children than in adults (0.0068 vs. 0.0103 g cm^{-2}) whereas there was no difference between children and adults for the total region of the left femur (0.0110 vs. 0.0117 g cm^{-2}). This result for the spine is likely explained by the fact that the greater transmission of X-rays through children means that there is less uncertainty in measured count rates, while for the proximal femur, errors arising from patient positioning dominate the uncertainty and are approximately the same for children and adults. Unfortunately, we have not yet established the precision of routine WBBMD measurements in adults so that we only have the value for children shown in Table 8.3 (0.0087 g cm^{-2}).

Precision was measured by each of eight technologists in order to determine the extent, if any, of differences between technologists in spine and hip BMD reproducibility. It was found that lumbar spine reproducibility ranged from a low of 0.008 g cm^{-2} to a high of 0.011 g cm^{-2}, values that were statistically not different from each other. In sharp contrast, for the total region of the left proximal femur, reproducibility ranged from a low of 0.006 g cm^{-2} to a high of 0.016 g cm^{-2}, values that were statistically different from each other. Even when the total regions of both hips were considered together, reproducibility varied from a low of 0.004 g cm^{-2} to a high of 0.011 g cm^{-2}, again values that were statistically different from each other.

8.3.4 In Vivo Long-Term BMD Precision in Adults

The measurement of long-term precision in patients presents a considerable challenge. As outlined in Sect. 8.2.3, the time interval between measurements must be sufficiently long to ensure that both the technologist and the patient are not influenced by recall of positioning strategies from the first measurement. In addition, the time interval must be long enough so that the factors that determine long-term precision have sufficient opportunity to be expressed. In addition, since the factors that do influence precision are more likely to exert their influence over extended periods of time, it is likely that long-term precision will increase as the duration of the period of assessment increases. For any reasonable estimate of long-term precision, the time interval required should be at least 1 year or, preferably, longer. During such long time intervals, there is every chance that BMD will change through normal, age-dependent bone mass adjustments (either positive or negative) and there must be an adjustment for such time-dependent changes. Long-term precision is determined from the

Table 8.5 Long-term, in vivo precision for DXA measurements of BMD

Adults	Long-term precision (g cm^{-2}) Linear bone change	Long-term precision (g cm^{-2}) Polynomial bone change
L1–L4 spine	0.0463	0.0295
Total femur	0.0224	0.0231
1/3 radius	0.0135	0.0116
UD radius	0.0128	0.0101

Long-term precision at the spine depends upon the model assumed for temporal changes in BMD

extent of the deviations between measured BMD values and the corresponding values predicted from a line fitted to all BMD measurements as expressed in (8.5).

Spine BMD was measured in a group of 13 postmenopausal women who attended the same Department of Nuclear Medicine that performed the same-day precision measurements as mentioned above. The women had originally belonged to a control group for a prospective study of the impact of low and medium dose hormone replacement therapy upon bone mass (Beaumont et al. 1996). Since the completion of the study, the women had been followed with frequent DXA measurements. None of the 13 women took any medication known to affect bone metabolism during the extended follow-up periods. The average age for the 13 women at the time of the first measurement was 54.9 ± 2.1 years and the average duration of follow-up was 18.6 years. There were a total of 217 lumbar spine BMD measurements with a total follow-up period of 241.6 person–years. The long follow-up periods meant that many different technologists performed the measurements and a variety of different densitometers was used. There was initially a Norland 2600 machine using a ^{153}Gd source that was followed, in turn, by a QDR 1000, a 4500A and a Discovery A X-ray based system from Hologic. Serial BMD measurements of the non-dominant radius and the total region of the left proximal femur were also performed for shorter follow-up periods in the same 13 women using only the X-ray based densitometers.

Table 8.5 shows that when it was assumed that age-dependent changes in BMD followed a linear pattern, long-term precision was 0.046 g cm^{-2} at the spine, 0.022 g cm^{-2} for the total region of the proximal femur and 0.013 g cm^{-2} for the radius. However, simple observation of the BMD changes over time showed that an assumption of linear change was inadequate. When it was assumed that the temporal changes in BMD were better modeled using a second-order polynomial expression, the long-term precision for spine BMD was improved to 0.029 g cm^{-2}. Long-term precision for the proximal femur and the radius was unchanged at 0.023 and 0.011 g cm^{-2}, respectively.

Long-term precision for the spine is almost three times worse than same-day precision, while long-term precision for the femur is twice the same-day precision. The site with the best long-term precision is clearly the radius. This suggests that the radius could be the most suitable site for the detection of BMD changes. However, it is not clear if important changes in BMD are expressed at the radius to the same extent as at the spine and femur.

8.3.5 Comparison with Published Precision Data

When 57 published papers concerning the reproducibility of BMD measurements were reviewed (Wilson and Smith 2009), median values for same-day, in vivo coefficients of variation for the spine and

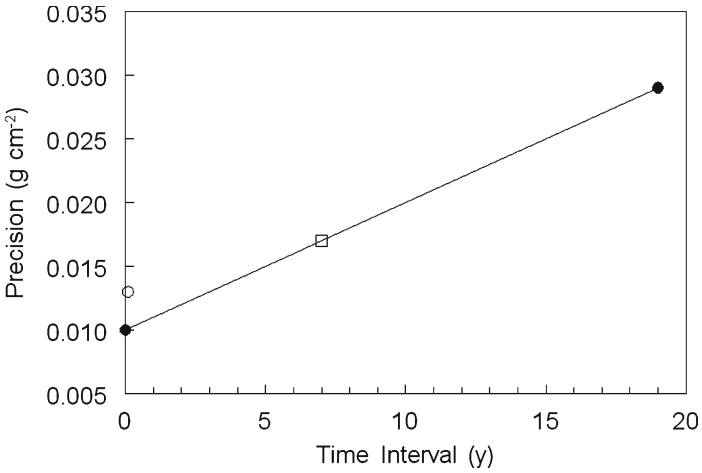

Fig. 8.3 Dependence of long-term precision upon the duration of the time interval for the collection of BMD measurements: results obtained from a routine, clinical department (●); from Leslie (2008) (○) and Patel et al. (2000) (□)

total region of the femur were found to be 1.10% and 1.20%, respectively. Unfortunately, reproducibility was only reported as a CV but if it is assumed that the mean spine and hip BMD was 1.0 g cm^{-2}, then same-day precision is 0.011 g cm^{-2} for the spine and 0.012 g cm^{-2} for the total region of the hip. These results correspond almost exactly to the same-day precision given in Table 8.4 for the spine and hip suggesting that it is possible for routine, clinical BMD clinics to achieve precision standards normally associated with research laboratories.

Short-term precision has been derived from spine BMD measurements that were separated by periods of between 3 and 49 days (Leslie 2008). Short-term precision was found to be 0.020 g cm^{-2} which was significantly worse than the same-day precision of 0.013 g cm^{-2}.

Long-term precision was measured by Patel et al. (2000) in 40 postmenopausal women each followed for up to 7 years. Again, precision was only reported as the CV which for the spine was 1.65% and for the total region of the hip was 1.57%. Assuming once more that the mean spine and hip BMD was 1.0 g cm^{-2}, the long-term precision is 0.017 g cm^{-2} for the spine and 0.016 g cm^{-2} for the total region of the hip. These values are better than those given in Table 8.5 (0.029 and 0.023 g cm^{-2}) which were derived over follow-up periods of almost 20 years. The results of same-day, short-term and long-term precision measurements for the spine are shown together in Fig. 8.3 and demonstrate a dependence of precision upon the time interval over which BMD measurements are performed. Measurement precision declines as the follow-up period is extended. This observation leads to the notion that there is an optimum time for the allowed interval between BMD measurements in a patient; that interval is determined by the balance between a longer interval to be sure a detectable BMD change will occur and a shorter interval to exploit the better long-term in vivo precision.

Patel et al. (2000) observed that a body mass index (BMI) greater than 28 kg m^{-2} had a negative impact on precision as did a large change in BMI during the follow-up period. Nelson et al. (2009) also showed that even though reproducibility for the lumbar spine did not differ between technologists, precision did worsen as the BMI of a patient increased. Again in contrast, there was no detectable dependency of proximal femur BMD precision upon BMI.

8.4 Body Composition Precision

In this section, the only body composition precision results obtained from the same densitometer used in Sects. 8.3.1–8.3.4 are those reported for children in Sect. 8.4.2. The other precision values reviewed in this section have been extracted from the literature.

8.4.1 Precision of Body Composition Measurements in Phantoms

Louis et al. (2006) scanned a Hologic whole body phantom on 18 occasions over a 5-month period and found a precision of 23 g for WBBMBC, 135 g for LBM and 171 g for FM (Table 8.6). A similar precision for WBBMC was found by Ellis et al. (2004) who reported a SD of 21 g for repeated measurements of a commercial phantom.

8.4.2 Same-Day In Vivo Precision of Body Composition Measurements in Children

The reproducibility achieved in a routine Nuclear Medicine Department for body composition measurements is listed in Table 8.7 for groups of younger and older children (Leonard et al. 2009). For adolescents, the reproducibility for WBBMC, LBM and FM was 18, 251, and 189 g, respectively with better precision obtained for younger children.

Other published reports have determined same-day precision in children. Wosje et al. (2006) measured reproducibility in 34 children using a Hologic 4500A densitometer. They reported values for WBBMC, LBM and FM precision of 0.02, 0.17, and 0.15 kg, respectively, results that are consistent with those given in Table 8.7. Margulies et al. (2005) used a Lunar Prodigy to measure precision in 49 children aged between 5 and 17 years. Reproducibility was reported as 48 g, 0.4 kg, and 0.3 kg, respectively. These results demonstrate a considerably poorer precision probably because a variety of scan modes ("thick," "standard," and "thin") were used in the analysis of DXA scans.

8.4.3 Same-Day and Short-Term In Vivo Precision of Body Composition Measurements in Adults

When reproducibility was assessed in 20 adults with immediate repositioning, SDs of 15, 348, and 278 g were obtained for WBBMC, LBM and FM, respectively (Jensen et al. 1997). Same-day precision for WBBMC is the same in adults and children whereas the precision for both LBM and FM is approximately 100 g worse in adults than in children. As shown in Table 8.8, when the time interval between pairs of total body DXA scans is extended to between 1 and 7 days the corresponding SDs increase to 24, 470, and 314 g (Jensen et al. 1997). When body composition reproducibility was determined from whole body scans obtained on each of four consecutive days, the SDs for WBBMC, LBM, and FM were 29, 532, and 389 g, respectively (Kiebzak et al. 2000). Short-term precision for LBM worsened by about 150 g while for FM, short-term precision was about 70 g worse than same-day reproducibility. These comparisons reflect the added variance introduced by day-to-day fluctuations in food and, particularly in the case of LBM, fluid balances.

Table 8.6 In vitro precision for DXA measurements of body composition in a phantom (Louis et al. 2006)

Phantom	Precision (g)
WBBMC	23
LBM	135
FM	171

Table 8.7 Same-day, in vivo precision for DXA measurements of body composition in children

Children	Same-day precision (g) age < 10 years	Same-day precision (g) 10 > age > 18
WBBMC	13	18
LBM	201	251
FM	172	189

Precision of body composition measurements is poorer in teenagers and adolescents than in younger children

Table 8.8 In vivo precision for DXA measurements of body composition in adults

Precision Number of subjects (*N*)	WBBMC (g)	LBM (g)	FM (g)	References
Same-day				
N = 20	15	348	278	Jensen et al. (1997)
Short-term				
N = 35	24	470	314	Jensen et al. (1997)
N = 20	29	532	389	Kiebzak et al. (2000)
Obese				
N = 9, *same-day*	40	530	590	Cordero-MacIntyre et al. (2002)
N = 20, *short-term*	30	1,679	1,559	Cordero-MacIntyre et al. (2002)

Precision of body composition measurements in adults is worse than in children particularly when measurements are recorded on different days and in the presence of obesity

Thomsen et al. (1998) found that same-day precision in eight subjects was 39, 503, and 395 g for WBBMC, LBM, and FM precision, respectively. When the same authors measured same-day precision eight times in a single subject, the corresponding values were 6, 96, and 97 g, respectively demonstrating that there are large differences in precision between subjects.

8.4.4 *In Vivo Precision of Body Composition Measurements in the Presence of Obesity*

As stated above, Wosje et al. (2006) observed that the same-day precision for 34 non-obese children was 0.17 kg for LBM and 0.15 kg for FM. At the same time, they found in 32 obese children, same-day precision was 0.47 and 0.50 kg for LBM and FM, respectively. That is, precision worsened for LBM and FM by factors of 2.8 and 3.3, respectively. The reproducibility for WBBMC was unaffected by the presence of obesity in children. In nine obese postmenopausal women, same-day reproducibility was 40, 530, and 590 g for WBBMC, LBM, and FM (Cordero-MacIntyre et al. 2002). As shown in Table 8.8, short-term reproducibility, when measured by the same researchers using the

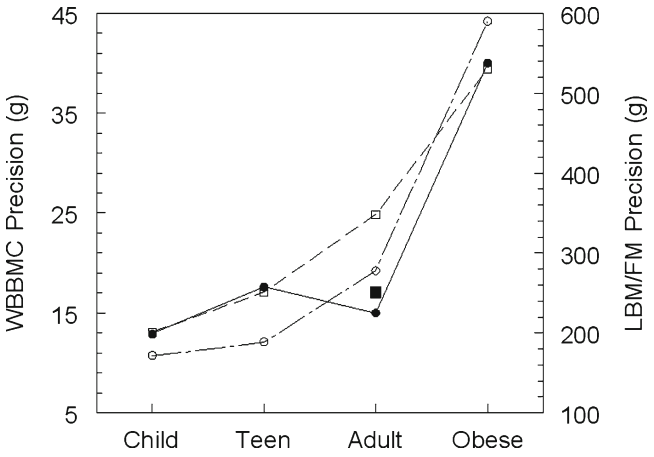

Fig. 8.4 Same-day Precision for measurements of WBBMC (●——●), LBM (□---□) and FM (○——○) in various groups of subjects. Also included is the precision of FM (■) in patients with AIDS (Cavalcanti et al. 2005)

same equipment in 20 obese postmenopausal women after an interval of 3 months, worsened for LBM and FM to 1,679 and 1,559 g, respectively (Cordero-MacIntyre et al. 2002). That is, precision for LBM and FM deteriorated by factors of 3.2 and 2.6, respectively, when short-term reproducibility was compared to same-day reproducibility. There is little relevance in measuring long-term precision of LBM and FM measurements because the time-dependent changes in soft tissue composition can be large over periods of time of 1 year or longer.

The impact of obesity upon reproducibility of body composition measurements is illustrated in Fig. 8.4 which shows results extracted from Tables 8.7 and 8.8 as well as the results of same-day precision measurements of FM in a group of 30 HIV positive subjects (Cavalcanti et al. 2005). WBBMC precision is similar for children and adults at about 15 g but deteriorates dramatically by a factor of about 3 with obesity. The precision of LBM and FM measurements is best in young children and is equal to about 200 g. Reproducibility worsens steadily for adolescents, adults and obese subjects; again, precision for LBM and FM is about a factor of 3 worse in the presence of obesity.

Summary Points

- Precision or reproducibility reflects the ability of a technique to produce the same result when the same variable is measured and establishes the smallest difference between successive measurements that can be considered to be significant.
- In vivo same-day precision is based upon the differences between two measurements of BMD performed in each of a representative group of subjects with repositioning between the two BMD measurements.
- In vivo long-term precision is based upon the individual differences between the measured BMD values recorded over an extended time period and the corresponding predicted BMD values derived from a mathematical fit to the complete series of BMD measurements.
- Precision is best expressed as a SD and not as a coefficient of variation.
- Same-day and long-term BMD precision for a spine phantom is better than 0.005 g cm^{-2}.
- Same-day precision for spine BMD in children is 0.007 g cm^{-2} deteriorating to 0.010 g cm^{-2} in adults.
- Same-day precision for BMD of the total region of the left hip in children is 0.011 and 0.012 g cm^{-2} in adults.
- Long-term BMD precision increases as the measurement time period is extended.

- Long-term precision over a period of close to two decades is 0.029 g cm^{-2} for BMD at the spine and 0.023 g cm^{-2} for the total region of the left hip.
- Same-day precision for WBBMC is better than 20 g in children and adults.
- Same-day precision for LBM is about 200 g in young children, worsens to 250 g in adolescents and to about 350 g in adults.
- Same-day precision for FM is about 170 g in young children, worsens to 190 g in adolescents and to about 280 g in adults.
- Short-term precision in adults deteriorates to about 470 g for LBM and to about 350 g for FM in comparison to same-day precision.
- In the presence of obesity, same-day precision for both LBM and FM in children deteriorates to about 500 g.
- In the presence of obesity, short-term precision for both LBM and FM in adults deteriorates to about 1,600 g.

Chapter 9
Self-Reported Anthropometry: Body Mass Index and Body Composition

Savvas P. Tokmakidis, Antonios D. Christodoulos, and Helen T. Douda

Abstract Obesity is a threat in our society, associated with several health-related problems. Monitoring body weight and height is the most commonly used, fast and easy method to evaluate overweight and obesity, assess related health risks and develop appropriate prevention strategies. Self-reported anthropometry frequently replaces actual measurements, mainly in population studies due to financial reasons. The purpose of this chapter is to examine the validity of self-reported body measures as a diagnostic method for the evaluation of overweight and obesity in different populations. Self-reported data for anthropometric indices derive from personal interviews, telephone interviews or mail questionnaires. Numerous studies have found that self-reported and actual measures are highly correlated; however, this approach may be misleading, given that sources of bias cannot be assessed by the correlation coefficient of the Pearson's r statistic. Reviews of validity studies show that height is mostly over-reported and weight under-reported. These misreports are reflected in the calculation of body mass index (BMI) and the subsequent assessment of overweight and obesity prevalence, which are all constantly underestimated. A number of factors have been reported to affect the extent of the bias between self-reported and measured anthropometrics, including – inter alia – age and gender distribution of the study population, weight status, race/ethnicity, socioeconomic status, cultural differences and variations in study protocols. Taken together, these findings suggest that, based on self-reported data, specific sub-groups would be incorrectly classified, which would lead to an inaccurate assessment of the obesity-related morbidity risk of a population, with important implications for health planning. Self-reported anthropometry could be more usable if appropriate correction factors were used in epidemiological studies, by taking actual measures from an independent sub-sample of the same population, by collecting specific socio-demographic characteristics and/or by lowering the BMI threshold for overweight and obesity.

Abbreviations

BMI	Body mass index
DM	Directly measured
F	Females
M	Males

9.1 Introduction

The prevalence and severity of overweight and obesity has increased in all sectors of the population over the last decades, becoming a worldwide epidemic (Wang and Lobstein 2006). Numerous research studies to date clearly demonstrate that obesity in childhood and adult life increases several metabolic risk factors related to cardiovascular disease (Poirier et al. 2006). The World Health Organization has declared obesity as one of the greatest challenges and chronic disease risk factors in this century. Therefore, identification and accurate monitoring of overweight or obesity prevalence are essential and can provide useful guidance to public health professionals in order to estimate the extent of the problem, assess secular trends and develop effective intervention strategies.

Obesity is the result of excess body fat. However, the accurate measurement of body fat mass requires sophisticated and often costly methods with limited applicability in the clinical setting. Thus, several measures of body weight standardized for height have been used as a proxy index of adipose tissue. The most commonly used screening tool for overweight and obesity is the body mass index (BMI), defined as body weight divided by height squared ($kg \cdot m^{-2}$). Given its strong association with adiposity measurements derived from dual energy X-ray absorptiometry (0.83–0.98), BMI seems to be an appropriate measurement for the indirect assessment of adiposity (Lindsay et al. 2001; Weerarathna et al. 2008).

Straightforward measurements of weight and height in large population samples and on a regular basis are not always technically feasible, due to financial limitations and time requirements. Thus, health research frequently uses self-reported data for height and weight as an alternative to actual anthropometric measures (Spencer et al. 2002; Lissau et al. 2004). The BMI derived from these reports is subsequently used to screen for overweight and obesity (Engstrom et al. 2003).

However, concern has been raised about the accuracy and validity of self-reported height and weight, given that existing research evidence has shown inconsistent outcomes. Some researchers suggest that self-reported anthropometry is valid and has an advantage compared to the directly measured body dimensions (see Table 9.1), since it is convenient, time-saving, requires no equipment and is easy to apply to large populations (Bolton-Smith et al. 2000; Stommel and Schoenborn 2009). In contrast, others consistently noted systematic bias in self-reported data (Gorber et al. 2007;

Table 9.1 Advantages and disadvantages of self-reported anthropometry

Advantages	Disadvantages
• Convenient • Time-saving • Low cost • Requires minimum equipment • Easy to apply to large-scale population studies	• Systematic and random bias, affected by age, gender, ethnicity, body composition and health status • Consistent underestimation of overweight and obesity prevalence • Misjudgement of obesity-related health risks

This table lists the pros and cons of using self-reported anthropometry instead of direct measurement of height and weight in order to assess BMI and estimate obesity

McAdams et al. 2007). The latter insist that these data could lead to erroneous estimating rates of overweight and obesity. Furthermore, the validity of self-reported anthropometry appears to vary in gender, age, race or ethnicity. In addition, weight status itself, i.e. being overweight or obese, may also affect the reported anthropometric values. In this context, the goal of the present chapter is to discuss these issues and examine the validity of self-reported body measures as a diagnostic method for the evaluation of overweight and obesity in different populations.

9.2 Differences in the Procedure of Self-Reported and Directly Measured Data

Self-reported data for anthropometric indices derive from personal interviews, telephone interviews or mail questionnaires. Subjects are generally randomly selected from a population and are asked to provide their height and weight, in addition to other demographic data (age, gender, education level, socio-economic class, health status, etc.). The interval between collection of self-reported and direct measurements in validity studies ranges from the same day to a few months, or is not reported (Boström and Diderichsen 1997; Sherry et al. 2007). The elapsed time between measures should be controlled and taken into account in analyses, given that changes in weight can occur over short time-periods (Gorber et al. 2007). Bias in self-reported weight and height is larger in telephone interviews than in in-person interviews (Ezzati et al. 2006).

Measured data for anthropometry are more reliable. In population studies, however, errors affecting the outcome of the data can also occur when researchers do not use standard procedures and consistent guidelines. Studies comparing self-reported versus measured data should be based on reproducible and appropriate procedures. Measurement methods, including the calibration of the equipment and details of the procedure should be reported. Measurement conditions such as the order of measurement, who is taking the measurements, what equipment is being used, as well as what clothes or shoes are worn should be provided. This is of importance when the measurements are determined to the nearest 0.1 cm and 0.5 kg. For instance, during measurements of adolescents, light clothing might be acceptable, but measuring height in growing subjects with shoes on is likely to cause errors (weight of shoes and height of soles and heels, especially among youth with regard to current fashion trends).

9.3 Correlations Between Self-Reported and Measured Anthropometry

Numerous validity studies have used correlation analyses to interpret associations between self-reported and measured anthropometric indices. Regardless of significant or trivial mean differences in height, weight and/or BMI, the vast majority of the existing literature on the validity of self-reported data reported high correlations between self-reports and actual measures (see Table 9.2). However, the use of correlation coefficients as an index of validity has been frequently criticized. This approach may be misleading, since this statistic has been designed to investigate bivariate relationships and to assess only the closeness to a linear relation between two methods and not agreement or whether the methods can be used interchangeably. Furthermore, sources of systematic bias cannot be assessed via Pearson's *r* coefficient of correlation.

This means that correlation coefficient analysis is insensitive to any possible differences in the means and variances of raw data. Consequently, the high correlations observed between self-reported

Table 9.2 Differences between self-reported and directly measured anthropometry, differences in the prevalence of obesity and correlation coefficient between the self-reported and measured values obtained from various studies

This table presents correlation coefficients between self-reported and measured anthropometrics, differences between self-reported and directly measured mean for height, weight and BMI, as well as differences between reported and observed prevalence of overweight and obesity, obtained from published studies
SR self-reported, *DM* directly measured, *M* males, *F* females, *OW* overweight, *OB* obesity, *NR* not reported

and measured anthropometric indices do not imply validity. However, based solely on high correlation coefficients, several studies suggest that self-reported height and weight should be considered as valid proxy measures for actual values, especially in analyses that use these values as continuous variables (Davis and Gergen 1994; Brener et al. 2003).

9.4 Differences Between Self-Reported and Actual Anthropometric Measures

A review of relevant studies revealed significant differences between self-reported and actual anthropometric measures (see Table 9.2). Height is mostly over-reported (Spencer et al. 2002; Brener et al. 2003; Shields et al. 2008; Stommel and Schoenborn 2009; Fonseca et al. 2009), but also under-reported (Dekkers et al. 2008; De Vriendt et al. 2009). The magnitude of the discrepancies between self-reported and measured height is relatively small (from -0.5 cm to ~2 cm), with the exception of one study (Brener et al. 2003), which reported differences of ~6.9 cm in US adolescents. It seems, therefore, that young individuals have a tendency to overestimate their body height to a greater extent compared to older age groups.

On the other hand, weight is systematically under-reported in most studies and the degree of under-reporting ranges from 0.5 to 4.5 kg in children, adolescents and adults. The mean errors in self-reported height and weight are relatively small; however, in most studies the standard deviations of the differences are large, implying significant between-subject variability in the accuracy of self-reported height and weight.

These misreports are reflected in the calculation of BMI, which is constantly underestimated, with distortions in weight influencing this underestimation to a greater degree than distortions in height. The magnitude of the discrepancies between self-reported and measured BMI ranges from no difference to ~2 $kg \cdot m^{-2}$, whereas standard deviations are smaller in comparison to the individual values of height and weight. In contrast to this trend, Bolton-Smith et al. (2000) found that BMI was overestimated in a Scottish population aged 25–64 years by a mean difference 0.2 ± 1.4 $kg \cdot m^{-2}$ in men and 0.2 ± 1.3 in women.

9.5 Factors Affecting the Bias

The magnitude of the observed differences between self-reported and actual anthropometric measures varies between studies. An array of factors may be associated with the inaccuracy of self-reported height and weight, including – inter alia – population characteristics such as age distribution, gender, ethnicity, weight status, socio-economic status, cultural norms, perceived body image or size, motivation and variations in study protocols (Bolton-Smith et al. 2000; Spencer et al. 2002; Dekkers et al. 2008). The main findings of relevant studies that investigated factors possibly affecting the accuracy of self-reported anthropometrics are presented below.

9.5.1 Gender Differences

Although self-reported BMI understates measured BMI for both genders, the patterns of accuracy in self-reported anthropometric measures appear to be influenced by gender, with females tending to underreport their weight to a greater degree than males (Ezzati et al. 2006; Shields et al. 2008;

Stommel and Schoenborn 2009); consequently, self-reported BMI is most often lower for females, compared to males, leading to the false conclusion that prevention programs should be targeted more at males. The bias towards greater under-reporting among females tends to disappear with older age (Stommel and Schoenborn 2009). Other surveys found no significant gender differences in the degree of inaccuracy in self-reported anthropometrics (Bolton-Smith et al. 2000; Tokmakidis et al. 2007; Fonseca et al. 2009). According to some authors, females report their weight and height more accurately than males and the resulting discrepancy in BMI is then smaller in females (Spencer et al. 2002). The greater discrepancy often observed in females may be associated with a socially desirable response, a reflection of the greater emphasis that women give on thinness and the perceived pressure to conform to cultural norms for social desirability (Brener et al. 2003).

9.5.2 Age Differences

Several studies have examined the possible associations between age and the accuracy of self-reports in height, weight and BMI, with conflicting results. Investigating the accuracy of self-reported height and weight in Belgian adolescents, De Vriendt et al. (2009) observed that age did not affect the extent of the bias in BMI values. Data on children and adolescents from our laboratory (Tokmakidis et al. 2007) revealed that high school students (aged 12.5 ± 0.3) tended to overestimate their height and under-report their weight to a greater degree than elementary school pupils (aged 11.4 ± 0.4). As a result, the understating of BMI was greater for high school compared to elementary school pupils (mean difference is measured vs. reported BMI: 1.61 ± 1.4 $kg \cdot m^{-2}$ vs. 0.79 ± 1.8 $kg \cdot m^{-2}$, respectively, $p < .001$).

Results from another data set in the United States, adolescents (Himes et al. 2005) indicated an increasing overestimation of height by males with age and less underestimation of weight in subsequent age groups in both genders. The greater biases in weight were observed at ages 12–14, possibly implicating enhanced body dissatisfaction or poor body image at early adolescence. Assessment of sexual maturation in self-report studies could be helpful in understanding deviations of self-reported anthropometrics from corresponding measured values in adolescence, given that maturity status may alter adolescents' body image perceptions.

Another contributing reason to the observed discrepancy in self-reported dimensions in the youth could be, at least partially, the large physical changes characterizing adolescence. Adolescents who undergo such rapid body changes without being regularly weighed and measured are less likely to be aware of their actual height and weight.

Data on Swedish adults 18–84 years (Bostrom and Diderichsen 1997) revealed that overestimation of height increased, whereas underestimation of weight decreased with age in both genders. Stommel and Schoenborn (2009) analyzed data from the National Health and Nutrition Examination Survey and found the larger underestimates of measured BMI among the youngest and oldest individuals (Fig. 9.1). Shields et al. (2008) reported that age was strongly associated with over-reporting of height and weakly related to BMI underestimation in the Canadian Community Health Study. In an adult Scottish population study (Bolton-Smith et al. 2000) there was no systematic trend by age, however the oldest individuals (55–64 years old) tended to underestimate their height the least and their weight the most. In contrast to the aforementioned studies, Dekkers et al. (2008) found that in Dutch overweight employees, the self-reported bias of body dimensions was not greater in older individuals than in younger individuals.

Over-reporting of height in older individuals may be associated with the height loss that commonly occurs among older subjects, as a result of the aging process, such as osteoporosis and/or loss of

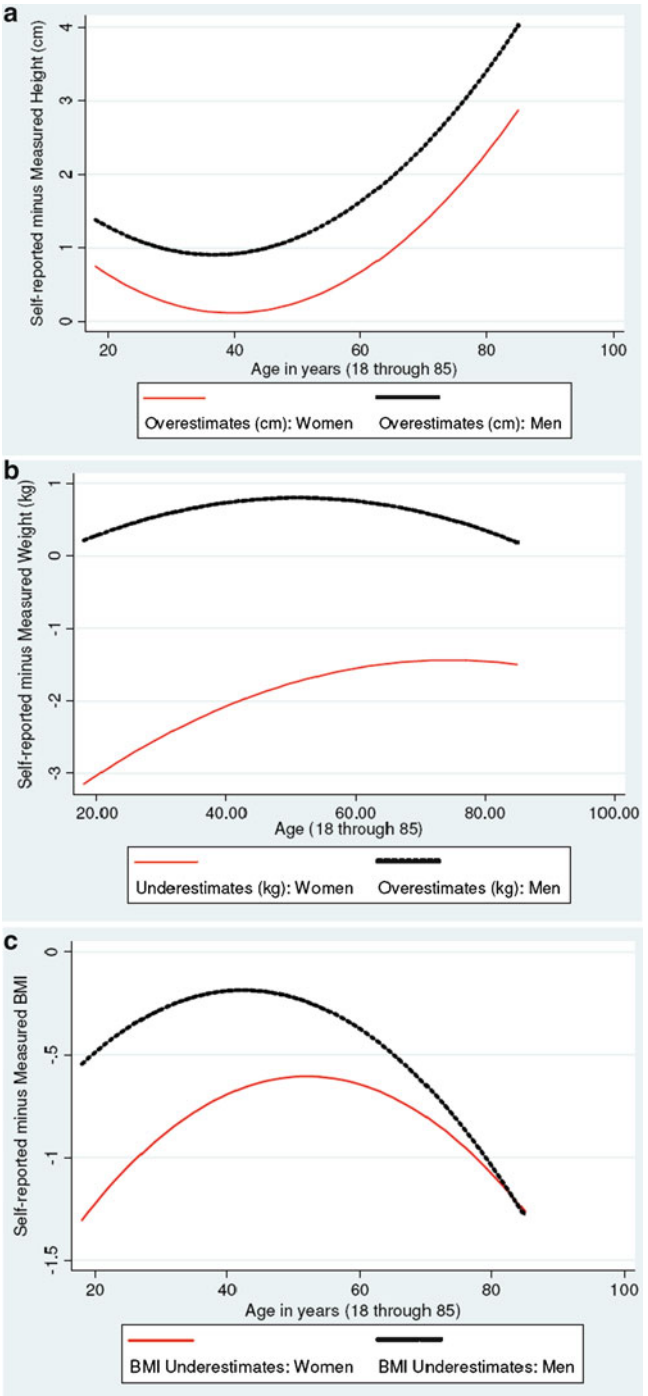

Fig. 9.1 Association of age and gender with discrepancies between self-reported and measured anthropometric indices. This Figure illustrates how age and gender are associated with the discrepancies between self-reported and measured height (**a**), weight (**b**) and BMI (**c**): Fitted values. (Reprinted from BMC Public Health, Stommel and Schoenborn (2009), p. 6, BioMed Central Ltd)

muscle tone. Stature declines with age in older individuals by up to 2 cm per decade after age 30 and this loss may not be perceived by the individuals, so they may report their height as it was in previous age periods (Shields et al. 2008). Moreover, access to routine health care or other issues related to the populations studied may account for the observed discrepancies.

Table 9.3 Differences in BMI values ($kg \cdot m^{-2}$) by BMI categories based on measured height and weight in selected studies

		BMI categories based on measured height and weight			
References	Sample	Underweight <18.5	Normal weight 18.5–24.99	Overweight 25.0–29.99	Obesity ≥30.0

This table focuses on the mean differences in BMI values across BMI categories based on actual measurements of height and weight. Positive values represent overestimates, negative values represent underestimates.
[a]Obesity Class I: 30.0 ≤ BMI ≤ 34.99; Obesity Class II: 35.0 ≤ BMI ≤ 39.99; Obesity Class III: BMI ≤ 40.0 (clinical obesity)
[b]BMI <25 $kg \cdot m^{-2}$ was classified as normal weight in this study

9.5.3 Weight Status

It seems that the magnitude of the discrepancy between self-reported and actual anthropometric measures is strongly affected by the actual body size, with heavier people mostly understating their weight (Spencer et al. 2002; Shields et al. 2008; De Vriendt et al. 2009; Stommel and Schoenborn 2009) and underweight individuals overestimating (Stommel and Schoenborn 2009), but also underestimating (De Vriendt et al. 2009) their weight.

Overall, the extent of underestimation of BMI increases with increasing weight and BMI category (Table 9.3). We found a significant effect of BMI status in the accuracy of self-reported parameters in Greek students, with a higher BMI resulting in trivial discrepancies in height, but in considerable biases in weight and BMI. The same pattern was observed when differences were computed for elementary and high school students separately (Fig. 9.2). Similarly, Himes et al. (2005) found out that the errors in self-reports became increasingly negative as weight and BMI categories increased, with steeper slopes in females (Fig. 9.3). These patterns of underestimation suggest that the greatest impact of the bias in self-reported BMI will be to systematically underestimate overweight and obesity prevalence, defined by the upper percentiles.

The bias towards greater under-reporting among the higher BMI categories is a notable consistent finding in the literature, indicating a general negative scaling pattern of errors in self-reported height, weight, and BMI relative to the measured dimensions. It is possible that some overweight and obese individuals avoid weighing themselves and consequently report their body dimensions less accurately. This could also be explained by the social sensitivity generally associated with body image (Bolton-Smith et al. 2000; Gorber et al. 2007; Stommel and Schoenborn 2009). Although it is clearly an objective, measurable phenomenon (i.e. BMI), obesity is also considered a subjective, emotional

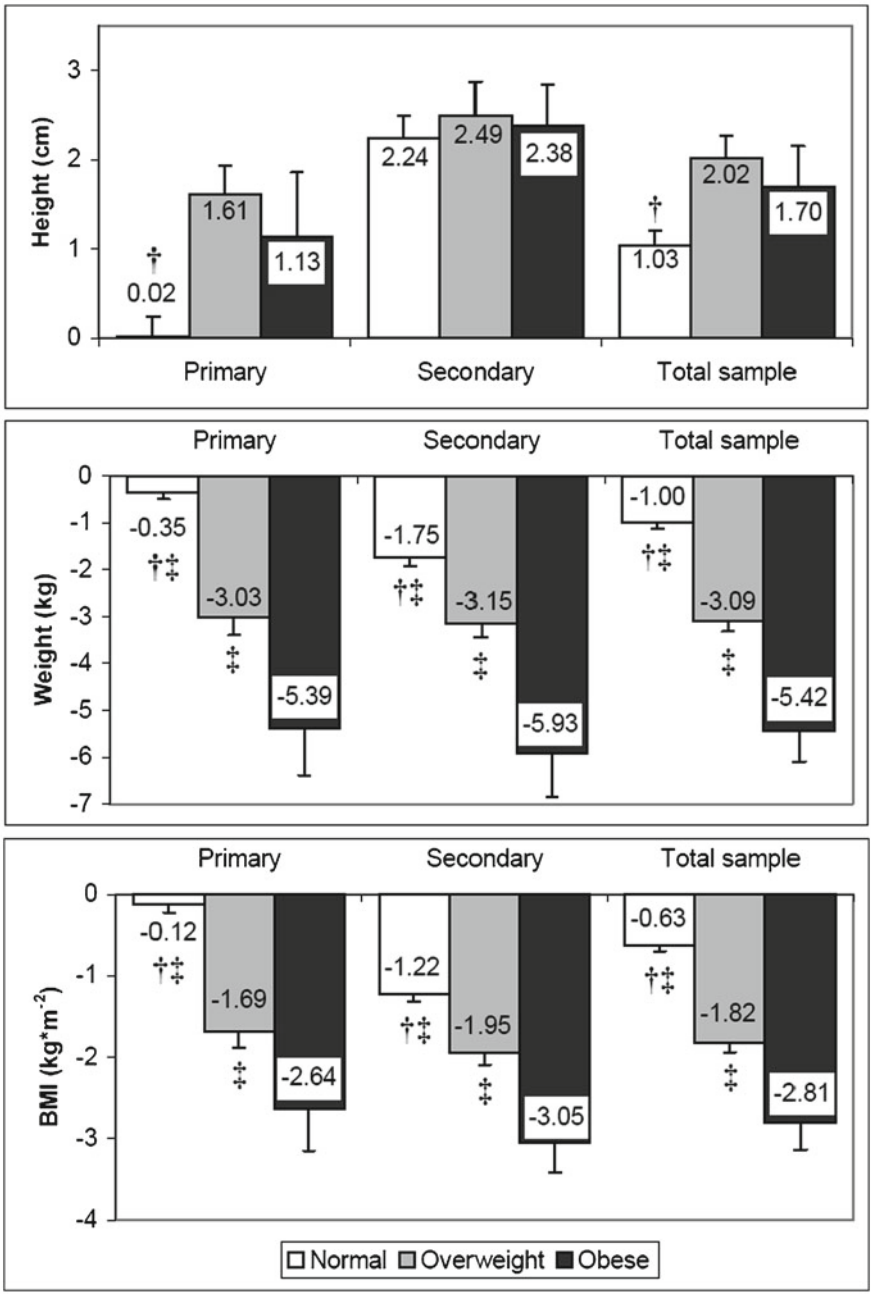

Fig. 9.2 The effect of BMI status in the accuracy of self-reported anthropometric parameters in Greek school children. This Figure illustrates the differences between self-reported and measured values of height, weight and BMI across BMI categories in Greek primary and high school students. Values significantly different: † vs. overweight (*p*-values between.004 and.001); ‡ vs. obese (*p*-values between.02 and.001) (Reprinted from Tokmakidis et al. (2007), p. 309, with permission from Elsevier)

experience of one's body and body image, and has been significantly associated with internal states such as low self-esteem (Goodman et al. 2000). Since a lower self-esteem is associated with greater bias in self-reported weight (Elgar et al. 2005), discrepancies in self-reported anthropometric values

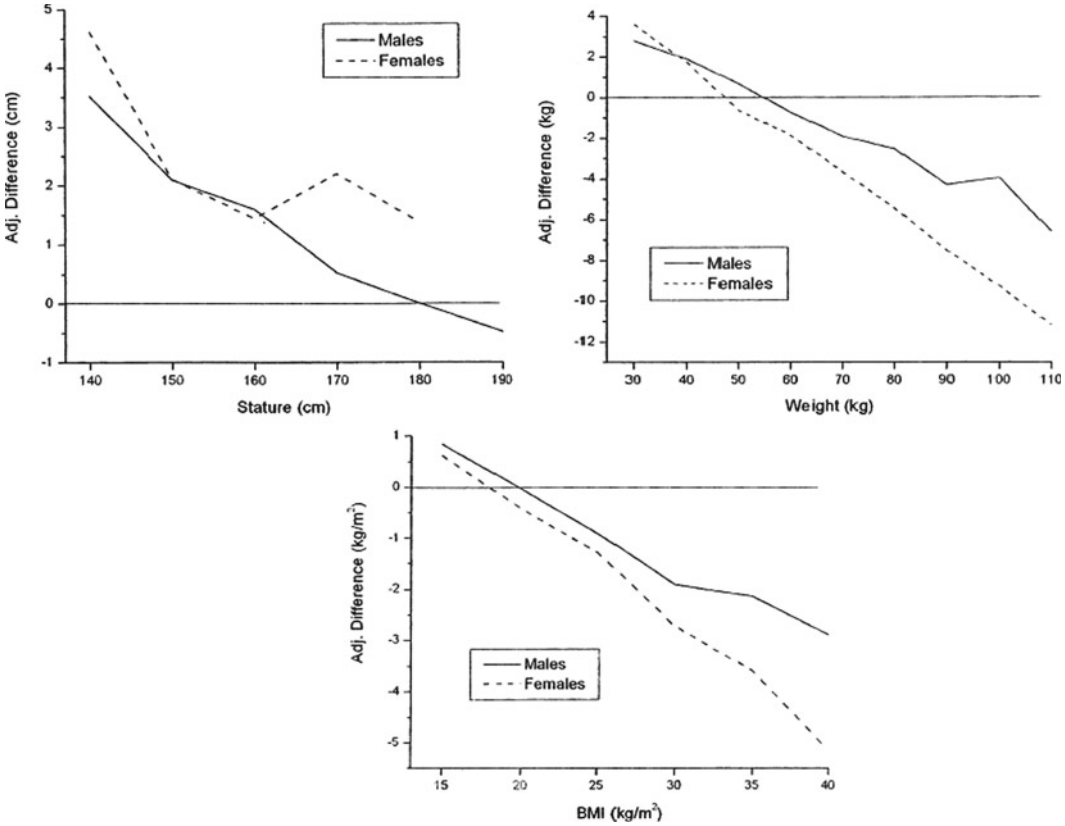

Fig. 9.3 Patterns of bias in self-reported anthropometric values relative to categories of the measured dimension by gender. This figure presents mean differences for self-reported minus measured dimensions, plotted separately for males and females relative to categories of the measured dimension (Reprinted from Himes et al. (2005), p. 275, with permission from Elsevier)

possibly reflect discrepant perceptions of body image among individuals, implying one's unwillingness or inability to acknowledge his or her obesity because of denial and/or social stigma.

9.5.4 Socio-Economic Status

Many investigators have pointed out social and economic status differences, indicated by several parameters, such as income, occupation, education, wealth and/or place of residence, as important determinants that appear to influence the prevalence of overweight and obesity. The extent of misreporting anthropometric indices seems to be greater in individuals with higher BMI values. Therefore, it is conceivable that social class differences could bias height, weight and BMI values based on self-reports (Table 9.4).

There is a limited number of studies examining the association of social and economic status indices with the accuracy of self-reported anthropometrics, with inconsistent findings. Both effects and no-effects have been reported. Himes et al. (2005) found that male adolescents in the highest

Table 9.4 Key features of socio-economic status

1. SES differences could have an influence on self-reported anthropometry
2. SES is a measure of an individual's or family's social and economic position in the community, relative to others
3. SES is determined based on a combination of variables including income, occupation, education, wealth and/or place of residence
4. SES is typically broken into three categories: high SES, middle SES, and low SES, which describe the three areas a family or an individual may fall into
5. Existing data on SES conditions and the accuracy of self-reported height, weight and BMI are inconsistent

This table lists the key facts of socio-economic status including definition, assessment methods, and categorization (American Psychological Association, 2007)

SES socio-economic status

socio-economic groups overestimated their height relatively more than males with lower socio-economic scores. However, data on British and the US adolescents revealed no association between social class or parental education and the accuracy of reported height, weight or BMI (Crawley and Portides 1995; Goodman et al. 2000).

Data from studies on adults implicate that less educated subjects, male non-manual workers and female manual workers underestimate actual weight respectively more than those with higher education, male manual workers and female non-manual workers (Boström and Diderichsen 1997; Dekkers et al. 2008). Further, women with a higher family income are more aware of their current weight and thus report their weight more accurately than women with a lower family income (Jalkanen et al. 1987).

9.5.5 Race and Ethnicity

The accuracy of self-reported anthropometric indices may differ among various ethnic populations, due to differences in body size, cultural norms and/or different sensitivities about being overweight (Dekkers et al. 2008; Stommel and Schoenborn 2009). Hence, a number of studies have investigated this issue.

Data analyses on US adolescents showed that race and ethnicity was not related to the bias between self-reported and measured BMI (Goodman et al. 2000; Brener et al. 2003). Himes et al. (2005) came to similar findings in a population of Minnesota adolescents, still, they further reported significant main effects of ethnicity for height and weight in males, with Asian males tending to overestimate height and underestimate weight more than black or Hispanic males.

Thai men and women showed results consistent with findings in Western populations, since they misreported their height and weight in ways similar to their counterparts in developed countries (Lim et al. 2009). On the other hand, Japanese showed extremely small height and weight discrepancies, compared to other studies, probably due to the practice of annual health checkups in Japan and the greater awareness of their body size (Wada et al. 2005). Findings from the National Health and Nutrition Examination Surveys II and III indicate a non-significant effect of race (white/black), but important, consistent ethnic differences between Mexican Americans and other groups, independent of other variables (Gillum and Sempos 2005). It is not unknown if these differences are due to cultural differences in awareness of body size, different cultural norms or differing views of body image (Himes et al. 2005) and further research is needed to clarify these issues.

9.5.6 Other Factors Affecting the Bias

A limited number of studies have included various factors that may be related to the accuracy of self-reported anthropometrics, such as smoking status, physical activity, health status, end digit preference, diet restraint, weight history and medication for cardiovascular risk factors. However, their findings are disparate and should be interpreted with caution.

The reasons for misreporting are multiple and complex. Hence, it becomes clear that apart from the aforementioned factors, several other factors could probably operate independently or simultaneously and affect the bias between self-reported and measured anthropometric values. For instance, clothes may account for some of the apparent underestimation in self-reported weight, since weighing at home is likely to be done in minimal clothing. Yet, weighing scales, even within clinics and hospitals, are significantly inaccurate (Bolton-Smith et al. 2000). Further research into the characteristics of over- and under-reporters will help to understand the reasons for misreporting, get more insight into this issue and improve the accuracy of self-reported anthropometric indices.

Self-reported data present a trend of bias towards the ideally expected value (wishful thinking). In industrialized societies, where the ideal of tallness and the desire to be slim prevail, people may tend to report values of height and weight that are close to their ideal values rather than to their actual measures. Short stature is socially undesirable, leading short individuals to report higher values of body height. On the other hand, the increasing prevalence of overweight and obesity in the recent years does not seem to have made excess weight more acceptable; thus, feeling the pressure to conform to "desirable" standards, individuals in the upper BMI categories tend to hide and under-report their weight. Individuals with body composition close to ideal fall within the appropriate confidence interval values.

9.6 Differences in Estimated Prevalence of Overweight and Obesity

The errors in self-reported height and weight are compounded in the derived BMI variable and this is particularly important when BMI values are used to classify subjects into standard categories of BMI (underweight, normal weight, overweight and obese). The substantial deviations of the self-reported from the actual BMI values, particularly at the high and low ends of the BMI scale, are large enough to result in misclassifications and underestimates of possible weight problems.

The majority of the reviewed studies found that the prevalence estimates of overweight and obesity were substantially lower with self-reported rather than measured data, with wide variability in the extent of underestimation (see Table 9.2 and Fig. 9.4). In the Canadian Community Health Study (Shields et al. 2008), the prevalence of overweight and obesity based on self-reports was respectively 2% and 7.4% lower than the estimate based on actual measurements, with particularly pronounced differences among older people (>65 years old). The obesity prevalence based on self-reported values was 15% and 13% lower for elderly men and women, respectively.

In a study from our laboratory (Tokmakidis et al. 2007), prevalence estimates in Greek students were 23.1% for overweight and 4.3% for obesity, but according to measured data the corresponding rates were 28.8% and 9.5%, respectively. Hence, the self-report screen missed 41.5% of overweight and 57.8% of obesity cases, leading to an underestimation of overweight and obesity by 3.7% and 5.8% respectively for elementary school and 8.4% and 4.4% respectively for high school students. The magnitude of underestimation for the total sample was comparable with that reported for overweight (4.8%) and higher than that reported for obesity (1.6%) in Welsh adolescents (Elgar et al. 2005). These differences imply that self-reported data might not be as valid as data obtained from actual measurements, calling into question the use of self-reports as a screen for overweight and obesity.

9.7 Implications for Health and Disease

Misclassification of overweight and obese subjects belonging to a lower BMI category would lead to erroneous estimating rates of overweight and obesity (Fig. 9.4). This means that, if self-reported data were used, overweight and obese individuals under-reporting their weight would be less likely to engage in weight control practices and receive appropriate interventions and education, given that they would be classified and would also continue to perceive themselves as having normal weight.

Children and adolescents having a wrong body image perception or being unaware of their weight problem may not be stimulated to take appropriate preventive steps and adopt healthy behaviors, in terms of a balanced diet and enhanced participation in physical activities, in order to limit further weight gain. For instance, based on self-reported data obtained from a nationwide sample of Greek school-aged children, Karayiannis et al. (2000) concluded that the prevalence of childhood overweight (15.3%) and obesity (1.8%) was lower in Greece compared to most other western countries, contradicting the corresponding prevalence estimates for overweight (21.6–30.3%) and obesity (5.6–9.5%) reported by studies based on actual measures from children and adolescents from several Greek regions (Fig. 9.5).

It is notable that the prevalence estimates of overweight and obesity observed in the aforementioned study, which was conducted in 1997–1998, were even lower than the percentages that were observed in a study carried out 15 years earlier in Crete. According to the study's conclusion, a significant proportion of overweight and obese children, who should be targeted for nutritional and physical activity advice, would be missed for intervention purposes. This is especially relevant in the light of evidence that obesity, as well as several obesity-related risk factors, tend to track from childhood and adolescence into adult life.

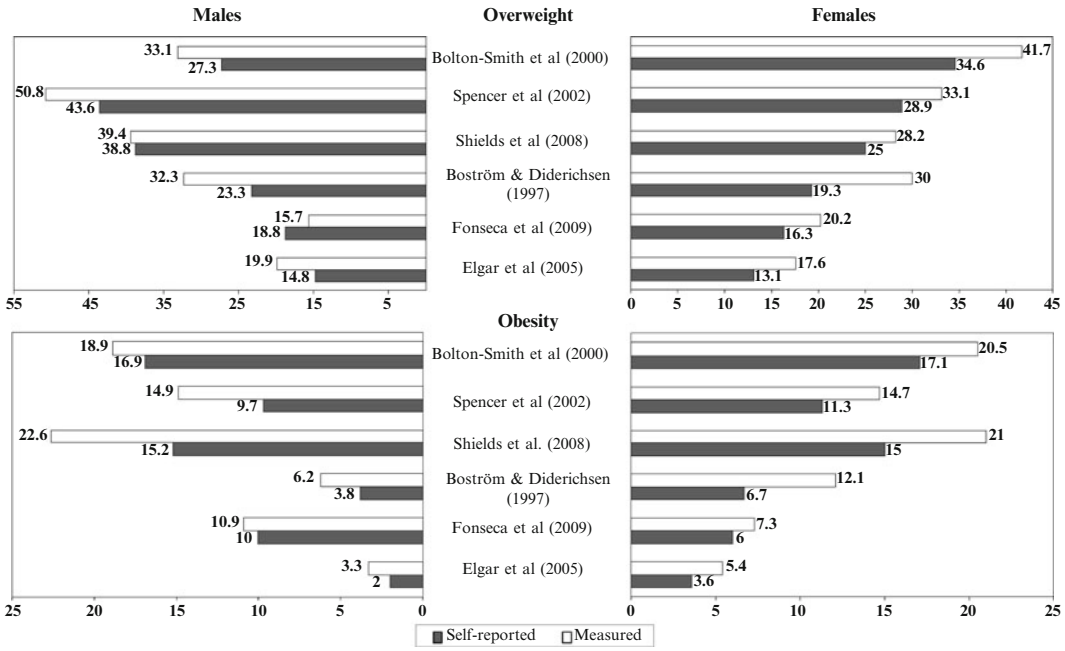

Fig. 9.4 Differences in prevalence estimates of overweight and obesity by collection method and gender in published studies. This figure illustrates differences in prevalence estimates of overweight/obesity between self-reported and measured anthropometry by gender in relative studies

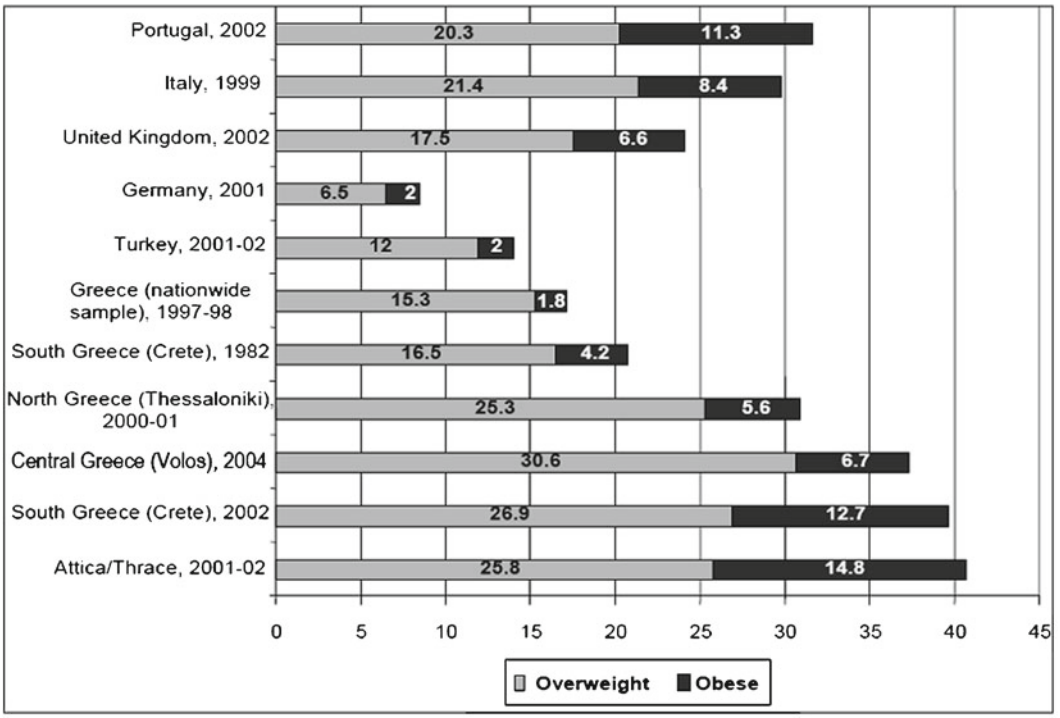

Fig. 9.5 Prevalence of childhood overweight and obesity in several districts of Greece and other European countries, according to published data. This Figure presents prevalence rates of childhood overweight and obesity in several districts of Greece and other European countries, according to published data (With kind permission from Springer Science+Business Media, Tokmakidis et al. 2006, p. 871)

Concerning the relationship of self-reported BMI to obesity-related health disorders, research evidence provides conflicting conclusions. It is often suggested that underestimating obesity prevalence may result in diminished associations between obesity and health outcomes. This is in contrast with another data set, which supports that misclassification of self-reported BMI leads to exaggerated associations between overweight and obesity and concomitant morbidity (Shields et al. 2008). Finally, data from the National Health and Nutrition Examination Study III showed that self-reported anthropometric data can provide sufficiently accurate information in epidemiological studies, in which the primary outcomes are disease biomarkers or obesity-related diseases (McAdams et al. 2007). Consequently, caution is necessary when assessing the association of obesity-related health conditions with self-reported anthropometrics.

9.8 Suggestions to Reduce the Bias

Over-reporting of height and under-reporting of weight increases with rising levels of BMI. There are data indicating that the reporting bias for weight has increased in the last years and the greater overall bias may reflect the increasing prevalence of overweight and obesity worldwide (Shields et al. 2008). In this context, it is important to measure the magnitude of the bias periodically, in order to examine if it changes over time.

Developing correction factors that could be applied to eliminate or at least decrease the magnitude of the biases in BMI associated with self-reported anthropometric values, is an attractive idea (Gorber et al. 2007). Hence, to improve the accuracy of BMI estimates, it has been suggested that future large-scale studies should take measured data from at least a random sub-sample of the cohort, in order to examine the size and direction of any bias as well as to identify the sources of this bias (Elgar et al. 2005; Ezzati et al. 2006; Danubio et al. 2008). Identified sources of bias can be entered into adequate models as explanatory variables along with reported values and the derived predictive equations can then be applied to the whole cohort to minimize the bias (Spencer et al. 2002).

Moreover, some researchers support that self-reported BMI scores could be further adjusted, based on a few, easily collected demographic data such as gender, age, race and ethnicity, marital status and household income (Stommel and Schoenborn 2009). By using the adjusted measures, overall estimates of the population overweight and obesity prevalence are substantially improved, whereas it seems that the adjusted self-reported scores deliver risk estimates that are close to those obtained on the basis of the actual BMI values, particularly if parametric prediction models are used.

Another simple method to obtain more accurate estimates of obesity prevalence from self-reports is the "reduced BMI threshold", which proposes the lowering of BMI cutoff-points for the overweight and obese categories, using receiver operation characteristic (ROC) techniques (Lim et al. 2009). Reduced BMI thresholds should be computed from ancillary data collected on a limited representative sample, if the method is going to be used in populations with different characteristics.

A practical and convenient approach, however, is to provide the appropriate information to the target population. Giving guidelines to the subjects, for instance, to get their body height and weight measurement prior to the participation in the survey and have a proper preparation for the report could reduce the error bias of self-reported data (De Vriendt et al. 2009).

9.9 Summary

The literature review showed that, overall, self-reported data provides useful information. Individuals are quite capable of reporting their height and weight. However, self-report should be used carefully when determining BMI-categories, given that systematic errors related to several population characteristics could lead to an underestimation of overweight and obesity. These biases in reporting may have important implications for appropriate health planning, especially if diagnostic, preventive or therapeutic decisions have to be taken. Identifying sources of misreporting and correcting for bias may improve health surveys of obesity and overweight problems. Given the time required as well as the high costs of actual data collection, self-reported body weight and height remains an important screening tool for population-based estimates of obesity-related risks.

Summary Points

- The utility of self-reported data depends on the purpose for which they are used
- Despite limitations and systematic biases, self-reported anthropometry remains a useful screening tool, when epidemic or large scale population studies require prompt proxy results
- Actual measurements should be preferred instead of self-reported data, when accuracy is the prerequisite
- The accuracy of self-reported-anthropometry depends on the study population
- Adults provide better self-reported figures than children and adolescents

- Overweight and obese individuals tend to misreport their body dimensions more than normal weight subjects
- Awareness of current body size as well as frequency of body measurements provide better self-reported values
- Identifying reasons of misreporting, understanding their potential interactions and developing correction factors may improve the accuracy of self-reported anthropometrics

Chapter 10
Body Composition Analysis Using Radionuclides

Themistoklis Tzotzas, Georgios Karanikas, and Gerasimos E. Krassas

Abstract Body composition studies were first recorded around the time of the Renaissance, and advances by the mid-twentieth century facilitated growth in the study of physiology, metabolism and different diseases. They are divided into two main groups, i.e. radionuclide and non-radionuclide methods. Simple methods based on body mass index (BMI), skinfolds and circumference measurements along with bioelectrical impedance analysis (BIA) technique are useful tools in everyday clinical practice, while more sophisticated non-radionuclide methods include underwater weighing (UWW), air-displacement plethysmography (ADP) and dual energy X-ray absorptiometry (DXA). In radionuclide methods, total body water (TBW) and total body potassium (TBK) are the two main traditional methods which were considered the 'reference' standard for body fat measurement. Computed tomography (CT), magnetic resonance imaging (MRI), positron-emission tomography (PET) scan and neutron activation analysis (NAA) are new methods which provide a detailed description of different tissues. Imaging methods (CT and MRI), in particular, opened a new era in body composition research by offering the possibility of qualitative and quantitative measurements of various tissues such as bone, skeletal mass, hepatic tissue and adipose tissue. CT and MRI estimates of visceral and ectopic adipose tissue using a single slice at L4–L5 level or multiple slices are considered the reference methods for assessing regional fat distributions. PET scan using specific radiopharmaceuticals can visualize active metabolic tissues like brown adipose tissue, which is found primarily in infants and has been considered to be essentially nonexistent and of no physiological relevance in adults. Additionally, this method can follow and provide direct depot-specific measurements of substrates uptake (e.g. insulin – stimulated glucose uptake) in various tissues and organs during insulin resistant states. Therefore, functional imaging with PET scan provides a tool for a better understanding of the physiology of obesity, type 2 diabetes mellitus and related metabolic disorders.

This chapter provides an overview of the present status, mainly of radionuclide methods in everyday clinical practice for patients with obesity and related metabolic diseases, as well as in human research.

Abbreviations

ADP	Air-displacement plethysmography
AT	Adipose tissue
BAT	Brown adipose tissue
BCM	Body cell mass
BIA	Bioelectrical impedance analysis
BMI	Body mass index
C/O	Carbon/oxygen
CT	Computed tomography
CV	Coefficient of variation
DXA	Dual energy X-ray absorptiometry
F-18-FDG	Fluorine-18-fluoro-2-deoxy-D-glucose
FFM	Free-fat mass
HD	Hydrodensitometry
^{40}K	Potassium-40
MRI	Magnetic resonance imaging
MIBG	^{123}I-meta-iodo-benzyl-guanidine
MRS	Magnetic resonance spectroscopy
NAA	Neutron activation analysis
PET	Positron emission tomography
PET-CT	Positron-emission tomography and computed tomography
SAT	Subcutaneous adipose tissue
TBW	Total body water
TBK	Total body potassium
TBCa	Total body calcium
TBN	Total body nitrogen
T2DM	Type 2 diabetes mellitus
UWW	Underwater weighing
VAT	Visceral adipose tissue
WC	Waist circumference
WHR	Waist to hip ratio

10.1 Introduction

Body composition studies were first recorded around the time of the Renaissance, and advances by the mid-twentieth century facilitated growth in the study of physiology, metabolism and different diseases including obesity (Fig. 10.1). Simple and practical methods were available to early investigators, such as anthropometry techniques based on skinfold and circumference measurements. From measurements of weight and length, the BMI [weight (kg)/height (m^2)] can be calculated, which is currently the most commonly used clinical index of under- and over-nutrition, and may be used to roughly predict body composition.

The discovery and continuous development of X-ray technology gave completely new insights into the composition of the human body – information which was available exclusively to the post-mortem investigator earlier.

In the beginning, body composition methods partitioned body weight into two compartments, fat and lean body mass, now referred to as free-fat mass (FFM) and various components (Wang et al. 1999)

Fig. 10.1 In the seventieth century Paduan physician Santorio Sanctorius (1561–1636), spent many years eating, sleeping and working in a 'statical' chair connected to the arm of a calibrated scale. He paved the way for the contemporary discipline of metabolism. (Reproduced from Heymsfield (2008). With permission)

	Methods		
TBK, TBN	TBK, DXA	CT, MRI, PET scan	Skinfold, BIA

A brief overview of the most often used compartment models according to the base for the description of the body in terms of atoms, molecules, etc. and the measurement methods to determine the size of various components are indicated

CHO carbohydrates, *TBK* total body potassium, *TBN* total body nitrogen, *DXA* dual-energy-X-ray photon absorptiometry, *CT* computed tomography, *MRI* magnetic resonance imaging, *PET* scan positron emission tomography scan, *BIA* bioelectrical impedance analysis

(Table 10.1, Fig. 10.2). Among these methods whole body K counting and UWW, were considered the 'reference standards' of their era for body fat measurement (Heymsfield 2008). These methods, however, were based on assumptions such as the constancy of FFM potassium content and density

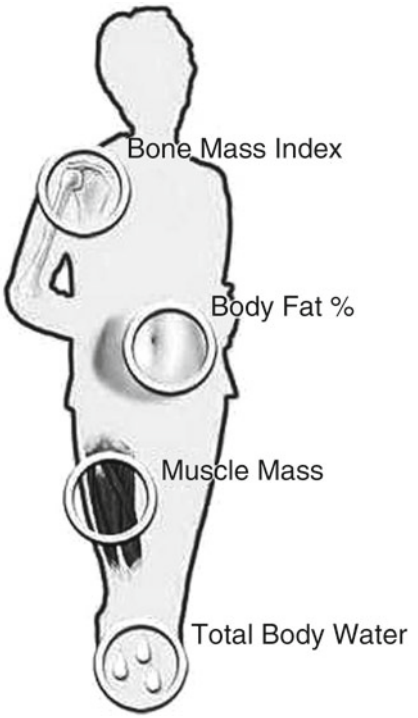

Fig. 10.2 In this cartoon the four main components of human composition are illustrated

(Heymsfield 2008). The two compartment model assumptions were recognized as of limited accuracy under certain conditions, for example, with disturbances in hydration.

A great step forward in in-vivo body composition analyses is connected to the intense development of medical imaging technology, first X-ray CT (Sjostrom et al. 1986) and later nuclear MRI (Foster et al. 1984) and magnetic resonance spectroscopy (MRS) (Boesch and Kreis 1997). This has given us a possibility of refining and detailing the various body composition models. In parallel to this intensive development of advanced analytical methods, there has been a need to develop more simple equipment such as instruments for ADP (to measure body volume as an alternative to UWW, 3D body volume scanning, BIA, as well as for stationary or portable DXA). In Table 10.2, the principal radionuclide and non-radionuclide methods are presented.

The aim of this chapter is to summarize 50 years of development in the field of body composition studies with special reference to the nucleotide methods and give the readers an understanding of the pros and cons of each measurement method.

10.2 Non-radionuclide Methods: Brief Report

(1) **Hydrodensitometry (HD) or UWW**: In this technique, body weight is determined in air and when the subject is fully submerged in the water. Body volume is calculated using Archimedes' principle and after correcting for residual lung volume, body density is obtained. The percentage of body fat can then be estimated from body density by using a number of equations, e.g. Siri' equations (Lukaski 1987). In obese subjects, deviation in FFM can occur because of changes in

2. Magnetic resonance imaging
3. Positron emission tomography scan
4. Neutron activation analysis

The most important non-radionuclides and radionuclides methods that are used in everyday clinical practice and for research purpose are indicated

hydration or proportion of bone mineral (Ellis 2000). Besides, obese people find the underwater position particularly uncomfortable.

(2) **ADP**: This recent technique uses the same principle as UWW with the difference being the subject is not immersed in water but in a closed air-filled chamber (Air – Displacement Plethysmography, BOD-POD® system) (Ellis 2000). Good correlations have been found between ADP and other methods, although some authors reported an underestimation of FFM and an overestimation of fat mass by ADP (Demerath et al. 2002; Le Carvennec et al. 2007). Although this technique is promising, it has to be tested more extensively for various populations and children.

(3) **BIA**: This technique measures the resistance or impedance, of the total body or body segments, to a small alternating current. BIA allows the determination of FFM and TBW in lean and obese subjects without significant fluid and electrolyte abnormalities, when using specific equations and established procedures (Jebb and Elia 1993). Its use has to be avoided in subjects at extreme BMI ranges (<16, >34 kg/m^2) or for those with abnormal hydration (Kyle et al. 2004).

(4) **DXA**: DXA has emerged as one of the most praised techniques for measurement of body composition. Its use is based on a three-compartment model that divides the body into body mineral, fat-free lean mass and fat tissue mass. Because these tissues have different densities and are penetrated to a different extent by the X-ray beam, DXA can derive the amounts of each tissue present (Ellis 2000). It is becoming the new 'gold standard' in body composition analysis because it provides a high degree of precision, specifically for adiposity evaluation (Mattsson and Thomas 2006). In obesity research, studies show the possibility of DXA estimating abdominal fat using a region of interest at the levels L2–L4 (Park et al. 2002). Cost and limited accessibility are some of the drawbacks of this reliable method.

(5) **Anthropometry (BMI, circumferences, skinfold thicknesses)**
BMI is primarily used to identify subjects as underweight (BMI < 18.5), within normal range (18.5 < BMI < 25), overweight (25 < BMI < 30) or obese (BMI > 30). For obesity, BMI as a predictor of body fat has a relatively large error at 4–6%, since this index does not consider situations such as edema, muscular hypertrophy etc. (Prentice and Jebb 2001).

Circumferences: They provide a good estimate of body composition in most obese populations and can be useful to quantify changes in an individual over time.

Waist Circumference (WC) provides a unique indicator of intra-abdominal body fat and is strongly associated with obesity-related metabolic risk factors. Men with WC > 102 cm and women with >88 are at increased cardiometabolic risk (Klein et al. 2007).

Waist to hip ratio (WHR) is a poor proxy of abdominal fat distribution because this marker is influenced by the size of the pelvis and soft tissues.

The measurement of **skinfold thicknesses** represents an attempt to make a direct measure of adipose tissue at particular sites (biceps, triceps, subscapular and supra-iliac) using specific calipers (Mueller and Stallones 1981). Estimation of total fat mass is then provided using previously standardized prediction equations (Durnin and Womersley 1974). Practical drawbacks of this technique include inter- and intra-observer reliability and the difficulties in accurately measuring the thicknesses in obese individuals (Jebb and Elia 1993).

(6) **Cadaver analyses**

Direct chemical analyses of the adult whole body were mainly reported in the 50s (Forbes et al. 1953) and have served on the reference base for the development of various models of body composition (Ellis 2000).

10.2.1 Key Points

Simple methods based on BMI, skinfolds and circumference measurements along with BIA technique are useful tools in everyday clinical practice to measure body composition and distribution. More accurate techniques using more sophisticated equipment are ADP and DXA.

10.3 Radionuclide Methods

10.3.1 Traditional (Old) Methods

10.3.1.1 TBW

Investigators have used the isotopes of hydrogen, deuterium and tritium, to quantify body water volumes by isotope dilution in healthy and diseased subjects. Some general assumptions of the isotope-dilution technique are that the isotope has the same distribution volume as water and non-toxic in the amounts used. Because of the ease of liquid scintillation counting, some investigators relied upon tritium dilution to measure TBW. The use of a radioactive tracer such as tritium is contraindicated in research involving children or women of child-bearing age. Increased use of deuterium occurred when newer techniques for the assay of deuterium in aqueous solution became available (gas chromatography, mass spectrometry and fixed-filter infrared absorption) (Lukaski 1987; Jebb and Elia 1993).

The procedure for using tritium or deuterium includes either the ingestion or the intravenous injection of a specified quantity of the tracer, an equilibration period and a sampling period. The calculation of TBW volume is based upon the simplified relationship: $C_1V_1=C_2V_2$, where C_1V_1 is the amount of tracer given, C_2 is final concentration of tracer in a biological fluid, and V_2 is volume of

TBW. It is important that the correction be made for urinary loss of tracer (Lukaski 1987; Jebb and Elia 1993).

The quantity of tracer given depends upon the type of tracer administered, the analytical system used and the objective of the research. In general, the smallest dose that allows good analytical precision and accuracy and is the lowest risk to the subject should be given. For healthy men and women a 10 g dose of deuterium oxide mixed with 300 ml of distilled-deionised water is used routinely (Lukaski 1987). When using gas chromatographic methods, it has to be given as an oral dose of deuterium oxide of 1 g/kg body weight. An oral dose of 2 g D_2O has been used for mass spectroscopy (Lukaski 1987). Among researchers using tritium as a tracer, a dose of 50 μCi is common (Lukaski 1987; Jebb and Elia 1993). When repeated body–water determinations are to be performed over short periods of time or in women or children, the use of deuterium as a tracer is suggested. The length of time required for tracer equilibration depends upon the characteristics of the study sample. In healthy men and women, equilibration of deuterium in saliva, plasma and urine occurs 2 h after ingestion of the tracer and remains at a constant concentration in these fluids for the next 3 h (Lukaski 1987). Although plasma or serum tracer concentrations have been used to calculate TBW, saliva concentrations may be useful in some conditions.

The use of oxygen-18 as a tracer to measure TBW was proposed because it avoids the exchange of label with non-aqueous hydrogen in the body that can overestimate body water by 1–5%. Implementation of this technique is difficult outside of a specialized research laboratory (Lukaski 1987).

Application in Obesity

This dilution technique is considered the reference for comparison with other measurements (Ellis 2000). However, while this approach works reasonably well for subjects with physiologic body composition, the error may be substantial for malnourished and obese fluid-loaded patients (Mattsson and Thomas 2006). In obese people, in particular, who present an increase in the hydratation of FFM and sometimes an edema, it is difficult to accurately estimate the true hydratation of FFM in a given circumstance. In addition, during periods of weight loss, changes in body composition may be erroneously estimated since the loss of water in association with glycogen during early weight loss, will be interpreted as a loss of 1.37 kg lean tissue for each kg of water which is lost (Jebb 1998). In a short weight loss study in obese subjects, TBW technique was found to underestimate body fat loss by 20% (Yang et al. 1977).

Other limitations of this method are high radiation exposure, the fact that the use of isotope-labelled water is time consuming and the need for multiple sampling and limited access to specialized equipment and laboratory capacity. Consequently, nuclide methods measuring TBW have essentially remained research tools (Mattsson and Thomas 2006). The precision of the method is 1–3%, the accuracy 5%, and minimum detectable change for an individual is 5% (Ellis 2000).

10.3.1.2 TBK

Potassium-40 (^{40}K) emits a characteristic gamma ray at 1.46 MeV and exists in the body at a known natural abundance (0.012%). Quantification of TBK requires specially constructed counters that consist of a large shielded room (to reduce background radiation from cosmic and terrestrial sources) containing a gamma ray detection system connected to a suitable recording device (Lukaski 1987; Jebb and Elia 1993). The detectors are of two types: large thallium-activated sodium iodide crystals, one or more of which are positioned near the subject, and large, hollow cylinders or half cylinders, the walls of which contain liquid or plastic scintillation material, into which the subject is placed as

to be completely or partially surrounded by the detector. These are referred to as 4π or 2π geometrical counters. The advantages of the crystal system are mainly very good energy resolution and low background (Lukaski 1987).

Different systems (single crystal placed adjacent to the subject or to pass over the subject, utilization 4π ^{40}K counting) were developed to measure ^{40}K and regarding which type of counting system is used, the variability of counting ^{40}K was >5% (Lukaski 1987). The most significant improvement in the whole-body-counting method is the development of techniques to provide absolute quantification of ^{40}K. A uniformly distributed cesium-137 source and a 54-detector whole-body counter are used to measure ^{40}K absolutely. By counting the gamma rays emitted from the cesium source, which is positioned briefly under the subject who is supine on a cot, attenuation factors are determined. These factors are used to correct for differences in body size and geometry and in gamma ray self-absorption for each subject. This permits accuracy and a precision of in-vivo ^{40}K counting within 3% (Lukaski 1987). Another finding that improves counting accuracy is the reduction of background bismuth-214 contamination. Radiobismuth is a decay product of atmospheric radon. Subjects should shower, wash hair, and wear clean clothing before undergoing whole-body counts (Lukaski 1987).

Application in Obesity

TBK has been used basically as a good estimate of body cell mass (BCM) – the body' metabolically active tissues – since potassium is found almost entirely (97%) within the cells (Pierson and Wang 1988). It has also been used to estimate FFM, assuming that TBK occurs at a constant concentration in the FFM. Unfortunately, the potassium content of FFM is variable and more of this element is found in muscles than in other lean tissues. Besides, it changes with age and can be distorted by diseases and use of diuretics (Jebb 1998).

The application of this method is influenced by body size and geometry. Therefore, in an obese state, there are two important limitations. The potassium concentration of lean tissue varies according to adiposity such that the concentration of potassium is lower in obese subjects than lean. Furthermore, adipose tissue (AT) exerts a shielding effect and fewer counts will be recorded in an obese subject as compared to a lean individual for a similar quantity of potassium. Appropriate correction factors must be employed to account for this attenuation (Jebb and Elia 1993).

During energy restriction and weight loss, depletion of potassium exceeds the loss of nitrogen, thus exacerbating the apparent loss of lean tissue and minimizing fat loss. This suggests that TBK method may not be the appropriate method to predict total body nitrogen in a changing nutritional state (Archibald et al. 1983).

The precision of the method is 1–3%, accuracy 5% and minimum detectable changes for an individual is 4% (Ellis 2000). This method does not expose the subject to any extra radiation and so can be repeated frequently.

10.3.2 New Methods

10.3.2.1 Imaging Methods: CT and MRI

The application of CT and MRI represents important advances in body composition analysis and its relationship with various metabolic diseases (Heymsfield 2008). These methods offer a possibility of qualitative and quantitative measurement of various tissues such as bone, skeletal mass, hepatic tissue

and AT (Mattsson and Thomas 2006). They are now considered also as the methods of choice for validation of other methods such as BIA and DXA (Mattsson and Thomas 2006; Kullberg et al. 2009).

CT

This approach relates the small differences in X-ray attenuation to differences in physical density of tissues to construct a two-dimensional image of the underlying anatomy in the scan area. The CT system consists of a collimated X-ray source and detector-rows (4–320) aligned at opposite poles of a circular gantry. Lying on a movable platform, the subject is advanced through the central aperture of the gantry. The field of vision or the designated area to be scanned, is a plane through the middle of this aperture and parallel to the gantry. As the X-ray beam is rotated around the subject, information about the intensity of the attenuated X-ray beams is recorded and stored. The scanner computer then applies complex algorithms to the stored series of profiles to reconstruct cross-sectional images (Hounsfield 1973; Lukaski 1987; Jebb and Elia 1993).

Each CT scan image or reconstruction is a matrix of pixels or picture elements, each about 1 × 1 mm, arranged in rows and columns. Because the depth of the scan or slice thickness is known, this is referred to as a voxel or volume element. For each individual volume of tissue, the CT scanner measures the X-ray attenuation within that voxel independently of the remaining tissue. The reconstructed picture represents not the image at the surface of a cut, rather an average representing the full thickness of the slice (Hounsfield 1973; Lukaski 1987; Jebb and Elia 1993).

The magnitude of the X-ray beam attenuation is reflected in the degree of pixel shading and is scaled as the CT number in Hounsfield Units. The gray scale shown on a CT scan uses the same linear attenuation coefficients used for conventional radiographic film. For example, lower densities appear black and higher densities are white, air and bone at the low and high ends of absorption, respectively. Thus, high image contrast is observed between bone, adipose, and fat-free tissues. Generally, CT scan is completed within 8–15 s. The number of slices depends upon the purpose of the CT scan (Hounsfield 1973; Lukaski 1987; Jebb and Elia 1993).

Different approaches have been used with the CT scanner to analyze body composition (Heymsfield 1985). The structure of interest can be traced directly on the viewing console with a cursor. The cross-section area of adipose, bone, muscle, or visceral organ can then be determined for each image using sophisticated software programs. Because the slice thickness is known, one can calculate the relative surface area or volume occupied by each organ or tissue in the reconstructed picture. These methods have been used to assess changes in muscle and AT in malnutrition (Heymsfield et al. 1982) and to describe cross-sectional differences in abdominal fat distribution during aging.

When no sharp boundaries between structures are apparent but the tissues differ markedly in radiographic density, the pixels in successive slices are plotted as a histogram separating the pixels into fat-free and ATs. Because the volume of each pixel is known, the volume of adipose and fat-free tissue in each slice can be determined from the number of pixels forming each slide and added for all slices performed.

Another method utilizes tissue matrices in which the individual components are smaller than one pixel. This approach has been helpful in diagnosing organ tumours, fatty liver and tissue iron content (Lukaski 1987; Jebb and Elia 1993).

Tomographic pixels derived from an area of AT represent adipocytes (triglyceride and protein matrix) and not just neutral fat. Thus, to determine fat mass one must first assume that a fixed fraction of AT is triglyceride. An alternative approach is to determine the volume of adipose by adding the appropriate number of adipose voxels and assuming a constant density for AT. Neither of these approaches has been validated against standard body composition methods.

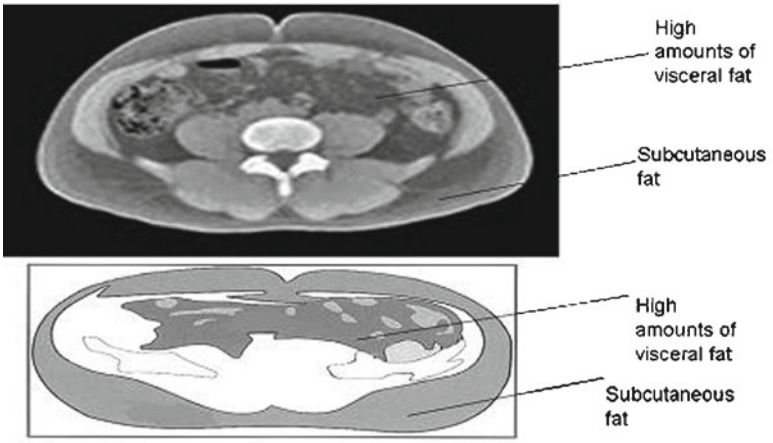

Fig. 10.3 This CT scan image shows the distribution of abdominal fat in an obese individual The visceral fat area is regarded as black colour and the subcutaneous fat area is regarded as grey colour

Application in Obesity

The value of CT scans for body composition studies was initially recognized by Borkan et al. in 1982. The authors suggested, for the first time, that a single abdominal CT scan obtained at the level of the umbilicus provides a good indication of fat content throughout the abdomen and differentiates intra-abdominal from subcutaneous fat (Borkan et al. 1982). Subsequently, a new segmentation approach for measuring regional AT volumes was developed using CT scan (Tokunaga et al. 1983). Thereafter, Sjostrom et al. (1986) compared CT with other radionuclide methods and concluded that the CT-based AT determination is the most reproducible examination available so far.

In more recent years, as more instruments became available, epidemiological studies began to appear that put the accent on adipose tissue topography and linked visceral AT (VAT) – but not subcutaneous AT (SAT) – with obesity metabolic complications and cardiovascular disease (Matsuzawa et al. 1995). In many of these studies, VAT is often reported as the area of a single slice which is usually performed at the L4–L5 level, including omental, mesenteric and retroperitoneal compartments (Fig. 10.3). However, it is important to recognize that single slice studies only provide an area of VAT (cm^2), in contrast to multiple-slice studies which report the volume of VAT (cm^3).

Thanks to recent imaging, a systemic classification of AT was possible based on topographic and metabolic characteristics (Shen et al. 2003). According to this classification, total body AT can be separated into two categories, subcutaneous and internal, the latter into discrete components, visceral and non-visceral. VAT should appropriately include two cavities: the thoracic and abdominopelvic cavity, which can be further divided into intraperitoneal and extraperitoneal region. The coefficient variations (CVs) for repeated SC and VAT measurements by CT are in the range of ~2% (Shen et al. 2003). CT images played an important role in identifying ectopic, metabolically active AT, such as intrahepatic, intramusular or pericardial AT which are associated with insulin resistance disorders and atherosclerosis, more than VAT (Lim et al. 2009; Shimabukuro 2009).

Repeated CT images were able to identify the respective changes of various AT compartments during weight loss achieved by low-calorie diet, pharmacotherapy and bariatric surgery (Chaston and Dixon 2008; Carroll et al. 2009). More importantly, new CT imaging contributed to the prediction and understanding of dysmetabolic conditions such as insulin resistance, type 2 diabetes mellitus (T2DM), nonalcoholic fatty liver disease, etc. (Bredella et al. 2009; Bray et al. 2008; Wagenknecht et al. 2009).

An obstacle to the use of CT, with multiple CT images in particular, is radiation exposure resulting in effective doses of the order of 10 mSV per investigation, precluding its use in young children and pregnant women (Heymsfield 2008). Other practical limitations of CT imaging are the high cost and limited machine availability.

MRI

The introduction of non-X-ray MRI in the 1980s was an important development in the field of body composition studies.

A method with great potential for the safe, non-invasive, direct assessment of human body composition is MRI. Unlike CT, it uses no ionizing radiation, but uses a powerful magnetic field to align the nuclear magnetization of atomic nuclei in the body. To-date routinely used scanners operate at field strengths of 1.5–3 T; however, for scientific purposes scanners with field strengths of 7 T or higher are used. In MRI, radio frequency fields are used to systematically alter the alignment of the magnetization, causing the nuclei to produce a rotating magnetic field detectable by the MR scanner. This signal can be manipulated by additional magnetic fields to build up enough information to construct an image of the body. The most frequently studied nucleus in biology is hydrogen, 1H, and in particular the hydrogen atoms of water molecules in cells and tissues. Hydrogen is the most abundant of atoms (or nuclei for MRI purposes) rather than as a percentage of body weight. The majority of these hydrogen atoms are present as part of water molecules. The hydrogen nucleus is the most amenable to MRI detection. Not only is the natural abundance of 1H high (99.98%), but the sensitivity of MRI to this nucleus, which is simply a proton, is greater than any other atomic nucleus (Lukaski 1987; Jebb and Elia 1993; Mallard 2006). Whereas conventional X-ray radiographic and CT images depend on electron density, MRI depends on the density of hydrogen nuclei and the physical state of the tissue as reflected in the magnetic relaxation times. Anatomical information has been obtained by comparing MRI images and corresponding frozen cross sections of normal animals. Tissue contrast is high between fat and muscle and can be enhanced by changing the magnetic relaxation time variable of the magnetic resonance instrument (Fig. 10.4). Application of MRI to differentiate malignant from benign processes have indicated differences in relaxation times between normal and cancerous tissues in rats and humans. Although exact interpretation of these observations is unclear, the data appear to indicate a correlation with degree of hydration of tissue (Lukaski 1987; Jebb and Elia 1993; Mallard 2006).

These findings have stimulated other investigators to estimate regional and TBW using MRI. Conventional MRI was used to quantify the water distribution of saline-filled and normal rat lungs in isolated and in situ preparations. Studies in isolated lung fragments showed an accuracy of 1%, and images of phantoms had an error of <3%.

In another study hydrogen associated with water was measured as the amplitude of the free-induction decay voltage. Body water calculated by multiplying peak amplitude by the experimentally determined constant for a water standard was similar to that determined gravimetrically in the same baboons. MRI has the capability to generate images in response to intrinsic tissue variables and represent gross chemical characteristics, such as level of hydration and fat content. In addition to hydrogen, MRI can image phosphorous and future prospects include carbon, nitrogen, sodium and chlorine.

Application in Obesity

The first study that reported MRI's ability to distinguish AT from the adjacent skeletal muscle was published in 1984 by Foster et al. In 1988, subcutaneous fat was measured for the first time by MRI

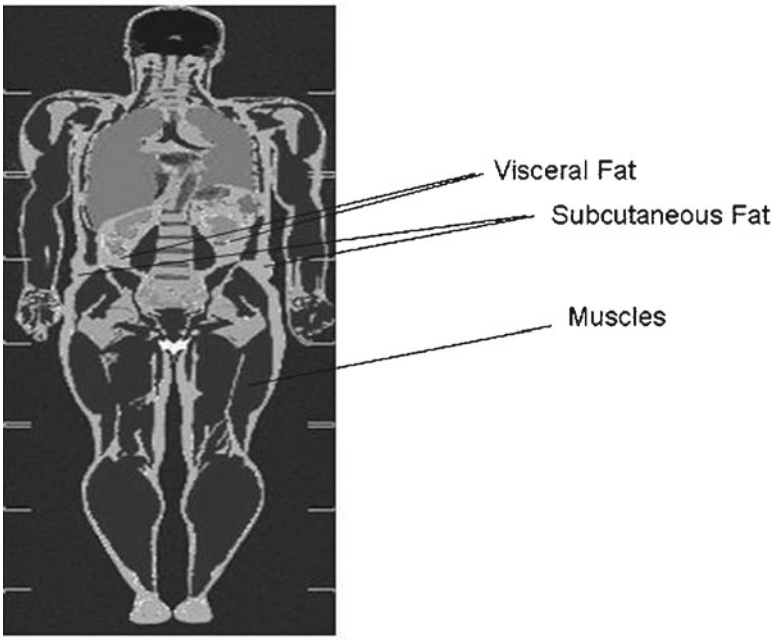

Fig. 10.4 This MRI scan image provides a detailed look at where fat is stored internally in the human body. The image is of an average-sized man who has a normal BMI of 21.7

and compared with other methods (Hayes et al. 1988) and during early 1990s accurate measurements of AT distribution were reported (Fowler et al. 1991; Ross et al. 1993). Since then, several studies have examined body fat compartments and lean tissue in various age and population groups (In utero, newborns, children, lean and obese males/females, etc.) (Ross 2003; Shen et al. 2009). As with CT, the observations in these studies are made with a single cross-sectional image. Several equations have been developed for the calculation of VAT and SAT area based on anthropometric measurements such as WC or skinfolds thickness. Additionally MRI, like CT, can identify and describe young and adult subjects at risk for cardiometabolic disorders such as metabolic syndrome and T2DM (Demerath et al. 2008; Cali and Caprio 2009; Gallagher et al. 2009). A significant advantage of MRI for body composition studies is its potential for providing multiple images without any recognized health risk for the subjects.

During the last two decades important advances have been made with MRI technology, from which research in the obesity field took much profit. These advances include the following: Functional MRI for evaluating the metabolic activity of organ and tissues (Holsen et al. 2006; Farooqi et al. 2007); Proton and phosphorous spectroscopy for quantification of lipid deposition (Johansson et al. 2008); Water-fat imaging for discerning tissue lipid and water content (Kim et al. 2008); Whole-body nuclear MR systems for quantifying total body lipid and water (Napolitano et al. 2008). As with CT, MRI helped in identifying and classifying subcutaneous fat and ectopic fat deposition other than VAT (Shen et al. 2003). The CV for measuring subcutaneous fat is similar in MRI and CT at about 2%, however, CV for VAT measurements is higher in MRI (between 9% and 18%) than CT (~2%) (van der Koory and Seidell 1993). The explanation for this discrepancy is that scan times for CT are shorter than for MRI and CT is thus less vulnerable to image artifacts. However, the one major disadvantage in CT is the radiation dose required per slice for imaging.

PET Scan

PET images biological processes in-vivo three-dimensionally. A specific radiopharmaceutical, labelled with a radioactive isotope is injected (Phelps 2000). PET has a broad scope and is very chameleonic and sensitive. Those facts make it one of the most powerful molecular imaging techniques currently available for clinical use. PET can image key biomedical functions in vivo. It can show them up under basal conditions and also during diverse pharmacological or physiological interventions.

The successful utilisation of PET in clinical use is based on up-regulation of key-enzymes and other proteins which regulate the intermediary cellular metabolism in malignant/inflamed transformed cells. The up-regulation of proteins and enzymes for glucose metabolism, such as glucose transporters and hexokinase is vitally important. These mechanisms are early events during the malignant/inflamed transformation, which proceed to morphological demonstrable changes on cellular or tissue level. This is the reason why PET, using fluorine-18-fluoro-2-deoxy-D-glucose (F-18-FDG) as a marker for glucose metabolism, is of potential value for the early diagnosis of several diseases. Further pros are that the whole body can be conveniently imaged with PET within an acceptable time at low radiation exposure (7–10 mSv whereas a contrast-enhanced CT produces 20–40 mSv) and that there are no pharmacodynamical side-effects (Phelps 2000; Rohren et al. 2004).

The PET scanner does not detect positrons directly, but the mechanism of positron annihilation which is important for the determination of their spatial location. The isotope is transformed by a process called beta decay: a proton turns into a neutron and a positron which is emitted and migrates through the tissue for a few millimetres. In the meanwhile, it loses its kinetic energy and forms a positronium (a positively charged electron). This positronium fuses with an electron in its vicinity. As a result, energy is transmitted and emitted as two gamma photons with 511 keV each (annihilation). This process can be localized and translated into images with photon detectors and photomultiplier tubes. The base of the detection and localization is the fact that the annihilation photons are emitted simultaneously and in opposite directions (Phelps 2000; Rohren et al. 2004).

Application in Obesity and Other Metabolic Diseases

Recently PET scan has been widely used in oncology to localize tumours and metastasis. It was, serendipitously, as a consequence of this use that PET-scan visualized increased tracer uptake in the upper parts of the body; it was then proved that these areas correspond to brown AT (BAT) (Nedergaard et al. 2007) (Fig. 10.5). BAT is known to be a very active tissue metabolically and studies in experimental animals proved its role in increasing energy expenditure in the form of thermogenesis mediated by the expression of the tissue-specific uncoupling protein-1 (UCP_1) (Basu 2008).

BAT has been considered of critical importance in neonates, small animals in cold environments and animals that hibernate, because of its role in cold-induced adaptive thermogenesis. In humans, it was generally believed that this tissue diminishes with age and disappears completely by adulthood (Cannon and Nedergaard 2004). The recent observation from F-18-FDG-PET imaging demonstrated that active BAT is still substantially present in adults – in the range of 10% – and is primarily located in the supraclavicular and neck regions (Nedergaard et al. 2007). The most common location for BAT that was detectable in adults by Positron-emission tomography and computed tomography (PET-CT) was the cervical-supraclavicular depot, in a distinct facial plane in the ventral neck, superficial and lateral to the sternocleidomastoid muscles. In patients with high F-18-FDG-avid fat extended inferiorly between the subscapularis and pectoralis muscles, posterior to the brachial plexus and proceeding through thoracic and abdominal paraspinal sites, with little perinephric activity (Cypess et al. 2009). Animal studies have previously shown that BAT is implicated in the development of obesity (Lowell et al. 1993). Accordingly, recent studies in humans using F-18-FDG-PET scan

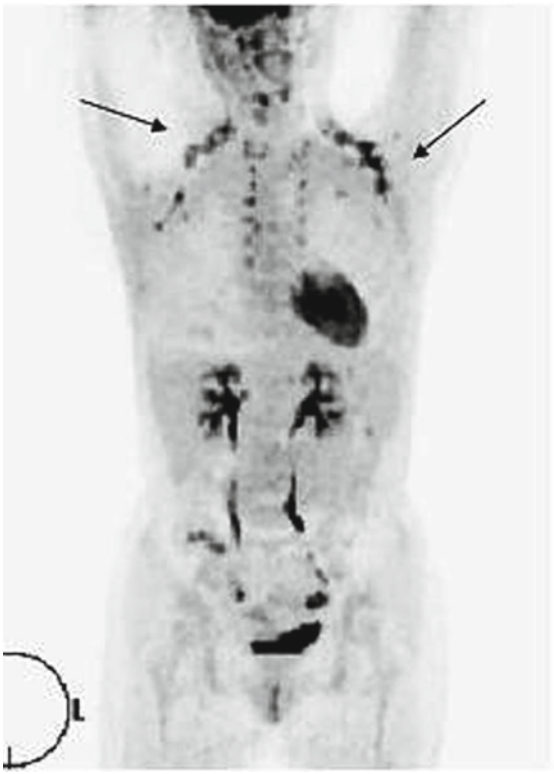

Fig. 10.5 Amount and activity of brown adipose tissue in a 22-year female. As depicted, brown adipose tissue is mainly located in cervical and periclavicular region

combined with CT showed an inverse association between the prevalence of BAT and BMI (Cypess et al. 2009; Saito et al. 2009).

Besides, in an elegant experiment using PET scan, Kajimura et al. (2009) were able to convert both mouse and human skin cells (myoblasts) into brown fat. This synthetic brown fat tissue was found to present the same biochemical characteristics as the endogenous one, and, according to the authors, could provide opportunities for the development of new therapies for obesity and T2DM.

F-18-FDG-PET scan was also used in studies in obese patients with insulin resistance and T2DM and contributed substantially to the understanding of mechanism of insulin resistance in AT and skeletal muscles in these patients (Virtanen et al. 2002, 2005). In abdominal obesity, insulin-stimulated glucose uptake rate is markedly reduced in skeletal muscle and in all fat depots, in target tissues and this reduction is reciprocally (and nonlinearly) related to the amount of intra-abdominal fat; mild, recent diabetes adds little insulin resistance to that caused by abdominal obesity; and despite fat insulin resistance, an expanded fat mass (especially subcutaneous) provides a sink for glucose, resulting in a compensatory attenuation of insulin resistance at the whole-body level in men (Virtanen et al. 2005).

In the future, the increased ability to quantify BAT with PET imaging with F-18-FDG or other radiopharmaceuticals will help to better understand its role in physiology and its potential as a therapeutic target in the treatment of obesity and other metabolic disorders.

NAA

The development of in vivo total-body NNA has proved the only technique currently available for the measurement of the multielementar composition of the human body. Absolute content of calcium, sodium, chloride, phosphorus and nitrogen can be determined safely.

Total-body neutron-activation systems designed for in vivo studies deliver a moderated beam of fast neutrons to the subject. Capture of these neutrons by atoms of the target elements in the body creates unstable isotopes such as calcium-49 and nitrogen-15. The isotopes revert to a stable condition by the emission of one or more gamma rays of characteristic energy. Radiation from the subject is determined using a recording of the radiospectrum of the emissions. The data are obtained from a subject positioned carefully with respect to a detector array in a highly shielded facility. Standard gamma spectrographic analysis is applied. The energy level identifies the element and the level of activity indicates its abundance (Lukaski 1987).

Neutron activation is an analytical technique based on nuclear reactions rather than chemical reactions. The essential variables include neutron flux density, isotopic abundance, cross-section of the target element, half-lives of the product isotopes, and emission energy of the induced activity (Lukaski 1987).

The first application of NNA to the assessment of human body composition was the determination of total body calcium (TBCa). The availability of neutron activation facilities to measure human TBCa is limited to some research centres (cyclotrons to produce neutrons of 3.5 and 8 MeV energy levels). The accuracy and precision of the activation procedure in an anthropometric phantom is 1%. In healthy adults measured over four to 5-year period, the precision of the repeated TBCa determination was 2.5%, which is suitable for studies of longitudinal changes. To quantify clinically meaningful differences in TBCa with aging or metabolic bone disease, specific procedures have been developed to normalize body calcium levels. Most importantly, normalization for anthropometric variables, such as age, gender, height and lean body mass, is necessary to reduce variability in heterogeneous samples. The ability of TBCa to discriminate abnormality may be due to this normalization procedure. The first nuclear methods for direct determination of total body nitrogen (TBN) in humans used the $^{14}N(n, 2n)^{13}N$ reaction and suffered from a lack of specificity because of interference from positron emitters from other body elements. The development of the prompt-gamma technique using the reaction $^{14}N(n, \gamma)^{15}N$, has led to the recognition of the clinical usefulness of body nitrogen measures in body-composition assessment (Vartsky et al. 1979).

Application in Obesity

NAA provides compositional information similar to that of cadaver analyses and, therefore, has become the reference norm most often preferred for evaluation or calibration of the alternate techniques such as CT, MRI, DXA and BIA (Knight et al. 1986; Mattsson and Thomas 2006).

The accuracy of the method is around 5% and values of CV are 4% for carbon as a measure for fat (Jebb and Elia 1993). Newer techniques of NAA (inelastic neutron scattering activation) measuring the carbon/oxygen (C/O) ratio can measure the axial distribution of fat because of the dramatic difference in C/O ration between fat and FFM (Kehayias et al. 1991; Kehayias and Zhuang 1993). The recent development of DXA, CT and MRI methods for determination of body fat distribution has, however, reduced the interest for NAA.

One major concern restraining a more general use of NAA is that of the associated radiation exposure. The doses for each of the in vivo NAA measurements of body carbon, nitrogen and the calcium are ~0.1, 0.3 and 3 mSV, respectively (Ellis 2000). Obviously NAA should be avoided for children and pregnant women. Besides, the equipment is large, uninviting and available in only a few centres worldwide.

A brief evaluation of principal radionuclide methods for body composition analysis in obesity is presented in Tables 10.3 and 10.4.

In conclusion, from the non-radionuclide methods, anthropometric measurements are the most popular in the clinical practice, while DXA is the most widely applicable technique. From the radionuclide methods, CT and MRI represent important advances in body composition analysis and its relationship

Table 10.3 Evaluation of radionuclide methods for body composition analysis in obesity

Method	Principals of method	Advantages	Disadvantages
Total body water	Quantification of body water volumes by isotope dilution	– Estimation of body fluids – Variety of tracers available – Reference method	– Radiation exposure – Blood samples (some methods) – Time consuming – Errors in obese fluid-loaded patients
Total body potassium	Estimation of total body potassium content	– Ideal for estimation of body cell mass – Non-hazardous – Can be repeated frequently (no radiation)	– Influence by body size and geometry – Variation of potassium in tissues – Instrument expensive – Long measurement time
Computed tomography	Attenuation of X-rays when passive through tissues	– High resolution images of various organs – Delineation of adipose tissue topography – New generation CTs; for understanding of dysmetabolic disorders	– Radiation exposure (– Excludes children, pregnant women) – Relative high cost – Limited availability for body composition measurements
MRI	A powerful magnetic field aligns the nuclear magnetization of atomic nuclei in the body	– Direct measure of organs – Assessment of fat distribution and ectopic fat – New generation MRIs for tracking the metabolic activity of tissues – No radiation	– Expensive instruments – Limited availability – Long scan times required – Less accurate for visceral fat than CT
PET scan	It images biological process in vivo three-dimensionally using specific radiopharmaceuticals labelled with a radioactive isotope	– Visualises small but active metabolic tissues (e.g. brown adipose tissue) – Follows substrates uptake in various tissues and helps understanding metabolic disorders	– Instrument very expensive – Limited availability worldwide
Neutron activation analysis	Irradiation of the body with neutrons and measurement of type and intensity of radiation	– In vivo measurement of the multielementar composition of the human body (Ca, Na, Cl, P, N) – Compositional information similar to cadaver analysis – Reference method	– High radiation exposure – Limited availability worldwide – High cost

Principals, advantages and disadvantages of most important radionuclides methods are briefly summarized

Table 10.4 Practical methods and techniques

Method	Patient information/ preparation	Examinations protocol	Results interpretation
Computed tomography	No pregnancy	Scan time: 1 min	Time of scan interpretation: 20 min
MRI	No magnetic material	Scan time: 30 min	Time of scan interpretation: 20 min
PET-scintigraphy	No pregnancy, no breast feeding, fasting condition, glucose levels <135 mg/dl	i.v. administration of PET-tracer, time of distribution: 45 min, scan time: 45 min	Physiological biodistribution: Brain, heart, renal elimination of the tracer time of scan interpretation: 20 min

Patients' precautions, duration of examination and time for results interpretation in the principal imaging techniques are briefly shown

with various metabolic diseases. These methods offer the possibility of qualitative and quantitative measurement of various tissues such as bone, AT, skeletal mass and others. They are now considered as the methods of choice for validation of other methods such as BIA and DXA.

Summary Points

- A number of body components can be quantified using a wide range body compositions methods and models. Mass, volume and distribution of various components (fat and fat-free mass, protein, water and minerals) are the primary measures in the field.
- In obesity, the early and simple methods based on height, body weight, skinfolds and circumference measurements are still in use to predict body composition and distribution. More accurate techniques using simple equipments are BIA, ADP and DXA. They tend to replace older heavy techniques such as body K counting and UWW, which they were considered the 'reference' standard for body fat measurements.
- The introduction and evolution of imaging methods (CT and MRI) opened a new era into the body composition research. These methods offer the possibility of qualitative and quantitative measurements of various tissues such as bone, skeletal mass, hepatic tissue and AT. Thanks to recent imaging, a systemic classification of AT is now possible based on topographic and metabolic characteristics. Besides, these techniques provide a detailed description of tissues changes during weight loss by different diets, pharmacotherapy or bariatric surgery.
- Nuclide imaging by PET scan has recently been widely used to localize tumors in oncology; additionally, using specific radiopharmaceuticals it can visualize active metabolic tissues, (e.g. BAT) and follow substrates uptake (e.g. insulin – stimulated glucose uptake) in various organs, therefore, providing a tool for better understanding the physiology of obesity and related metabolic disorders.
- The ongoing development of new technology such as functional MRI and MRS, together with PET scan will enable studies of the condition of tissues and organs, their composition, nutrient utilization, blood flow and other properties in the field of obesity. However, we should keep in mind that the simple, reliable and cheap methods like anthropometric measures and BIA have to be preferred for obesity and weight loss evaluation in everyday clinical practice.

Key Features of Radionuclides

1. A radionuclide (or radiosotope) is an isotope of artificial or natural origin, which has an unstable nucleus and emits radiation.
2. As radionuclide gathers in an organ or tissue, radioactive signals may be measurable by a detector which is called gamma camera.
3. Radionuclides of familiar elements such as carbon can serve as tracers because they are similar to the non-radioactive nuclides.
4. Radionuclides can be used in two major ways: first for their chemical properties and second as sources of radiation in nuclear medicine.
5. Using their chemical properties, radioactive isotopes are useful for labelling compounds that subsequently are used to investigate various aspects of metabolism of protein, carbohydrates and lipids.
6. In nuclear medicine, radioisotopes are used for diagnosis and treatment. Radioactive tracers emitting gamma rays or positrons can give diagnostic information on an individual's internal anatomy and organs functioning.
7. This principle is used in imaging techniques such as tomography, single photon emission, CT and position emission tomography scanning.

Chapter 11
Three-Dimensional (3-D) Photonic Scanning: A New Approach to Anthropometry

Jonathan C.K. Wells

Abstract Anthropometric measurements, such as body mass index (BMI) and body girths have long been used to assess nutritional status in all age groups. Although most such measurements are merely one-dimensional (1-D), they are often used to index body shape. Examples include BMI, waist–hip ratio or waist–height ratio, each of which acts as a proxy for whole-body or regional-body shape. Recently, whole-body photonic scanners developed by the clothing industry have appeared, and offer a new approach to body shape assessment. Although a variety of technologies have been developed, all photonic scanners project light onto the surface of the body, and record the surface topography. Initial data capture provides a 'point-cloud', which is then processed using computer algorithms to extract the skin surface topography. Automatic landmark identification then allows an 'e-tape measure' to be applied, extracting multiple girths, distances, diameters and two-dimensional (2-D) cross-sectional areas. Current software allows around 200 such measurements to be extracted, making the technique ideal for large anthropometric surveys. However, the major potential of the technique lies in its ability to go beyond 1-D measurements and extract more complex topographical and shape outcomes. The technology offers numerous benefits over traditional approaches, with the digital data facilitating rapid processing and archiving, the application of diverse analytical software programmes, and repeat scans allowing change in shape to be quantified. 3-D scanning has recently been applied in several large National Sizing Surveys, allowing exploration of the associations of age, gender and nutritional status with body dimensions. Validation studies against manual measurements indicate high consistency in ranking individuals compared with manual measurements, but systematic differences in average values, due to differences in the way that the data is obtained. 3-D photonic scanning is easy, quick and cheap to apply, as well as being non-invasive and well-accepted by the majority of adults. The technology offers a novel approach to anthropometry and is likely to be adopted increasingly in large surveys of size, growth, nutritional status and health.

11.1 Introduction

Anthropometry has been used for centuries to assess growth and nutritional status. Although not often considered from such a perspective, measurements of body shape have arguably been used in this context for over a century. Given the high correlation between body weight and body volume,

Quetelet's index (now known as body mass index (BMI), and calculated as weight divided by height squared) can be considered a crude index of relative volume. The higher the BMI value, the larger the shape and weight of the individual. In the 1980s, overweight and obesity were defined as BMI >25 and >30 kg/m^2, respectively (Garrow and Webster 1985), and chronic energy deficiency as BMI <18.5 kg/m^2 (James et al. 1988). BMI has been associated with health outcomes in numerous subsequent studies, with both low and high BMI values linked with poorer health. The main limitation of BMI is that it gives no indication of the composition or regional distribution of weight; hence there has been growing interest in more specific shape indices capable of discerning health and disease risk with greater accuracy.

Throughout the twentieth century, body shape has been assessed by a limited number of anthropometric measurements, most commonly girths of the torso and limbs. Again, these have been used to categorise both under-nutrition and over-nutrition. Mid upper arm circumference is widely used to assess nutritional status in developing countries, with cut-off values of 23 and 22 cm defining adult under-nutrition in males and females, respectively, and lower values defining acute malnutrition (Ferro-Luzzi and James 1996). A similar approach is also used in children. Waist girth, or waist–hip ratio, is widely used to assess central adiposity or truncal obesity. The waist–height ratio, like BMI, gives an indication of relative volume, but with greater capacity to index relative abdominal volume. Waist girths of 100 and 95 cm in adult males and females, respectively have been proposed to define truncal obesity (Zhu et al. 2005), although lower values have been proposed for Asians due to their higher visceral fat content for a given BMI value (Misra et al. 2006). Public health messages have emerged from this work: for example, the recommendation to 'keep your waist to half your height'. In children, ethnic-specific waist girth *z*-scores have likewise been published (Fernandez et al. 2004).

These anthropometric measurements are widely used to assess nutritional status alongside others, such as weight, height and skinfold thicknesses, and have collectively provided the 'backbone' of nutritional status assessment for many decades. Anthropometric measurements are generally simple, cheap, quick, non-invasive and applicable in each of clinical practice, clinical research and large-scale epidemiological studies. These numerous benefits are likely to account for the persistence of their use even though many other outcomes are now measured with substantially greater technological sophistication. Only at the end of the twentieth century did anthropometry begin to benefit from technological advances that would bring it into the new digital age.

For internal body composition characteristics, MRI and CT scanning now provide unprecedented detail on the distribution of adipose tissue and diverse components of lean tissue. The main limitation of these technologies is their high expense and restricted access, such that they can only realistically be applied in small-scale research studies. However, as reviewed previously (Wells et al. 2008a), external measurements of body shape are highly predictive of health and disease, and already play a major role in clinical monitoring and in epidemiological investigations of disease risk. What new photonic technology can now introduce into this arena is the capacity to accumulate a much greater range of anthropometric indices, at a much faster rate of data collection, and with even less physical perturbation of the subject.

These advances have been made possible by the development of three-dimensional (3-D) whole body photonic scanners, a technology originally developed for the clothing industry, but now increasingly explored in biomedical applications. 3-D photonic scanners have been used by the retail industry to improve the fit of garments, both by providing up-to-date information on the range of shape in modern populations, and also by converting 1-D or 2-D measurements into genuine 3-D measurements of shape (Treleaven and Wells 2007). A typical body girth, such as that of the waist, is a 1-D measurement, namely the distance around the torso, and the same distance could, in fact,

derive from numerous different shapes. Thus 2-D measurements can dramatically increase the amount of information available, and given these benefits, it is clear that 3-D measurements offer a further potential improvement.

3-D photonic scanners are now set to transform the measurement of anthropometry and body shape in human epidemiology, clinical research and clinical practice. There is the potential to explore a wide range of novel outcomes, and to test their associations with indices of health and disease. Initial work has been extremely promising, and is uncovering new areas for application. This chapter describes progress to date and indicates future directions.

11.2 3-D Photonic Scanners

Three-dimensional modelling of body shape and tomography emerged independently in a number of branches of medical research. Early work comprised stereo-photogrammetric technology, whereby at least two overlapping photographs of the body are obtained in order to develop contour lines of the body surface (Pierson 1963). Whilst the information was considered valuable, the process was costly due to the mathematical processing, photography and technology required. Subsequent work involved the projection of strips of light onto the body, allowing contour maps of the front and the back of the body to be obtained (Pierson 1963). This approach has subsequently evolved into a rapid-operation and convenient system, by surrounding the body with a number of different cameras.

Over the last 2 decades, whole body photonic scanners, based on either photogrammetric or laser technology, have been developed for clothing industry requirements. Rapid advances in photonic technology, accompanied by similar progress in computerised modelling, have greatly improved the reconstruction of human body surface topography. All photonic techniques involve the projection of light onto the body surface, followed by the use of mathematical algorithms to reconstruct surface topography. Technological approaches can be divided broadly into three categories. First, photogrammetric (light stripe) approaches involve the projection of visible light onto the body, and the use of cameras or a video projector to record the resulting distorted patterns. An example of such instrumentation is the $[TC]^2$ scanner, recently utilised in a number of national sizing surveys (Wells et al. 2007). Second, laser techniques use harmless invisible lasers to project points or lines onto the body, while further cameras offset from the laser source capture this data and use triangulation methods to calculate the location of the points or lines. An example of this instrumentation is the Hamamatsu bodyline scanner, recently used in research on obesity (Wang et al. 2007). Finally, radio wave technologies use linear array radio waves to scan the body through clothing. Although such instrumentation has been developed, such as that produced by Intellifit, it is not yet commercially available and may present ethical issues concerning personal privacy. Nevertheless, several different hardware options are currently available, although some are less suitable for routine use, and further developments are ongoing. Of particular note, whole-body scanners are likely to diverge into two groups: increasingly accurate instrumentation for high-quality clinical data; and increasingly cheap instrumentation for basic widespread epidemiological application.

In practice, currently available scanners tend to take the form of a large photo booth, comprising an array of cameras or light sensors surrounding a central space where the subject stands for a period of a few seconds holding a standardised pose. The subject is requested to wear close-fitting underwear, to ensure that clothing does not obscure the details of the body surface topography. In addition to the scanner itself, a screened area where the subject can dress and undress must be made

available, along with a computer area for operating the technology. Such scanners can be installed without difficulty in clinics and other health-care locations, but are not readily portable due to the need to maintain alignment of the cameras. Mobile scanning units are currently under development, which can potentially be taken to clinics, schools, shopping centres and rural locations, thus greatly improving access to this modern technology.

Over the last decade, large national sizing surveys have been conducted in the UK (Wells et al. 2007), France, United States (Wells et al. 2008a), Mexico, Australia and Thailand, while others continue. These surveys have provided abundant evidence that the vast majority of those aged 16 years or older are willing to undergo a whole body scan, and have no undue concerns about the invasiveness of the process, or data security. Pilot studies on younger age group suggest that general acceptance is again high, although younger children may have difficulties standing still for the required scanning periods, and overweight teenagers may be reluctant to undergo the process due to their heightened sensitivity in relation to their body shape. However, some groups may have concerns about acceptability of the process given that it captures information about body shape, and further work is required to see how this situation can be addressed. Contrary to most participants' assumptions, there is no need for a full-body image to be constructed and visualised during the analysis process, instead anthropometric measurements can be extracted and used in purely digital format.

11.3 Digital Anthropometric Data

One of the key strengths of 3-D photonic technology is its provision of digital information. Such information is readily stored, processed and retrieved, facilitating longitudinal assessments of individuals. Measurements can be exchanged rapidly between locations, allowing data collected in a mobile unit, for example, to be downloaded in the clinic or by a research partner.

Raw scans can be processed with a variety of software, offering the potential to re-analyse existing scans with newly developed algorithms quantifying novel shape outcomes. Each scan also provides a wide range of information, including distances, diameters, girths, surface area, surface topography, and regional and total volumes. New software now allows the change in the shape of an individual to be assessed, by overlaying sequential scans in order to identify body regions that have expanded or contracted. The digital nature of the data also facilitates its integration with other such outputs, potentially including internal MRI data on anatomical tissue distribution, or DXA data on bone characteristics. The possibility of converting simple distances or girths into more sophisticated 2-D or 3-D indices of shape could transform the way in which physical measurements of the body could be used to index health and disease.

Efficient use of this enormous amount of information will require a new generation of software, capable of extracting both detailed information and broader assessments of change over time. The digital nature of photonic data is capable of transforming the use of anthropometry in clinical practice. Inter-observer error has long been one of the limitations of such data, with individuals varying in where measurements are taken, and in what style. 3-D technology can potentially overcome such inter-observer error, by using automatic landmark identification software. Alternatively, the cursor may be moved manually over the scan to extract a particular digital measurement. This manual extraction approach would allow multiple observers to train on a single scan, or the average of two different observers' measurements to be used for each scan, thus improving precision.

Because anthropometric data are a key means of monitoring risk of the metabolic syndrome and of response to treatment, data may be collected at multiple sites using a common photonic approach

and integrated within a database held at the patients' GP practice. With photonic technology set to play an increased role in the clothing industry, in fitness centres and in other areas of retail, there is the potential for body shape data to be collated across different dimensions of an individual's lifestyle, thereby clarifying actual shape changes and linking these with health outcomes. Shape appeals to individuals at many levels (body aesthetics, fashion, fitness), and integrating health issues within this broader niche is likely to prove beneficial to both the individual and the clinician. Such progress will take time, but is clearly possible given the nature of the technology. The software and infrastructure requirements of such an approach are similar to those of other areas recently revolutionised by digital technology, such as online banking.

11.4 Computer Modelling of Body Dimensions

In raw format, photonic technology provides body surface shape data as a point cloud, a series of unconnected data points distributed in 3-D space. In order to convert such information into measurements and dimensions, computer algorithms must be applied. These reconnect the points and reconstruct surface topography. A variety of different mathematical approaches have been used for this purpose, including triangulation methods, spline curve fitting and canonical representation models. Further advances in this area are expected, increasing the sophistication of shape outcomes that can be generated.

Initially, the data are cleaned through the rejection of inconsistent data points that arise from random reflections in the scanning booth. Some software systems incorporate automatic landmark identification, whereby the algorithms automatically extract key anatomical locations. For example, the girth of the waist may be located by first identifying the small of the back, and then calculating the smallest circumference within a certain number of centimetres above or below this point. These automatic landmarks are then used to guide an 'e-tape measure' across the body surface, providing a large number of girths, depths and diametres, as well as the height above the ground at which each measurement was taken. Figure 11.1 illustrates the stages from raw cloud point data to 'e-tape' measure output.

To date, validation studies have shown fair to high accuracy, depending on the scanner model and outcomes assessed. Wang et al. (2006) showed good accuracy for regional volumes and girths measured using a Hamamatsu scanner. Manual and 3-D measurements showed significantly different average values for the TC^2 model, which could be attributed both to differences in the measurement procedure and in the location measured; however, both techniques ranked individuals similarly (Wells et al. 2007). Further work must be directed to validation, but the key strength of 3-D photonic scanning lies in its ability to measure 2-D and 3-D outcomes, and other 3-D techniques, such as MRI and CT, rather than manual girth measurements, will be required to assess accuracy. Precision is a separate issue also meriting attention. Imprecision derives in part from computer algorithms, but also in part from inconsistency in the posture adopted by the subject.

Because the technology was developed by the clothing industry, the initial outcomes were targeted at their needs, and a range of 1-D measurements were provided across the entire body surface to improve clothing fit. New medical software is now being developed to index novel shape parameters likely to be more strongly predictive of health and disease risk. For example, along with extraction of girths at the abdomen, waist and thigh, calculation of the lateral and dorsal diametres and the cross-sectional surface areas is now possible (Wells et al. 2010).

In addition to these novel shape outcomes, a further important component of the technology comprises its capacity to visualise features of the body. Although the technology does not produce

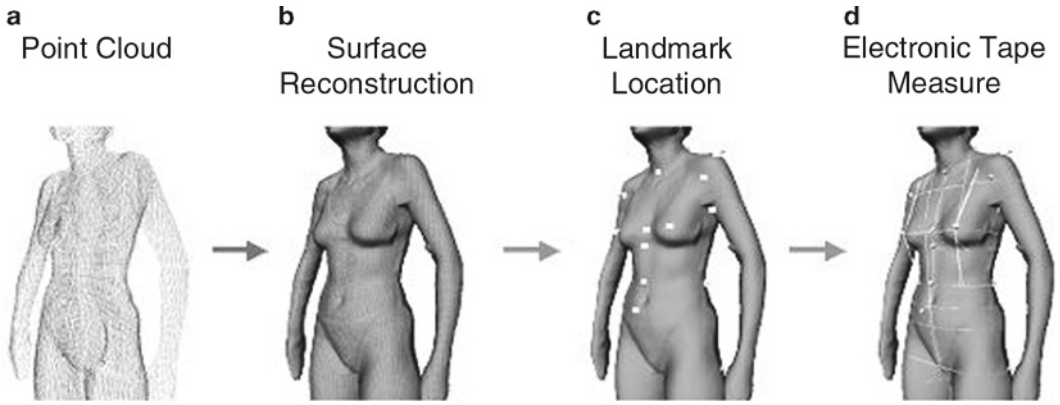

Fig. 11.1 Stages of data processing from capturing raw photonic data to generating final shape output. (**a**) The initial point cloud; (**b**) the application of a smoothed skin surface; (**c**) the automatic location of landmarks and (**d**) the application of a digital 'e-tape' measure. Reproduced with permission (Wells et al. 2007)

outputs of the same image density as conventional photography, the 3-D nature of the images offers novel information. Using 3-D photonic imaging, surfaced topography is explicitly captured rather than inferred, and can then be expressed in diverse formats. Examples include a 2-D silhouette, smoothed or mesh 3-D surfaces, or transverse sections through the body at any height (Wells et al. 2008a). The body topography may be viewed from any plane or angle, allowing a vast number of shape properties and dimensions to be evaluated. Of particular potential value is the capacity of photonic scanning to display within-person change over time. To achieve this, images are superimposed, and colouration used to discern those areas that have undergone change.

Whilst the outcomes described above refer to the anthropometry of the individual, large data sets also enable population-based outcomes to be developed, using more complex statistical approaches. Each individual's reconstructed surface topography can be converted to a common format, using processes such as canonical sampling, template optimisation or voxel representation. They can then be aligned using a generalised procrustes alignment procedure to reduce any orientation error, and hence ensure that only variation in 3-D shapes is captured in subsequent modelling processes. Independent component analysis has been applied to data from the UK sizing survey, in order to identify distinct and independent notes of variation in body shape. Figure 11.2 illustrates four dimensions of variability in female shape, with each image superimposing, for front and side views, the variation in shape of individuals at ±2 SD of the population range for each dimension. Here, the first dimension reflects differences in overall size, the second reflects differences specifically in height and girth of the entire chest and abdomen, the third reflects differences in upper torso posture, and the fourth differences in lower torso posture. This statistical approach is likely to play a key role in enabling access to novel shape outcomes, first by identifying the different independent modes of shape variability, and second by allowing all individuals to be ranked in terms of the population distribution.

11.5 National Sizing Surveys: Main Findings

Initial analysis of sizing survey data was restricted to conventional anthropometric indices, such as a range of body girths. The main findings published to date, therefore, reflect the availability of shape data in large multi-ethnic national samples. Ongoing work is applying novel shape software to these

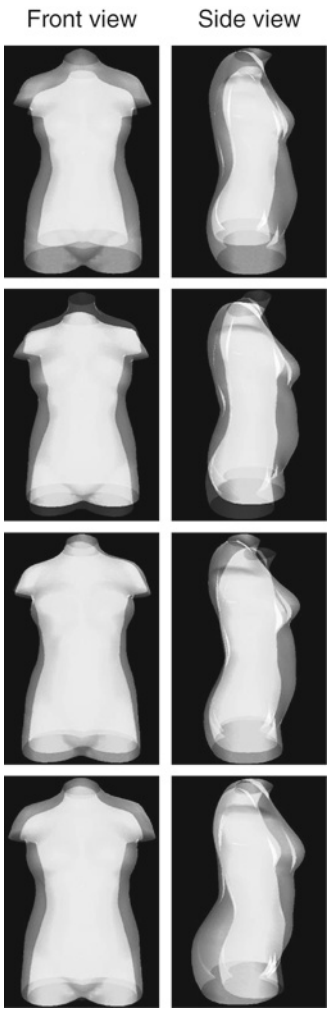

Fig. 11.2 Four dimensions of variability in female shape generated using independent component analysis of data from Size UK. Each image superimposes, for front and side views, the variation in shape of individuals at ±2 SD of the population range for each dimension. Reproduced with permission (Wells et al. 2008a, copyright Tony Ruto)

samples, and is elucidating further information about body shape. Nevertheless, analyses of size UK and size USA have already revealed important biomedical findings.

Analysis of the size UK demonstrated that greater height was positively associated with all body girths except waist girth in males, and thigh, arm and waist girths in females (Wells et al. 2007). This analysis indicates that, whether for physiological or allometric reasons, shape is not constant across the range of height, but rather alters with taller individuals having relatively lower waist girth. Possible explanations include genetic factors affecting both growth and body composition, or a possible link between stunting in early life and subsequent fat distribution. Further analysis demonstrated both significant sex-differences in shape, and varying effects of age on those sex differences (Wells et al. 2007, 2008c). Whereas waist–chest and waist–hip ratios are relatively constant with age in males, they are initially lower in females, but by old-age have converged on the male values. Female body shape also demonstrates a significant redistribution of body weight, presumably fat, between the lower and upper body with age. More detailed analyses indicate that this redistribution occurs independently of any age-changes in BMI.

Analysis of Size USA focused on inter-population and inter-ethnic differences. These analyses demonstrated significant ethnic variability in shape, with Hispanic Americans tending to have relatively greater central adiposity, but African Americans relatively less central adiposity, compared

to white European Americans (Wells et al. 2008b). Although no data on health profile was available in either of these sizing surveys, such ethnic differences in shape are highly consistent with ethnic variability in the metabolic syndrome reported in other studies (Park et al. 2003), although it should be noted that the metabolic syndrome has inconsistent associations with cardiovascular risk across ethnic groups (Mensah et al. 2005).

11.6 Body Shape and Health

3-D photonic scanning is still a relatively new technology, but there is already a substantial and strengthening evidence base linking body shape with a range of health outcomes. This evidence, largely based on conventional manual shape measurements, gives confidence that photonic technology can revolutionise an area of research and practice already much valued in medicine.

The majority of work has focused on the metabolic syndrome, a condition strongly associated with nutritional status and adiposity. Despite continued reliance on BMI for the clinical categorisation of overweight and obesity, studies increasingly demonstrate that body shape parameters are more sensitive indices of clinical risk. Analysing data from over 27,000 adults distributed across 52 countries, Yusuf et al. (2005) found that the risk of myocardial infarction in those of low BMI with high waist girth exceeded those of high BMI with low waist girth. In a meta-analysis, waist-to-height ratio was found to be a better discriminator than BMI for hypertension, diabetes and dyslipidaemia in both men and women (Lee et al. 2008). Figure 11.3 illustrates the odds ratios of diabetes per 0.5 SD increase in either BMI, waist girth or waist–hip ratio (Huxley et al. 2010). These data strongly indicate that the health risks of obesity are disproportionately due to abdominal fat (visceral and deep subcutaneous fat) rather than peripheral subcutaneous fat located in the limbs.

Neither waist nor hip girth is considered particularly invasive by most people, and the majority of adults will be familiar with them in other context, such as when purchasing clothing. Their increasing use in clinical practice offers an advantage over BMI or weight, where changes may be due to lean mass, as well as fat.

Nevertheless, the current utilisation of data on waist and hip girth remains an extremely simplistic approach. Recently, a number of studies have reported the development of more sophisticated body shape outcomes, and have investigated their associations with the risk of diverse diseases and health outcomes. Of particular importance, contrasting with the association of increased abdominal fat with disease risk, peripheral gluteo-femoral fat appears protective against disease. For example, greater hip girth appears beneficial for the risk of diabetes, hypertension, dyslipidaemia and markers of inflammation (Snijder et al. 2003), with this finding replicated across diverse ethnic groups (Snijder et al. 2004). Likewise, thigh girth has tended to be associated with a protective effect for both cardiovascular disease and type 2 diabetes (Snijder et al. 2003). Whilst much of this work has been conducted in adults, the same findings are increasingly emerging in paediatric research. These findings merit further exploration, as childhood interventions may be particularly valuable in reducing prevalence of the metabolic syndrome, and 3-D photonic scanning is suitable for the majority of the paediatric age range.

Collectively, these studies indicate an untapped potential of body shape outcomes to evaluate health status. Most existing work has remained based on 1-D measurements, for example, the distance around the waist, or the distance from the front to the back of the abdomen. Cross-sectional areas of the abdomen or limbs would represent 2-D outcomes, and these could then be summed to provide volumes, or to express more complex body features, such as topographical contours. Thus, despite substantial interest in the association between body shape and health, the 3-D topographical landscape of the human body has yet to be exploited adequately as a source of information. Recent work has considered how girths from different body locations differentially index peripheral vs. internal body fat, or skeletal

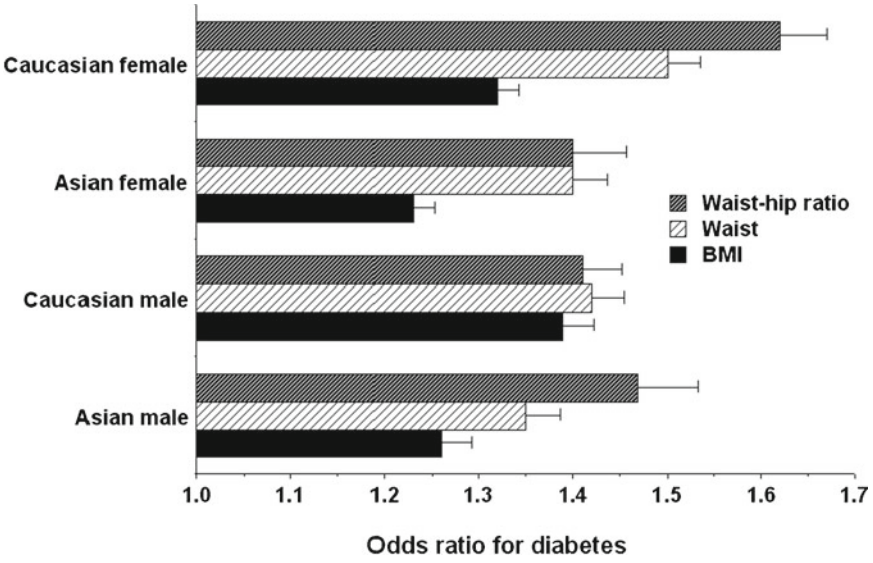

Fig. 11.3 The odds ratios of diabetes per 0.5 SD increase in either BMI, waist girth or waist–hip ratio in Asian or Caucasian males and females. Adapted and redrawn from Huxley et al. (2010)

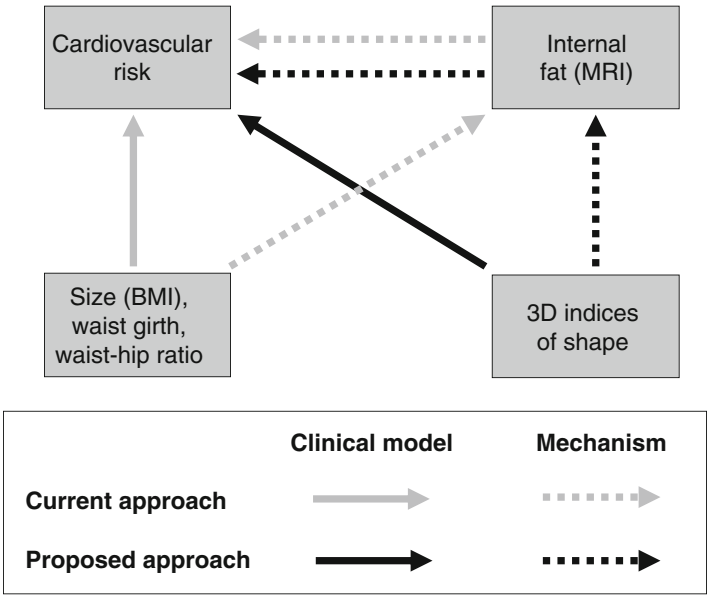

Fig. 11.4 The rationale for 3-D photonic shape outcomes replacing the existing conventional, but crude shape outcomes as indices of cardiovascular risk. 3-D shape can potentially index more subtle components of fat and lean distribution than conventional anthropometry, and hence predict risk with greater sensitivity

muscle mass. Calf and arm girths proved the best indicators of muscle mass, waist girth of visceral fat, and waist and hip girths of internal visceral fat (Heymsfield et al. 2008). The application of 3-D photonic technology to this generic approach is likely substantially to improve such predictions.

Figure 11.4 illustrates the rationale for 3-D photonic shape outcomes replacing the existing conventional, but crude indices of shape as predictors of health. Such an approach would be justified

Table 11.1 Key points

1. Digital anthropometric data can now be obtained using whole-body 3-D photonic scanners. This hardware generates 3-D 'point clouds', which can then be subjected to sophisticated computer processing.
2. Current software uses automatic landmark identification to fit an 'e-tape measure' over the body skin surface, allowing the extraction of around 200 body measurements, such as girths, diameters and distances.
3. Validation studies show systematic differences between such 3-D measurements and manual measurements, due to differences both in the style of measurement (projecting light onto, vs. touching, the skin) and in the exact location measured. Consequently, while the methods show excellent consistency in ranking within a population, cannot be used interchangeably to provide absolute data on any given trait.
4. Digital anthropometric data offer numerous advantages over conventional measurements. The data are quick and easy to obtain, with high acceptance levels encountered in recent National Sizing Surveys.
5. Each 10 s scan provides substantial potential for computer analysis, and current work is addressing not only conventional outcomes (girths, diameters), but also novel 2-D and 3-D indices, such as cross-sectional areas or regional volumes and surface topography.
6. Photonic digital information is readily archived and retrieved, and allows comparison of repeat scans to identify change in shape.
7. Photonic scanning is likely to shift attention away from 1-D anthropometric measurements to more complex 3-D anthropometric shape outcomes.
8. Research is underway to identify more sensitive shape indices of disease risk, focusing, in particular, on the metabolic syndrome, obesity and type 2 diabetes.
9. The technique is particularly valuable because the same data is relevant to, and increasingly used by, the lifestyle and retail industries addressing fitness and clothing requirements.
10. 3-D photonic scanning can change not only the type of anthropometric data collected, but also the way in which it is used in health care monitoring.

primarily by physiological studies demonstrating better associations between 3-D photonic outcomes and internal adiposity, compared to those between BMI or waist girth and adiposity. However, as discussed above, shape may index more than adiposity, and further work should address this issue too. Of critical importance is that studies already suggest that anthropometric outcomes may index risk as strongly as MRI or DXA measurements of internal fat distribution (Sierra-Johnson et al. 2004; Scherzer et al. 2008), suggesting no significant loss of sensitivity from the use of a much cheaper and more convenient technology. The potential for 3-D photonic scanning to transform the use of anthropometry in health care is summarised in Table 11.1.

11.7 3-D Assessment of Obesity

One area of particular interest concerns novel categorisations of obesity. Research has increasingly demonstrated the limitations of BMI as the primary index of obesity, as discussed above. This is particularly the case with children (Wells 2000), where growth further confounds simple interpretation of BMI. Another key problem area concerns ethnicity, with variability in physique again confounding the interpretation of BMI. For example, Asian children tend to have greater body fat content, including visceral fat, for a given BMI value compared to white Europeans, whereas Afro-Caribbean of African children have reduced body fat (Haroun et al. 2010). However, ethnicity is itself a difficult outcome to asses, in part, because categorisations such as 'Asian' or 'black' fail to address the substantial variability within such groupings, and in part, because an increasing proportion of children derive from mixed-ethnic unions. It is possible that more detailed categorisation of physique, based on body landmarks, such as knee girth or ankle girth, will improve the accuracy, whereby excess adiposity (e.g. waist girth) is indexed, thus obviating the need for qualitative information on family ancestry.

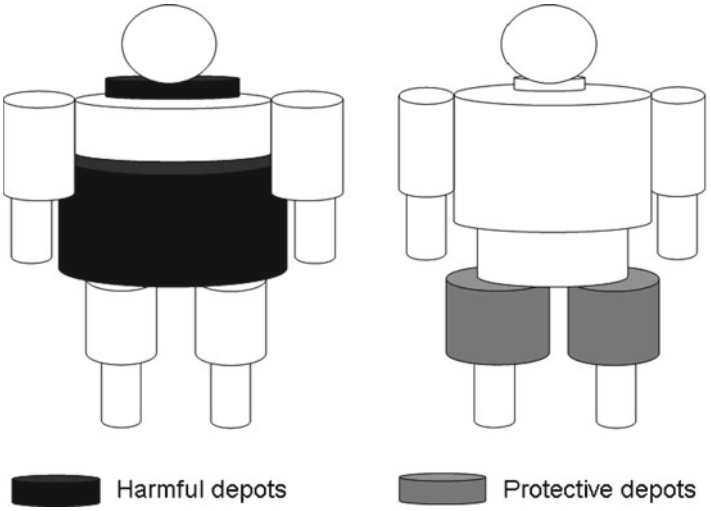

Fig. 11.5 Schematic diagram illustrating contrasting body shape profiles according to the relative size of segmental body volumes. The left-hand figure has enhanced neck and lower abdominal volumes, both associated with increased cardiovascular risk, and reduced gluteo-femoral volumes, associated with protective effects. The right-hand figure shows the inverse shape profile with low-cardiovascular risk

Compared to BMI, measurements of body shape offer more specific assessments of central adiposity, demonstrated by increasing use of waist girth, or waist–height ratio. Photonic instrumentation allows substantially greater information about abdominal shape to be captured. For example, segmental body volumes may be developed; alternatively, cross-sectional areas or diameters may be determined. The distribution of weight between these segmental volumes may then be assessed.

Figure 11.5 illustrates two profiles of body shape, one emphasising enlarged lower abdominal and neck volumes (both indices of cardiovascular risk, as discussed above), and the other emphasising moderate neck and abdominal volumes, but enhanced gluteo-femoral volumes, which have been associated with protective effects. 3-D technology can provide quantitative indices of these contrasting segmental volumes, providing a more sensitive index of obesity profile than BMI. For example, using 3-D scanning, Wang et al. (2007) have shown a disproportionate increase in trunk volume relative to limb volume in obese adults, especially in men. This replicates similar findings in children using more conventional technology (Wells et al. 2006). Indeed, the 3-D approach is likely to particularly beneficial in children, as adjustment may readily be made for variability in age or height. Likewise, ethnic variability in physique may also be addressed by clarifying variable normative ranges of different regional body volumes.

11.8 Continued Development of the Technology

The main focus of development at the current time is improved software for categorisation of body shape outcomes. Automatic landmark location in combination with new topographical features can dramatically improve the capture of information relevant to health from photonic shape data. Also, there is a current paucity of datasets combining 3-D outcomes with indices of cardiovascular risk. Lin et al. (2002) studied novel shape indices in 1,204 adults from Linkou, Taiwan, and found stronger associations with metabolic risk that those for either BMI or waist–hip ratio. Ongoing work by

the author's own group is exploring the association between body shape, internal fat distribution and metabolic risk in adolescents of different ethnic groups. Such work will help demonstrate the potential of photonic technology to play a new role in epidemiological research and clinical practice.

11.9 Applications to Other Areas of Health and Disease

3-D photonic scanning is increasingly used in diverse areas of medical research and practice, as reviewed previously. Lung function is a particularly intriguing area, as 3-D chest measurements may relate to it better than 1-D measurements, and real-time data capture could be used to assess breathing characteristics. Other areas of particular interest include cranio-facial surgery, the construction of high-quality prosthetics, and screening for conditions, such as scoliosis and obesity. The technology offers the capacity for these diverse applications to be integrated, such that on the one hand, nutritional status is addressed when body information on body topography is required, and on the other hand, information on body topography is used to interpret nutritional status. The digital nature of the information is key to this integration, and indicates that anthropometric information can be used much more widely than is currently the case.

Summary Points

- There is now compelling evidence that body shape is associated with a variety of health and disease outcomes, most notably the metabolic syndrome.
- Existing anthropometric shape indices, constructed from manual measurements, are relatively cumbersome to obtain and convey only crude information about shape. 3-D photonic scanning represents a more sophisticated approach to shape assessment.
- 3-D photonic scanning offers many practical advantages over manual anthropometric measurements. The digital data can be readily captured and archived, processed by a variety of different software programmes, and used to assess shape change over time by overlaying repeat scans.
- Large sizing surveys have demonstrated significant variability in 3-D body shape in relation to age, gender and ethnicity. Much of this variability is not revealed by BMI, the conventional index of obesity and nutritional status.
- 3-D body scanning represents a new technique for anthropometric surveys and obesity screening, ideal for large sample sizes and most age groups >4 years. It will shift emphasis from individual girths and dimensions to more composite shape outcomes.

Chapter 12
3D Craniofacial Anthropometry, Simplified and Accelerated by Semi-Automatic Calliper

Constantin A. Landes, Michael Trolle, and Robert Sader

Abstract Anthropometric standard callipers are used in craniofacial conformation assessment of patients with malformations, such as cleft lip and palate, hypoplastic or excessive jaw development, or for aesthetic reasons.

Roentgenocephalogram analysis is the mainstay in diagnosing craniofacial osseous and soft-tissue conformation and development. Also called cephalometry, it is based on lateral and posterior–anterior standardized roentgenographs and several insecure landmarks that show considerable intrarater and interrater variation. Moreover, radiation exposure, constant object positioning and the use of costly roentgen equipment is inevitable.

Anthropometry, as mostly presented in the literature, is time consuming and cannot reproduce 3D craniofacial conformation. Insecure landmark definitions and soft tissue resilience foster systemic measurement errors. Therefore, a few, easily accessible landmarks, closely related to the underlying bone were selected, measured and reconstructed in their 3D conformation as a wire frame. A soft tissue mask, concentrating on the mid-sagittal profile was added. Facial growth was monitored, growth functions generated and postoperative outcomes evaluated against the preoperative situation.

To simplify general anthropometric data acquisition by calliper, a *semiautomatic* calliper was developed. With its data-input switch connected by optical data cable to a standard personal computer (PC), this calliper permitted completion of standard data sheets, interrater and intrarater validated in test collectives and patients.

A major volunteer collective with repeat measurements served for standards and for reliability assessment. Normal growth functions, differentiated by sex, were assessed with 95-percentiles and 5% relative error. Full manual viscerocranial Am was thrice as time-consuming as the semi-automatic calliper-mediated direct data input to the computer. Gauging of the distance of the calliper ends by ruler, taking down the numbers manually, and lastly computer data input were rendered superfluous, and standard relative error decreased.

The developed craniofacial Am proved reliable and valid for measurement of craniofacial growth, diagnosis and treatment control. Relative measurement errors are smaller than the systematic

magnification and distortion in lateral cephalograms. The Am allowed reliable, objective, independent calculation of cranial bone relations and soft tissue projection, sensitive to facial asymmetry. Easy application, versatility and economy were obvious in the assessment of facial proportions, soft tissue ratios, operation planning and follow-up. Semiautomatic anthropometric callipered data acquisition was shown to be faster than the manual technique and equally reliable: measurement errors were effectively diminished and oversight errors avoided. The craniofacial anthropometric routine has been in use over 10 years and proven valuable in growth comparison of different regimens of cleft lip and palate treatment as well as with jaw development in microsomia and jaw deformity treatment, such as dysgnathia.

While treating specific craniofacial syndromes, many specialists have needed to assess postnatal growth patterns *as a background consideration*. Normal development and knowledge of soft-tissues-to-bone relationships and their interaction and the interaction between functional–aesthetic regions have been given high importance in prospective treatment rationales and outcome assessments. *Using anthropometric standard callipers, craniofacial features, e.g. of patients with malformations such as cleft lip and palate, dysgnathia (hypoplastic or excessive jaw formation), craniosynostosis are assessed today, as are proportions in the trunk and extremities, with dedicated measurement routines*.

Abbreviations

2D	Two-dimensional
3D	Three-dimensional
Am	Anthropometry
Ar	Articulare
Crtl	Control
CT	Computer tomography
Gn	Gnathion
Li	Labiale inferius
Ls	Labiale superius
Mn	Mandibulare
MRI	Magnetic resonance imaging
Mx	Maxillare
N	Nasion
N’	Soft tissue nasion
P	Postgingivale
PC	Personal computer
Pg	Pogonion
Pn	Pronasale or nasal tip
Rcm	Roentgenocephalometry
Sm	Supramentale or supramental fold
Sn	Subnasale or columellar base
T	Tragus or tragion
Ti	Trichion

12.1 Craniofacial Anthropometry Versus Roentgenocephalometry

In the historical context, after the pioneering work of Aleš Hrdlička (1869–1943) for the head and face region, Hellmann (1932) introduced Am in the craniofacial region shortly after roentgenocephalometry (Broadbent 1931). This has since been developed popularized and summarized by Farkas and Munro (1987), Farkas (1994), and Kolar and Salter (1997) among many others. These authors only showcase over a 100 different anthropometric distances of interest in the head and face region alone.

Metric calliper assessment of craniofacial proportion can valuably be performed by Am (Farkas and Munro 1987; Farkas 1994; Kolar and Salter 1997; Arnaud et al. 2001; Evereklioglu et al. 2002; Farkas et al. 2002; Teichgraeber et al. 2003; Mortenson and Steinbok 2006; Bozkir et al. 2006). This serves for growth-monitoring in order to compare different treatment modalities as in craniofacial malformations e.g. cleft lip and palate treatment (Bitter 1992, 2001), jaw microsomy and dysgnathia management (Landes et al. 2002a, b). Similar anthropometric calliper measurements are also used in the trunk and extremities, e.g. for determination of total body fat or muscle length measurement (Harpenden's calliper).

Simple calliper Am, in spite of its diagnostic value, is not a routine procedure in everyday practice as it requires comparison of individual measurements in large tables and yields no three-dimensionality (Farkas and Munro 1987; Farkas 1994; Kolar and Salter 1997).

Regarding the popular *roentgenocephalometry* on lateral and posterior–anterior projections, Rakosi (1982) cites over 100 methods to analyse craniofacial growth by roentgenocephalometry (Rcm). Correct positioning of anatomical landmarks during roentgenographic examination is mandatory, while projections of anatomical structures are mainly used to measure distances or angles. Natural or pathological asymmetries are not considered when both sides are overprojected, as, e.g., in patients suffering from hemifacial microsomy (Farkas and Munro 1987). Furthermore, both facial sides are projected with different magnification. Focus-object and object–film distance and the divergence of the x-rays create a systematic magnification between 4% and 7%. The positioning of the landmarks by one observer, as well as by different observers, in repeated analyses is variable. It is also difficult to establish a correlative norm because there is insufficient correlation between the biological structures of the human cranium and findings in cephalograms. Therefore, many authors use intraindividual correlations instead of "norm values". Specific individual measures are correlated to judge the skull in two dimensions. Lastly, radiation exposure limits the repeatability of roentgenocephalograms (Landes et al. 2002a). Based on the *Broadbent* (1931; Landes et al. 2002b) standards of cephalometric radiography, cephalograms most often serve for operation planning and control in orthognathic surgery.

Apart from the disadvantages of cephalometry, calliper Am even with recent methods (Evereklioglu et al. 2002; Czerwinski et al. 2005; Farkas and Forrest 2006) cannot reproduce cranial three-dimensionality as photographic optical or roentgenographic scanning (computed tomography) methods do. Only roentgenographic methods can assess soft tissues and bone substructure together within one examination without the registration problem in image fusion. Optical data acquisition is confined to the skin surfaces.

Another disadvantage within any calliper Am technique is that the investigator, clinician and their co-workers are required to perform multiple measurements with an anthropometric or blunt drawing calliper. Their span has to be transferred to a ruler, if not integrated in the calliper, and recorded manually either on paper or computer. These manoeuvres are time-consuming and therefore unpopular.

Electronic callipers have been used; however, data transfer continues to be manual, observers annotating the indicated measures from the digital display (Bozkir et al. 2006). Digital virtual callipers

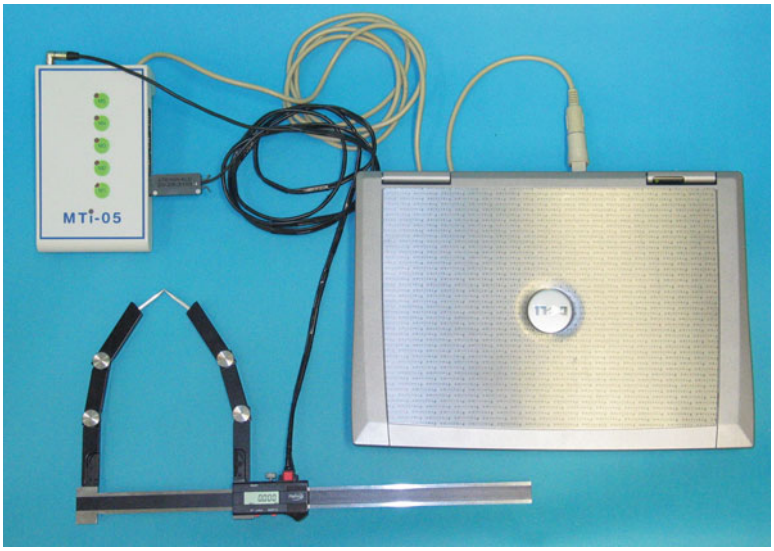

Fig. 12.1 The slide-gauge calliper with optical output, cable, interface to the laptop and footswitch replaced here by a manual control switch. The scale with hand-operated input (*red push button*) can be calibrated to zero in any calliper-arm position. Opening and closing the lock bolts can bend calliper-arms

cannot be used directly on patients, but only in virtual reproductions. These are cone beam computed tomography, or classic computed tomography that require specialized equipment and include radiation exposure and are therefore of limited in their repeatability (Baumgaertel et al. 2009).

12.1.1 Semiautomatic Callipering

To overcome the disadvantage of lack of three-dimensionality and non-haptic conformation assessment in tables, as well as the tedious callipering, a 3D craniofacial Am with a calculation algorithm and an easy-to-use semiautomatic calliper have been developed.

The semiautomatic calliper provides direct computed data input (Fig. 12.1, Landes et al. 2007; Trolle 2008). Moreover, it is designed to be applicable with any anthropometric measurement routine featuring an input table in any PC-keyboard to enter measurement values by footswitch or handswitch in the cursor position in e.g. Excel®- or MS-Access® (Microsoft Company, Mountain view, CA, USA).

Comparative full manual examination was performed with a blunt anthropometric calliper (AA 842, Aesculap, Tuttlingen, Germany) and compared with the semiautomatic anthropometric calliper measurement, both done with identical routines (Landes et al. 2007). The semiautomatic calliper was created on the basis of a technical standard electronic slide calliper (Helios Messtechnik GmbH, Schwäbisch Hall, Germany). Double measurements were performed: fully manual and semiautomatic by the same investigator and repeated at two different interviews. This routine was double assessed by two different investigators to quantify the intrarater and interrater measurement error. The calliper has a 30 cm range (11.81 in.) and a 0.01 ± 0.03 mm measurement resolution, according to the manufacturer. Measurement can be taken in millimetres or inches.

Inwardly curved brass calliper branches with tapered tips were initially attached later replaced by double-hinged arms of tempered steel. These permit free changes of measurement angle and reach less accessible anthropometric landmarks such as the tuber maxillae.

An optical data cable (OPTO RS 232/10 poles, Steinwald Datentechnik GmbH, Marktredwitz, Germany) was connected to the interface. Ten poles were adapted as follows: Pin 1 earthing, Pin 2 data transmission, Pin 9 + 10 with 5 V loading each, to keep the interface charged (Fig. 12.1).

The interface (IMP Ingenieurgesellschaft mbH, Osnabruck, Germany) at the keyboard cable (PS 2-norm) connection to the motherboard has 5 input channels and a hand- or foot-operated switch. The input data are entered at the cursor position; a synchronous acoustic feedback signal is generated. Furthermore, two serial interfaces are included (SIO, "serial in out" 1/2) and the interface's plugging chart obtained from the authors.

A turn-switch modifies the cursor position after data input to either Enter or Space, Tab, to Ctrl function. Windows 2000® (5.0), or Vista® (Microsoft Corporation, Mountain view, CA, USA) equipped standard PCs are used, with Intel Pentium 3® to dual core® processors (Intel Corporation, Santa Clara, CA, USA).

12.1.2 3D Craniofacial Anthropometry

For high availability, portability and low cost, a 3D craniofacial Am was developed of earlier reports and clinically applied (Landes et al. 2002a, b). From the visual configuration of the resulting wire frame, it could be shown that several simple measurements can reconstruct a 3D osseous and soft-tissue "wire-frame". A caveat though: today *3D surface imaging* systems offer a quick and practical method of quantifying craniofacial variation and appear to be highly reliable; however, some sources of measurement error have not yet been thoroughly evaluated. Besides, 3D surface imaging depends on costly equipment that is not always available, at least not globally, and if used for assembling osseous and soft tissue conformation analysis, radiation exposure is inevitable (Heike et al. 2009).

Extraoral, easily accessible anatomical landmarks were selected see Tables 12.1 and 12.2 and marked on the skin, which maintain a close and reproducible relationship to underlying bone:

- Tragus (T also "Tragion" left and right) and
- Nasion (N) form a triangle representing the cranial base
- Maxillare (Mx) also "gingivale superius" at the insertion of the upper median labial frenulum into the maxillary alveolar ridge
- Mandibulare (Mn) also named "gingivale inferius" at the insertion of the inferior median labial frenulum into the mandibular alveolar ridge
- Postgingivale (P) or "tuber" was located at the dorsal endpoint of the maxillary alveolar crest at the tuber maxillae

Generally in calliper Am, soft tissue resiliencies beneath accessible landmarks on the skin are permanent sources of error, and several landmark definitions are insecure. Therefore, osseous landmarks with reduced soft tissue resilience were chosen, as the skin or gingiva is normally thin there. For setting a correlative norm, a collective, of 540 asymptomatic, sex and age differentiated, volunteers are evaluated by Landes et al. (2002a).

The interlandmark distances are measured:

- Tl-Tr (Tragus "left", Tragus "right")
- Tl-N
- Tr-N

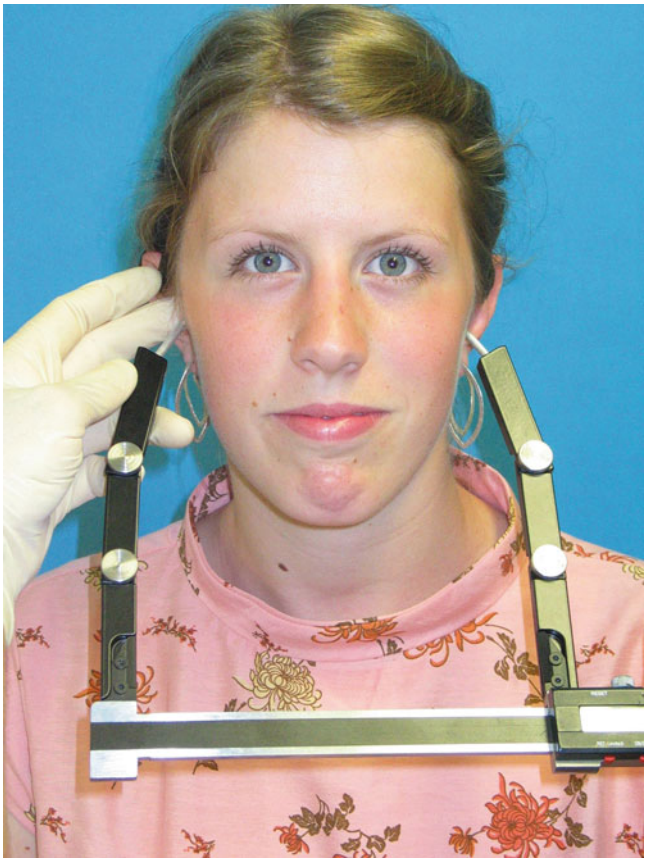

Fig. 12.2 A volunteer patient with the demonstrated tragus left-tragus right distance measurement. The measurement position is a relaxed, upright, sitting posture with moderate pressure on the osseous landmarks

- Tl-Mx
- Tr-Mx
- Tl-Mn
- Tr-Mn
- Tl-Pl
- Tr-Pr
- Pl-Mx
- Pr-Mx
- Pl-Pr
- N-Mx
- Mx-Mn

The measurements are shown with the new semiautomatic calliper prototype in Figs. 12.2–12.5 before wireframes (Fig. 12.6a, b) and growth diagrams are created (Fig. 12.6c). Altogether *14 measurements for osseous conformation of the maxilla and mandible to the cranial base are now established*. Kephalometrie 1.1 is a C^{++} based calculator for a wire-frame in three dimensions, based upon the 14 given triangularly arranged measurements of osseous and soft-tissue landmark distances (free distribution by the author for investigatory use, Bitter 2001; Landes et al. 2002a, b).

Fig. 12.3 A volunteer patient with the demonstrated tragus left-subnasale distance measurement. Measurement of the distance tragus left to columellar base (subnasale, soft tissue landmark) displayed on the scale in total millimetres and two decimal places

The "Kephalometrie" algorithm reconstructs the triangles to a wire frame in virtual space. For comparison, sagittal projection (assessment of osseous profile conformation, Fig. 12.6a) and axial projection (assessment of lateral asymmetries and lateral rotation of the maxillary triangle, Fig. 12.6b) were mainly used, though *any projection angle can be chosen at will*.

Table 12.1 Key features of 3D-craniofacial anthropometry (Am), simplified and accelerated by semi-automatic calliper

1. Threedimensional craniofacial Am is a considerably simple technique that yields high availability and portability at very low cost.
2. Semiautomatic computer-connected callipers can more than double the registration speed.
3. Measurement in concealed landmarks, not accessible to surface scanning is enabled with anthropometric callipers due to the double hinged calliper arms.
4. A calculator reset is permitted in any measurement position.
5. Measurement of osseous as well as soft tissue landmarks can be done simultaneously.
6. A dislocation of measurement tips and therefore falsification of distances upon calliper removal from the actual landmarks is avoided due to immediate data input at activation of the input button.
7. Three dimensional reconstruction of multiple (triangulated) 2D measurements is possible.

This table lists the key facts of 3D-craniofacial Am and its simplification and acceleration by semiautomatic calliper

Fig. 12.4 A volunteer patient with the demonstrated tragus left-maxillare distance measurement. Measurement of the distance tragus left to maxillare or supradentale. Therefore the lip is held away by a medical spatula

Table 12.2 Key facts on soft tissue and osseous landmarks

1. Landmarks represent crucial anatomic structures valuable for anthropometric measurements.
2. Landmarks have to be readily accessible for measurement, e.g. the nasal tip
3. Landmarks should be easy to reproduce in order to diminish interrater and intrarater measurement variation.
4. Landmarks have slightly different names in-between different authors and measurement techniques.
5. Landmarks should be picked in sensible numbers: not too many, not too few, in order to clearly represent the region and structures of interest.
6. Landmarks in close relationship to underlying bone are called osseous landmarks; in a radiography they can be virtually located in lieu of osseous structure projection.
7. Landmarks close to essential soft tissue structures are soft tissue landmarks. They often have a variable inconstant relationship to underlying bone.

Some key facts on anthropometric landmarks are listed.

12.1.3 Anthropometry of the Soft Tissue Profile

In the second step, a soft tissue profile projection was included, because on the one hand, photographs and Rcm, acetate tracings or digitized analyses reduce a complex 3D conformation to a practical and manageable procedure. On the other hand, roentgenocephalometry, interprets only a vector displacement due to the shifting of anatomic and constructed landmarks in two dimensions: lateral asymmetry is not considered, both sides become overprojected due to x-ray divergence projection distances being subject to a distortion of 4–7% (Landes et al. 2002b). Photographs display a three dimensional

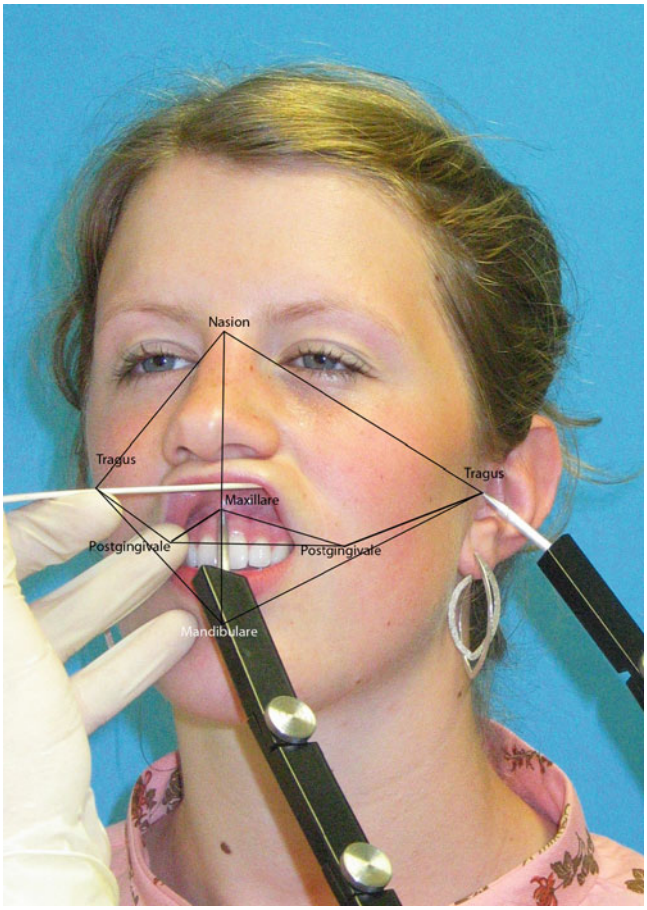

Fig. 12.5 A volunteer patient with the demonstrated tragus left-maxillare distance measurement as in Fig. 12.4. Additionally all osseous distance measurements are drawn. Identical measurement with the osseous distances outlined (tragus right is projected, as this landmark is not visible on the photo). When measurements are put together, they generate the 3D osseous wireframe of craniofacial conformation. That is: skull base, maxilla and mandible, represented by tragus, N, supradentale, infradentale and postgingivale landmarks

situation reduced to two dimensions with a distortion due to perspective and angulation of projection. Although standards of photo-documentation have been established, 3D measurements can only be performed indirectly. Frontal, 45° view i.e. half profile and lateral photographs cannot yield a reproduction of the 3D patient. Postoperative predictions do not integrate different soft tissue tension and tonicity following osteotomy. Thus, soft tissue prediction is insecure (Landes et al. 2002b).

Heike et al. (2009) recently assessed the reliability of stereophotogrammetry for measuring craniofacial characteristics in 40 individuals, including 20 volunteers without craniofacial conditions and 20 with 22q11.2 deletion syndrome. Thirty anthropometric measurements were obtained on participants and on 3D images. Their results showed intrarater and interrater reliability for most interlandmark distances on 3D images, had intraclass correlation coefficients greater than 95%, mean absolute differences of less than 1 mm, relative error measurement less than 5% and technical error of measurement less than 1 mm. The Pearson correlation coefficients of greater than 0.9 for most distances suggested high intermethod reliability between direct and image-based measurements. 3D image-based measurements were systematically larger for the head length and width, forehead and skull base widths and upper and lower facial widths.

In contrast to photogrammometric measurements that merely cover soft tissue landmarks, the developed 3D cephalometry routine covers both, soft tissues and osseous landmarks, that is, landmarks with a close relationship to underlying bone and thin soft tissue cover. Essentially, this soft tissue cover can be thinned by moderate pressure during the measurement.

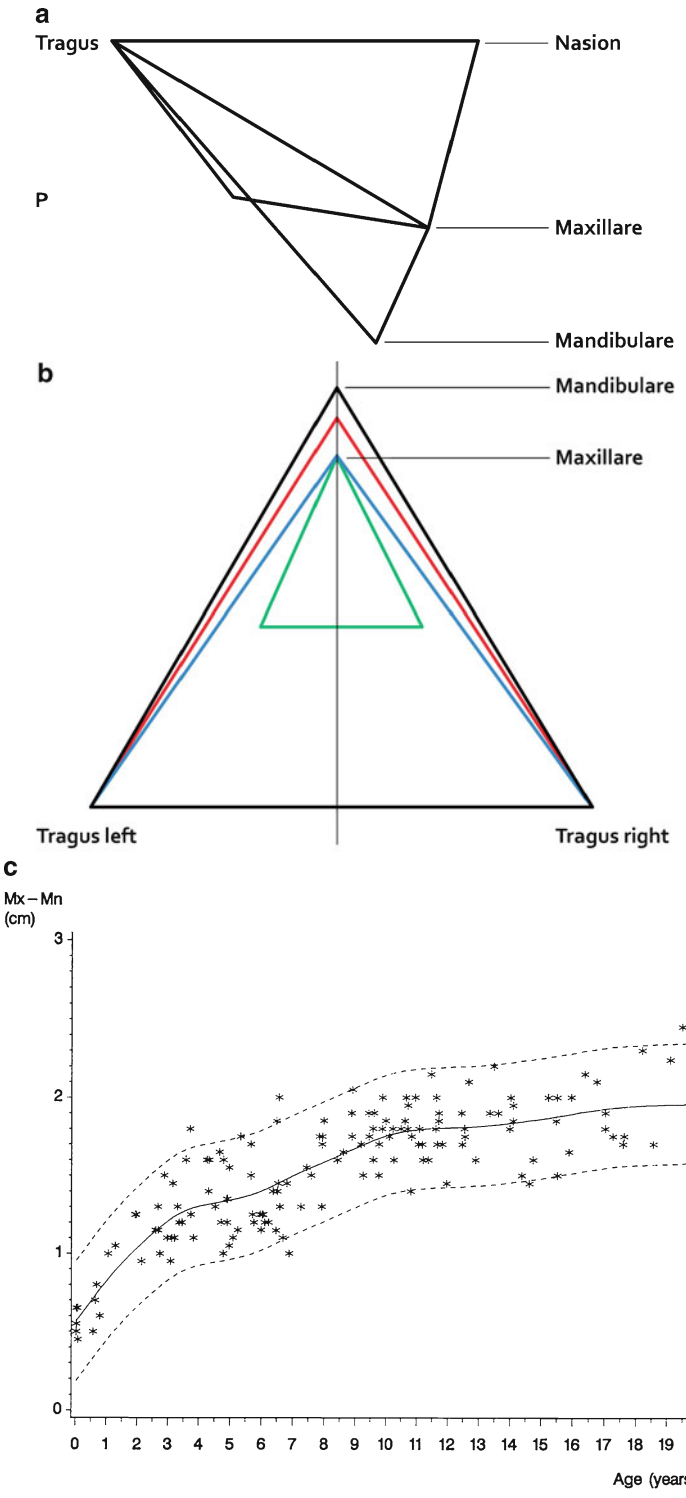

Fig. 12.6 (**a**) The volunteer patient's wireframe resulting from the computation of the osseous distances. The wire frame is shown in sagittal projection of a harmonic osseous conformation of maxilla and mandible relative to the cranial base represented by the distance nasion-tragus. (**b**) The volunteer's wire frame in axial projection. The wire frame shown with axial projection deducts a slightly asymmetric positioned maxilla slightly inclined to the right. (**c**) The volunteer population's growth function of the distance Maxillare–Mandibulare. The growth function was generated by the test collective for the distance Maxillare–Mandibulare in girls (Landes et al. 2002a)

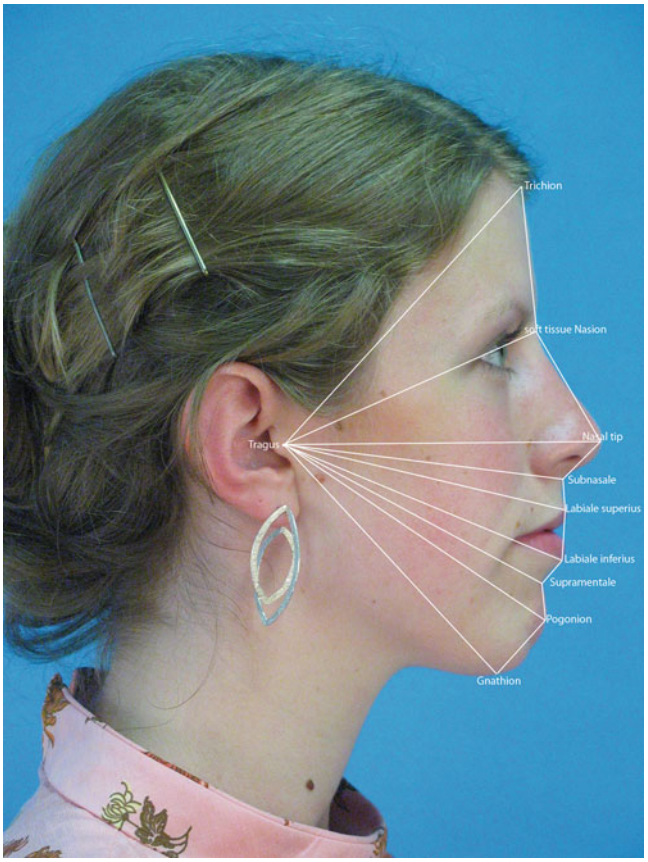

Fig. 12.7 The volunteer in profile with drawn soft tissue measurements. The soft tissue measurements were put together for creation of the wire frame. All landmarks were located according to standard definitions

All soft tissue landmarks that are included are easily accessible, relevant and not too many to keep the measurements comprehensible. Soft tissue ratios have been established without the use of any sophisticated technical means (Landes et al. 2002b). Osseous changes were assessed independently from the soft tissue alterations. Further, inter- and intraindividual measurement reliability was quantified. Lastly, the examination procedure should only require a minor amount of time. A major collective of 100 patients was assessed with repeated examinations preoperatively and postoperatively.

Regular assessment included the above-named landmarks and the following:

- Trichion (Ti) as the crossing of the median sagittal profile-line and the anterior hairline was defined as most superior soft tissue landmark
- Soft tissue nasion (N′)
- Nasal tip (or pronasale Pn)
- Columellar base (or subnasale Sn)
- Labiale superius (Ls)
- Labiale inferius (Li)
- Supramental fold (or supramentale Sm)
- Pogonion (Pg)
- Gnathion (Gn)

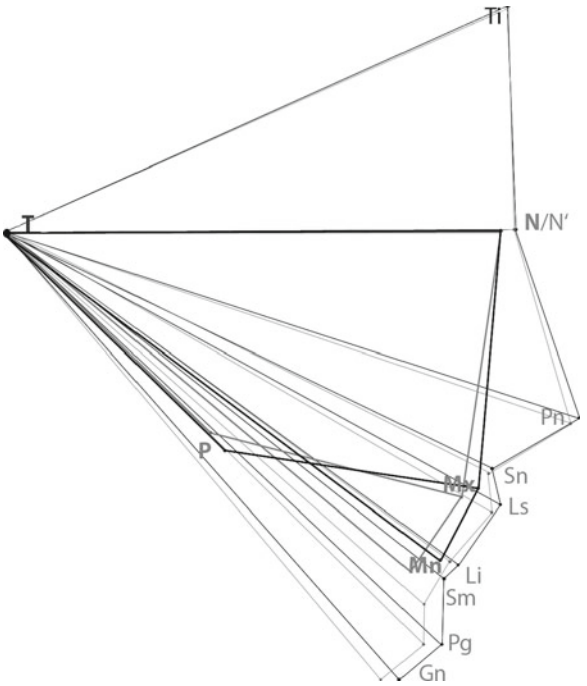

Fig. 12.8 An exemplar patient's preoperative and postoperative wire frame superpositioned in sagittal view. Shows a preoperative and postoperative superposition in lateral view of the measured distances, reconstructed as preoperative and postoperative wire frames. The bold lines represent the osseous landmarks' wireframe, the landmarks are given with their abbreviations, see text. The patient shown here had a mandibular advancement and maxillary impaction

These were selected according to their commonly used definitions (Farkas and Munro 1986). Distances between T and the landmarks above and between neighbouring landmarks were measured (Fig. 12.7). Thus, a slightly more complex soft-tissue wire frame resulted, indicating the facial protrusions from the virtual intertragus line.

Lateral cephalograms taken the same day were parallelly scrutinized for similar landmarks: Porion for T, N, N′, supradentale, infradentale, tuber point, nasal tip, Sn, Ls, Li, Sm, soft tissue Pg and soft tissue Gn (Landes et al. 2002b).

Figure 12.8 shows an exemplar picture of a super-positioned preoperative and postoperative craniofacial conformation when the upper and the lower jaw position were changed within a bimaxillary osteotomy. Within this exemplar operation, the major directions of jaw movement were defined as mandibular and maxillary advancement or setback, maxillary impaction or elongation. Each direction of jaw repositioning was calculated separately in every patient for postoperative soft tissue changes relative to the changes in osseous landmark projection. For assessment of soft tissue ratios in relation to surgical bone repositioning, preoperative distances were subtracted from postoperative distances (Landes et al. 2002b): dTMn – dTLi: Changes in Li projection were compared to changes in the projection of Mn. Comparing data from roentgenocephalometry and Am assessed the validity of Am for planning surgical treatment: e.g. articulare-nasion (Ar-N) as a measure of cranial base length was compared to tragus-nasion (T-N) in Am. The global soft tissue ratios as well as the ratios according to the separate jaw movements were comparable to values obtained from lateral cephalometry or CT reports in the literature (Landes et al. 2002b). However, variation was generally high, and ratios calculated separately according to the direction of jaw movement decreased the standard deviation. Soft tissue responses were bigger following mandibular advancement than after setback. Anthropometry required the same amount of time as did roentgenocephalometry.

12.2 Methodological Considerations

Thinking back to our childhood, most of us spent hours discussing with our mothers whether somebody was actually "tall" or "small", "slender" or "obese". This means Am is really popular and we start using it very early in life though ordinal (Paul is taller than Christine) and later through metric evaluation (last year I measured 135 cm now I am 165 cm tall). Therefore, Am provides the most popular direct way to analyze the 3D conformation of human beings.

This goes also for faces: big nose, crooked nose etc. From the instinctive qualitative evaluation to a more exact compilation, Am becomes more elaborate and is therefore less widespread whether the manual classical callipering method or recent surface recognition scanning methods. Acceptance of more complex anthropometric callipering measurement sequences suffers from the relative measurement effort and, moreover, scanners are limited in distribution due to their high acquisition costs. Calliper Am is currently the only alternative to computed tomography, when *at the same time*, bone and soft tissue landmarks become integrated.

Measurement of direct distances in millimetres is preferred today as most anthropometric distances have to be compared with large lists of norm values or normograms and do not permit a immediate visual assessment of proportions (Landes et al. 2002b).

12.2.1 Acceleration of Calliper Data Acquisition

The semiautomatic calliper is a major acceleration in the calliper data acquisition process. "Kephalometrie" enables calculation of an individual measurement profile at a few mouse clicks, and it is hoped to dramatically accelerate its popularity as norm values and measurement sequences are already established (Landes et al. 2007). Moreover intrarater and interrater absolute and standard error are minimized.

The semiautomatic anthropometric calliper is fairly easy to assemble and every tab-stop in any datasheet can be consecutively filled-out with anthropometric measurements one-by-one, according to the preference of the investigator.

12.2.2 Sources of Error in the Callipering Method in the Craniofacial Area

The absoute and relative error of the callipering method in the craniofacial area was recently given as 0.7–1.5 mm (about 0.7–1.6%) intraobserver error (retesting variability) for correct assessment of the orbitozygomatic complex. The interobserver variability ranged from 2.9 to 9.1 mm (3–9.6%) (Czerwinski et al. 2005).

Another study of sagittal orbital Am discerned 0.2 mm exactness of the orbital anthropometer, which, however, differed significantly from the semiautomatic anthropometric calliper used in this review. Furthermore, 1% intraobserver error and mostly nonsignificant interobserver differences were reported (Kohout et al. 1998). The semi-automatic calliper values were comparable, and the semiautomatic assessment reduced errors successfully (Landes et al. 2007). A further advantage of the semiautomatic measurement is a >60% time saving and less effort on the patient's as well as on the investigator's side. The authors hope that, the introduced technique will simplify regular Am in clinical practice.

12.2.3 Kephalometrie Algorithm

The "Kephalometrie" program can output individual measures in a norm diagram as well as visualize the craniofacial osseous and soft-tissue conformation in a wire-frame. Commercial operation planning software disposes of integrated ratios for an approximate soft tissue prediction. Yet it can create a faulty postoperative image when a minor initial prediction error in the deformation database for the soft tissue reaction to bone repositioning is aggravated in proportion to the distance of the planned jaw movement. Operative bone positioning primarily influences the neighbouring soft tissues. Thus, a separation of the osseous movements in patients with, e.g., simultaneous reposition of the maxilla and mandible or "bimaxillary" surgery according to the direction of jaw movements is rational.

Within the author's earlier measurements, the average soft tissue responses in mandibular advancements were 114% in Am and 130% in Rcm (Landes et al. 2002b).

Labrale inferius moved 106% in Am and 88% in Rcm. Sm moved 103% in Am, 142% in Rcm and Pg 120% (Am) and 188% (Rcm).

In the literature, a 97–100% ratio for Pg and Sm is given, whilst labiale inferius only moves 62% in advancements (Landes et al. 2002b).

Prospectively, the paramedian "social" profile will become integrated with the landmarks: endocanthion, exocanthion, alare, cheilion and Gn. Such refinements will provide estimation, for example, of the accuracy in fragment positioning of different surgical fracture repositioning techniques (Czerwinski et al. 2005). Recognition of patterns of specific conformational proportions, pathognomonic for certain syndromes may even be developed (Farkas and Forrest 2006; Guyot et al. 2003).

Using the ophistocranion as the dorsal landmark (z-axis definition) was considered less exact and reproducible than the *T*.

Several two-dimensional (2D) surgical treatment planning computer programs are in existence, which combine skeletal and soft tissue analysis. However, flaws exist in representing a 3D structure in 2D form: facial depth and shape are not accounted for. In addition, the patient may have some difficulty in fully understanding the postoperative prediction plan because the changes and postoperative prediction are usually displayed as a lateral view only.

Patients are not able to see their own profiles and are more concerned with frontal view problems they can see easily on an everyday basis in the mirror. To address these problems, a 3D modality is required. Although 3D imaging has been regularly used in computer animations, video surveillance, and anthropology, its use in medicine is in its infancy. Recent advances in technologies have generated a variety of 3D techniques to capture facial topography and overcome the deficiencies of conventional photographic and radiographic methods. Cephalometry, morphoanalysis, Moiré topography, 3D CT, 3D ultrasonography, laser scanning, and digital stereophotogrammetry have been included. For many of these recent techniques, normal data are limited. Yet 3D evaluations and the characterization of surface anatomy are fundamental in objectively analyzing facial anatomy. By using the various techniques available, accurate surface measurements can be made, volumetric changes assessed, and the facial shape, texture, and skin tone captured and evaluated in 3D (Honrado and Larrabee 2004).

12.2.4 New Technological Advances

As inherent in any new technological advance, the accuracy of these newly developed 3D imaging systems in recording facial morphology must first be assessed. Several recent studies have focused on determining the reproducibility of identifying landmarks using various 3D modalities. Accuracy values range from 0.2 to 1 mm, meaning that these imaging techniques are very reliable in recording facial morphology and could be used to acquire normal data in three dimensions and to measure and

calculate changes after surgery. As emerging technology yields comparable measurement results, no reliable standard of measurement technique currently exists (Guyot et al. 2003).

Three-dimensional CT and MRI still have problems with measurement of segmental bone movement (McCance et al. 1997). 3D Photogrammetry or holography cannot yet combine osseous and soft tissue capturing (Bongartz et al. 2000). Commercialized operation outcome predictions are based on weak data collections from cadaver studies that are not readily transferable to live patients for tissue tonicity and turgor.

The cost of these 3D imaging systems is the biggest hindrance for a regular surgical clinical department at present. Costs range from $25,000 to $150,000 for the products alone, not including software. In comparison, the presented semiautomatic calliper costs $1,500. Future reduction in price is certain with the common trend of developing smaller dimensions in electronic components as well as infrared or other cordless data transmission techniques. Pressure gauges at the measurement tips may permit reproducible contact pressure for soft tissue and "osseous" landmarks. This will reduce the overlap of, for example, soft tissue nasion and N, as in Fig. 12.8, as well as the systematic error in assessing soft tissue resilience.

12.3 Applications to Other Areas of Health and Disease

A 3D simple wire frame was derived out of triangularly arranged anthropometric measurements for assessment of craniofacial conformation. **Triangular designed measurements can generally be assembled to wire frames and can also be designed for other body regions.**

Wireframes provide a simplified, sizeable, visual 3D impression of the structures under observation.

Semiautomatic measurement significantly speeds up and simplifies measurement in the presented work of maxillofacial conformation including osseous and soft-tissue landmarks.

Systematic error from soft tissue resilience over bone landmarks was reduced by carefully selecting landmarks with thin soft tissue covers, e.g. Mx and Mn.

The semiautomatic calliper used here can be used in any anthropometric measurement beneath the maximum span of 30 cm. However a longer slide gauge in the construction will enable longer distances to be measured with minimal effort. The cursor position controlled by the hand-operated input switch fills out any data sheet independent of the software used.

Rapid callipering speed accelerates the acquisition of the most important soft tissue as well as osseous landmarks of the median profile, cranial base, maxilla and mandible. Prospective inclusion of paramedian landmarks will become possible in the future to allow an analysis also of the "social" 45° of half-profile. **The semi-automatic device can be used with any Am measurement routine, when patient measurements have to be included into a datasheet. Long-term quantified evaluation of developmental, presurgical and postsurgical conformation will assess the individual amount of deviation including the relation of bone landmarks chosen with the above-named confinements of thin soft tissue cover.**

The relative proportion of soft tissue secondary to bone movement was focused on here.

Recognition of patterns of specific conformational proportions, pathognomonic for certain syndromes or diseases may thus be developed.

Summary Points

- The presented semiautomatic calliper can be used with any 2D distance measurement.
- The maximum measurement distance is 30 cm but with a bigger calliper this distance can be increased.

- The footswitch proved to be less available during measurement than the handswitch for data input; the pushbutton was therefore preferred.
- For the measurement routine used here, firm pressure must be exerted upon osseous landmarks to reduce soft tissue resilience and systematic measurement error; for soft tissue landmarks use light pressure.
- Triangularly oriented unidirectional measurements can be assembled to 3D wireframes.
- Craniofacial development can be judged as well as the mandibulomaxillary conformation relative to the cranial base.
- Operative or growth-related changes of jaw position can be monitored.

Chapter 13
Issues in Measurement of Pubertal Development

Frank M. Biro and Lorah D. Dorn

Abstract Teenagers mature along several areas, including social, cognitive, and biologic realms. The biologic changes called "puberty" can be defined by stage, timing, and tempo. The pubertal stage traditionally has been called "Tanner stages", and more recently as "Sexual Maturity Rating" (SMR). These stages describe changes in breast tissue, pubic hair, and external genitals. There are several approaches to pubertal staging in research projects, including questionnaires and rating by self, parent or trained professional. Rating by a trained professional is considered the most accurate approach, but the research setting may limit the choice available. This chapter discusses historical perspectives in maturation assessment, provides current approaches with practical guidelines, and presents recent data about the timing of pubertal onset and the potential impact of early or late maturation timing.

Abbreviations

BMI	Body mass index
PBIP	Picture-based interview about puberty
PDS	Pubertal development scale
SMR	Sexual maturity rating

13.1 Overview and Historical Perspectives

Teenagers can be described using several different perspectives, such as chronologic age (that is, "teen years"), cognitive development (whether concrete, as contrasted to formal operational), as well as biologic maturation (puberty). There is a rich history relative to the measurement of maturation in the adolescent. For example, the concept of physiologic age, rather than chronologic age, is attributed to Crampton from a paper in the early twentieth century, where he suggested that chronologic age might not best represent the physiologic and morphologic changes experienced by teenagers (Crampton 1908). This was further described and expanded by Boas, who delineated chronologic, physiologic, morphologic, and social processes in adolescents (Boas 1941). Tanner, in his classic treatise

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_13,

Growth at Adolescence, discussed four systems that were utilized to assess developmental age: skeletal age, dental age, morphologic age, and secondary sex character age (Tanner 1962). Similarly, Brooks-Gunn and Warren discussed "maturational events", which included the measurement of secondary sexual characteristics (breast, body and pubic hair, penile and testicular development, and menarcheal status), as well as anthropometric characteristics (bone age, height, weight, and body composition) (Brooks-Gunn and Warren 1985). Tanner noted that skeletal age had been the indicator of developmental age most commonly used, until the introduction and popularization of pubertal maturation systems. Of note, skeletal age is still used in clinical practice to assess physiologic maturation of those with advanced or delayed pubertal maturation or short stature, based on a radiograph of the left wrist and hand, using the same standards published by Greulich and Pyle over 50 years ago (Greulich and Pyle 1950). Given the several studies that note earlier maturation of girls, the research and clinical world may wish to consider whether to update these time-accepted standards of bone age.

A brief discussion of morphologic age is warranted before turning the remainder of the chapter to the assessment of pubertal maturation. Morphologic age is based on size, height, and body proportions. Although height age (the age based on the 50th percentile for that height) is still used by clinicians, the utility of that measure is limited because of the confounding of physical maturation and anticipated height based on gender and mid-parental height. Height may be predicted by examining bone age (physiologic age); height and chronologic age (Bayley and Pinneau 1952); bone age, height, chronologic age, and midparental height (Roche et al. 1975); or simply by determining midparental height and modifying by gender (adding 6.5 cm for boys, and subtracting 6.5 cm for girls) (based on Tanner 1970). Predictive height continues as a useful clinical tool to allow the clinician to understand better the disparity between observed and theoretical height. Other concepts imbedded in morphologic age include body proportions; that is, relative proportions of various body parts. Medawar described a quantitative approach to the developmental changes in volume of head to trunk, and trunk to limb length (Medawar 1944), and Simmons described quantitatively the changes in distal and proximal limb segments during childhood and adolescence (Simmons 1944). Although these constructs provide an understanding of changes during growth, there is a limited specificity for a precise definition of developmental age.

13.2 Pubertal Assessment

Currently, the standard used most frequently to assess physiologic age in adolescents is sexual maturity rating, often described as "Tanner stages." These stages examine pubic hair and breast maturation in girls, and pubic hair and gonadal maturation in boys. It is somewhat unclear who originally described and characterized these changes. A review of the history of breast maturation assessment notes that Stratz early in the twentieth century described four stages of breast development (Stratz 1909); Reynolds and Wines described five stages of breast development as utilized currently, but also incorporated two other measurements, breast shape and breast size (Reynolds and Wines 1948). Tanner utilized the breast staging system of Reynolds and Wines, but not shape or size (Tanner 1962), and he is credited with the breast staging system commonly used, as described below. Several years later van Wieringen published a series of photographs utilizing this five stage system (van Wieringen et al. 1985). Other authors have proposed different mammary maturation systems, based on the areola and papilla (Garn 1952), or the size of the papilla (Rohn 1987; Aygün et al. 1998). These authors have offered that evaluation of breast maturation may be influenced by several factors, especially obesity. It appears that there may be some over-estimation of breast maturation in obese peri-pubertal girls, although breast and areolar maturation assessments are highly correlated with each other (Biro et al. 1992). Pubic hair maturation assessment is attributed to several groups, including Preisel and Wagner, Pryor, Dupertuis et al., Reynolds and Wines, and Marshall and Tanner

(Preisel and Wagner 1931; Pryor 1936; Dupertuis et al. 1945; Reynolds and Wines1948; Marshall and Tanner 1969, 1970). The traditional system incorporates five stages, as described below, although many have incorporated a final sixth stage, as the hair continues to advance to the umbilicus, along the linea alba. In boys, "gonadal" staging has been utilized, as well as assessment of testicular volume. Gonadal staging in boys had been utilized by Marshall and Tanner, Reynolds and Wines, and Stolz (Reynolds and Wines 1948; Stolz and Stolz 1951; Marshall and Tanner 1970). Several groups, however, noted that gonadal staging was an unreliable sign for the onset of pubertal development in boys (Taranger et al. 1976; Largo and Prader 1983; Biro et al. 1995), and recommended evaluation of testicular volume. In these three studies, boys with no pubic hair but with testicular volume of ≥3 ml were found to be in early puberty; additionally, testicular volumes of ≥3 ml were associated with pubertal values of testosterone (Biro et al. 1995; Sorensen et al. 2010).

Several studies have examined the reliability of various maturation techniques: trained professional, self or parent assessment, and utilizing various scales. Although maturation assessment by a trained professional is considered the standard for pubertal assessment (Dorn et al. 2006), there is no perfect agreement between examiners. The Kappa statistic compares observed agreement between examiners to agreement expected by chance alone. Values of Kappa range from 0.50 (based on 25 comparisons) (Hergenroeder et al. 1999) to 0.86 (56 comparisons) (Herman-Giddens et al. 1997), with 0.67 (127 comparison) (Biro et al. 2010) and 0.78 (20 comparisons) (Britton et al. 2004), observed in two other studies. Coleman reviewed the literature and compared different approaches to assessment of pubertal maturation, including several different self/parent report techniques, and noted that professional assessment was the most accurate, the Pubertal Development Scale (PDS) (Petersen et al. 1988) the least accurate, and assessment by the participant or parent the intermediate (Coleman and Coleman 2002). Several papers have examined self/parent-assessment, as well as reviews of the published work in this area. Several studies have suggested that self/parent assessments may serve as a reasonable substitute for the assessment by a trained professional, but many studies suggest that self/parent assessment does not serve as a reliable approach to the determination of maturation status. There is a discrepancy when contrasting agreement by the Kappa statistic or merely association by correlation coefficients. Dorn summarized 14 studies that examined agreement between trained examiner contrasted to the self or parent report; kappa coefficients varied from 0.34 to 0.91 (Dorn et al. 2006). She noted there may be nonrandom errors in the measurement; for example, boys tend to overestimate their maturation. Additionally, those adolescents who matured earlier or later than their peers tend to rate themselves on-time rather than off-time, suggesting a normalization of their pubertal timing. A subsequent study compared self-assessment to assessment by a pediatric endocrinologist; Kappa coefficients were.49–.68, and the authors drew the conclusion that self-assessment was unreliable (Desmangles et al. 2006). Similarly, Shirtcliff compared several different pubertal assessments, including direct examination; the PDS, a picture-based interview about puberty (PBIP); and multiple salivary samples for hormone analysis (Shirtcliff et al. 2009). In this study, the two self-report scales (PDS and PBIP) were moderately correlated with each other, but both had modest agreement with physical examination (Kappa =.36 for both). Feasibility is often cited as a reason to utilize self/parental assessment, but several studies have incorporated professionally trained staff in a variety of settings, including schools and youth serving agencies. Lastly, some studies have utilized hormone analyses of different body fluids, including blood/serum, saliva, and urine. Studies have incorporated less sensitive analytic techniques, such as radioimmunoassay that cannot reliably distinguish between pre- and early-pubertal status; this is contrasted to the recently developed assays that have much greater sensitivity, such as high-performance liquid chromatography followed by tandem mass spectroscopy (Kushnir et al. 2009). In short, evaluation by trained professionals leads to the greatest degree of accuracy, but may not be the most convenient approach in all settings. Given differences in accuracy of these approaches, the investigator should consider carefully what level of accuracy is necessary to yield valid conclusions for the study.

13.3 Practical Techniques

13.3.1 Maturation Staging

Sexual maturity ratings are demonstrated for girls in Figs. 13.1–13.4, and for boys in Figs. 13.6 and 13.7. Figure 13.1 has photographs that demonstrate each breast stage, whereas Fig. 13.2 is a template currently being used in several studies with both graphic and verbal descriptions of breast stages.

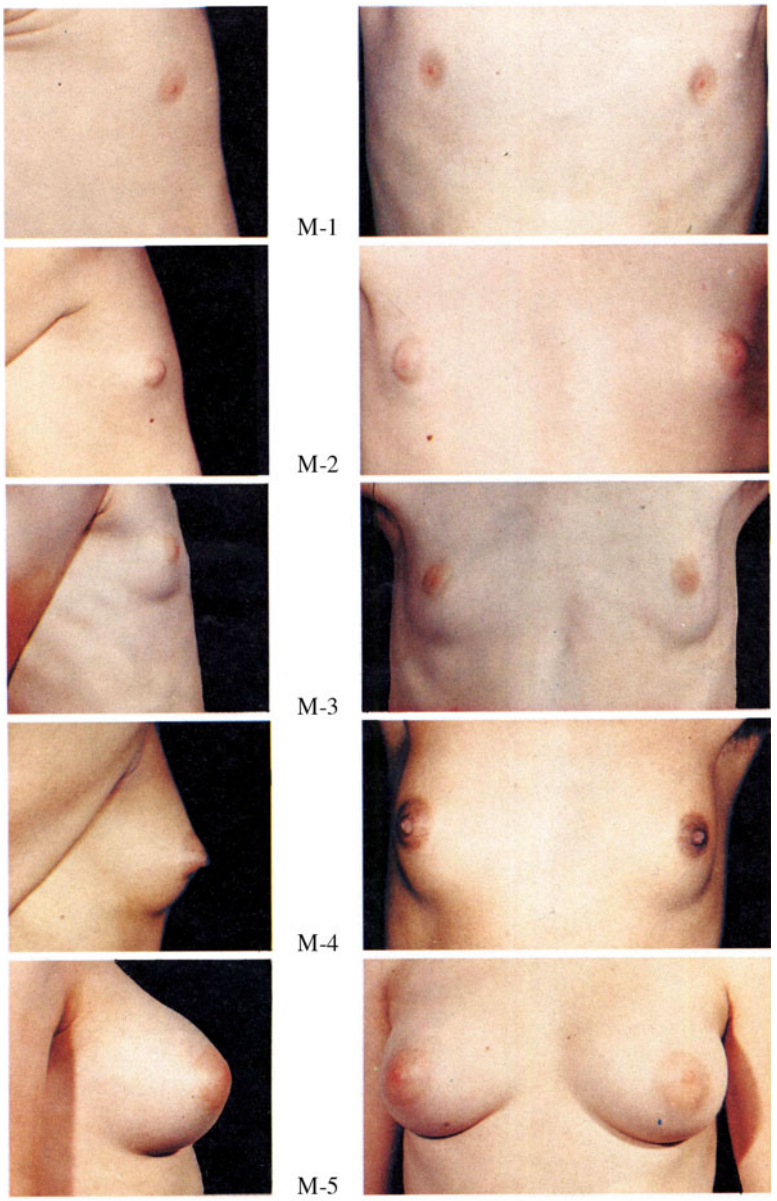

Fig. 13.1 Stages of breast development in girls. Photographs demonstrating stages of breast development; see Fig. 13.2 for the description of each stage

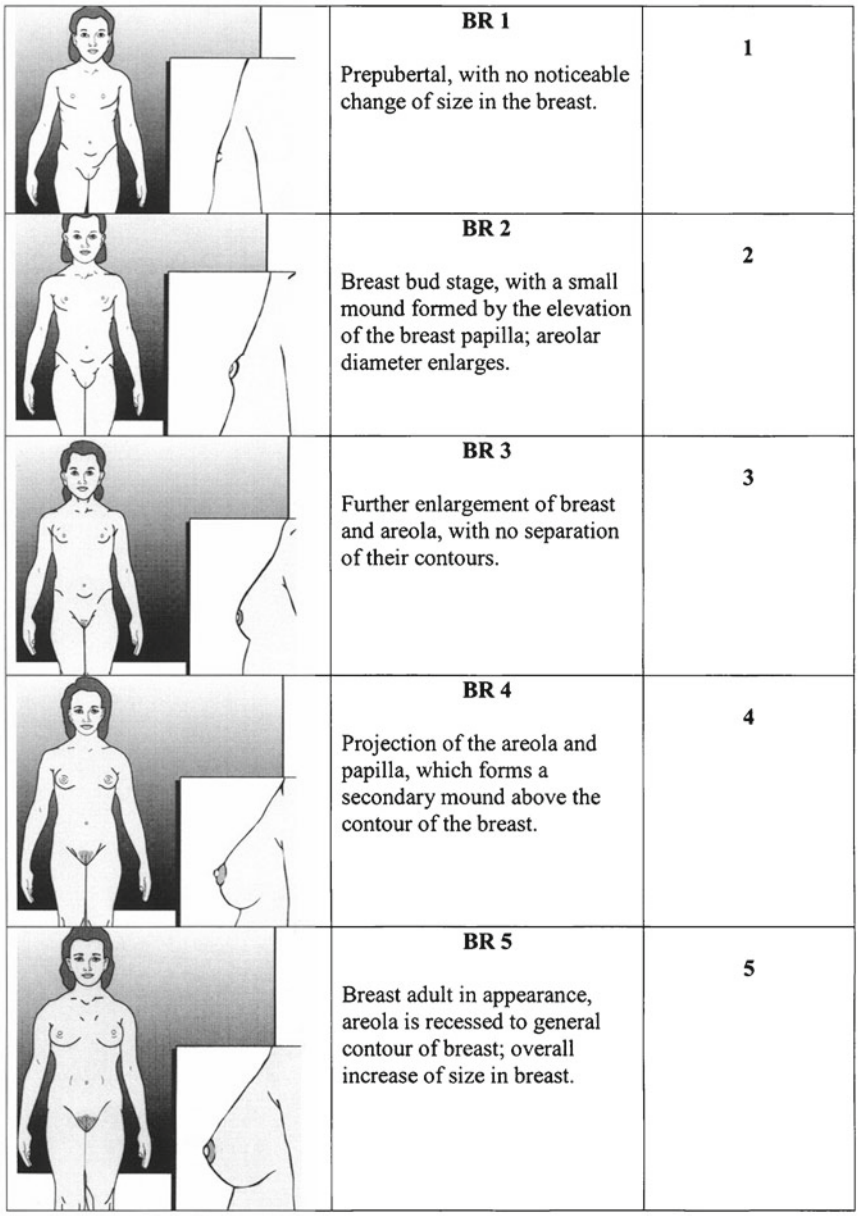

Fig. 13.2 Description of individual breast stages. Template used by ongoing studies exploring pubertal maturation; developed by the first author

Figures 13.3 and 13.4 demonstrate the same principles for public hair staging. Sexual maturity stage 1, regardless of gender or characteristic (that is, breast or pubic hair, or genital stage) represents a prepubertal stage, and sexual maturity stage 5 represents complete maturity of that characteristic. Of note, description of the pubic hair staging system is identical for boys and girls, and some authors have described "stage 6" pubic hair, which refers to hair extending from the pubic area up along the linea alba.

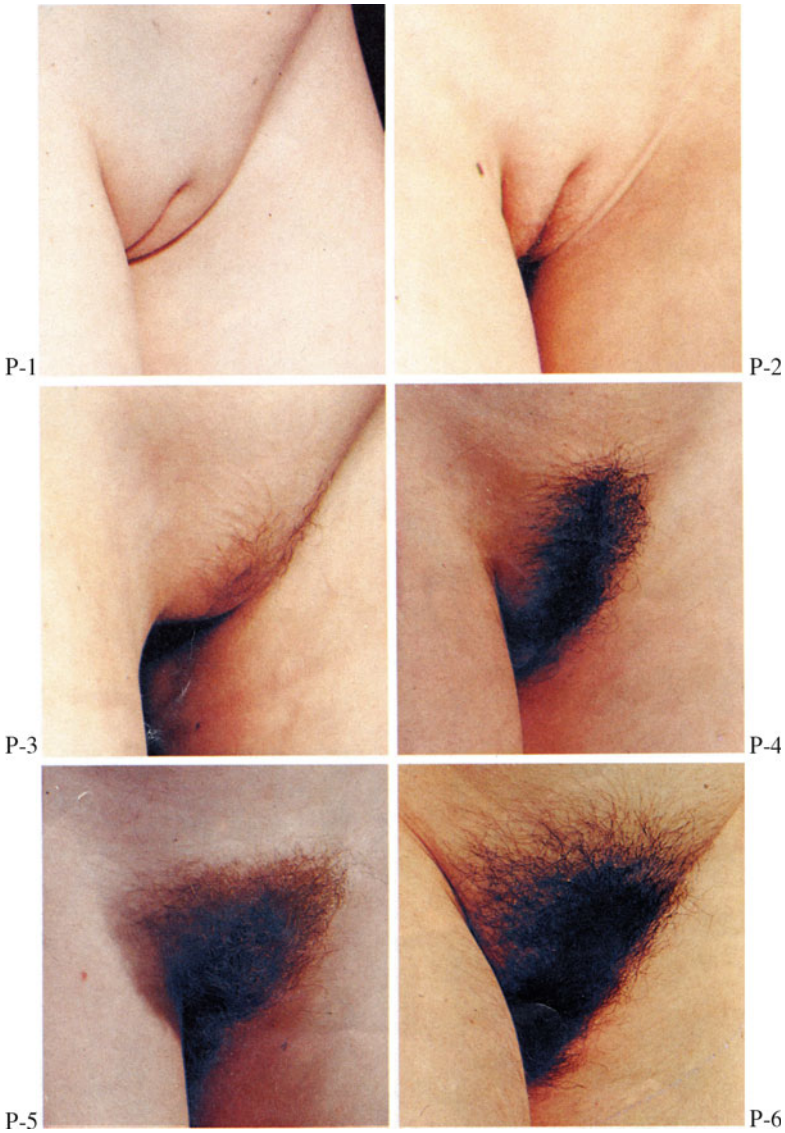

Fig. 13.3 Stages of pubic hair development in girls. Photographs demonstrating stages of pubic hair development; see Fig. 13.4 for the description of each stage

The development of secondary sexual characteristics in girls occurs relatively late in puberty. That is, breast development occurs approximately 1 year after girls begin their pubertal growth spurt (Biro et al. 2006), and studies have demonstrated an increase in ovarian as well as uterine volumes before the development of secondary sexual characteristics (Saladari et al. 1985; Holm et al. 1995). Some authors have proposed that the development of pubic hair, without breast development, may represent a "pathway" into puberty (Biro et al. 2003, 2008; Schubert et al. 2005), rather than solely a manifestation of adrenarche. However, the majority of studies utilize the onset of breast development as the start of puberty in girls. The interrelationships of various pubertal and growth parameters in girls are shown in Fig. 13.5.

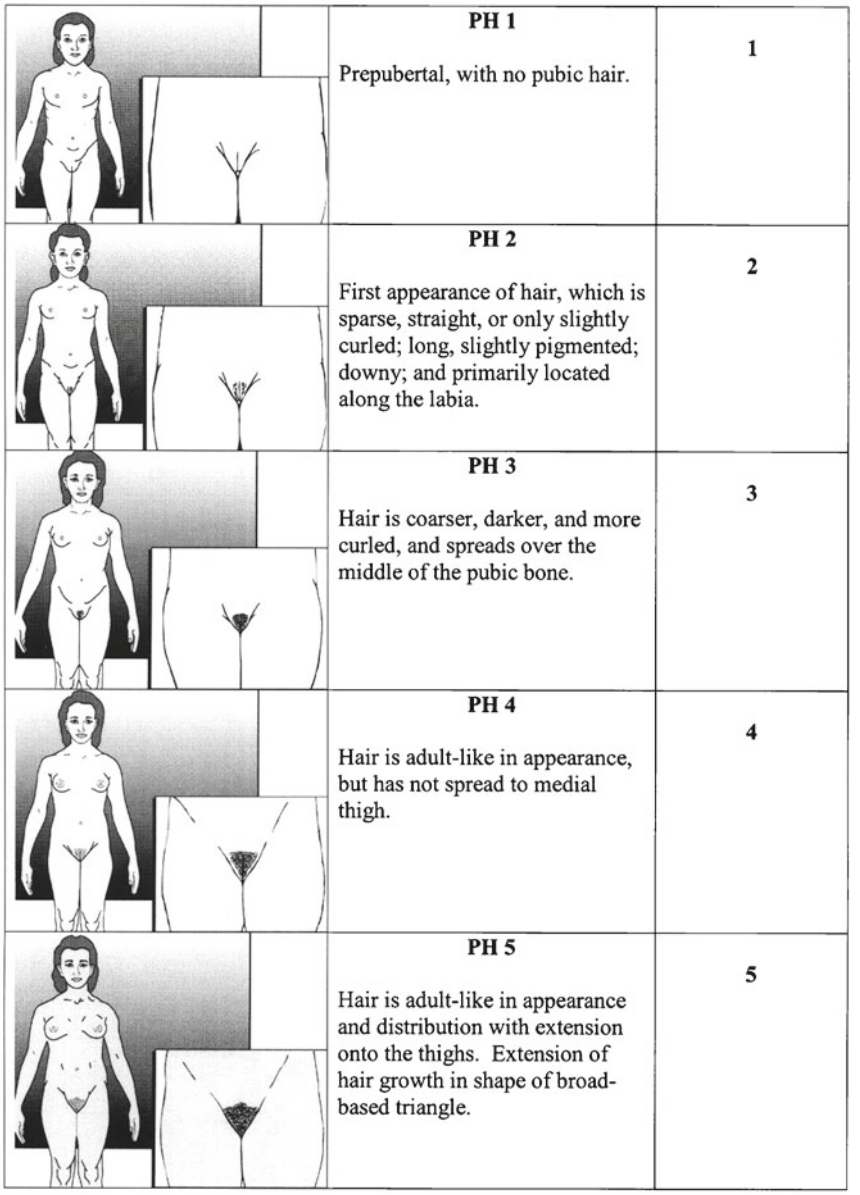

Fig. 13.4 Description of individual pubic hair stages in girls. Template used by ongoing studies exploring pubertal maturation; developed by the first author. Of note, same description applies to the pubic hair in boys

Boys can be measured along several different characteristics, including pubic hair, testicular volume, and genital stage; as noted earlier, the genital stage may be an unreliable system to assess the initiation of puberty in boys (Taranger et al. 1976; Largo and Prader 1983; Biro et al. 1995). Boys typically experience an increase in testicular volume before the development of pubic hair, and puberty in boys typically begins approximately a year later than girls. A system utilizing pubic hair and testicular volume has been proposed by several authors (Zachmann et al. 1974; Largo and Prader 1983; Biro et al. 1995). The Photographs for pubic hair staging in boys are shown in Fig. 13.6.

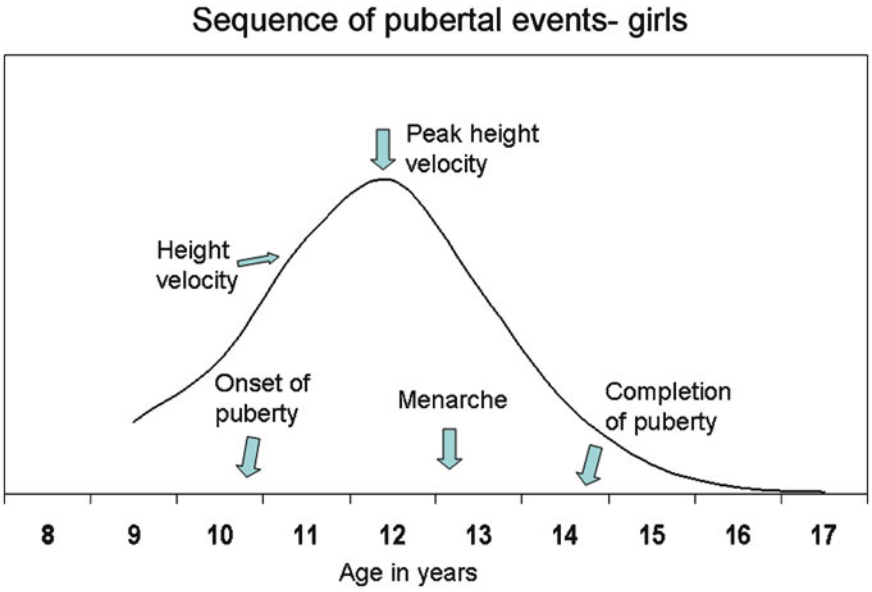

Fig. 13.5 Sequence of pubertal events in girls. Longitudinal data from NHLBI Growth and Health Study (tabular data from Biro 2006)

The relationship between pubic hair stage and testicular volume is shown in Fig. 13.7; the relationship between a modified pubertal stage (pubic hair stage 1 with increased testicular volume) and serum testosterone concentrations has been reported by several authors (Biro et al. 1995; Shirtcliff et al. 2009; Sorensen et al. 2010). The interrelationships of various pubertal and growth parameters in boys are shown in Fig. 13.8.

13.3.2 Contemporary Trends in the Onset of Puberty

A symposium of international experts gathered recently to discuss several topics regarding trends in onset of puberty, as well as potential factors influencing the age of onset of puberty. The majority of the expert panelists agreed that the data were sufficient to suggest a trend toward the earlier breast development onset, and noted that the earlier onset was related to increasing obesity, exposure to endocrine disrupting chemicals (EDCs), and increasing hyperinsulinemia and insulin resistance (Euling et al. 2008). A more recent study examining two cohorts of girls in the Copenhagen puberty study, utilizing the same examiners and technique, noted that girls in more recent cohorts had breast development nearly 1 year earlier, when contrasted to girls born 15 years earlier (Aksglaede et al. 2009). Of note, although the age of menarche in the United States has decreased slightly when compared to data collected 10 years earlier, it appeared that the decline was due to changing racial and ethnic demographics, and, in part, to increasing body mass index (BMI) (Anderson and Must 2005). The expert panel felt that the data regarding earlier maturation of boys were not as strong as the data regarding girls, although several studies did support earlier development of pubic hair (approximately 0.5 years) and genital stage 2 (approximately 1 year) (Euling et al. 2008). More recently, a modest decline in the onset of puberty was noted in boys in the Copenhagen Puberty Study (0.26 years) (Sorensen et al. 2010).

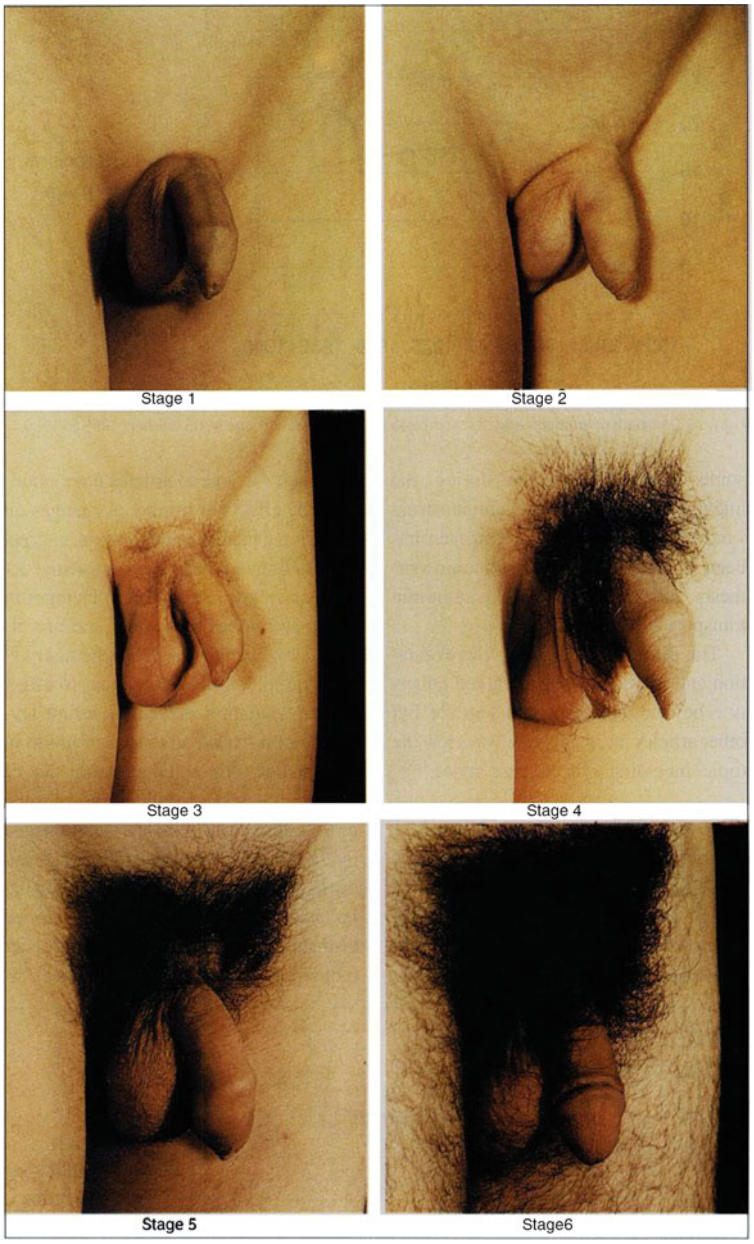

Fig. 13.6 Stages of pubic hair development in boys. Photographs demonstrating stages of pubic hair development; see Fig. 13.4 for the description of each stage

13.3.3 Relative Timing of Puberty

The relative timing of puberty can be defined using several different parameters, as well as through several different statistical approaches. Adolescents can self-report their relative timing of maturation compared to their peers (Graber et al. 1997, 2004; Siegel et al. 1999), and that perception may be as important as any other approach to determine the relative timing of puberty, depending on the

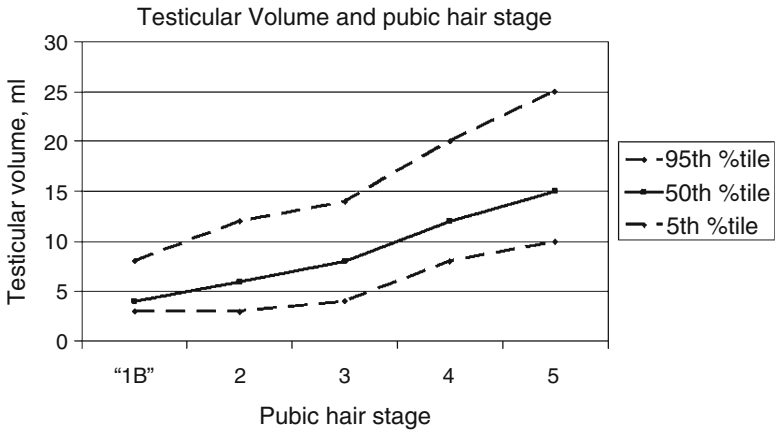

Fig. 13.7 Testicular volume and pubic hair in pubertal boys. Median, 5th, and 95th percentile values for the testicular volume by pubic hair stage; data from Biro (1995)

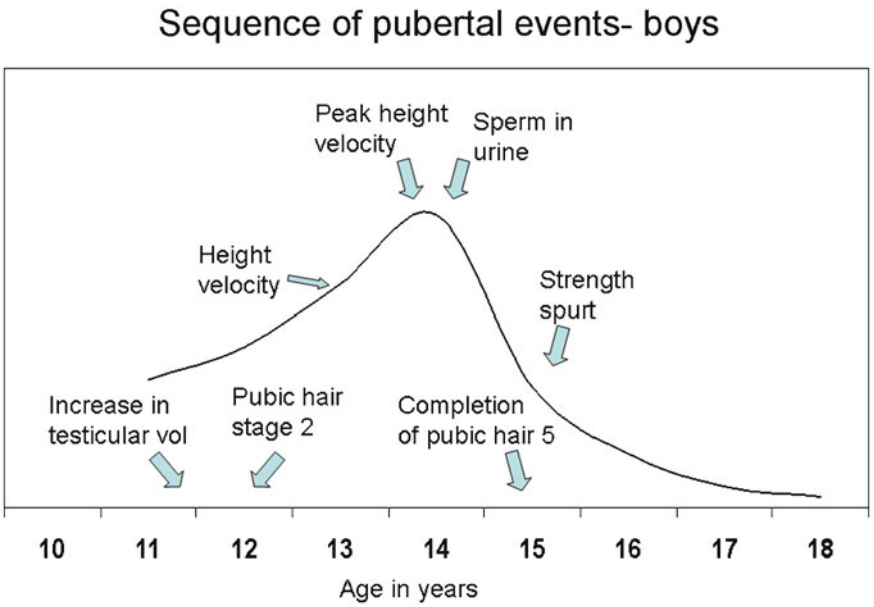

Fig. 13.8 Sequence of pubertal events in boys. Longitudinal data generated from Biro (1995)

question at hand (Dorn et al. 2006). Researchers can utilize different parameters, including scores on self-report instruments such as the PDS (Petersen et al. 1988); through age of menarche (Biro et al. 2001; Ge et al. 2001; Striegel-Moore et al. 2001; Johansson and Ritzén 2005); relative timing of examiner-assessed breast development (Huang et al. 2009); relative height (Wehkalampi et al. 2008); or growth velocity (Ferrández et al. 2009). Of note, there are differences when contrasting timing as established by physical examination to timing as perceived by the adolescent (Dorn et al. 2003). Relative timing of puberty – early, on-time, and late – can have an impact on the adolescent both physiologically as well as socially. Several papers have noted greater weight and BMI among girls who mature early (Biro et al. 2001; Anderson and Must 2005); some studies have noted shorter

height in earlier maturers (Garn et al. 1986; Biro et al. 2001), whereas other studies reported no impact on final adult height regardless of timing (Gasser et al. 2001; Vizmanos et al. 2001). Huang noted when considering timing relative to menarche, early maturers were shorter, but when considering timing relative to breast maturation, early maturers attained the same height as on-time and late maturers (Huang et al. 2009). Alternatively, Bratberg noted that boys and girls who matured early with low central adiposity were shorter, contrasted to those with normal or greater central adiposity, who had similar heights to the other timing groups (Bratberg et al. 2006). A recent review commented that altered puberty timing may result in adverse outcomes, but some of those outcomes may be due to exposure to potential endocrine-disrupting chemicals impacting pubertal timing as well as physiologic or metabolic processes (Golub et al. 2008).

Earlier maturation in girls is associated with lower self-esteem and less favorable perceived body image (Siegel et al. 1999; Striegel-Moore et al. 2001), greater rates of eating problems (Swarr and Richards 1996), and higher rates of depression (Ge et al. 2001) and suicide attempts (Graber et al. 1997; Wichstrom 2000). They are more likely to be influenced by deviant peers (Ge et al. 1996), and have a greater likelihood of substance use (Dick et al. 2000; Lanza and Collins 2002; Graber et al. 2004), and norm-breaking behaviors (Johansson and Ritzén 2005), with earlier onset of sexual intercourse (French and Dishion 2003), although these may be mediated through greater involvement with and influence by deviant peers (French and Dishion 2003). Early maturing girls had poorer adjustment skills and relationships as adults (Graber et al. 1997, 2004), whereas late maturing boys were more likely to have disruptive behavior and substance abuse as adolescents and as adults (Graber et al. 1997, 2004). Of note, later maturing women had greater educational attainment and were more likely to be on-time college graduates (Graber et al. 2004).

Timing of puberty may have an impact on adult morbidity and mortality as well. Age of menarche is noted to be earlier in women with breast cancer. For example, the risk for breast cancer is 1.2–2.2 times greater among those with an earlier age of menarche when contrasted to those with later age of menarche (Garland et al. 1998; Titus-Ernstoff et al. 1998). Women with endometrial cancer also have a younger age at menarche (Brinton et al. 1992; McPherson et al. 1996). Girls who mature earlier have a greater BMI in childhood as well as in adulthood; when examined longitudinally, most of the apparent effect of early menarcheal timing on obesity was due to the influence of childhood obesity on both menarcheal age and adult obesity (Freedman et al. 2003). Earlier maturation (measured by age of menarche) is also associated with hyperinsulinemia, and elevated blood pressure in girls (Frontini et al. 2003).

13.3.4 Closing

This chapter has reviewed trends in the measurement of pubertal development, as well as recent trends in the onset of puberty, relative timing of puberty, and the relevance of off-timing. As noted above, given the mounting data of earlier maturation in girls, and data suggesting earlier maturation in boys, researchers may consider re-examining standards for bone age, redefining on-time, early, and late pubertal maturation.

Summary Points

- Pubertal maturation is characterized by increased growth velocity, development of secondary sexual characteristics, changes in body composition, and the attainment of fertility.
- Pubertal maturation can be assessed in the clinical and research areas through the assessment of sexual maturity ratings, historically called “Tanner stages”. These scales incorporate changes in

secondary sexual characteristics, which include pubic hair, genital changes in boys, and breast development in girls.

- Several studies have suggested that the assessment of pubic hair and testicular volume is a better approach to pubertal staging in boys, rather than assessment of genital changes and size.
- There are several approaches to assess pubertal maturation in a research study, including self- or parent-assessment, completion of checklist forms, and physical assessment by a trained examiner. A trained examiner yields the most accurate approach, although the research question and study setting may determine the best approach.
- Several studies suggest that pubertal maturation is occurring earlier. Experts agree that the scientific evidence supports an earlier onset of breast development of girls, but that the evidence of earlier maturation in boys is not as strong.
- Relative timing of puberty appears to have an impact on several physical, social, psychological outcomes. Girls maturing earlier generally have a greater body mass index (BMI) as teens and as adults, and have a greater risk of insulin resistance and high blood pressure. Additionally, women with breast cancer and endometrial cancer are noted to have a younger age of menarche (first menstrual period). Earlier maturing girls have a lower self-esteem and more norm-breaking behaviors which occur at younger ages. Late maturing boys are more likely to engage in disruptive behaviors and substance abuse.

Key Features

- Teenagers mature along several different lines, including chronologic age, cognitive development (from concrete to abstract thought), and biologic maturation, also known as puberty.
- There are well-defined stages during pubertal maturation that incorporate assessment of physical changes in the genitals and breasts. These are called “Sexual Maturity Ratings”, or sometimes “Tanner stages”.
- Assessment of pubertal maturation represents one of the best choices to determine whether physical changes during the teen years represent physiologic (typical) or abnormal changes.
- There are three components in pubertal maturation – the determination of sexual maturity rating (stage of or sequence in puberty), relative timing (early, on-time, or late), and tempo. Pubertal stage and timing are the two most important concepts, and are related to physical characteristics (such as body size and adiposity), as well as psychosocial outcomes (such as self-esteem and risk behaviors).

Chapter 14
New Anthropometric History: An Analysis of the Secular Trend in Height

Laurent Heyberger

Abstract In using human-height measurements as a gauge of the biological standard of living of a given population, anthropometry (in this regard not unlike demography) offers an alternative to the standard indexes of economic history. For instance, anthropometry reveals that a paradoxical phenomenon occurred during industrialization in eighteenth-century Europe: a decline in human height – in tandem with downward trends in real wages and in temperatures – was accompanied by a population increase, thereby contradicting, for the first time, the famous Malthusian theory that population growth is eventually checked by widespread famine and disease. The decreasing human height in Europe and North America in the nineteenth century, in spite of improvements in the standard of living as measured in terms of real wages income, is a reminder of the negative consequences of the early industrialization that Marx, among others, decried. In contrast, while the standard indexes record economic stagnation during the first half of the twentieth century, height increased, reflecting improvements in public health, thanks largely to progress in the field of medicine. On another front, anthropometric history, with its reliance on impartial demographic index, permits an accurate appraisal of the economic performances of totalitarian regimes and, more generally, of the well-being of all those populations who have been excluded from the standard indexes of economic and social performance: most notably, Afro-American slaves, eighteenth-century European craftsmen and peasants, and nineteenth-century Western women.

Abbreviations

AGS	Adolescent Growth Spurt
GDP	Gross Domestic Product
GNP	Gross National Product
HDI	Human Development Index
MHR	Minimum Height Requirement

Table 14.1 Key facts of industrialization

- Industrialization is a global process, including technological and economic changes, but also urbanization and cultural changes such as the spread of literacy.
- Industrialization began, in the eighteenth century, with improvements in the productivity of the textile industry and in agriculture, and it ended, in the twentieth century, with the tertiarisation of the economy.
- During industrialization, there was a dramatic productivity increase not only in the industrial sector, but also in agriculture, thanks to technological changes.
- During the entire period of industrialization, there was a dramatic increase in the standard of living.

Industrialization is not just a question of improved productivity in the industrial sector but rather a global – economic, social, and cultural – process

14.1 Introduction

Beginning with the early industrialization (Table 14.1), in Europe, about 300 years ago, huge advances in the sciences, industry, and medicine caused both an unprecedented population explosion and a tremendous increase in average human height. This complex interaction between technological improvements and acquired, reversible improvements in human biology is called techno-physio-evolution by Nobel Prize Laureate Robert W. Fogel (Fogel 2004). But why did the stature of Europeans, considered as an index of the biological standard of living, decrease during most of the eighteenth century? Why did North Americans and Australians remain quite tall (compared with Europeans) during industrialization? Why did the United Kingdom, the USA, and Australia, experience significant declines in height whereas Japan, France, and Sweden experienced the opposite? During the nineteenth century, were there significant differences in the height trends for men and women, and for white Americans and American slaves? As for anthropometric changes during the twentieth century, were there significant height differences between the populations of democracies and those living under totalitarian regimes? For 30 years, anthropometric historians have been exploring a variety of original data in order to answer these and other such questions and thereby create a more accurate portrait not only of Europeans but of the populations of all five continents.

14.2 Stature and the Other Economic and Demographic Historical Indexes

14.2.1 Stature and Other Economic Indexes

In the analysis of historical trends in well-being, mean height serves a double function. On the one hand, it obviates a reliance on extrapolations in the absence of standard indexes of the standard of living. For instance, it is nearly impossible to calculate per capita GNP or even real wages (i.e., wage estimates that take into account not only income but also the cost of living) for any eighteenth-century population; nineteenth-century women, because their domestic work is not included in GNP estimates; and for American slaves, since they earned no wages.

On the other hand, when estimates of GNP, per capita income, real wages, or other data are available, height data can complement the standard indexes; this is the case not only for "the early-industrial-growth puzzle" of Europe and the USA (Komlos 1998; Steckel 1998), and for

Table 14.2 Provincial differences in the quality of life according to three measures in the Netherlands, 1820–1913

	Real incomes			Provincial rankings			HDI		
	1820	1850	1913	1820	1850	1913	1820	1850	1913
Urban core	110	109	111	8	8.7	2.7	0.542	0.451	0.722
Noord-Holland	113	110	111	10	7	1	0.568	0.430	0.716
Zuid-Holland	107	109	113	9	9	3	0.522	0.482	0.722
Utrecht	109	107	108	5	10	4	0.537	0.440	0.726
High income agricultural	117	104	85	8.3	5.5	5.7	0.542	0.434	0.648
Groningen	113	94	82	8	4	7	0.526	0.398	0.638
Friesland	125	111	84	6	1.5	2	0.538	0.418	0.639
Zeeland	113	108	88	11	11	8	0.561	0.485	0.666
inland provinces	76	78	73	3.4	4.7	8.2	0.425	0.395	0.607
Gelderland	81	87	97	2	6	6	0.450	0.402	0.689
Overijssel	84	82	77	7	3	5	0.422	0.424	0.613
Noord-Brabant	70	76	69	3	8	11	0.397	0.348	0.606
Limburg	61	67	63	1	5	9	0.394	0.368	0.591
Drenthe	82	79	58	4	1.5	10	0.464	0.432	0.535
The Netherlands	100	100	100	3.4	4.7	8.2	0.489	0.421	0.649

Here the HDI includes per capita GDP, life expectancy at the age of one, infant mortality, the literacy rate and mean height. This HDI describes a decline in the quality of life of city-dwellers in the mid-nineteenth century. This decline is not reflected in per capita real incomes. The negative externalities of modern economic growth and the growing social inequalities that accompany the early stages of industrialization go far to explain this gap

"Real income" means income estimates that take into account the cost of living (index 100 = national average). HDI stands for Human Development Index, GDP for Growth Domestic Product. $N = 135$. The "negative externalities" of modern economic growth are urban pollution, factory labour, diseases, and other threats to biological well-being (Horlings and Smits 1998, with permission of Franz Steiner Verlag)

Table 14.3 Key facts of the HDI

1. The HDI usually comprises three measures of the standard of living: life expectancy, education, and per capita income.
2. It is a non-weighted average of these three measures.
3. It ranges from zero to one (the optimal standard of living).
4. It was created in 1991 by the United Nations.
5. It does not include the political dimensions of well-being (human rights).

Like human height, the HDI provides an alternative to the standard economic indexes

twentieth-century industrialized countries, but also for communist countries, whose official statistics are based on a GDP calculation different from that used by liberal economists, and whose published data are not reliable.

Thus, in the Dutch case presented here (Table 14.2), during the nineteenth century, the HDI (Table 14.3) includes per capita GDP, life expectancy at the age of one, infant mortality, the literacy rate and mean height, but it does not point to the same conclusions as per capita GNP. The indexes are well synchronized for the beginning and the end of the period under consideration. Nevertheless, the HDI describes a decline in the quality of life of city-dwellers in the mid-nineteenth century (compared with their previous position but also with the inland and high-income agricultural provinces), a decline that is not reflected in per capita real incomes. The negative externalities of modern economic growth (urban pollution, factory labour, diseases and other threats to biological well-being) and the growing social inequalities that go with early industrialization go far to explain this gap between the standard economic indexes and anthropometric ones.

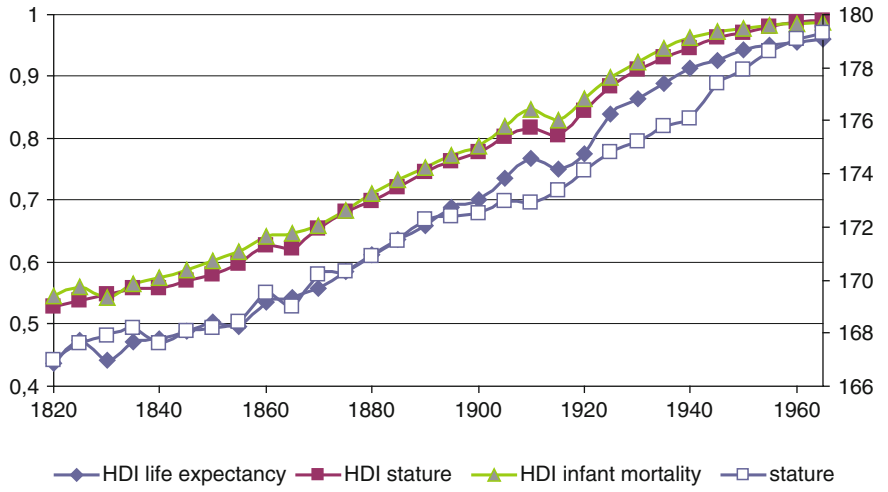

Fig. 14.1 Human development indexes (HDI) and stature in Sweden, 1820–1965. On the historical scale, stature is closely correlated with other demographic indexes such as life expectancy, mortality, and infant mortality. Thus, substituting here life expectancy at age one for stature or for infant mortality when calculating the HDI provides almost identical results throughout the course of industrialization. "HDI" means Human Development Index. "Stature" means mean height (cm), $N = 120$. (Sandberg and Steckel 1997, with permission of the University of Chicago Press)

Thus, the aim of anthropometric history is to identify height trends among populations defined by geography or social groups and to analyze these trends in terms of the standard indexes of economic history.

14.2.2 Stature and Other Demographic Indexes

For numerous reasons, stature is closely correlated with education: educated parents tend to take better care of their children during pregnancy and early childhood; they tend to provide their children with relatively abundant cultural and economic capital; their children are spared the hardships of physical labour and so on. The positive influence of education is noticeable even after control for income. In other words, the link between literacy and stature is of an economic as well as cultural nature.

On the historical scale, stature is closely correlated with other demographic indexes: life expectancy, mortality and infant mortality, which is a major component of the crude death rate and the life expectancy. Thus, the Swedish case presented here (Fig. 14.1) shows that substituting life expectancy at age one for stature or for infant mortality when calculating the HDI provides almost identical results for the entire 1820–1965 period, i.e., throughout industrialization. Stature can complement or even replace other demographic indexes. Anthropometric history was born of a debate over the cause of the decline in the mortality rate during industrialization: a debate between those who claimed that the causes were nutritional and those who claimed that they were epidemiological (Komlos 1998; Steckel 1998). Because of this lack of consensus, and for the sake of clarity, in Sects. 14.4 and 14.5, we present the determinants of height according to crude nutrition (energy input) and net nutrition (input minus the caloric expenditures caused by diseases, physical work, etc.).

14.3 Practical Methods and Techniques

14.3.1 The Data Used by Anthropometric History

Various problems arise when anthropometric historians process their data. Registers of convicts, migrant workers and (mostly eighteenth-century) army volunteers; nineteenth-century passports; nineteenth- and early-twentieth-century school surveys: all of these data sources are problematic because they are confined to one socio-economic group or another. Thus, the class composition of the sample must be compared with the closest census whenever possible. Furthermore, since prisons, military barracks and ships are especially crowded when times are hard, results have to be controlled for the year of measurement and the birth year, the category of the crime committed, etc. The use of statistical regression with several explanatory variables is one of the defining characteristics of anthropometric history.

Contrary to the above-mentioned sources, conscription registers, available in Europe since the end of the eighteenth century, provide information about nearly all of the men in a given birth cohort. Furthermore, there was a widespread problem of incomplete height records, partly on account of absenteeism, in France and Italy throughout the nineteenth century.

14.3.2 The Problem of the Minimum Height Requirement

Military sources pose a particular problem in the case of volunteer armies: the existence of a MHR, below which measurements are rarely recorded. Throughout the eighteenth century, the MHR and the mean height of a given population were nearly identical. The identification of the truncation point of the sample is made through visual inspection of the relevant distribution histograms, which are always expressed in the original unit of measure (Komlos 2004). Most of the statistical methods used when dealing with this problem are based on the assumption that stature follows a normal distribution pattern. However, the distortion of the curve on the left-hand side (over-representation of numbers below mean height due to bad living conditions, mainly during the AGS) makes it preferable to use, when possible, a method that does not pose the hypothesis of the Gaussian distribution and therefore does not lead to an overestimation of the mean height.

14.3.3 Anthropometric History and Auxology

Offering continuous and homogeneous serial data is one aim of historians. Thus observations are standardized, the age of subjects being limited from 23 to 49, as a rule. This policy raises auxological problems, since the AGS of all the subjects did not occur simultaneously and did not have the same amplitude that they would today, but instead varied according to the region, era, and group in question. As a result, the policy has been modified: measurements made during adulthood are now quoted according to the year of birth, since variations in adult height are best explained by living conditions in early childhood.

The maximum socio-economic influence on final height is experienced in the most intensive biological-growth periods: mostly in utero and in early childhood but also during adolescence. Nevertheless, stature is a synthetic index of the standard of living, whereas one knows precisely in which year a GDP or any other index is measured; correspondences between anthropometric and economic data must be made with great care.

Historians in certain fields include in their research an analysis of human skeletons belonging to pre seventeenth-century populations, unaccompanied by any corroborative written data. Thanks to such research the frontiers of anthropometric history now stretch from the Roman Empire by way of medieval Europe to precolonial America. The study of human skeletons remains, for now, a marginal aspect of anthropometric history.

14.4 Explaining Mean Height from the Historical Point of View: The Part Played by Inputs

Mean height can be considered as an index of net nutrition, that is, total nutritional input minus the energy expended on maintaining a basal metabolism, on physical effort and on disease resistance. Although biological and medical studies stress the importance of the synergy in this double process of input and caloric expenditure, historical studies depend on sources that provide explanatory variables only on the aggregate scale, thereby underestimating its importance. For the sake of clarity, we shall examine separately the respective roles of inputs and expenditures.

14.4.1 Stature, Income and Crude Nutrition

The close correlation between per capita income and mean height in the nineteenth and twentieth centuries underlines the positive influence of inputs on stature. Nevertheless, some populations have been taller than their per capita income would lead one to expect: chiefly, those of early-nineteenth-century Ireland and America; this anomaly was thanks to a protein-rich diet and a healthy environment, and therefore was not directly correlated with income.

The positive influence of crude nutrition has been proved in many cases, mostly in the eighteenth and nineteenth centuries. For instance in Italy, the increase of food intake explains 60% of the anthropometric growth between 1854 and 1913, whereas an improvement in environmental conditions generally explains 30% of this growth. In antebellum America, county-level records indicate a positive correlation between surplus food production and stature. This correlation was particularly evident in the peripheral states, which were not yet fully integrated into a nationwide market, and where, therefore, produce was still consumed locally. The positive effects of crude nutrition are confirmed when one adds to the equation the mortality variable, considered as an index of the quality of the epidemiological environment. At this point it becomes evident that crude nutrition and diseases have a synergic effect on stature.

During early industrialization, city-dwellers' nutrition was inferior to that of country dwellers, largely because the cost of transportation increased the cost of food. This discrepancy diminished in the second half of the nineteenth century, with the arrival of railways and, later, refrigerated cars and boats, which also made it possible for city dwellers to add perishable dairy products and more meat to their diet.

14.4.2 Anthropometric Convergence and Divergence

The study of anthropometric convergence and divergence among socially or geographically distinct groups allows one to test the economic theory of Kuznets, according to which social and geographic discrepancies during industrialization formed an inverted-U-shaped curve: at first relatively small;

they steadily increased, eventually levelled off, and then steadily declined. This pattern is found elsewhere as well; early in the industrialization process, an increase in income among the wealthiest part of the population translates into an increase in GNP, but has little or no influence on mean height. Since the quantity and quality of the food consumed by the well-to-do was already satisfactory, its increase did not translate into an increase in average height. On the other hand, even just a small increase in income among the lower classes is reflected in anthropometric measurements, because they used the money to purchase nutritious food, which had previously been beyond their means. Thus, the inequalities in the distribution of wealth which accompanied the rise of modern capitalism would seem to have translated into class-defined inequalities in stature. The British enclosure movement (eighteenth century), like the privatisation of communal lands in Saxony (early nineteenth century) and in Mexico and southern India (late nineteenth century), deprived peasants of essential nutritional resources and thus contributed to the decline or the stagnation in stature among the poorest portion of the British population at that time.

In the Belgian province of Liège, the height difference between the richest and the poorest reached a peak of 8 cm. in the first half of the nineteenth century and later declined, primarily because of a height increase among the poor. The same phenomenon occurred more or less simultaneously in the USA, the UK, and France. The discrepancy was particularly striking among children; the young son of an English lord would have had a 15-cm. height advantage over a street urchin like Oliver Twist. Height data for the early nineteenth century parallel income data; farm and textile labourers are the shortest, white-collar professionals are the tallest, and craftsmen are found somewhere in between. However, the proximity of nutrients still played a positive role, as testified by the fact that farmers and foodstuff traders were taller than their income would suggest.

Contrary to most techniques for measuring the standard of living, those of anthropometric history include the analysis of height trends according to gender, thereby elucidating patterns of energy input and caloric expenditure within the household. It seems that women are more sensitive to economic cycles than men, perhaps because of nutritional and other health-related discrimination, or perhaps because of an innate biological process of adaptation to deprivation. For instance, in Scotland in the 1840s, a decade marked by severe malnutrition, the average height of women steadily declined, whereas that of men, paradoxically, soared. The same phenomenon occurred among emancipated slaves in Maryland. In early-nineteenth-century Bavaria, the average height of women paralleled the unequal distribution of agricultural products among districts more closely than did that of men. However, there are at least two exceptions to this rule: in Australia in the first half of the twentieth century, and in nineteenth-century India, there was no discernible difference between the sexes when it comes to nutrition-related changes in average height. Unfortunately, since military files are the primary source of information available to anthropometric historians, data on women are scarce, and therefore a well-documented analysis of sex-specific height trends remains elusive.

14.5 Explaining Mean Height from the Historical Point of View: The Part Played by Energy Expenditures

14.5.1 Stature and Urbanization

As Rousseau and Dickens observed, the industrialization was especially hard on city dwellers, whose below-average caloric input and above-average caloric expenditure account for their below-average height. As the twentieth century approached, however, improvements in medicine and hygiene on

the one hand and a diminution in the physical hardships of industrial labour (tertiarisation) on the other resulted in a reversal of this trend.

During the early years of the industrialization, the European city was an environment with nothing but negative potential for physical human growth: lack of sewage systems and poor sanitation generally combined with overcrowded living conditions and child labour to create a disease-ridden, malnourished, physically diminished population. The fact that this was a world-wide phenomenon explains why nineteenth-century city-dwellers were shorter than their rural counterparts not only in the UK, but in Italy, Canada, Australia, Austria, Japan and the USA, as well.

There were some exceptions, but they were confined to countries where an archaic social structure persisted, where cities therefore could remain relatively small, and traditional trades were able to survive (this was the case in Spain, Germany, and Russia). The height decline among New Yorkers was, despite a dramatic increase in the city's population, less than that among residents of other American cities thanks to its dominant role in the national and international wheat market, which had obliged the establishment of an efficient system of food distribution as early as the 1850s.

In accordance with a fundamental economic principle, countries that are late to industrialize have an advantage over those countries that were pioneers, because they can learn from the pioneers' problems and remedies. This advantage is reflected in their citizens' superior rate of anthropometric growth. For example, Japan began to industrialize only after other, industrialized nations had instituted public-health policies and researchers had proven that germs caused the spread of infectious diseases; the average height of its population, therefore, did not decline (Fig. 14.5). This was also the case in Sweden, Germany, Austria, Hungary, Poland, the Iberian Peninsula, Italy and Argentina (Steckel 2009).

14.5.2 Stature, Diseases, Child Labour and Medical Care

Japanese prefectural records for the years between the two World Wars reveal direct correlation between improvements in health services and increases in stature. In the case of backward economies, such as that of early-nineteenth-century Sweden, even just a modest increase in public-health spending may have had beneficial effects, reflected in height statistics. In France during the latter half of the nineteenth century, as well as in the first half of the twentieth century in Japan, an increase in the number of midwives in a given region was directly correlated with an increase in average height. This correlation demonstrates the importance of good health care in early childhood and confirms the hypothesis that, during the first year of life, such care has a greater impact on growth than does crude nutrition.

The impact of energy expenditure is more difficult to quantify on a historical scale than is the role of nutritional input. Nevertheless, it seems that malaria and other diseases linked to irrigated agriculture played a role in the stagnation or decline in height that occurred in India and in South-East Spain during the nineteenth-century and in Burma during the rice boom at the end of the century.

In the USA, the fact that the steepest decrease in height occurred in the coal-producing states (mainly in the Midwest) in the 1870s–1890s could be explained by the spread of respiratory diseases. In the UK, the prevalence of tuberculosis, prior to the 1860s in towns and cities may have contributed to a height decline, and the fact that the subsequent eradication of tuberculosis was accompanied by a height increase may not have been merely coincidental. In Australia, the radical decline in stature during the 1890s may have been partly due to the many epidemics, including Melbourne's typhoid fever, that afflicted urban areas.

Finally, child labour may have a negative influence on stature but is very difficult to measure on the historical scale and offers little help to those anthropometric historians trying to solve the early-industrial-growth-puzzle.

14.6 The Early-Industrial-Growth-Puzzle

The social and economic history of the eighteenth- and nineteenth-century features the self-regulating relationship between population and resources, first described by Thomas Robert Malthus in 1798, on the one hand, and the more immediate human cost of the early industrialization on the other. In both matters, anthropometric history provides new evidence. It highlights two main periods during which height declined in Europe: the 1760s to the 1800s (Figs. 14.2 and 14.3) and the 1830s to the 1860s. This second decline extended to the USA, where it persisted into the 1890s.

14.6.1 The First European Decline in Height (Eighteenth Century)

The first period of anthropometric decline shows a considerable decrease in real wages (Table 14.4), and therefore in purchasing power, simultaneous with falling temperatures and a growing population. The decline in grain production, on account of cooler temperatures, not only caused an increase in the price of bread but also had a negative impact on cattle production. Because of increased productivity in the industrial sector (chiefly textiles), the price of manufactured goods increased at a slower rate than that of agricultural products, and, for instance in Great Britain, the price of grain-based products increased at a slower rate than that of meat. Grains, therefore, were substituted for meat, making for a diet poorer in animal protein and richer in carbohydrates. The price for this dietary shift – a secondary consequence of the early industrialization (chiefly the textile industry)– was a decrease in average human height; on the positive side, it permitted the population to increase without falling into the Malthusian trap, that of a massive population decline due to starvation and epidemic disease.

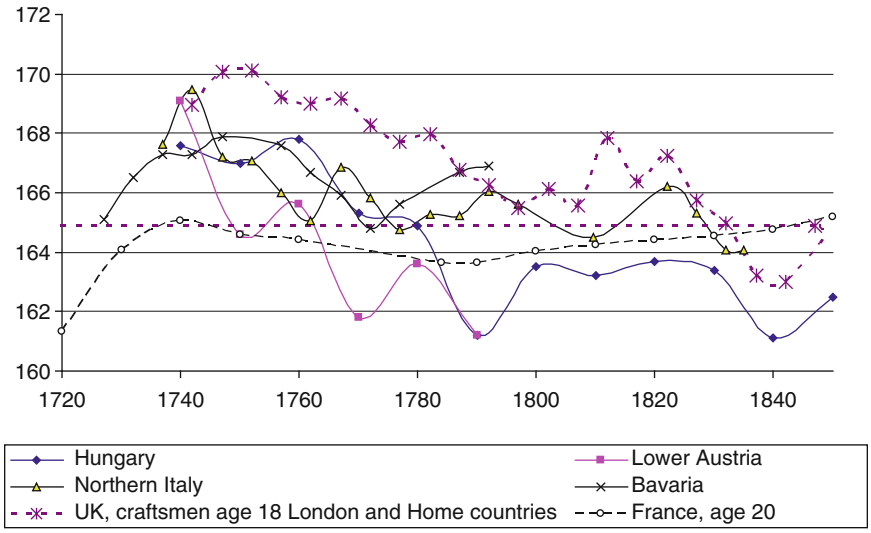

Fig. 14.2 The early-industrial-growth-puzzle in Europe, eighteenth–nineteenth centuries. During industrialization in eighteenth-century Europe, a decline in human height went in tandem with downward trends in real wages and in temperatures. A second decline occurred during the first half of the nineteenth century, in tandem with upward trends in GDP and in real wages, hence the phrase "early-industrial-growth puzzle." Mean heights, cm, $N = 83$. (A'Hearn 2003; Baten 1999; Cinnirella 2008; Komlos 1989 and 2003; Weir 1997)

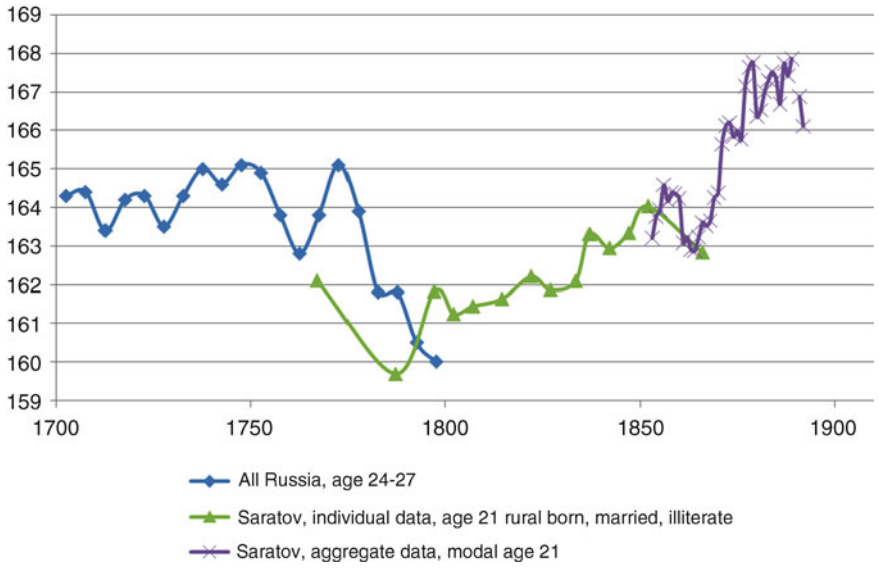

Fig. 14.3 Secular trend of stature in Russia, eighteenth–nineteenth centuries. Not unlike Europe, Saratov, a province of southern Russia, experienced a decline in height in the second half of the eighteenth century. Nevertheless, Saratov experienced no height decrease during the first half of the nineteenth century. Mean heights, cm, $N = 74$. (Mironov 2005; Mironov and A'Hearn 2008)

Table 14.4 Key facts of real income

- Income consists not only of wages, but also of all other sources of income (sales from domestic production, etc.).
- Income is real (as opposed to nominal) when income estimates take into account not only income but also the cost of living, i.e., prices.
- When nominal income increases more than nominal prices, then the purchasing power of the worker increases.
- When nominal income increases less than nominal prices, then the purchasing power of the worker, and hence his real income, decreases.
- The trend in real income depends mainly on which products are chosen for inclusion in the basket of products that is used to calculate whether there has been a change in nominal prices.

Real income is used to estimate the trend in the standard of living by taking into account the trend in prices

14.6.2 The Decline in Height in Europe and America in the Nineteenth Century

During the 3 decades preceding the Civil War, the height of Americans declined and their mortality rate increased, despite sustained economic growth. This paradox is known as the "Antebellum Puzzle" since it had not occurred during the first, European, period of decline, in the late eighteenth century. There was a significant decline in height at this time in the UK, as well, even as the early industrialization got under way: hence the phrase "early-industrial-growth-puzzle." Height declines were also recorded during the first half of the nineteenth century in Italy, Hungary, the Netherlands, Saxony, and some regions of France.

The solution to the Antebellum Puzzle may lie in the notion of net nutrition. Transcontinental migration may help generate wealth, but it also results in a loss of microbial resistance of the human bodies and therefore in the spread of cholera, typhoid, typhus, malaria, and dysentery, which shared

responsibility for both the declining height and the increasing mortality. An American county on a railway or on a waterway was able to profit thereby, but people living here were shorter, thereby confirming the hypothesis that height decreased on account of diseases that exploited the spreading network of transportation routes. In addition, the export to distant markets of meat products, high in protein that had previously been consumed locally had a negative effect on the nutrition, and therefore the height, of people living in peripheral regions.

The fact that only slaves maintained their stature suggests that height loss was primarily due to deficiencies in crude nutrition, for if the height loss were only epidemiological in origin, slaves' height, like everybody else's, would have declined on account of widespread diseases, whereas in fact the only blacks to register a height decrease were freed slaves. Adult slaves were a valuable commodity – their price rose by 64% relative to that of food – so (while slave children were kept undernourished, their diet improving only once they were old enough to work) their owners invested in the maintenance of their physical health.

Mexico and Canada experienced the same decline in height in the second half of the nineteenth century (in fact, Mexico's height decline extended into the twentieth century), although these countries were far less industrialized than the USA. Political turmoil helps to explain the Mexican trend; however the Canadian one is primarily due to urbanization. Australia is another example of a young country in which the development of towns, which as a rule is accompanied by a deterioration in sanitary conditions, led to epidemiological problems that account for the otherwise paradoxical phenomenon of declining height during a period of economic growth (Table 14.5 and Fig. 14.4). The extensive economic systems of three relatively young countries – the USA, Australia, and Canada – meant that at first most of their inhabitants enjoyed a high biological standard of living. Subsequently, at the end of the nineteenth century, urbanization and the development of national markets facilitated the spread of infectious diseases and thus led to decline in height, whereas in Europe height figures turned around after having hit, at mid-century, a record low.

Some Europeans countries were spared a major decline in height during the nineteenth century. France, where industrialization began relatively early and was not concentrated in big cities was the first country to experience the demographic transition, featured a new ability on the part of parents to invest in their children's health. Sweden, where industrialization had even less of an impact than in France, enjoyed an exceptionally high rate of literacy. Along with Denmark, nineteenth-century Sweden experienced no major decline in height.

14.6.3 The Trends in Height in Asia and Other Parts of the World in the Nineteenth Century

The decline in height did not extend beyond Europe and the USA; for instance, Saratov, a province of southern Russia, experienced no height decrease during the first half of the nineteenth century, nor did Argentina. This contradicts the standard, bleak image of postcolonial South America (Table 14.5). The same holds true for India (Table 14.5). Along with other demographic indexes, the stature index permits a reconsideration of the standard notion that the economic divergence between Europe and Asia dates as far back as the end of the eighteenth century. This pessimistic vision of Asia's socio-economic history, based largely on the estimations of economic performance presented by the famous economist Maddisson, has been reconsidered in light of the current acceleration of Chinese economic growth. Records reveal that during the first half of the nineteenth century, average height in southern China stagnated but did not decline (Table 14.5, Figs. 14.2, 14.4, and 14.5). It was only after the first Opium War (1839–1842), by means of which

Table 14.5 Key points of the decline in stature during industrialization in Europe, America, Asia, and Australia, eighteenth–twentieth centuries

Country	Decline in stature	Birth cohorts (approx. dates)	Amount of decline (cm)
Argentina	No	1785–1839 and 1916–1950	
Australia	Yes	1867–1893	3
Lower Austria	Yes	1730–1799	7,9
Belgium (Liège province)	Yes	1800–1869	1.2–3.5 (local estimates)
Burma			
Lower Burma	Yes	1868–1882	2.1
Upper Burma	No	1848–1882	
Canada	Yes	1800–1899	Ill-defined
China	Yes		
southern part		1840–1859	1.5
		1860–1879	1.4
Denmark	No	1830–1962	
France	Yes	1717–1724	2.6
		1741–1760	1.5
Mulhouse (Alsace)		1796–1821	1.2
Limousin (central part)		1790–1799	2.7
Brie (near Paris)		1781–1793	1.9
		1852–1879	1.3
Germany	Yes	1705–1744	4
Saxony		1750–1763	1.2
		1770–1784	1.1
		1780–1839	8.1
Bavaria		1750–1779	2.7
Württemberg		1860–1872	2.5
		1879–1885	2
Hungary	Yes	1740–1799	6.8
Age 21–22		1820–1849	2.6
India	No	1794–1899	
Italy (northern part)	Yes	1740–1779	4.7
		1790–1819	1.6
		1820–1834	2.1
Japan	No	1872–1965	
Mexico	Yes

(Women)	Yes	1790–1815	2.5
		1835–1855	2.5
US	Yes	1830–1890	4

A'Hearn (2003), Alter et al. (2004), Bassino and Coclanis (2008), Bassino (2009, personal communication); Baten (1999); Boldsen and Søgaard (1998); Cinnirella (2008a, b); Cranfield and Inwood (2007); Drukker and Tassenaar (1997); Heintel et al. (1998); Heyberger (2005); Komlos (1989, 2003); Martínez Carrión and Pérez Castejón (1998); Mironov (2005); Mironov and A'Hearn (2008); Morgan (2009); Olds (2003); Salvatore (1998, 2009); Steckel and Floud (1997); Wheatcroft (1999); Whitwell et al. (1997)

Almost all countries experienced a decline in height during industrialization, $N = 30$ countries or regions. The decline is reported if exceeding 1 cm. On the historical scale, populations can gain – or lose – on average 1–1.5 mm per year. If the answer in col. 2 is "No," dates in col. 3 refer to the extreme dates of the quoted study

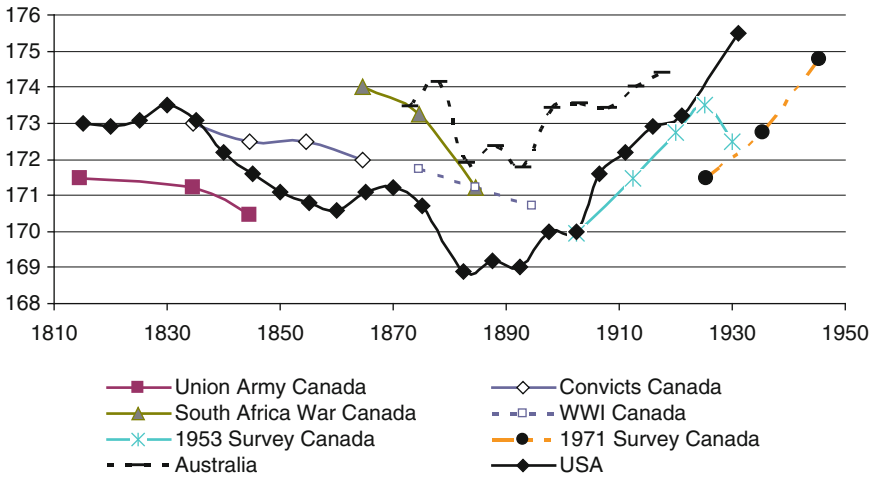

Fig. 14.4 The Antebellum Puzzle in "young countries", nineteenth–twentieth centuries. During the nineteenth century there was a decline in height caused by urbanization and the development of national markets not only in the USA, but also in Canada and Australia. This height decline occurred in spite of improvements in the standard of living, whether it was measured in terms of real wages, of income, or of GDP: hence the phrase "Antebellum Puzzle." Mean heights, cm, $N = 75$. (Cranfield and Inwood 2007; Steckel 1991; Whitwell, de Souza, Nicholas 1997)

the British forced China to open its ports to foreign trade, that stature started to decline. However, this decline was not directly due to the intrusion of foreigners, as Marxist historians would have it, but rather to chronic social unrest in southern China throughout the second half of the century. Northern China was one of the few regions worldwide that experienced a height decline between the late 1890s and the late 1920s. An increase in income in northern India, due to the opening of the market during the third quarter of the century, was reflected in a height increase, which slowed down slightly toward the end of the century and then stagnated until the 1950s, as the population expanded (Brennan et al. 1994, 1997). Then the late period of the British colonization did not provide any improvements in the biological standard of living.

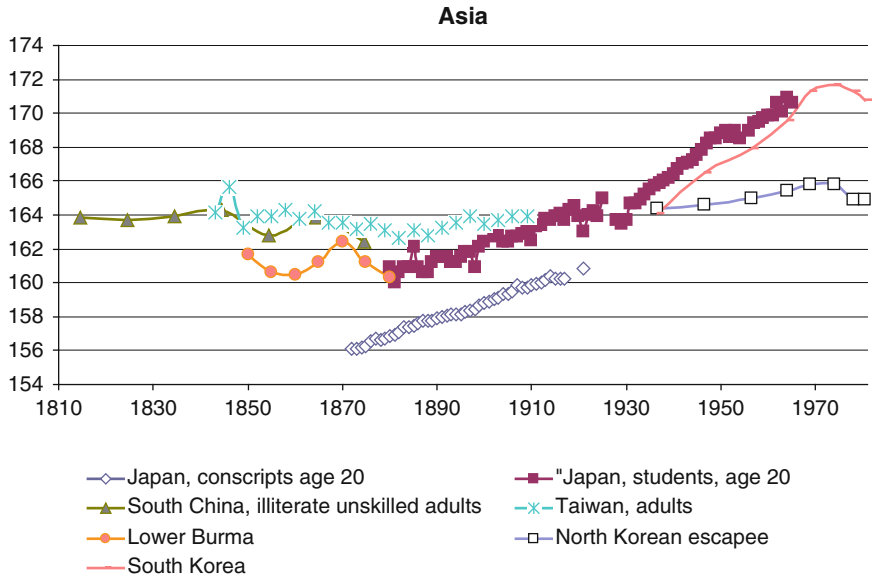

Fig. 14.5 Secular trend of stature in Asia, nineteenth–twentieth centuries. During the nineteenth century Asia, unlike Europe and America, experienced no major decline in height. However, in the second half of the twentieth century there was a secular upward trend in height throughout Asia, with the exception of North Korea. Mean height, cm, $N = 233$. (Bassino and Coclanis 2008; Bassino 2009, personal communication; Morgan 2004,2009 ; Olds 2003; Pak 2004)

14.7 Anthropometric History of the Twentieth Century: Political Issues

The economic history of the twentieth century is primarily about governmental, public policy, not private-business cycles. Anthropometric history can help to expose the truth about Nazism, communism, colonialism, liberalism: ideologies that boasted of their successes on the standard-of-living front. Data used to be derived primarily from registers or studies of adults; now, most data are on children and adolescents and are more abundant than previous data, thanks to the records kept by primary and secondary schools, which are more numerous than ever. The height of a child or an adolescent is in the short term a far more sensitive indicator of biological well-being than is the height of an adult. Thus, height data on children and adolescents provides the most accurate gauge of the success of public-health policies of the countries under study.

The purpose of historical research is not to justify injustice –or justice-. The height of American slaves in the nineteenth century does not make slavery any less immoral. In the same way, the deterioration of anthropometric indexes, which is much more notable during the economic crisis of the first 30 years of the USSR than during the smaller – but equally disastrous – Nazi economic autarchy of the 1930s, cannot be used to assess a so-called superiority of one model over another.

14.7.1 Trends in Height in the Major Western Liberal Democracies

In the Western world, the agricultural depression of the years 1873–1896 caused anthropometric indexes to decline but this was not, surprisingly, the case with the Great Depression for the major Western liberal democracies – the USA, the UK, and France – in spite of the emergence of a new

scourge: mass-unemployment. One explanation is the fact that these three countries had invested in improved public-health policies in the late nineteenth century, providing their citizens with a socio-medical safety net, albeit a minimal one. Such investments are not included in the GDP of the 1930s: hence the lag between standard indexes and anthropometric ones, which measure the standard of living. Argentina provides a similar example: a decline in the cost of food helps explain a height increase during the 1930s, in contrast with the subsequent Peronist years. Again, anthropometric indexes provide a historical perspective that raises questions about the adequacy of standard ones.

14.7.2 Trends in Height in Totalitarian and Authoritarian Regimes

In contrast, children, adolescents or even – more rarely – adults suffered a height decrease during the 1930s in the following countries: the USSR, with its planned economy; Germany, because of the Nazi autarchy; Spain, where the Civil War raged; and Japan, engaged in expansionist military actions. This was also the case for the 1940s and 1970s, as far as the USSR is concerned. Nevertheless, the standard economic indexes paint a rather rosy picture of these countries, not very different from that of the positive political propaganda of the time. Mao's Great Leap Forward (1958–1961) was accompanied by a decline in the height of adolescents that persisted until 1965: scarcely surprising in light of the fact that the resulting famine claimed around 30 million victims.

14.7.3 Anthropometric History and Colonialism

The height of Koreans declined during the 1920s, when the country was under Japanese colonial rule and a considerable amount of its rice was exported to Japan. In contrast, Taiwan actually recorded a height increase during the first years of Japanese rule; this may be because of Japanese efforts to improve sanitary conditions, in an effort to stamp out malaria. Australia offers a simpler scenario: the height of male Aborigines, relegated to the fringes of society, and confined to camps, stagnated at the beginning of the century, whereas the height of whites increased.

14.7.4 The Second Half of the Twentieth Century: Anthropometric History, the Welfare State and the End of Communism

During the twentieth century, the geographical and class patterns in human heights that marked the nineteenth century began to blur. In early-nineteenth-century Great Britain, the working class was on average five inches shorter than the upper class; this gap has narrowed to one inch. After the Second World War, Southern Europe (Greece, Italy, the Iberian Peninsula) caught up with Northern Europe (Austria, Belgium, Denmark, Finland, Ireland, Sweden), despite the fact that the latter continued to experience a height increase. The rise of the welfare state meant a reduction of inequalities and thus a record-breaking adult height in Scandinavia; its demise in the USA helps to explain the current obesity epidemic there.

In Russia, the transition from communism to capitalism had negative consequences, reflected in the anthropometric indexes for babies born shortly after the dissolution of the USSR, in 1991. This

phenomenon, very rare in the twentieth century, confirms the idea of a chaotic Russian transition in contrast with the better-managed Chinese one, a pairing popularized by Nobel Prize Laureate Joseph Stiglitz in *Globalization and Its Discontents* (2002). At the same time in North Korea, one of the few communist countries still in existence, the anthropometric indexes of children began to decline after having held their own for several decades, in sharp contrast with similar indexes for South Korea, despite the fact that the two populations share one genetic heritage (Fig. 14.5).

The life sciences and anthropometric history have much to gain by increasing their cooperative efforts. The life sciences can provide data on a vast array of contemporary socio-economic determinants of height. In turn, anthropometric history can provide historical data that offer new perspectives on current socio-economic policies: not only their causes, but also their possible consequences (Steckel 2009).

Summary Points

- An index of the biological standard of living.
  Contrary to the standard indexes of the standard of living such as per capita Growth Domestic Product, consumption, and wages, the mean-height index helps to account for the negative externalities of modern economic growth. The mean-height index is especially useful when it comes to analyzing eighteenth- and nineteenth-century populations for which indexes are either unreliable or simply nonexistent.
- The existence of the Minimum Height Requirement (MHR) represents the main statistical difficulty that anthropometric history has had to overcome. Reliable methods of analysis are now available to resolve this problem.
- Not only overall income and food-consumption levels, but also their distribution among social and ethnic groups and between the sexes must be taken into account –whenever possible- in any analysis of height trends in a given population over the course of history.
- The high price and scarcity of nutritious food, overcrowded and unsanitary housing, spreading diseases, and inhuman labour conditions go far to explain the decline in average height among city dwellers during the early years of the industrialization.
- During the second half of the eighteenth century, as a result of mounting population pressure and falling temperatures affecting European countries' mainly agrarian economies, the height of Europeans declined. However, the direst consequences of the population principle proposed by Malthus were not realized, thanks to certain beneficial aspects of the early industrialization but at the cost of malnutrition caused by a decline in the nutritional quality of most Europeans' diets.
- Whereas the standard economic indexes emphasize a steady improvement in the first half of the nineteenth century, the stature of Americans and Europeans declined; this is the human cost of the early industrialization, paid by city-dwellers as well as their rural counterparts. At the same time, heights in China and India remained constant.
- Under twentieth-century totalitarian and authoritarian regimes, children and adolescents paid the human cost of the political decisions made by dictators. This was the case in Hitler's Germany, Stalin's USSR, and Mao's China.

Acknowledgments I thank Jean-Pascal Bassino for providing data for Japan (Fig. 14.5), Francesco Cinnirella for providing data for England (Fig. 14.2), Edwin Horlings and Jan-Pieter Smits for their permission to publish Table 14.2, John Komlos for providing data for eighteenth-century France (Fig. 14.2), Gilles Postel-Vinay for providing his unpublished paper, Julie Smith and Laurent Tourrette for the English translation, and the University of Chicago Press and Franz Steiner Verlag for their permission to publish Fig. 14.1 and Table 14.2.

Tools and Techniques in Anthropometry: Water, Hydration and Surface Area

Chapter 15
Total Body Water in Health and Disease: A Look at End-Stage Renal Disease

Luigi Vernaglione, Carlo Lomonte, and Carlo Basile

Abstract Methods for determining body composition have improved over the past 20 years, greatly increasing the accuracy and ease of making these measurements. Body composition measurements may be useful in the clinical management of patients suffering from several diseases such as obesity, diabetes, metabolic syndrome and renal failure.

The measurement of body composition may include direct or indirect measurements of total body water (TBW), body fat mass (FM), fat-free body mass (FFM) and bone mass, and sometimes of the distribution of fat between the visceral or subcutaneous compartments. The choice of method depends on which of these compartments is of interest, whether the measurement is for clinical purposes or research, and the degree of precision that is required. For the purposes of anthropometric measurement, for estimating adiposity, fat distribution and body composition, together with densitometry, isotope dilution, impedance measurement and imaging techniques are now available.

For practical reasons, the direct measurement of body composition is essentially limited to research centres. For general uses, indirect methods of predicting body composition, such as the development of regression equations or the bioelectrical impedance analysis (BIA), have been based on anthropometric variables or electrical measurements. In the case of end-stage renal disease, TBW assessment by means of BIA has three main targets: (a) assessment of the body dry-weight; (b) evaluation of the nutritional status (considering TBW together with FM, FFM and body cell mass); (c) calculation of the dialysis adequacy.

Currently available guidelines have underlined the need for sensitive measures of both nutritional and hydration status to prevent malnutrition and oedema in kidney patients; BIA represents an attractive clinical tool to detect early changes in body composition in this clinical setting.

15.1 Introduction

Methods for determining body composition have improved over the past 20 years, greatly increasing the accuracy and ease of making these measurements. Body composition measurements may be useful in the clinical management of patients suffering from several diseases such as obesity, diabetes, metabolic syndrome and renal failure. This paper will review body composition and the methods available for its measurement. Moreover, the evaluation and the clinical significance of measuring total body water (TBW) in normal subjects and renal patients will be discussed (Table 15.1).

15.2 Models of Body Composition

Body composition can be viewed from five perspectives (Wang et al. 1992):

15.2.1 Atomic Composition

As reported in Table 15.2, in normal subjects weighing 70 kg, oxygen, carbon, hydrogen, nitrogen, calcium, phosphorous, sulphur, potassium, sodium, chlorine and magnesium account for more than 98% of body mass, while less than 2% is contributed by the other 44 elements that are present.

15.2.2 Molecular Composition

More than 100,000 chemical compounds can be identified in the human body, ranging from simple to very complex; water, lipid, and protein are the major components (Fig. 15.1).

Table 15.1 Key features of assessing body composition in health and renal diseases

1. The assessment of body composition covers an important role in establishing nutritional and hydration status both in health and disease
2. Regression equations based on anthropometrical parameters (age, gender, BW, H) have been developed, in healthy people, to predict the body composition
3. Ease of determination, cost and accuracy make BIA a useful tool for assessing body composition. The assessment of body composition by BIA in healthy subjects has allowed the development of estimating equations and the *RXc*-graph method setup
4. Complex changes in body composition occur in patients with kidney diseases of various degrees.
5. Once the patients have started the dialysis the DW, the dialysis adequacy and the nutritional needs can be at least approximately established by means of BIA appropriately performed

This table lists the five main points that will be treated in the chapter

Table 15.2 Atomic composition of the body

	%
Hydrogen	10
Oxygen	61
Carbon	23
Nitrogen	2.6
Calcium	1.4
Phosphorus	<1
Potassium	
Sodium	
Chlorine	
Magnesium	
Other	2

This table lists all the atomic components of the body reported as percentage of the total. Data are considered for a normal subject weighing 70 kg

- Water represents about 60% of the normal male (and 50% of the normal female), of which approximately 26% is extracellular (ECW) and 34% intracellular (ICW).
- Body fat ranges from less than 10% in well-trained athletes to slightly over 50% in obese patients. Two to three percent of lipids in fat are essential structural lipids; the remainder are fat stores.
- Proteins represent 15% of normal body composition.
- Minerals comprise 5% of normal body composition.

Thus, water, lipid, protein, and minerals account for 99.4% of the molecular constituents of the body.

15.2.3 Cellular Composition

The body is composed of cell mass, extracellular fluid, and extracellular solids. Fat cells, osteoclasts, osteoblasts and the cellular elements of blood are components of connective tissue. Muscle cells include skeletal muscle, smooth muscle, and cardiac muscle. Epithelial cells include the cells lining a hollow viscus. The potassium content in the body is the most widely used indicator of body cell mass (BCM) because potassium is the principal intracellular cation (Maynard et al. 2001).

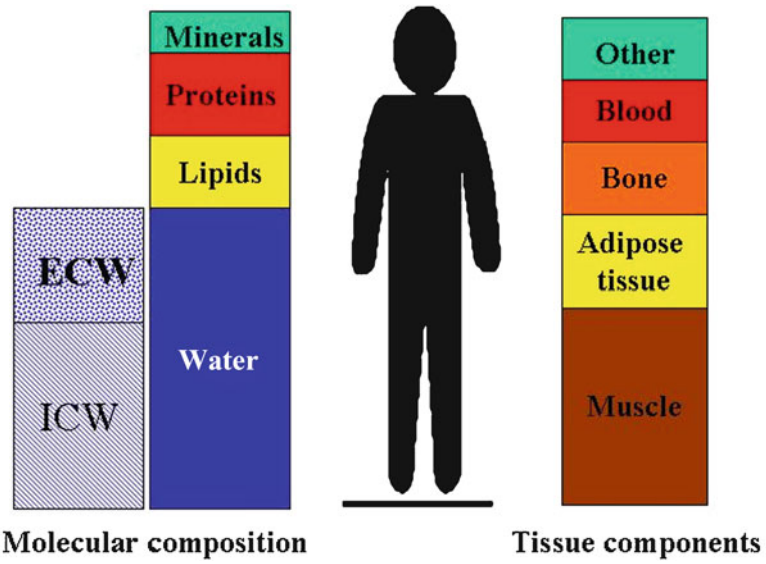

Fig. 15.1 Molecular composition and tissue components of a normal subject weighing 70 kg. More than 100,000 chemical compounds can be identified in the human body, ranging from simple to very complex; water, lipid, and protein are the major components Body weight (BW) represents the sum of the muscle tissue, connective tissue, epithelial tissue, and nervous tissue. Bone, adipose tissue and muscle make up 75% of BW

Extracellular fluid is approximately 94% water distributed into the plasma, in the intravascular space, and the interstitial fluid in the space outside the vascular compartment. Plasma and interstitial fluid account for approximately 5% and 20% respectively, of body weight in normal subjects.

15.2.4 Tissue Components

Body weight (BW) represents the sum of the muscle tissue, connective tissue, epithelial tissue, and nervous tissue. Bone, adipose tissue and muscle make up 75% of BW (Fig. 15.1).

15.2.5 Whole Body

The whole body represents the final perspective on body composition. There are at least ten different components of the whole body that may be measured, including stature, segment lengths, circumferences, skin fold thicknesses, body surface area, body volume, BW, body mass index (BMI) and body density.

15.3 Practical Methods and Techniques of Measuring Body Composition

The measurement of body composition may include direct or indirect measurements of TBW, body fat (FM), fat-free body mass (FFM), and bone mass and sometimes of the distribution of fat between the visceral or subcutaneous compartments. The choice of method depends on which of

Table 15.3 Instrumental methods for assessing body composition

	Cost	Ease of use	Accuracy	Can measure regional fat	External radiation
Hydrodensitometry	Low	Easy	High	Not	
Plethysmography	High	Easy	High	Not	
DEXA	Moderate	Easy	High	Yes	Trace
Isotope dilution	Low	Moderate	High	Not	
BIA	Low	Easy	High	Yes	
K40 counting (^{40}K)	High	Difficult	High	Not	
CT scan	High	Difficult	High	Yes	Moderate
MRI scan	High	Difficult	High	Yes	
Neutron activation	High	Difficult	High	Not	High
Ultrasound	Low	Moderate	Moderate	Yes	

This table lists the costs, the ease of use, the accuracy, the possibility to measure regional fat and the need of radiation of the instrumental methods mostly employed for assessing body composition

these compartments is of interest, whether the measurement is for clinical purposes or research and the degree of precision that is required. Table 15.3 reports the most commonly used methods for determining body composition subdivided according to ease of determination, cost, accuracy, use of radiation and utility for assessing regional body fat.

15.3.1 Anthropometric Measurements

15.3.1.1 Estimates of Adiposity

Height (*H*) and BW are the most commonly measured parameters and can be determined with great accuracy. BW is the easiest measurement of body composition but it does not differentiate between FM and FFM. The overweight is characterized by a rise in BW by 20–40% of the standard values for age and height (*H*); BW higher by 40–100% than standard values configures moderate obesity; severe obesity is defined by a rise of BW above 100% of standard values. Several indices have been proposed to relate *H* and BW; at the present time, the most widely used are BMI, weight-for-height, triceps skin fold thickness (TSF), and waist circumference or waist-to-hip ratio (WHR). BMI is the current standard measure of obesity; waist circumference and WHR are used primarily for research purposes.

The BMI is the most practical way to evaluate the degree of excess BW. It correlates with FM and is relatively unaffected by *H*. It is calculated from the ratio of BW (kg) to the square of the *H* (m^2). BMI varies with age and gender. BMI is a good predictor of adiposity in a healthy population (Maynard et al. 2001). However, BMI is not a direct measure of adiposity, and may slightly overestimate fatness in subjects who are short or have a relatively high muscle mass.

BW-for-*H* measurement is another means to assess adiposity and is the preferred method for clinical assessment of obesity or failure to thrive in children younger than 2 years. Overweight, simple obesity and morbid obesity are sometimes defined as BW-for-*H* measurement greater than 110, 120, and 140 percent of the expected, respectively (Kuczmarski et al. 2000). For children older than 2 years, BMI has replaced BW-for-*H* estimates as the standard measure for adiposity because BW-for-*H* measurements do not correlate well with FM and are affected by *H* to a greater degree.

15.3.1.2 Fat Distribution

The most widely used measure of regional fat distribution is the waist circumference, the WHR or the ratio of waist circumference to the *H* (WHT). Recently the waist circumference has replaced the ratio because it is easier to measure. Waist circumference >102 cm in men or >88 cm in women is indicative of central adiposity. It is measured just above the uppermost lateral border of the right ilium, at the end of a normal expiration. The hip circumference is measured in a horizontal plane at the level of maximum circumference of the hips and buttocks. Men with a WHR of 0.95 or more and women with a WHR of 0.85 or more are considered to be at increased cardiovascular risk. The WHT is another measure of abdominal adiposity that has been associated with cardiovascular risk. Analysis of the data from NHANES III indicates that the WHT may be a better predictor of increased low-density lipoprotein cholesterol, total cholesterol, and fasting triglycerides than BMI in children aged 4–17 years (Kahn et al. 2005).

15.3.1.3 Body Composition

The most widely used anthropometric measurements to assess body composition are the TSF and the mid-upper arm circumference. The TSF reflects body fat and the mid-upper arm cross-sectional area reflects FFM. As the precision and reproducibility of these measures is low, they add little to the clinical evaluation for most patients (Campanozzi et al. 2008).

Measurements of skin fold thickness are used widely because the technique is non-invasive, inexpensive, and easy to perform. However, measurements of skin fold thickness often are less accurate than are measurements of *H* or BW, particularly in obese subjects (Watts et al. 2006). This kind of measurement may be useful in the long-term monitoring of nutritional therapy in subjects who are malnourished, have diseases that are associated with changes in body composition, or are obese (Mascarenhas et al. 1998).

The mid-arm muscle circumference (MAMC) is mostly used in children. It can be calculated from the TSF and mid-arm circumference (MAC) as follows:

$$\text{MAMC} = \text{MAC} - (3.1416 \times \text{TSF})$$

The measured values for TSF and MAC and the calculated MAMC are compared with reference values (Frisancho 1981). Values less than the fifth percentile for age are consistent with acute malnutrition, and values greater than the 90th percentile are consistent with obesity.

15.3.2 Densitometry

The underwater weighing is the oldest method for determining body density; it is mostly performed in children and has been largely replaced by dual energy absorptiometry (DEXA) (see below). Body density is estimated from the BW of the subject in air and water, using appropriate correction factors for temperature, air in the respiratory tract and constants for the densities of FM and FFM (Moore et al. 1968).

15.3.3 Isotope Dilution

Along with densitometry and DEXA scanning (see below), isotopic dilution provides the most accurate assessment of FM. In this technique, the volume of a body compartment is determined by

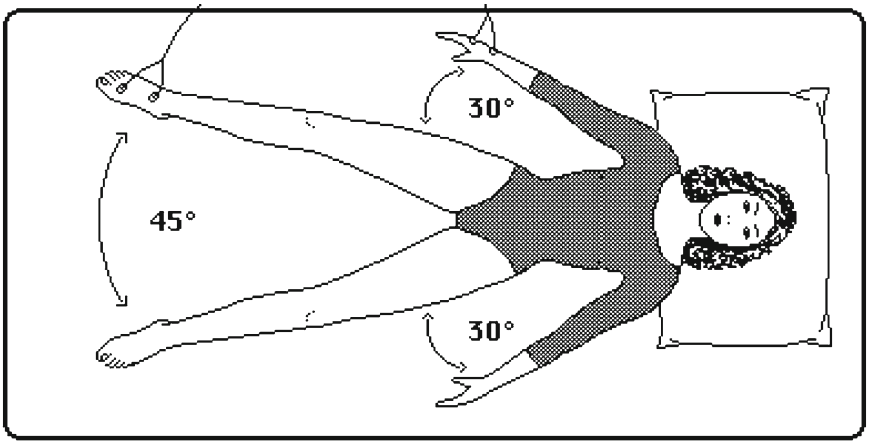

Fig. 15.2 Position of the subject undergoing BIA. The arms should form an angle of 30° with the trunk and the legs should be open with an angle of 45° (see the text for further information)

the ratio of the dose of a tracer, administered orally or intravenously, to its concentration in the body compartment after a sufficient equilibration period has elapsed. TBW, as an example, is estimated by isotope dilution using the stable isotopes of deuterium ($_2H_2O$) or oxygen ($H_{218}O$) (Schoeller et al. 1980). Once the TBW has been determined, the FFM of the body can be calculated, based on the assumption that the hydration of lean tissue is constant across a broad range of ages and for both genders. Isotope dilution is impractical in the clinical setting because of the expense of the stable isotopes and the analytical equipment.

15.3.4 Impedance Measurement

Bioelectrical impedance analysis (BIA) relies on electrical current to measure the FM and FFM of the body (Ellis 1996). The lean tissues of the body, because of their dissolved electrolytes, are the major conductors of electrical current, whereas body fat and bone are relatively poor conductors. The impedance to electrical flow is directly proportionate to the amount of fat and indirectly proportionate to the amount of lean tissue in the body. BIA frequently is used because it is non-invasive, portable and inexpensive. However, small changes in body water result in large differences in the estimate of FFM. In addition, the placement of the electrodes is site-specific and can compound errors of measurement. It should be measured in standardized conditions (quiet environment, ambient temperature of 22–24°C and after being at rest in the supine position for 20 min) by applying electrodes to one arm and one leg on the same side of the body, injecting 800 μA and 50 kHz alternating sinusoidal current with a standard tetra polar technique (Fig. 15.2) (Basile et al. 2008). Impedance is proportional to the length of the conductor and inversely related to the cross-sectional area of the conductor. Accuracy in placement of electrodes is essential because even small variations can cause relatively large errors in the measurement of impedance and corresponding errors in the estimate of TBW considered as the sum of intra- and extracellular body water.

A variety of formulae has been developed to convert the impedance which measures TBW into an estimate of fat. Most formulae for estimating fat from BIA underestimate fat as FM increases (Chumlea et al. 2001). The error in this procedure is similar to that obtained by measurements of skin

fold thickness or *H*/BW indices. However, the relatively low cost of the equipment and the ease with which impedance can be measured have led to its use in a variety of clinical settings (end-stage renal disease, over-/under-nourishment and obesity).

15.3.5 Air-Displacement Plethysmography

Air-displacement plethysmography is a method of determining lean body mass. Using the same whole-body measurement principle as underwater weighing, air-displacement plethysmography measures a subject's mass and volume, from which the whole-body density can be determined. The subject is placed inside the device; computerized pressure sensors then determine the amount of air displaced by the subject's body. FM and FFM can then be calculated (Fields et al. 2005).

15.3.6 Imaging Techniques

15.3.6.1 DEXA

The introduction of photons or low energy X-rays for the measurement of differential energy absorption by tissues has replaced densitometry as the best method for determining body composition. DEXA estimates FFM, FM and bone mineral density by using the differential absorption of X-ray or photon beams of two levels of intensity. DEXA relies on the principle that the intensity of an X-ray or photon beam is altered by the thickness, density, and chemical composition of an object in its path (Lukaski 1993). The precision of DEXA (coefficient of variation) is less than 2%, and it is becoming more readily available in the clinical setting.

15.3.6.2 Magnetic Resonance Imaging (MRI) and Computed Tomography (CT)

MRI or CT can be used to measure visceral adipose tissue in a research setting. The technique usually quantifies adipose tissue in a single-slice cross section at the level of the L4/L5 lumbar disc. The subcutaneous fat (outside the abdominal musculature) may be measured in the same image. These measures of visceral adiposity correlate with insulin resistance, triglycerides, hepatic steatosis and other components of the metabolic syndrome (Taksali et al. 2008).

15.3.7 Neutron Activation Analysis

Body composition techniques, such as electrical impedance, tracer dilution, and DEXA provide information related to tissue density or volume but not chemical content. In contrast, neutron activation analysis allows the direct elemental analysis of the body. Virtually all the major elements of the body can be assayed in vivo: hydrogen, oxygen, carbon, nitrogen, calcium, phosphorus, sodium, chlorine and potassium. The method uses the principle that exposure to a given dose of neutrons generates a known amount of radioactivity within a given mass (Heymsfield et al. 1993). The use of this technique is limited by its expense and radiation exposure.

15.3.8 Total Body Potassium

Total body potassium count, another method that determines elemental composition, measures the content of radioactive potassium ($_{40}K$) in the body while the subject lies between detectors in a well-shielded metal counting chamber (Ellis and Nichols 1993). Radioactive potassium emits a characteristic high-energy gamma ray that in turn serves as a marker for total body potassium, BCM and FFM. Although this method is non-invasive and safe, the limited availability of the instrument renders this method impractical in the clinical setting.

15.4 Applications of Body Composition Measurement in Health and Disease

The measurement of body composition has been assuming greater importance in assessing nutritional and hydration status in both health and disease. Direct measurement, however, is essentially limited to research centres due to practical reasons. For general uses indirect methods of predicting body composition have been based on one or more anthropometric variables. The calculation of whole body composition is essential both in determining and adjusting the TBW values obtained with the different tools that will be discussed below.

For example, Moore et al. (Moore 1963) used multiple-isotope methods in healthy adult subjects of normal *BW* to develop regression equations for calculating body composition. These equations, based on sex, BW and age, predicted TBW with correlation coefficients of 0.61 for males and 0.65 for females. In 1969, Hoeffer et al. (Hoeffer et al. 1969) demonstrated a tight relationship between whole body BIA and TBW and suggested further development of this potentially useful clinical tool. Thus significant relationships between BIA and hydrodensitometry, TBW and total body potassium determination have been reported with the possibility of developing predictive formulae for assessing TBW, FM, FFM and BCM from BIA (Segal et al. 1985).

The accurate measurement of TBW is difficult, requiring isotopic dilution techniques which are not easily applicable to the clinical setting. BIA is a non-invasive method of body composition analysis. Impedance is represented with a complex number (a point) in the real-imaginary plane (*Z* vector) that is a combination of resistance (*R*) (i.e., the opposition to flow of an alternating current through intra- and extracellular ionic solutions, representing the real part of *Z*) and reactance (*Xc*) (i.e., the capacitive component of cell membranes and organelles and tissue interfaces, representing the imaginary part of *Z*) (Ellis 2000; Kushner 1992). Thus, *R* is low for blood, urine and muscle but high for adipose tissue, bone and air, which contain little or no fluid or electrolyte ions (Kushner 1992). For a constant signal frequency (at 50 kHz), the electrical impedance of a conductor is proportional to the specific impedance (Ohm × *m*) multiplied by the length and divided by the cross-sectional area of the conductor (Piccoli 1998; Di Iorio et al. 2004). Since current tends to follow the path of least resistance, measured *R* correlates most strongly with TBW and correlations decrease for other body composition components, depending on the amount of water in these components. In the human body, more than 90% of the measured impedance is composed of *R*. For this reason, most BIA applications use *R*, rather than impedance, to predict body composition (Sun et al. 2003). TBW measured by BIA is highly correlated with TBW measured by the isotopic dilution techniques (Hannan et al. 1994).

Based on these assumptions it is clear that BIA done on healthy subjects has been performed in order to derive an equation for predicting body composition in patients suffering from several diseases. For example, vector BIA (*RXc*-graph method) is a pattern analysis of direct impedance

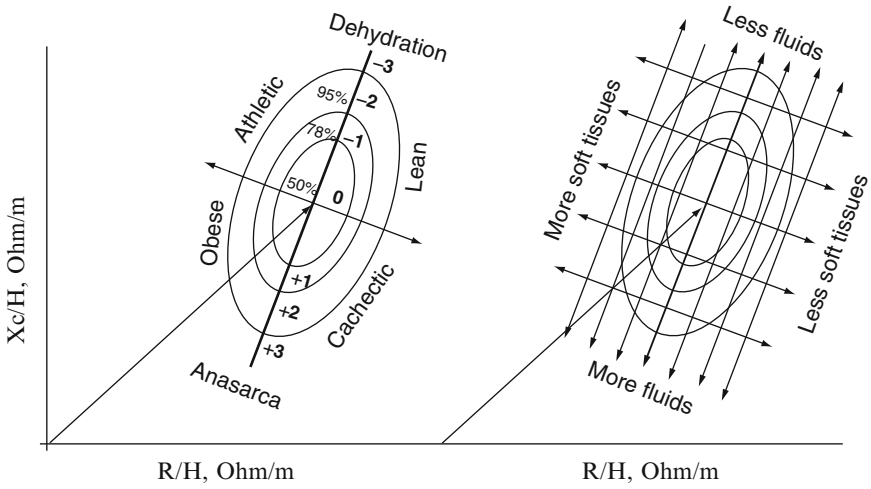

Fig. 15.3 BIA *RXc* graph. The ellipses represent the normal population variability (50%, 75%, and 95% of cases). The association of particular diseases and the graph regions has been verified. The graph allows three kinds of BIA evaluations: (*1*) individual vector; (*2*) follow-up; (*3*) groups of subjects

Table 15.4 Anthropometrical formulas derived for the estimate of TBW in normal subjects

	Males	Females
Watson (Watson et al. 1980)	2.447 – (0.09516 × age) + (0.1074 × *H*) + (0.3362 × BW)	−2.097 + (0.1069 × *H*) + (0.2466 × BW)
Hume (Hume and Weyers 1971)	−14.01 + (0.2968 × BW) + (0.1948 × *H*)	−35.27 + (0.1838 × BW) + (0.3445 × *H*)
Sun (Sun et al. 2003)	1.20 + (0.45 × H^2)/*R* + (0.18 × BW)	3.75 + (0.45 × H^2)/*R* + (0.11 × BW)

This table lists three of the most used anthropometrical formulas for estimating TBW in normal subjects. Age is in years, *H* in centimetres, BW in kilograms and *R* in Ohms

measurements (*R* and *Xc*) plotted as a bivariate vector standardized by the subject's *H* (i.e., expressing *R*/*H* and *Xc*/*H* in ohm/*m*). This method was described as a useful tool for monitoring the hydration status in renal (Sun et al. 2003; Piccoli et al. 1994, 1998) and critical care (Piccoli et al. 2000) patients and in the follow-up of obese subjects during weight loss (Piccoli et al. 1998). In the clinical setting, the advantages of vector BIA reside in the absence of algorithms for conversion of raw impedance data into body composition. Therefore the results are not biased by the choice of the regression equation or the selection of the reference population. However the results of the vector BIA analysis must be stratified according to race or ethnicity, BMI, age and gender (Piccoli et al. 1995). According to the *RXc*-graph methods, each subject can be identified by a point determined by his *Xc*/*H* value on the *Y*-axis (fluid status: dehydration or hyper hydration for higher or lower values of the ratio respectively) and the *R*/*H* value on the *X*-axis (body mass components: overweight or underweight for lower or higher values of the ratio respectively). The reference population (healthy subjects) fall in the 95%, 75%, and 50% confidence interval ellipse in the middle of the graph (Fig. 15.3).An alternate method for body composition assessment is anthropometry. For this purpose many formulae have been derived for the estimate of body composition (Table 15.4). The widely used equations by Watson et al. (Watson et al. 1980) were based on a meta-analysis of

previous studies where TBW was estimated using a variety of dilution techniques and markers of water volume in 458 adult males and 265 adult females. The equations by Hume were derived using tritiated water as a marker (Hume and Weyers 1971). In 2003, Sun et al. (Sun et al. 2003) presented a new way of estimating TBW by means of equations derived by mixing anthropometrical parameters and BIA-derived *R*.

Our group has published a study (Basile et al. 2008) aimed at comparing TBW estimated by means of Watson's and Hume's anthropometrical equations with TBW obtained by BIA equations (Sun's equations), in a very large group of white, disease-free individuals and in a large group of white haemodialysis (HD) patients, pair-matched by age, *H* and *BW*. In our hands anthropometrical equations could be used only within a specific population in order to assess individual differences; they could not be used in order to compare two, not pair-matched populations. Actually, subjects with the same BW or BMI, with or without oedema, had the same TBW estimated by Watson's and Hume's formulae while TBW resulted statistically significantly different only when applying Sun's equations.

The importance of deriving population-specific equations for TBW was already underlined by Chertow et al. in 1997 (Chertow et al. 1997). The authors examined more than 3,000 end-stage renal disease (ESRD) patients with BIA and developed an estimation equation in which age, gender, diabetic status, BW, H were included. The estimated TBW resulted not significantly different from the TBW measured by BIA.

15.5 Focusing on BIA Usefulness in ESRD

The assessment of body composition is assuming an important role in the clinical evaluation of the general population and patients suffering from alterations of the nutritional status and metabolic diseases. Both direct and indirect measurements of the body components are helpful for clinicians in order to make proper therapeutic decisions.

As stated above, water is the most abundant compound in the body and is an essential regulator of its internal environment. TBW must be constantly maintained in normal individuals (Chumlea et al. 2001). However, TBW is largely altered by disease. The choice of method for measuring TBW depends on whether the measurement is for clinical purposes or research and the degree of precision that is required. The calculation of TBW represents a useful tool in the clinical management of patients with chronic liver disease, in under-/over-nourished adults and in subjects with ESRD.

In the ESRD setting the TBW calculation has three main targets: (a) assessment of the body dry-weight (DW); (b) evaluation of the nutritional status (considering TBW together with FM, FFM and BCM); (c) calculation of the dialysis adequacy.

(a) Patients with ESRD are characterized by the impairment of kidneys in handling the body fluids that leads to a status of chronic over-hydration with tendency to develop oedema (Charra et al. 1996). Taking into account this frame, the assessment of TBW by means of BIA in these patients can provide useful information in both clinical practice and research.

From a clinical point of view, the *RXc* graph method is routinely adopted in order to evaluate the position of the patient in respect to the ellipses of the reference population. This comparison allows for the modulation of the DW of the single patient targeting the 95% confidence interval that indicates the normal body composition.

In the field of clinical research the TBW calculation by means of BIA can be used in order to estimate the exact body DW that the single patient has to reach when starting dialysis treatment.

We developed and validated BIA derived prediction equations for DW in haemodialysis patients by using anthropometrical parameters and *R* (Basile et al. 2007):

$$\text{In males} = [(0.008995 \times \text{age}) - (0.01116 \times R) + (0.871078 \times H) - 75.55197] \times \text{post} - \text{dialysis BMI}/23.1$$

$$\text{In females} = [-(0.01389 \times R) + (0.62956 \times H) - 36.31924] \times \text{post} - \text{dialysis BMI}/21.7$$

where age is in years, *H* is in centimeters and *R* in ohms.

(b) Depending in part on the method used and the population studied, from 40% to 70% of patients with ESRD present protein-energy wasting, a complication that appears to be associated with increased mortality (Lowrie and Lew 1990). In 2006 Bellizzi et al. (2006) demonstrated that despite the absence of overt malnutrition or oedema, patients with chronic kidney disease exhibit altered BIA variables (both *RXc* graph and *R* considered alone) from the early phases of renal disease. These alterations are related to the renal dysfunction, are more marked in the presence of diabetes and mainly indicate the presence of over-hydration in the absence of oedema. As a result of the frequency of malnutrition and over-hydration, periodic assessment of nutritional status should be part of the routine care of dialysis patients to permit early recognition and the institution of appropriate therapy. In the clinical assessment of the nutritional status of these subjects, the BIA-derived parameters (FM, FFM, TBW) cover an important role taken together with dietary intake reporting, lab parameters (amino acids, creatinine production, blood urea nitrogen, haemoglobin, serum levels of albumin, prealbumin, transferrin and total cholesterol) and anthropometrical measurements (TSF or MAMC). Also in this field, the RXc graph of the single patient may help clinicians in targeting nutritional treatment.

(c) The National Cooperative Dialysis Study (NCDS) showed that urea clearance is a better measure of dialysis adequacy than time-averaged urea concentrations. As urea rapidly distributes in TBW, its fractional clearance (*Kt*/*V*) is easily determined from pre- and post-dialysis blood samples (Daugirdas et al. 2008). Thus *Kt*/*V* (where *K* = dialyzer clearance; *t* = time of treatment; and *V* = urea volume distribution, equal to TBW calculated by means of Watson's formula) became the standard for assessing dialysis adequacy. This practice seemed to be validated by large observational studies that found associations between *Kt*/*V* and mortality (Daugirdas et al. 2008). As already stated, the *V* of the formula is represented by the TBW estimated by means of the Watson's equations.

Outcome analyses in observational studies showed that smaller patients (low *V*) tended to do poorly relative to their larger counterparts (Daugirdas et al. 2008). The association of outcome with size suggested a relative shortfall in the dose of dialysis provided to smaller as compared with larger patients, despite similar values of *Kt*/*V*. A recent randomized trial, the HEMO Study, found that gender modified the association between dialysis adequacy and mortality (i.e., a beneficial effect of higher *Kt*/*V* in women but not in men) (Daugirdas et al. 2008).

Such results led some authors to find other body size-related parameters as an alternative to *V* in order to avoid these discrepancies (gender and *V* related) in calculating the dialysis adequacy. Body surface area, resting energy expenditure, high metabolic rate and organ mass and liver volume have been proposed (Daugirdas et al. 2008). However, we demonstrated that *Kt*/*R* (where *R* = resistance evaluated by BIA) correlates better than *Kt*/*V* and all the other proposed methods of evaluating dialysis adequacy, with patient outcomes (Basile et al. 2010). Probably, the better performance of *R* in predicting mortality derives from its relationship with TBW. Moreover the use of *R* instead of *V* as denominator avoids all the discrepancies related to gender and size of patients.

Summary Points

- The assessment of body composition covers an important role in establishing nutritional and hydration status in both health and disease. However its direct measurement is essentially limited to research centres due to practical reasons. For general uses, indirect methods of predicting TBW, FM and FFM have been studied.
- Regression equations based on anthropometrical parameters (age, gender, BW, H) have been developed, for healthy people, to predict the body composition. The estimations provided by these anthropometrical equations are less reliable in case of diseased people because anthropometrical parameters could be similar in subjects characterized by different clinical features.
- Ease of determination, cost and accuracy make BIA a useful tool for assessing body composition. By means of BIA physical electrical variables such as *R* and *Xc* can be directly measured and the body composition can be estimated using regression equations or the *RXc*-graph method.
- The assessment of body composition by BIA in healthy subjects has allowed the development of estimating equations and the *RXc*-graph method setup. Thus the BIA has been widely applied to the clinical evaluation of patients suffering from alterations of the nutritional status and metabolic diseases.
- Complex changes in body composition occur in patients with kidney diseases of various degrees. Since the first referral, although non-oedematous, those patients present signs of over-hydration and lower BCM at the *RXc* graph method in the absence of overt signs of malnutrition or pathological estimates made by anthropometrical equations (Di Iorio et al. 2004).
- Once the patients have started the dialysis, DW, dialysis adequacy and nutritional needs can be at least approximately established by means of BIA appropriately performed at any time during the post-dialysis period, provided the hydration status does not change due to food or drink consumption (Di Iorio et al. 2004).

Chapter 16
Bioelectrical Impedance Vector Analysis for Assessment of Hydration in Physiological States and Clinical Conditions

Henry C. Lukaski and Antonio Piccoli

Abstract Although the importance of assessing hydration is well recognized, traditional laboratory methods and clinical impressions are impractical or lack sensitivity to be useful in physiological and clinical conditions. Alternate approaches using bioelectrical impedance measurements to estimate fluid volumes utilize regression equations and depend on physical models unproven in physiological systems; they result in large errors in the prediction of fluid volumes notably in individuals with altered hydration. Bioelectrical impedance vector analysis (BIVA) overcomes these limitations because it only uses determinations of resistance (*R*) and reactance (*Xc*) normalized for height and yields a vector of specific magnitude (length) and direction (phase angle). This vector, for either an individual or a group, is evaluated on the bivariate *R–Xc* graph, which is a probability distribution derived from a reference population of healthy, matched controls. Comparison of an individual or group vector to the mean vector of the reference population provides reliable and accurate classification and ranking of hydration that is independent of body weight. Applications of BIVA in healthy adults include assessment of over-hydration in pregnancy and weight loss in obesity. BIVA also has broad uses in the evaluation and management of clinical groups including the characterization of patterns of hydration change during hemodialysis (HD) and peritoneal dialysis and use of this information to prescribe dialytic therapy; identification of under-hydration in critically ill patients and guidance for administration of fluid therapy; assessment and monitoring of tissue hydration status in congestive heart failure; and identification of regional edema in patients after vascular surgery. Because of its practicality and reliability, BIVA can be used in observational and longitudinal studies of hydration in patient care and management and in field conditions.

16.1 Introduction

Assessment of hydration status (under-, adequate, or over-hydration) remains an enigma for clinical investigators despite the recognition of its importance more than 50 years ago (Edelman and Leibman 1959). Knowledge that altered hydration status impacts morbidity and mortality (Manz 2007) and influences physiological function and performance (Armstrong 2007) reinforces the need for practical and reliable methods to assess it. Although an assortment of techniques for the in vivo assessment of altered hydration status (e.g., under-hydration or over-hydration) is available, none has universal acceptance (Kavouras 2002). Standard approaches that use physical or chemical characteristics of urine or blood involve laboratory equipment and can be invasive. Dilution methods also are impractical because of the need for tracers (isotopes and non-isotopes), costly equipment and trained staff; they also are time-consuming and lack reference ranges for interpretation. In contrast, changes in body weight are simple and cost effective, but have limited value because they require baseline measurements at normal hydration and may include changes in body constituents independent of fluid.

Bioelectrical impedance analysis (BIA), which is a safe, practical, and non-invasive method, overcomes many of these limitations. BIA relies on the conduction of an applied, radio-frequency electrical current by the fluid (water) and electrolytes in the body (Lukaski 1996). Many BIA approaches are available to estimate body fluid volumes. Single- and multiple-frequency impedance devices either directly measure or indirectly determine resistance (R), reactance (Xc) or impedance (Z), and are included in multiple-regression equations to predict total body water (TBW) or extracellular water (ECW) and, by calculation, intracellular water (ICW). Bioelectrical impedance spectroscopy (BIS) couples multiple-frequency BIA with the Cole model and mixture theory to predict TBW and ECW (De Lorenzo et al. 1997). Single- and multiple-frequency impedance methods are inadequate to assess hydration status because of large variability in individual predictions of fluid volumes (Sun et al. 2003) attributable to the use of sample-specific prediction models (Jaffrin and Morel 2008) that yield unrealistic estimates of TBW and ECW in patients with altered hydration (Kyle et al. 2004). Similarly, limitations in the application of mixture theory in multicellular, physiological systems of the human body unfavorably limit the validity of BIS to estimate fluid volumes in adults with altered fluid status (Ward et al. 1998; Buchholz et al. 2004; Earthman et al. 2007). Thus, these BIA applications fail to provide precise and accurate estimates of fluid volumes for an individual with altered hydration.

This chapter describes bioelectrical impedance vector analysis (BIVA) and its expanding use in the classification and ranking of hydration status in conditions with perturbations in fluid balance. It discusses the applications of BIVA in physiological conditions in which cases of over-hydration are validated with isotope dilution data, and provides important examples of the use of BIVA to classify hydration in patients, to monitor the changes in hydration in response to therapeutic interventions and to identify opportunities in which BIVA provides unique information to improve patient care and clinical outcomes.

16.2 Bioelectrical Impedance Vector Analysis (BIVA)

An alternative impedance approach is the utilization of the spatial relationships between *R* and *Xc* to assess soft tissue hydration (Piccoli et al. 1994). Use of the hand-to-foot electrode placement and a phase-sensitive instrument (50 kHz) yields a *Z* vector that is a combination of *R* (i.e., opposition to the flow of an alternating current through intra- and extra-cellular ionic solutions) and *Xc* (i.e., capacitative component of tissue interfaces, cell membranes and organelles). The geometric relationship between *R* and *Xc* is expressed as the arc tangent of *Xc*/*R* or the phase angle (PA).

Measurements of *R* and *Xc*, normalized for standing height (*H*) to control for inter-individual differences in conductor length and plotted on a bivariate graph (Fig. 16.1), yield a vector that has length and direction (Piccoli et al. 1994). The length of the *Z* vector is inversely related to TBW (Lukaski et al. 2007), and the combination of the *Z* vector length and its direction, defined as the PA, is an indicator of tissue hydration status (Piccoli 1998; Lukaski et al. 2007).

Assessment of fluid status with BIA becomes a decision of whether to quantify TBW and its distribution or to classify (i.e., normal or abnormal) and rank (i.e., more or less than before intervention) hydration. Estimates of TBW and ECW originate from multiple-regression prediction equations and rely on physiological constants that are invalidated by illness. These models universally use

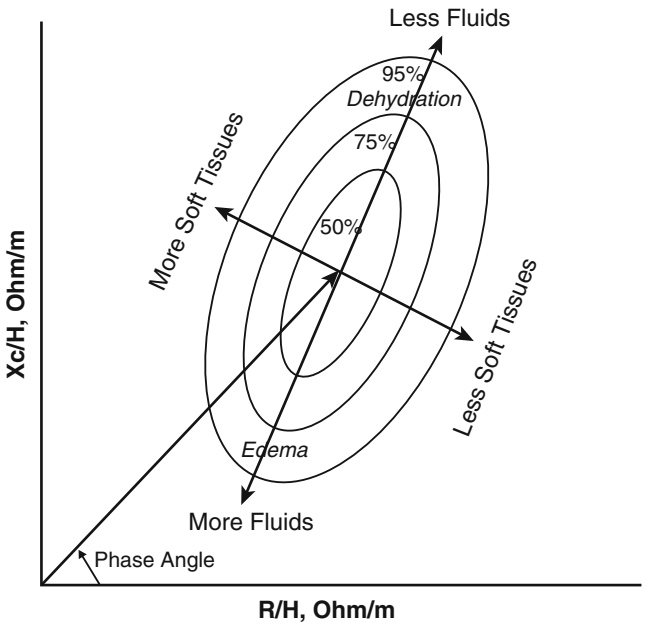

Fig. 16.1 Model of bioelectrical impedance vector analysis to rank hydration and soft tissue mass. A general depiction of the use of an impedance vector used to categorize or classify an individual's or group's level of hydration or soft tissue distribution. *R* resistance, *Xc* reactance, *H* height. (Adapted from Piccoli (2005). With permission)

the impedance index (i.e., H^2/R) and other independent variables, such as extrapolated Z values, body weight, age, gender and H (Kyle et al. 2004). These predictions have multiple sources of error, including BIA measurement error and reproducibility, regression error [SEE of prediction model (>10%; Sun et al. 2003)], technical error in the reference method (i.e., dilution methods), bio-electrical volume model (i.e., anisotropy of tissues and geometry other than a cylinder) and biological variability (i.e., inter-individual body composition differences) that propagate. In contrast, the BIVA method only depends on the reproducibility and accuracy of BIA measurements and intra-individual variability in body composition. Therefore, for an individual, classification and ranking of hydration is more precise and accurate than is quantification of fluid volume because it is independent of regression models that are generated in limited and specific samples and, thus, are not robust in the assessment of hydration outside of the group in which they were developed and illness.

16.3 Reference Intervals

Application of BIVA requires comparison of an impedance vector to reference intervals that have been derived in a large sample of age-, gender- and ethnicity-matched control or healthy subjects (Piccoli et al. 1995, 2002; Bosy-Westphal et al. 2005) on an *R–Xc* graph (Piccoli et al. 1994). The *R–Xc* graph is a probability distribution that classifies a vector according to its distance from the mean vector of the reference population. The distribution of the variability of the reference vector is expressed as percentiles of the tolerance ellipses (Fig. 16.1). Vector position is interpreted relative to the two directions on the *R–Xc* plane. Vector displacements parallel to the major axis of the tolerance ellipses indicate changes in hydration (e.g., more or less fluids). Vectors within the 50th percentile reflect normal hydration, whereas lengthening vectors from the 51st to 75th percentile and >76th percentile in the upper range of the tolerance ellipses indicate mild and severe dehydration, respectively. Conversely, shortening vectors from the 51st to the 75th percentile and >76th percentile in the lower range of the tolerance ellipses designate mild and severe over-hydration, respectively. Vectors positioned to the left of the major axis reflect increased cell mass, whereas vectors to the right of the major axis indicate less cell mass (Fig. 16.1). Analysis of impedance vectors may occur for an individual (e.g., point vector) or a group either for an observational ranking of hydration or longitudinal monitoring of changes in hydration status in response to a physiological condition or an intervention.

Appropriate derivation of the *R–Xc* graph and implementation of BIVA require the proper determination of *R* and *Xc* with a phase-sensitive impedance instrument. Failure to use a phase-sensitive instrument can result in significant errors of up to 10 Ω for *R* and 10–12 Ω for *Xc* (Chumlea et al. 2002). These errors can significantly (8–10%) reposition the mean vector and reference ellipses of the reference population as well as individual and group vectors and, therefore, make reliable and valid assessment of hydration status problematic and dubious.

16.4 BIVA Applications in Healthy Adults

Physiological conditions that result in significant gains or losses of body weight and composition concomitantly impact TBW, its distribution and, thus, hydration. Pregnancy and weight loss are dynamic physiological conditions that profoundly change TBW and have been described by using isotope dilution methods. BIVA affords an opportunity to non-invasively and reliably assess hydration status (Table 16.1).

Table 16.1 Key features of BIVA for classification of hydration in health and disease

- Classification and ranking of tissue hydration depends on measurements of *R* and *Xc* that produce a vector whose position is evaluated relative to tolerance intervals and is interpreted as normal or abnormal hydration based on distance from the mean vector derived from a healthy reference population. Migration of the vector (shortening or lengthening) due to progression of a physiological process, pathology or an intervention indicates changes in hydration (i.e., gain or loss of fluids).
- Classification of hydration status (normal or abnormal) with BIVA avoids the problems of insensitivity (>10%) associated with use of regression equations to predict TBW and ECW; it also does not rely on the use of body weight that limits its validity to assess hydration.
- BIVA accurately detects increases in TBW (vector shortening) measured with deuterium dilution throughout pregnancy and post partum, and specifically identifies individuals with excess TBW gain during the third trimester of pregnancy. BIVA also reliably detects TBW losses (vector lengthening) and identifies individuals with altered fluid distribution (*E*/*I*) before and during weight loss.
- Use of BIVA improves the prescription of ultra-filtration (UF) in dialysis by monitoring the backward–forward displacement of vectors in relation to the wet–dry cycle of hemodialysis (HD). It also enhances decision-making in dialysis by facilitating the interpretation of alterations in blood pressure relative to hydration status and, thus, adjusting UF.
- BIVA at 50 kHz provides important information regarding tissue hydration during dialysis that is not evident with BIS. Examination of *R* values at 50 kHz correlated with other *R* values determined at wide ranging frequencies with BIS reveals high correlations and no unique contributions from BIS for monitoring changes in hydration.
- Among critically ill patients, BIVA is significantly and inversely correlated with CVP. On the *R*–*Xc* graph, impedance vectors of patients with low, normal and high CVP moved downward and outside of the 75% tolerance level with increasing CVP, which indicates excess fluid accumulation.
- Assessment of regional edema following peripheral vascular surgery is enhanced by using BIVA. Measurements of lower limb *R* and *Xc*, corrected for the length, before and after surgery reveal significant downward vector migration only in the affected leg compared to the non-surgical leg. A similar, albeit more modest, pattern is observed when whole-body measurements are made on the surgical compared to the control side.

This table summarizes the fundamental principles and advantages of the bioelectrical impedance vector analysis method, including its applications in the classification of normal and abnormal hydration states in physiologic and pathologic states. *BIVA* bioelectrical impedance vector analysis, *R* resistance, *Xc* reactance, *TBW* total body water, *ECW* extra-cellular water, *E/I* ratio of extra- to intra-cellular water, *HD* hemodialysis, *UF* ultra-filtration, *BIS* bioelectrical impedance spectroscopy, *CVP* central venous pressure

16.5 Hydration Changes During Pregnancy and Postpartum

Hydration status was determined longitudinally with BIVA and deuterium dilution in women before conception, every 90 days during pregnancy and 8–10 week postpartum (Lukaski et al. 2007). Throughout all stages, vector length was inversely related to TBW ($r = -0.79$; $p < 0.0001$), and changes in vector length also were related inversely to changes in TBW ($r = -0.599$; $p < 0.001$). These findings provide the first validation that *Z* vector length is a reliable indicator of fluid volume during dynamic changes in TBW.

With the pre-pregnancy impedance data as the reference, the group vector shortened significantly and displaced downward during the second ($p < 0.007$) and third ($p < 0.0002$) trimesters of pregnancy (Fig. 16.2). These vector displacements were affected by significant decreases in *R*/*H* in the second ($p < 0.02$) and third ($p < 0.0001$) trimesters with a concomitant decrease in *Xc*/*H* ($p < 0.02$) in the third trimester and no changes in PA. The mean postpartum vector was similar to the pre-pregnancy vector.

Examination of the individual vectors of the women during the third trimester of pregnancy shows individuals with over-hydration (Fig. 16.3). The vectors of three women were outside of 75th tolerance ellipse.

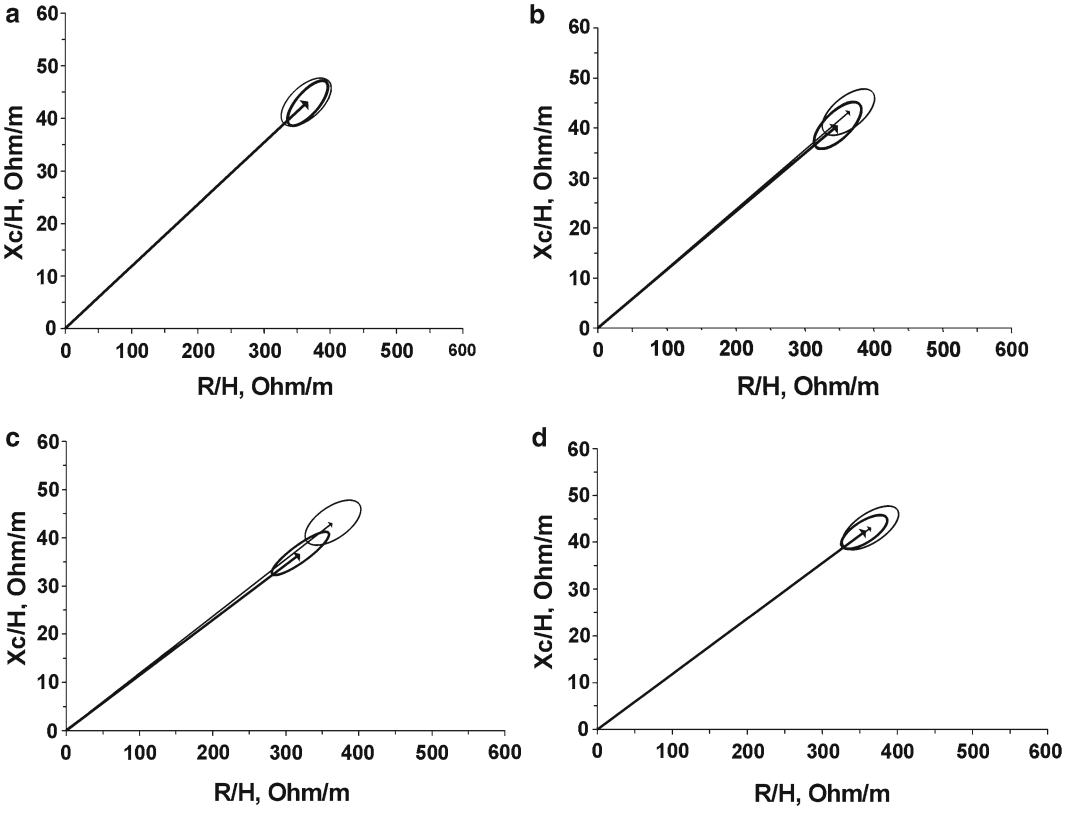

Fig. 16.2 Mean vectors with 95% tolerance intervals of women before, during, and after pregnancy. Panels show mean vectors of 12 women studied longitudinally at trimester 1 (**a**), trimester 2 (**b**), trimester 3 (**c**), and postpartum (**d**) in reference to pre-pregnancy (*light ellipse*). Mean vector length decreases significantly throughout pregnancy and returns to near pre-pregnancy length post-partum. *R* resistance, *Xc* reactance, *H* height. (Reprinted from Lukaski et al. (2007). With permission)

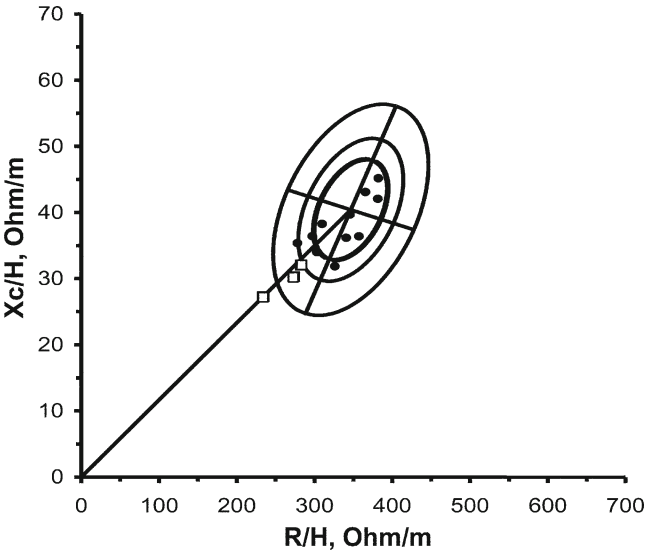

Fig. 16.3 Distribution of individual vectors during third trimester of pregnancy compared to pre-pregnancy reference tolerance ellipses. *Solid squares* indicate individual vectors of three women with over-hydration (see text for details). *R* resistance, *Xc* reactance, *H* height. (Reprinted from Lukaski et al. (2007). With permission)

Review of the TBW data found that the TBW gain of these three women was 10 l compared to only 5 l for the women whose vectors were within the 75th tolerance ellipse. Thus, BIVA correctly identified the women whose hydration was excessive (i.e., over-hydrated) during the third trimester.

16.6 Hydration Changes During Weight Loss

Whereas obesity is characterized by excess adipose tissue mass, alterations in fluid distribution (*E*/*I*) in obesity and after weight reduction have been reported (Waki et al.. 1991; Van Marken Lichtenbelt and Fogelholm 1999). Sixteen obese women participated in a 4-month controlled weight loss program in which BIA, TBW (deuterium dilution) and ECW (bromide dilution) were determined at regular intervals (unpublished observations). Weight loss was 18 kg ($p < 0.0001$) with a 3.5 l loss of TBW ($p < 0.001$). Vector length was significantly and inversely related to TBW throughout weight loss ($r = -0.85$; $p < 0.0001$). Compared to pre-weight loss, the mean group vector lengthened significantly ($p < 0.05$) after weight loss. Before weight loss, the individual vectors of seven women were downward and outside of the 75th percentile and had *E*/*I* ratios of 0.81 compared to 0.70 for the women whose vectors were within the 75th tolerance ellipse (Fig. 16.4). After weight loss, only three vectors exceeded the 75th percentile and the *E*/*I* ratios of these women were greater (0.75 vs. 0.65) compared to the women whose vectors were within the 75th percentile (Fig. 16.4). These preliminary findings support the validity of BIVA to rank hydration status during weight loss.

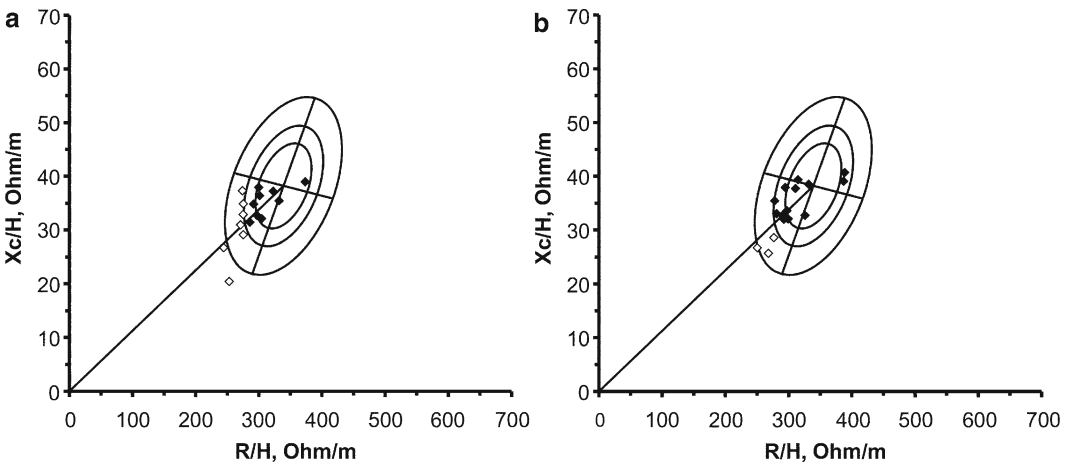

Fig. 16.4 Individual impedance vectors before (**a**) and after (**b**) weight loss in relationship to a reference population of age-matched, non-obese women. *Solid squares* represent individual vectors of seven women with over-hydration compared to nine women with normal or minor over-hydration (*panel A*). Despite an average weight loss of 18 kg, the impedance vectors of three women indicated over-hydration in contrast to the vectors of 13 women reflected normal hydration (*panel B*). *R* resistance, *Xc* reactance, *H* height. Unpublished data from HC Lukaski

16.7 Clinical Applications of BIVA

The principal use of BIVA is the assessment of hydration status in patients with fluid overload and the evaluation of clinical procedures that aim to establish homeostasis without incurring unwanted adverse effects. Renal disease, hemodynamic impairment and vascular surgery are the conditions in which BIVA has been used effectively to classify and rank hydration and to monitor changes in hydration in response to interventions (Table 16.1).

Traditional methods for assessment of hydration are insensitive and ineffective in clinical situations. Anthropometric formulas have limited value because they are functions of body weight and are completely insensitive to fluid overload in patients with apparent edema (Piccoli 2004; Pillon et al. 2004). Determination of TBW with dilution methods is limited because of problems associated with gastric emptying, fluid sequestration and tracer penetration and equilibration in all water pools that contributes to over-estimation of TBW.

16.8 Hydration Status in Dialysis

Dialysis, particularly HD, is an excellent model of fluid removal (1–5 l in 4 h) and overload (1–5 l in 2–3 days). Adequacy of body fluid volume control through UF improves short- and long-term outcomes. The routine evaluation of hydration status based on body weight and blood pressure changes overtime can be misleading because the changes are not uniquely determined by variations in body fluid volume. Edema is not usually detectable until the interstitial fluid volume has exceeded 30% of the above normal (i.e., 4–5 kg of body weight), while severe dehydration can develop before the appearance of clinical signs. Therefore, traditional indicators of over- and under-hydration in patients with renal disease are inadequate and insensitive (Piccoli 2004).

HD often results in bringing the patient either to dehydration or to fluid repletion. Dehydration can be symptomatic (i.e., decompensated with hypotensive episodes in the latter part of the session, malaise, exhaustion, cramps, or dizziness after dialysis) or asymptomatic (i.e., compensated). Fluid overload is mostly symptomatic with pitting edema, worsening of hypertension, edema, or pulmonary congestion during the inter-dialytic interval. The so-called dry weight is the post-dialysis weight at which all or most excess body fluid has been removed. The optimal post-dialysis target weight is determined clinically, in general, as the lowest weight a patient can tolerate without intra-dialytic symptoms or hypotension. However, body fluid volume is continuously changing even in asymptomatic HD patients, in whom euhydration and euvolemia only last for a limited time (i.e., a few hours) in the inter-dialytic period.

Peritoneal dialysis (PD) can also bring the patient either to dehydration, characterized as a decrease in residual urine output and peritoneal UF, or to fluid overload, expressed as pitting edema with worsening of hypertension and impairment of peritoneal UF. Maintenance of euhydration and euvolemia in PD patients is recommended to minimize cardiovascular risk and to maximize UF in the long term.

16.9 BIVA in Hemodialysis

16.9.1 Dynamic Vector Patterns Associated with the HD Cycle

The standard thrice weekly HD cycle of body fluids is characterized by fluid removal with the UF during the dialysis session (3–5 h) and a progressive fluid repletion over the short (48 h) or long (72 h) inter-dialytic period. Figure 16.5 shows vector migration for an individual over a complete HD cycle of

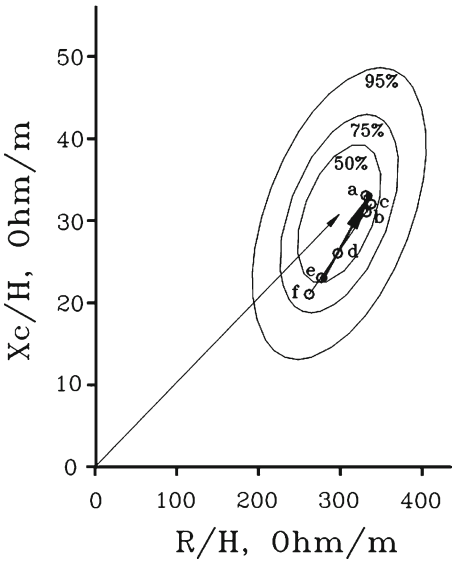

Fig. 16.5 The impedance vector migration associated with the HD cycle over 3 days is depicted on the *R–Xc* graph. Reference values for an individual vector (*thin arrow* to the center of ellipses) are depicted as 50%, 75%, and 95% tolerance ellipses derived for the male, Italian population. Solid circles represent vectors at the start and the end of the dialysis session (fluid removal 2.8 l). *Open circles* represent vectors after 30 (*label a*), 60 (*label b*), 120 min (*label c*), and in the next days, after 24 (*label d*, +1.4 l fluid increase), 48 (*label e*, +1.2 l), and 68 h (label f, +0.8 l for a total of 3.4 l in 68 h). The vector lengthening during the hemodialysis session is represented by the bold arrow in the direction of the major axis. The trajectory followed by vector shortening after dialysis is represented by segments of a linear path still parallel to the major axis of tolerance ellipses. *R* resistance, *Xc* reactance, *H* height, *HD* hemodialysis. (Reprinted from Piccoli and Codognotto 2004. With permission)

three days (Piccoli and Codognotto 2004), during which vector lengthening during UF was parallel to the major axis of tolerance ellipses. Vectors measured within 120 min after the session randomly fluctuated close to the end-dialysis vector. After 24, 48, and 68 h, vectors progressively shortened and returned in the same direction associated with the UF. Interestingly, the vector at 48 h reached the baseline vector position at the start of the HD session, indicating a same fluid repletion, while the vector measured after 68 h shortened further, indicating a greater fluid overload during the long inter-dialytic period. The post-HD random fluctuation for 120 min excludes an "electric rebound" phenomenon and supports the validity of immediate post-HD measurement (i.e., patient's time saving).

The linear trajectory of vectors can be observed during the HD session at any current frequency, which demonstrates the same information at any frequency (Piccoli et al. 2005). The linear trajectory both in the intra- and inter-dialytic period supports validity of monitoring with only pre- and post-dialysis measurements. We previously described in 1116 HD patients how the wet–dry weight cycling was associated with a pattern of cyclical, backward–forward displacement of the impedance vector (Piccoli 1998)

16.9.2 Normal Versus Abnormal Vector Trajectories in HD

The classification of vectors as normal or abnormal with respect to the reference third quartile (75% tolerance ellipse) is based on electrical properties of soft tissues, independent of the body weight of patients. Vectors from 72% of the 1116 asymptomatic HD patients were within the 75% reference

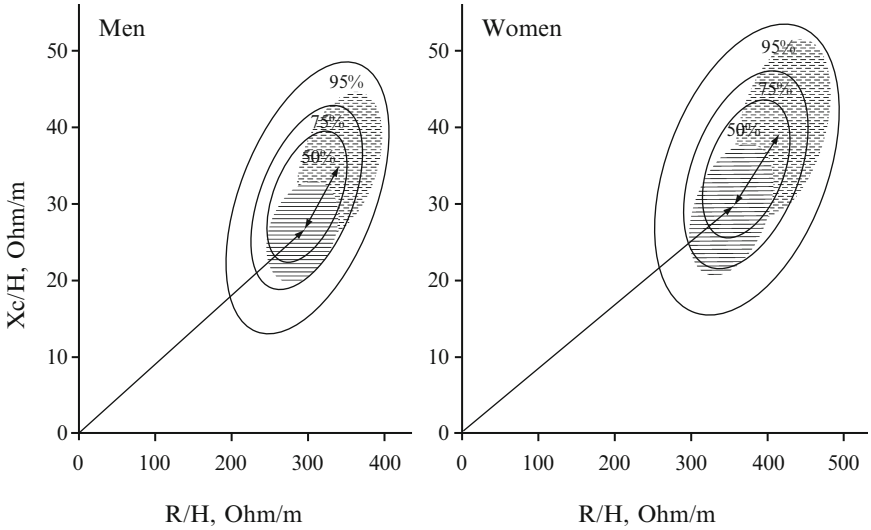

Fig. 16.6 Examples of the effect of hemodialysis on the distribution of the impedance vectors from asymptomatic patients. *Dotted ellipses* represent the distribution of 50% of the impedance vectors from individual HD asymptomatic male and female patients before (horizontal lines in the lower ellipse) and after fluid removal (abbreviated lines in the *upper ellipse*). *Double headed arrows* represent the vector cycling from before to after HD. *Dotted ellipses* are plotted over the reference, gender-specific, 50%, 75%, and 95% tolerance ellipses of the healthy population. *R* resistance, *Xc* reactance, *H* height. (Reprinted from Piccoli 2004. With permission)

tolerance ellipse before the HD session. At the end of the session, vectors of 55% of the asymptomatic HD patients were within the 75% reference tolerance ellipse. Therefore, most vectors cycled within the 75% tolerance ellipse, which indicates that a full restoration of electrical properties of uremic tissues was achieved with HD (Piccoli 1998) (Fig. 16.6).

Figure 16.7 shows vector trajectories (measurements at the start and every hour during HD) spanning within (solid circles) or out (open circles) of the 75% tolerance ellipses during 3–4 h of UF in representative HD patients. Trajectories can be classified into *normal* (within 75%) or *abnormal* (out of 75%) assuming that a normal hydration in HD patients is the normal hydration of the healthy population, as reflected by impedance vector distribution of the reference population (726 males and females, BMI 17–31 kg/m^2; 15–85 years) (Piccoli et al. 1995).

The first and more frequent pattern is a vector displacement parallel to the major axis of the tolerance ellipses. According to the general patterns defined in Fig. 16.1, long vectors migrating across the upper poles indicate dehydration (dry vectors), and short vectors migrating across the lower poles indicate fluid overload (wet vectors). Vector trajectories spanning on the left side vs. trajectories on the right side of ellipses are from patients with more vs. less soft tissue, respectively. For example, the lengthening and steepening of vectors in obese subjects (BMI 31–41 kg/m^2) undergoing a same UF are comparable to those of lean subjects, although spanning in the left side of ellipses (Piccoli et al. 1998).

The second pattern associated with UF is a flat vector migration to the right side, due to an increase in *R*/*H* without a proportional increase in *Xc*/*H* caused by severe loss of soft tissue mass. This pattern is characteristic of patients with severe malnutrition or cachexia, and is never observed in vectors lying on the left of the ellipses. Average pre-HD vectors of 251 hypotensive and malnourished patients were longer and with a smaller phase angle compared to asymptomatic HD patients. The vector displacement induced by a comparable fluid removal was significantly shorter and less

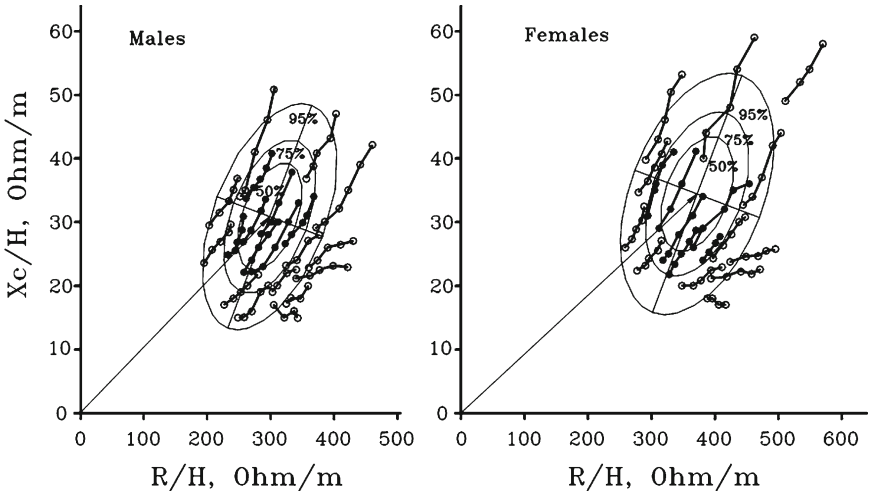

Fig. 16.7 Normal and abnormal trajectories of impedance vectors derived from individual patients during a HD session. *Solid* and *open circles* indicate the vector trajectories that spanned within (normal) or out (abnormal) of the 75% tolerance ellipses, respectively, during 3–4 h of UF in a representative HD patients. Two dynamic patterns of abnormal vector trajectories are characteristic in HD patients during UF. The first and more frequent pattern is a vector displacement parallel to the major axis of the tolerance ellipses, leaving or ending out of the 75% tolerance ellipse. Long vectors overshooting the upper poles indicate dehydration (dry vectors), and short vectors migrating across the lower poles indicate fluid overload (wet vectors). Vector trajectories spanning on the left side vs. trajectories on the right side of ellipses are from patients with more vs. less soft tissue mass, respectively. The second pattern of UF is a flat vector migration to the right, due to an increase in *R*/*H* without a proportional increase in *Xc*/*H* due to loss of cells in soft tissue. This pattern is characteristic of patients with severe malnutrition or cachexia. It is never observed in vectors lying on the left of the ellipses. *HD* hemodialysis, *UF* ultra-filtration, *R* resistance, *Xc* reactance, *H* is height. (Reprinted from Piccoli (2005). With permission)

steep in hypotensive patients, in whom the concentration of both hemoglobin and albumin was also decreased. We speculated that malnutrition was involved through the loss of interstitial gel leading to a reduced volume of interstitial fluid, in both gel and free form, which decreased the effectiveness of the vascular refilling (Piccoli 1998).

16.9.3 Adequate Versus Inadequate Vector Trajectories in HD

As with any diagnostic test, intervention studies are needed to establish whether dialysis prescription that induces normal vs. abnormal trajectories is associated with adequate vs. inadequate UF, ultimately leading to different outcomes. In practice, the first target can be fixed to the normal range whose assessment for adequacy requires clinical validation. The change of vector target will follow in feedback with the clinical course of individual patients. For example, an abnormal, long vector overshooting the upper 95% pole that is associated with an asymptomatic UF and a good control of blood pressure can be considered an adequate (dry) vector. The same abnormal long vector in a patient with hypotensive episodes is an inadequate vector. Yet, an abnormal short vector in a patient with hypotension may be more adequate than a normal vector associated with more hypotension episodes. Thus, the full restoration of the electrical properties of tissues is the first target, but the outcome will ultimately define clinical adequacy of treatment in the individual patient.

In a large multi-center, observational study (3,009 patients in US dialysis centers), shorter pre-HD vectors, indicating more fluid repletion and probably inadequate UF, were associated with a greater multivariate relative risk of death after 1 year of follow-up (Piccoli et al. 2004). In a small observational study, longer post-HD vectors out of the upper pole of the 75% tolerance ellipse were associated with a higher frequency (73%) of symptomatic hypotension and cramps, but 57% of (still) asymptomatic patients were classified as dehydrated due to their long vectors. A follow up of clinical course in the next sessions was not performed. The classification of volume status based on conventional BIA equations was insensitive to the clinical course (Guida et al. 2000).

16.10 BIVA in Peritoneal Dialysis

In chronic ambulatory peritoneal dialysis (CAPD), peritoneal UF is obtained with 2 l of hypertonic glucose solutions (1.36% or more) or icodextrin infused within the abdomen and exchanged with 2 l of fresh solution every 6 h. Increased glucose in the solution stimulates more UF. The process is continuous rather than cyclical as in HD. Adequate UF should keep hydration of CAPD patients close to normal.

Use of BIVA enabled the establishment of the optimal tissue hydration in CAPD patients. Among 200 patients, 149 were without edema and asymptomatic and 51 had pitting edema due to fluid overload. Whole-body impedance measurements were performed before and after 2 l of fluid infusion into the abdomen. There was no difference in both *R* and *Xc* values before and after infusion of the fluid in the abdomen. This finding was expected because the impedance of the trunk is low due to the large cross-section and the contribution of free fluid in cavities is negligible (pure *R* without *Xc* component) compared with fluid in soft tissues. Vector distribution of the CAPD patients was compared with that from 726 healthy subjects, 1116 HD patients and 50 nephrotic patients, all with a same BMI. In asymptomatic CAPD patients, the vector distribution close approximated that of the healthy population (50%, 75%, and 95% tolerance ellipses) and to the distribution of asymptomatic HD patients before the dialysis session (Piccoli 2004) (Fig. 16.8). We also determined the optimal vector distribution of asymptomatic patients undergoing CAPD without edema and with a residual urine output >1,000 ml/24 h and only using 1.36% glucose. There was no significant difference between this group and the asymptomatic group with less urine output and a greater glucose concentration. Vectors from patients with edema were displaced downward on the *R–Xc* graph, were out of the 75% ellipse (88% sensitivity and 87% specificity) and were close to vectors from nephrotic patients not undergoing dialysis. Therefore, the pattern of fluid overload with the vector displacement in the direction of the major axis was also observed in CAPD patients. This pattern can be utilized in dialysis prescription using vector displacement for the feed-back on glucose solutions to keep or achieve a normal hydration without the knowledge of the body weight.

16.11 Key Contributions of BIVA in Dialysis

The methodology of BIVA, applied to whole-body, 50 kHz single frequency impedance measurements can contribute to dialysis prescription with unique information that can not be obtained with currently available techniques or approaches.

The impedance vector of a patient is compared with the tolerance intervals of a reference population, which allows classification of tissue hydration into normal or abnormal, independent of the body weight. Abnormality is ranked as a distance from the mean vector of the reference population.

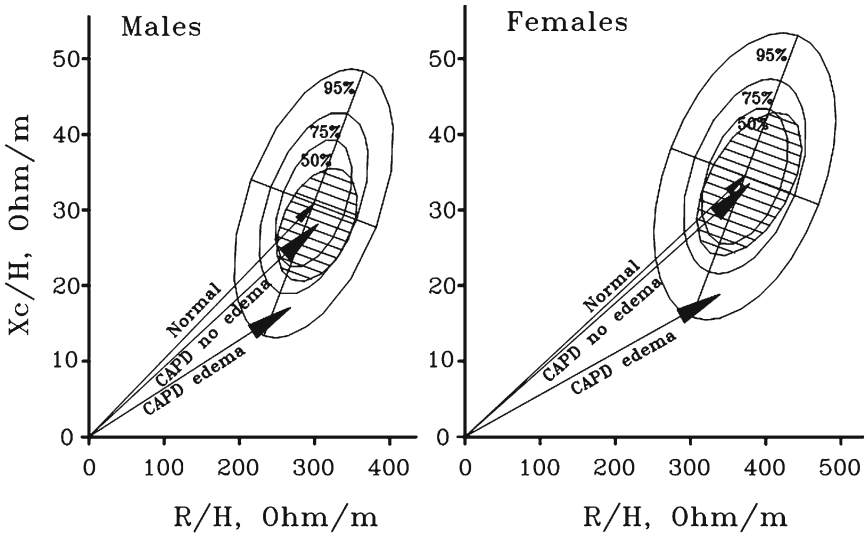

Fig. 16.8 Impedance vector distributions of CAPD patients with and without edema. *Hatched ellipses* represent the distribution of 50% of impedance vectors from individual CAPD patients without edema, plotted on the reference, gender-specific males and females, 50%, 75%, and 95% tolerance ellipses of the healthy population. Two big arrows indicate mean vectors of CAPD groups (edema and no edema). *Large-headed arrows* represent the mean vector of HD patients before (*lower arrowhead*) and after a HD session (*upper arrowhead*). *CAPD* chronic, ambulatory peritoneal dialysis, *R* resistance, *Xc* reactance, *H* height. (Reprinted from Piccoli (2004). With permission)

In particular cases, an abnormal hydration can be considered an adequate hydration if it is associated with less morbidity (see below).

BIVA enables the identification "by exclusion" volume-dependent hypertension and hypotension. Specifically, a long vector indicating dehydration in a patient with hypertension allows exclusion of volume-dependent hypertension. Further UF is not expected to decrease blood pressure. The same vector in a patient with hypotension is compatible with a volume-dependent hypotension, which can be corrected by reducing UF (i.e., feedback with vector shortening). A short vector in a patient with hypertension is compatible with volume-dependent hypertension, which can be corrected increasing UF (i.e., feedback with vector lengthening). The same vector in a patient with hypotension allows exclusion of volume-dependent hypotension. No correction is expected increasing UF.

As shown in Fig. 16.1, different vector patterns indicate the nature or composition of body weight change only based on electrical properties of tissues. This indication is particularly useful in obese patients in whom interpretation of changes in body weight is often impossible to establish with clinical acumen.

The association between impedance and UF is strong although not linear. The wet–dry weight cycling of HD patients is associated with a cyclical, backward–forward displacement of the impedance vector on the *R–Xc* plane (Piccoli 1998). Vector displacement follows a fluid volume change in the order of 500 ml (Figs. 16.5 and 16.7) (Piccoli and Codognotto 2004). Despite this definite association, the linear correlation between vector components and the amount of fluid removed by UF is weak using either single or multiple frequency impedance techniques. UF is the amount of fluid volume that is removed from vessels during a dialysis session or in one day of CAPD. Body impedance reflects the effect of UF on soft tissues through the slow suction of interstitial fluid into vessels in HD (vascular refilling) or into peritoneal cavity in CAPD (Piccoli 2004). Indeed, the change in tissue impedance in dialysis is mainly determined by the change in the interstitial hydration with neither contribution of intravascular volume change nor of peritoneal solution.

As compared to BIS, BIVA provides better information describing hydration during dialysis (Piccoli et al. 2005). Intra- and extra-cellular current flow cause equivalence of information based on functions

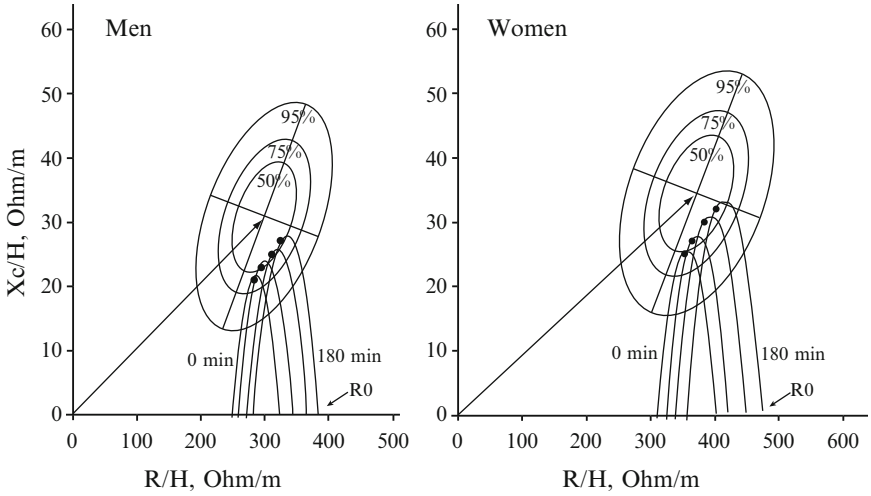

Fig. 16.9 Sex-specific impedance vectors at 50 kHz derived serially during HD approximate the values at the characteristic frequency derived by using the Cole model and multiple-frequency impedance spectroscopy. The 50%, 75%, and 95% tolerance ellipses indicate the sex-specific, reference intervals for an individual random vector (normalized by the stature, *Z*/*H* in Ω/*m*) at 50 kHz, and point vectors represent the mean vectors of dialysis patients, plotted on their hourly Cole's semicircle. Vectors at 50 kHz are close to the top of the semicircles (characteristic frequency and calculated as the mid point between R_o and R_∞). Compared to male patients, Cole's arcs from women were larger and more translated to the right (longer 50 kHz mean vectors at a same time point), but their position in the *R*–*Xc* graph followed a same pattern (comparable hydration status) from 0 to 180 min, with vector displacement parallel to the major axis of the tolerance ellipses. In practice, the centripetal property of 50 kHz vectors with respect to the corresponding Cole's semicircle, allows tracking of fluid removal with a direct comparison of impedance readings with reference intervals of the healthy population. R_o resistance at low or near 0 frequency, R_∞ resistance at very high or near infinity frequency, *R* resistance; *Xc* reactance, *H* height. (Reprinted from Piccoli et al. (2005). With permission)

of *R* and *Xc* measurements made at 50 kHz compared to other frequencies. With whole-body BIS before and during fluid removal (2.5 kg during a session of 0, 60, 120 and 180 min) in HD patients, with increasing current frequency, *R* decreases and *Xc* moves along the Cole's semicircle on the *R*–*Xc* plane. The Cole's semicircles progressively enlarge and move to the right on the *R*–*Xc* plane following fluid removal (i.e., an increase in both *R* and *Xc* values at any given frequency) (Fig. 16.9). *Xc* values at 5 kHz (expected values close to 0 Ω) reach 70% of the maximum *Xc*, indicating an intra-cellular current flows at low frequencies. The correlation coefficient between *R* at 50 kHz and *R* at other frequencies ranges from 0.96 to 0.99. In the clinical setting, the comparison of vector position and migration with target, reference intervals represents an additional advantage of BIVA, which is not allowed with BIS.

16.12 BIVA in Critically Ill Patients

Determinations of fluid volumes or estimates of body composition of patients in the intensive care unit (ICU) are neither practical nor reliable. Limitations in the use of tracer dilution methods and violations of the assumption of constant hydration of soft tissues severely diminish the validity of the dilution method and BIA in critically ill patients. In the critical care setting, however, central venous pressure (CVP) values, obtained from either CVP catheter or more invasive hemodynamic monitoring (i.e., pulmonary artery flotation catheter), are used as a guide for fluid infusion. Low CVP values are observed with true or relative hypovolemia, once a negative intra-thoracic pressure has been excluded. Conversely, high CVP values indicate true or relative hypervolemia and fluid overload.

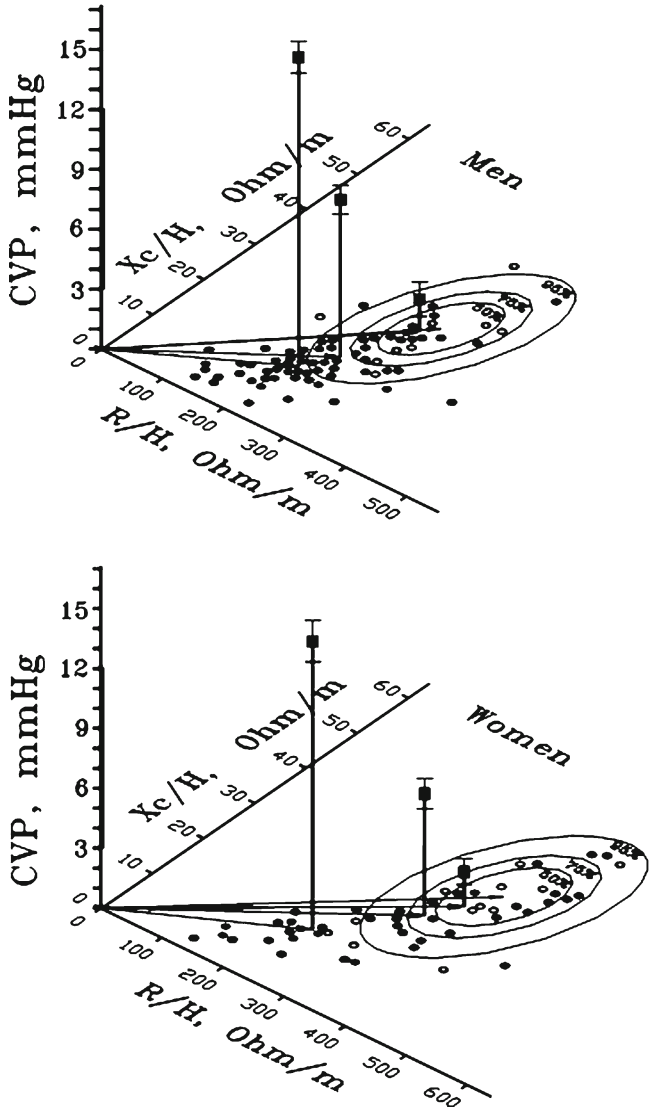

Fig. 16.10 BIVA discriminates mean CVP values in critically ill patients. Three groups of patients are represented with CVP values ranging between 0 and 3 mm Hg (low), between 3 and 12 mm Hg (medium), and above 12 mm Hg (high). Average CVP values are plotted (*solid squares*) vertically with 95% confidence intervals (*bars*) on the corresponding average impedance vector (*solid arrows*) over the reference, gender-specific, 50%, 75%, and 95% tolerance ellipses of the healthy population (average reference vector depicted as *open arrow*). *Open circles*, *donuts*, and *solid circles* represent impedance vectors from individual patients with low, medium, and high central venous pressure values, respectively. *CVP* central venous pressure, *R* resistance, *Xc* reactance, *H* height. (Reprinted from Piccoli et al. (2000). With permission)

BIVA was examined as an indicator of fluid status compared to CVP in ICU patients. Among 121 consecutive patients, CVP values were 8.1 mm Hg on average and ranged from 0 to 20 mm Hg (Piccoli et al. 2000). Both components of the impedance vector were significantly, linearly and inversely correlated with CVP values, namely $r = -0.53$ for R/H and $r = -0.52$ for Xc/H (Fig. 16.10). We classified patients with respect to their CVP values into three groups, namely low (0–3 mm Hg), medium (4–12 mm Hg) and high (13–20 mm Hg).

A progressive increase of the CVP was represented on the *R–Xc* plane with backward and downward displacement of the impedance vector from the target 75% tolerance ellipse to the region of

fluid overload (Fig. 16.10). The agreement between methods in determining the fluid status of the individual patient was greater for higher CVP values and shown as short impedance vectors out of the target ellipse (e.g., BIVA pattern indicating fluid overload), moderate for medium CVP values and poor for lower CVP values, which were associated with most vectors of normal length (62%) and with only 10% long vectors overshooting the upper pole of the 75% reference ellipse (i.e., BIVA pattern indicating tissue dehydration; refer to Fig. 16.1).

In the clinical setting, these results support a new operative definition of the optimal hydration status in ICU patients, considering that tissue hydration is governed by capillary and venous pressure together with systemic and local control factors. Therefore, the combination of a bedside measure of effective tissue hydration (i.e., tissue electrical conductivity) with one of venous system pressure provides a consistent opportunity to score a patient with both CVP values and impedance vectors within norms of the reference population as a patient with optimal hydration status. A patient with a BIVA pattern of tissue dehydration and with low CVP values then can be scored clinically worse than one with normal central venous pressure values. Similarly, a patient with a BIVA pattern of tissue hyper-hydration and with high CVP values can be scored clinically worse than one with normal CVP values.

The combined evaluation of tissue hydration by BIVA and CVP provides a useful clinical evaluation tool in the planning of fluid therapy for ICU patients, particularly in those patients with low CVP. Indeed, a different response or tolerance to fluid infusion is expected in dehydrated compared to well hydrated patients with the same low CVP (in the range of 0–3 mm Hg), where BIVA could identify those with reduced, preserved, or increased tissue fluid content.

16.13 BIVA in Congestive Heart Failure

The clinical validation of BIVA in HD patients allows direct extension of the same BIVA patterns to the congestive heart failure patients. Similar to the HD cycle, heart failure is characterized by a cyclical fluid overload (pulmonary and peripheral congestion) and removal (diuretics, extracorporeal fluid removal with dialysis). Despite current therapy, the high rate of re-admission indicates that the present criteria for discharge, typically based mostly on subjective impressions, correlates poorly with clinical stabilization.

Current practice uses a blood biomarker for interpretation of over-hydration, NT pro-BNP, in the diagnosis of heart failure. Values between the lower threshold point for “ruling out” acute heart failure and the higher, aged-adjusted indicator point for “ruling in” acute heart failure are referred to as “gray zone” values. In the situation of a “gray zone” diagnosis, clinical judgement of congestion is often necessary to ascertain the correct diagnosis. It is possible that the diagnostic and prognostic values of the NT pro-BNP depend on the level of congestion (i.e., “wet” worse than “dry” NT pro-BNP). In 315 patients admitted to the emergency department for acute dyspnea, NT pro-BNP was used as biomarker of heart failure, lung ultrasound was used to detect pulmonary congestion, and BIVA was used to detect latent peripheral congestion (i.e., without apparent edema) (unpublished observations). Patients were classified into two categories: cardiac-related dyspnea ($n = 169$) or non-cardiac-related dyspnea ($n = 146$).

The mean impedance vector was significantly shorter in patients with cardiac-related dyspnea, with a parallel decrease in both R and Xc components. BIVA was able to detect a “latent peripheral congestion” in dyspneic patients with NT pro-BNP in the “gray zone”. Ongoing intervention studies are needed to establish the region of the R–Xc plane where the individual vectors should be brought following an adequate fluid removal; the region where an optimal “dry” patient will decrease the rate of re-admission.

16.14 Segmental BIVA in Vascular Surgery

Direct measurements of segmental *Z* can be evaluated with BIVA. Edema localized in one leg frequently follows a femoral-popliteal bypass. We sought to establish how this localized edema can bias the interpretation of whole-body impedance (Codognotto et al. 2008). Limbs and trunk contribute differently to whole-body *Z* (90% and 10%, respectively). The *R* and *Xc* components of *Z* vector were measured at 50 kHz in 20 adult male patients without edema, before and three days after a femoral-popliteal bypass that induced pitting edema in the leg. Whole-body *Z* was measured from hand to foot of the right and left side. The impedance of each leg was measured from the pair of electrodes on foot and the other pair on the trochanter (Fig. 16.11).

Before surgey, the position of the mean whole-body and leg *Z* vectors from either side of the body was not significantly different (overlapping 95% confidence ellipses). After surgery, mean whole-body and leg *Z* vectors from the side without edema did not change position in the *R–Xc* plane with respect to before surgery position (Fig. 16.12). In contrast, mean whole-body and leg *Z* vectors of the body side with edema significantly shortened according to the BIVA patterns of fluid accumulation (along a down-sloping trajectory), due to a combined decrease in both vector components (*R* and *Xc*).

Because whole-body *Z* vector from the side of the body without edema was not sensitive to the edema localized in the leg of the opposite side, it can be utilized in the assessment of body composition also in patients with edema in one leg. Furthermore, a complete resolution of the fluid accumulation in the leg is expected to bring *Z*-leg to the baseline postition before surgery. Similar evidence cannot be obtained with other BIA methods.

Previously we demonstrated that sensitivity and specificity in detection of fluid overload in renal patients with diffuse edema, obtained with whole-body *Z* at 50 kHz, were comparable to those obtained with segmental *Z* of limbs and trunk.

The fact that in the non-edematous side both whole-body and leg *Z* vectors were insensitive to the fluid accumulation in the edematous leg indicates that the electric current path through soft tissues is largely determined by body geometry, and the contribution of body segments is likely different in any individual subject. This finding indicates that it is impossible to model the contribution of body segments to whole-body impedance.

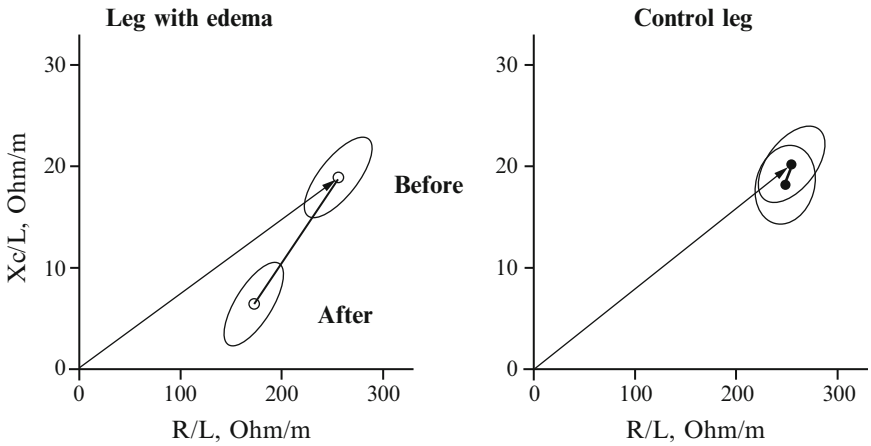

Fig. 16.11 Identification of edema in the leg with segmental BIVA. The mean impedance vector is normalized by the length of the leg (i.e., *Z*/*L*= *R*/*L*, *Xc*/*L*). A significant vector displacement (separate 95% confidence ellipses) was observed after the appearance of edema on the leg that underwent the surgical procedure compared to the non-affected leg. (Reprinted from Codognotto et al. (2008). With permission)

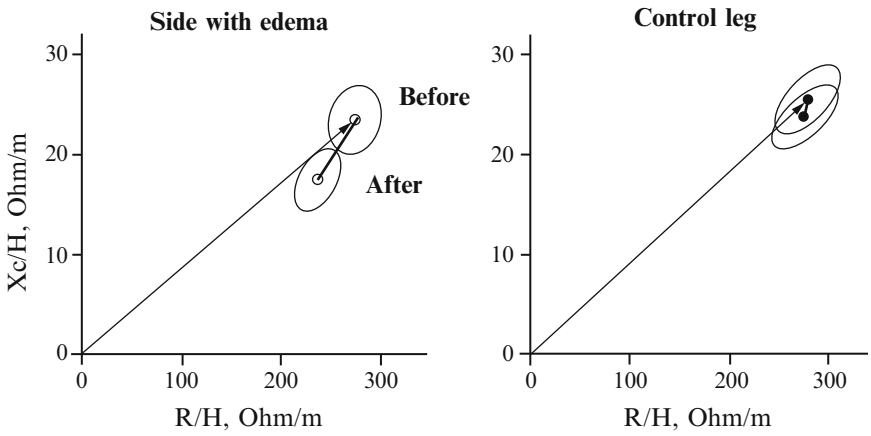

Fig. 16.12 Limb edema identified with the whole-body impedance vector. Whole-body mean impedance vector is normalized by the subject's height ($Z/H = R/H$, Xc/H). A significant vector displacement (separate 95% confidence ellipses) was observed after the appearance of edema on the leg of the body side following surgical procedure. No vector displacement (overlapping 95% confidence ellipses) was observed on the other body side. (Reprinted from Codognotto et al. (2008). With permission)

Summary Points of BIVA and Its Applications in Health and Disease

- BIVA is a safe, practical and non-invasive method. It relies on simple, whole-body measurements of *R* and *Xc* to produce an impedance vector that is compared to tolerance intervals to classify and rank hydration of an individual. Hydration status is characterized by distance from the mean vector of the reference population.
- BIVA offers advantages to conventional methods of assessment of hydration. It does not use regression equations or physiological constants, which are not valid in individuals with altered hydration, or body weight to predict changes in tissue hydration.
- BIVA accurately classifies over-hydration in women during pregnancy and obese individuals before and after weight loss. Thus, BIVA has the capacity to identify individuals at risk for complications associated with over-hydration during pregnancy and in obesity.
- Use of BIVA can contribute uniquely to dialysis prescription because it is able to track changes in tissue hydration status with a minimal detectable change of less than 500 ml. Adequacy of volume of fluid removed during the dialysis session reduces morbidity and improves patient outcomes.
- BIVA discriminates the composition of weight change associated with fluid and soft tissue gain or loss.
- BIVA offers a convenient alternative to the invasive procedures conventionally used in critical care patients to ascertain their need for fluid infusions.
- BIVA offers a potential advance in the assessment and monitoring of cyclical fluid overload in patients with congestive heart failure. Reliance on clinical impressions and many biomarkers fails to provide the sensitivity needed to positively affect readmission rates.
- Direct measurements of the impedance vector of body segments, such as the legs, and analysis with *R–Xc* graph and tolerance intervals provide a novel assessment of regional edema that can not be ascertained with whole-body measurements.

In summary, BIVA is a safe, simple and convenient method for the non-invasive, real-time assessment of hydration status that overcomes many of the limitations of techniques and approaches currently used.

Although its immediate use is in assessment and monitoring of hydration in dialysis, other clinical applications in critical care medicine, congestive heart failure and regional edema would benefit from its incorporation.

Chapter 17
The Uses and Misuses of Body Surface Area in Medicine

James Heaf

Abstract The practicing physician uses anthropometry in two ways: (1) to adjust variables for body size in order to define "pathological" values and (2) to dose medicine correctly. Two questions need to be answered in this context. Which background population is to be regarded as "normal"? Which is the best method of indexing? Based largely in nineteenth century principles of physiology, medical variables have traditionally been adjusted for body surface area (BSA). There are a number of problems with this approach. BSA is an essentially indefinable concept, its size varying according to the magnification used. Measurements of BSA have been plagued by methodological problems. The current standard BSA of 1.73 m^2 bears little resemblance to the BSA of modern Western populations. Empirical studies of physiological variables, even commonly used ones, such as glomerular filtration rate (GFR) and cardiac output (Q), have shown that BSA is not the best indexing parameter, or is simply wrong. Since anthropometric variables, such as weight, height, sex and ethnicity are easily available, it is suggested that medical correction formulae should be of the form

$$\text{Corrected variable} = \text{Variable} \cdot \left(A + B \cdot \text{Weight}^{C} \cdot \text{Height}^{D}\right) \cdot f_1(\text{Sex}) \cdot f_2(\text{Ethnicity})$$

where *A*, *B*, *C* and *D* are constants, and *f* are defined functions of sex and ethnicity, all of which are determined empirically. Derived constants, such as BSA and body mass index (BMI) should be abandoned, or their use empirically justified. More sophisticated adjustments using fat-free mass (FFM), total body water (TBW) or extracellular water (ECW) may be indicated, but should be justified empirically, as should more complex formulae.

Abbreviations

BMC	Bone Mineral Content
BMD	Bone Mineral Density
BMI	Body Mass Index = Weight in kilogram/(Height in metres)^2
BMR	Basal Metabolic Rate
BSA	Body Surface Area
ECW	Extracellular Water

17.1 Introduction

The assessment of physiological variables in medicine serves a precise goal, viz. the distinction between health and disease. Traditionally, "healthy" is initially defined as "normal", i.e., within the reference interval. The reference interval is defined as the interval within which 95% of the background population lie, 2.5% being above the interval and 2.5% below. For normally distributed variables, this interval will be almost identical to the mean average ± two standard deviations (SD), but for skewed variables, a more sophisticated analysis is required. "Healthy" is of course not identical with "normal"; subsequent research defines the precise relationship between the two concepts. The application of anthropometry in medicine is necessary for this definition. Since physiological variables often vary according to the size of the patient, small patients will a priori have smaller values for the variable, without this necessarily implying disease. Thus, variables should be corrected ("indexed", "normalised" or "scaled") for body size to achieve a definition of normality that is independent of body size. There is, however, a major problem with this approach: by implication, the background population is regarded as 95% healthy. However, most populations include both obese and cachectic individuals, and, in Western populations, the proportion of obese individuals exceeds 2.5% by an order of magnitude. Both excess and insufficient weight is associated with well-recognized increased morbidity and mortality. Should their physiological variables be included in the definition of "normal"? If not, which cutoff values should be accepted? And if obesity is to be excluded, how is this to be defined? Traditionally, obesity is defined as a BMI > 30 kg/m^2, measured by dividing a patient's weight in kilograms by the square of body height in metres. This definition will, however, include large, muscular individuals, who by any definition would be regarded as healthy.

These problems are particularly pertinent in the choice of indexing method. Most methods will give similar results, for average sized individuals, the main deviation occurring at the extremes of body size.

Table 17.1 Anthopometry-related physiological variables used in medicine

Parameter	Abbreviation	Usual normalisation index
Obesity		$Height^2$
Bone mineral content	BMC	Weight (complex function)
Bone mineral density	BMD	Weight (complex function)
Forced expiratory volume	FEV1	Logarithmic function of weight
Forced vital capacity	FVC	Height
Oxygen consumption		$Weight^{2/3}$
Glomerular filtration rate	GFR	BSA
Protein synthesis	PNA	Weight
Cardiac output	Q	BSA
Left ventricular mass	LVM	BSA

17.2 Indexing Criteria

Indexing methods should fulfill a number of criteria:

1. The indexing parameter should express a fundamental physiological truth, e.g., metabolic rate. Indeed, if the indexing parameter is valid for inter-species comparisons, more faith will be placed on it.
2. The correlation to the investigated variable should be documented in a large background population.
3. The indexing parameter should be linearly correlated to the investigated variable. In principle, more sophisticated equations are acceptable, but complicated adjustments are less likely to be adopted by the medical community, and should preferably be justifiable by reference to criterion (1). A good example of the latter is the reference interval for bone mineral density (BMD). This is conventionally assessed by two indexed variables: the *T*-score, being the number of SDs that the BMD differs from a young healthy individual, adjusted for weight, sex and height; and the *Z*-score, the number of SDs differing from a healthy individual of the same age, weight, sex and height. Both the *T*-score and the *Z*-score require complex formulae. The *T*-score is relevant for assessing absolute fracture risk, while the *Z*-score registers pathological values for bone mass, recognizing physiologically well described reductions in BMD with age and the menopause as being "normal".
4. The correlation line should cross the *Y* axis at an *X* value not significantly different from zero, i.e., one would expect infinitely small individuals to have infinitely small (but positive) physiological measurements. If the indexing parameter fulfills criteria 3 and 4, corrected values of the variable should no longer be correlated to the indexing parameter.
5. After indexing, the variable should result in similar reference intervals for males, females, children and differing races. If not, differences between groups should be explainable as "real", i.e., an expression of a fundamental physiological difference.
6. When comparing indexing parameters, the parameter that reduces the coefficient of variation of the variable the most, is to be preferred.

17.3 Indexing Variables

Various approaches to indexing have been proposed:

1. *Body weight (W)*. The major advantage of this approach is simplicity, and the main disadvantage is that obese and muscular individuals, with radically differing physiologies, will be treated identically.

Table 17.2 Formulae for calculating total body water (TBW) and extracellular water (ECW) in litres from age, weight (W) in kg and height (H) in cm

	Males	Females
TBW		
Watson et al. (1980)	$2.447 - 0.09516 \times \text{Age} + 0.1074 \times H + 0.3362 \times W$	$2.097 + 0.1069 \times H + 0.2466 \times W$
Hume and Weyers (1971)	$-14.01 + 0.1948 \times H + 0.2968 \times W$	$-35.27 + 0.3445 - H + 0.1838 \times W$
ECW		
Peters (2004)	$0.02154 \times W^{0.647} \times H^{0.724}$	$0.02154 \times W^{0.647} \times H^{0.724}$

2. *Body height (H)*. This is rarely used on its own, as it is too inexact a measure of body size. However, it is the logical choice when distance is a factor in the measurement, e.g., in bioimpedance studies where bodily electrical resistance is proportional to the distance between the electrodes.
3. *Body surface area (BSA)*. Rubner (1894) found that basal metabolic rate (BMR) in different mammals correlated better to BSA than body weight with values lying between 900 and 1,200 kcal/m^2/day. The BMR of young healthy adults is constant at 920 kcal/m^2/day. This correlation is plausible, since a large proportion of BMR is devoted to replacing heat losses through the skin. The application of BMR, and, therefore, BSA to other physiological variables relies upon the assumption that these are causally related to BMR.
4. *Total body water (TBW)* or extracellular water (ECW). The justification here is that many body functions, e.g., cardiac function and renal clearance would a priori be expected to correlate linearly with TBW. TBW is, however, difficult to measure directly, and derived equations from weight, height and sex are often used (Table 17.2). The increasing availability of multi-frequency bioimpedance tools allows simple and direct assessment of individual TBW. The measurement of GFR using radioactive tracer excretion rates and integrative mathematical techniques permits the simultaneous determination of ECW, assuming that the tracer is distributed uniformly in the ECW (Visser et al. 2008). TBW is the implicit choice of indexing for virtually all biochemical variables, which are measured per unit blood volume or body fluid.
5. *Fat-free mass (FFM)*, i.e., body mass minus adipose tissue. This is usually measured by dual energy X-ray absorptionometry (DEXA). The concept here is that the metabolic rate of adipose tissue and bone is very low, and that metabolic rate will, therefore, be closely correlated to FFM. Lean body mass (LBM) is a similar concept, usually defined as ECW, cell mass and non-fatty intercellular connective tissue. The concepts are not identical: cell membrane fat is excluded from FFM, but not LTM. TBW is approximately 73% of LBM. Another approach to excluding the effect of obesity is to use the ideal body weight (IBW), i.e., the weight associated with the lowest mortality for the patient's height, derived from actuarial tables, e.g., the Metropolitan Life Insurance Company (1980) (see Table 17.3). Obesity is here defined as the ratio between actual weight and ideal weight. Other concepts of non-obese weight are adjusted body weight and predicted normal weight (the latter two primarily developed for pharmacokinetics).
6. *Assumption-free Modelling*. An alternative approach to indexing is to ignore criteria 1, 3 and 4. Here, the variable is measured in a large background population, and an algorithm derived using multiple regression analysis, allometric scaling and all available indexing parameters, usually height, weight, sex and race. Instead of automatically assuming that the correlation is linear, i.e., the power exponent of the relationship is equal to 1, the optimal allometric exponent is measured empirically. For paediatric populations, the algorithm must be forced to cross the Y axis at an X value of zero, but this is not necessary for adult populations. Criterion 5 will automatically be fulfilled, but the resulting algorithm will make no pretence of expressing any fundamental physiological knowledge. Physiologists are welcome to philosophise as to whether the algorithm parallels BMI, BSA, LBM, BMI, TBW, W or H, or any other theoretical construct, but this is of secondary importance to the practising physician.

Table 17.3 Estimates of non-obese body weight. Weight (W) in kg and height (H) in cm (Green and Duffull 2004)

	Males	Females
Ideal body weight	$50 + 0.89 \times (H - 152.4)$	$45.4 + 0.89 \times (H - 152.4)$
	$52 + 0.75 \times (H - 152.4)$	$49 + 0.67 \times (H - 152.4)$
Fat-free mass	$0.285 \times \text{TBW} + 0.00121 \times \text{H}^2$	$0.287 \times \text{TBW} + 0.000974 \times H^2$
Adjusted body weight	$\text{IBW} \times 0.4 \times (\text{TBW} - \text{IBW})$	$\text{IBW} \times 0.4 \times (\text{TBW} - \text{IBW})$
Predicted normal weight	$1.57 \times W - 0.183 \times \text{BMI} \times W - 10.5$	$1.75 \times W - 0.0242 \times \text{BMI} \times W - 12.6$
Lean body mass	$1.1 \times W - 0.0128 \times \text{BMI} \times W$	$1.07 \times W - 0.0148 \times \text{BMI} \times W$
	$1.10 \times \text{TBW} - 120 \times \text{TBW}/H^2$	$1.07 \times \text{TBW} - 148 \times \text{TBW}/H^2$
Percentage of body fat (%BF) (Gallagher 2000)		
White and Afro-Americans	$48.1 - 809/\text{BMI} + 0.084 \times \text{age}$	$64.5 - 848/\text{BMI} + 0.079 \times \text{age}$
Asians	$51.9 - 740/\text{BMI} + 0.029 \times \text{age}$	$64.8 - 752/\text{BMI} + 0.016 \times \text{age}$

17.4 Problems with Body Surface Area as Indexing Parameter

As stated earlier, the use of BSA is popular, being based on early studies of metabolic rate. There is, however, a number of problems associated with its use (Heaf 2007).

1. The fractal problem. Surface area is a fractal variable (Mandelbrot 1982), i.e., the more it is magnified, the more details become apparent, and the greater the total surface area becomes, virtually ad infinitum. Thus BSA is essentially just as indefinable as the length of the British coastline, and just as immeasurable (Fig. 17.1).
2. The theory for the choice of BSA as index is that it is an expression of a universal physiological law, viz. that body metabolism is proportional to BSA. Thus, metabolism should be proportional to $W^{2/3}$, even when different species are compared. As originally described by Kleiber, this ratio is actually $W^{3/4}$, and the toxicological studies have also supported this ratio. Similarly, the optimal scaling index for oxygen uptake in humans is $W^{0.75}$. The explanation appears to be that muscle mass increases disproportionally with body size. The law that BMR is proportional to BSA breaks down when age is taken into account: the BMR of children falls linearly from 1,300 kcal/m^2/day at birth to 900 at 15, and oxygen consumption from 180 to 150 mL O_2/m^2/min.
3. The most commonly used formula for determining BSA is the Du Bois (1916) formula from 1916. BSA was determined by tightly covering the patients with manila paper moulds (or indeed, in some instances, pouring melted paraffin over the body). The moulds were then removed, opened and placed flat on photographic film. The film was subsequently exposed to light. Finally, the unexposed film was cut out and weighed. The BSA was derived from the weight by dividing by the average density of the photographic area. While the methodology was impeccable, only ten adults and one child were studied. The child was a cachexic girl weighing 6.27 kg at 21 months of age, and the adults included the notorious Mrs. McK, a 1.5 m tall lady weighing 100 kg, who is an outlier in many subsequent equations. Other patients included an 18-year-old with cachexia due to Type 1 diabetes and a 36-year-old man with the physical development of an 8-year-old and two patients with amputations. The derivation of the equation was based on the arguable philosophical premise that, since BSA is two-dimensional, the sum of the exponent power for weight multiplied by three, added to the power for height had to be exactly 2. In addition, the authors described equations for calculating BSA from bodily dimensions.

   Given these methodological problems, it is surprising that the Du Bois formula performs reasonably well in normal adults, but it, however, breaks down in children and the obese. Tucker

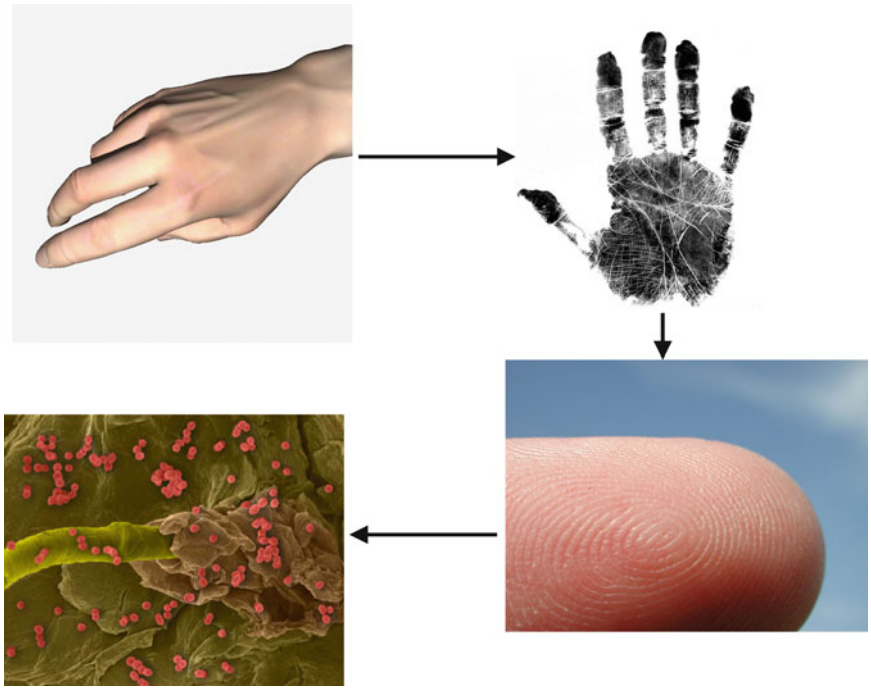

Fig. 17.1 The fractal problem. The body surface area expands with increasing magnification. The BSA can neither be defined nor measured

and Alexander (1960) attempted to assess its relevance for extremely obese patients (>100 kg), but experienced considerable difficulty: "it was difficult for the four obese people to stand up for the time required for the entire taping process"; it was decided to use "the measurement in which the tape followed all the folds of the skin as opposed to a straight-line measurement between two points"; "the exact location of the superior border of the greater trochanter was difficult to determine", etc. (Fig. 17.2). They concluded that the Du Bois formula was reasonably accurate (–11 to +2%), while the derived formulae were unsatisfactory (–8 to +20%). Similarly, Livingstone and Lee (2001) studying obese patients and using the Du Bois derived formulae, found that the Du Bois equation underestimated BSA by as much as 20%. Revised formulae were presented (Table 17.4). The Livingstone formula has been shown to be superior to the Du Bois formula in predicting body volume and body fat percentage. Other approaches are based on the assumption that BSA must in principle scale to $k \times W^{0.67}$, deriving values for k of 0.103–0.123. These formulae perform poorly compared to formulae including height. Most scientists prefer to use the formulae developed by Gehan and George (1970) or Haycock and Schwartz (1978), (for children) both of which are based on a large number of patients (401 and 81 respectively), although the superiority of these formulae to the Du Bois formula remains to be clearly proved (van der Sluys and Guchelaar 2002). Yu et al. (2003) have recently studied 3,951 Chinese individuals using three-dimensional whole body scanning. Their formula could be regarded as the definitive for BSA, but suffers from the disadvantages that the power exponents for height and weight were arbitrarily chosen as 0.5, and the maximum BSA in the study was only 2.09 m^2.

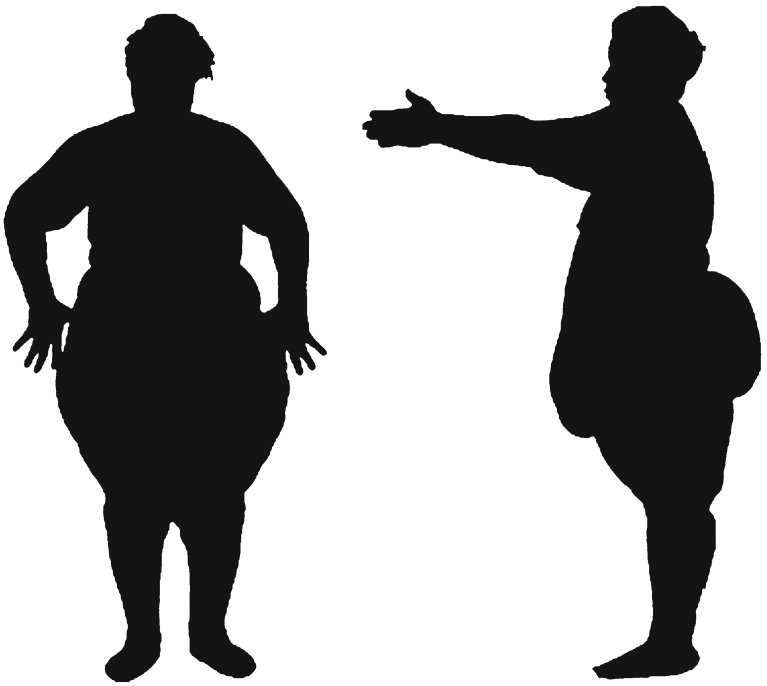

Fig. 17.2 Problems associated with measuring body surface area in the obese. Measuring BSA in the obese is difficult because of skin folds and poorly defined promontories (Tucker and Alexander 1960)

Table 17.4 Formulae for BSA

Equations are of the form

$$\text{BSA}\left(\text{cm}^2\right) = A \cdot \text{Height}\left(\text{cm}\right)^B \cdot \text{Weight}\left(\text{kg}\right)^C$$

Author	No. of patients	A	B	C
Du Bois and Du Bois (1916)	11	71.84	0.725	0.425
Banerjee and Sen	15	74.66	0.725	0.425
Boyd	411	178.27	0.5	0.4838
Gehan and George (1970)	401	235	0.42246	0.51456
Haycock and Schwartz (1978)	81	246.5	0.3964	0.5378
Nwoye (Africans)	21	13.15	1.2139	0.2620
Kurazumi		100.32	0.383	0.693

Mostellers adaptation[a]		167	0.5	0.5

[a] $$\text{BSA}\left(\text{m}^2\right) = \frac{\sqrt{H \cdot W}}{3{,}600}$$

17.5 The Origins of the 1.73 m² Norm for Body Surface Area

In these evidence based times, it is perhaps surprising to read how little documentation was required for the derivation of this figure, which first appeared in a study by McIntosh et al. (1928) (Fig. 17.3). On the basis of urea clearance studies of eight children and seven adults, the paper states: "Our experience

> Our experience confirms that of Addis and his colleagues. More constant normal values are obtained if one substitutes *A* (= surface area) in place of *W* in the clearance formulae. We have found it convenient to use as a unit the surface area 1.73 square meters, which is the mean of the areas of men and women of 25, estimated from the adjusted medico-actuarial tables of Baldwin and Wood Published by Fiske and Crawford (5).

Fig. 17.3 The birth of a number. The first mention of 1.73 m^2 as the norm for body surface area was made by Mcintosh et al. in (1928)

confirms that of Addis and his colleagues. More constant normal values are obtained if one substitutes *A* (= surface are) in place of *W* (= weight) in the clearance formulae. We have found it convenient to use as a unit, the surface area 1.73 m^2, which is the mean of the areas of men and women of 25, estimated from the adjusted medico-actuarial tables of Baldwin and Wood published by Fiske and Crawford", The Du Bois formula was used. The tables described young US citizens applying for life insurance. They were not referenced directly, but an adjusted version was published by Fisk et al. in 1927. While these individuals had been examined fully clothed, every effort was made to reach as accurate an estimate as possible: the figures for men were "adjusted from the Medico-Actuarial Tables by subtracting 1 inch from height in shoes, and 5 pounds from weight in clothes", and for women by subtracting 1½ in. and 4 lb, respectively, thereby giving us an insight into American clothing standards in the 1920s. There is a minor error in the calculation: the correct figure derived from the tables is 1.72 m^2.

The figure 1.73 m^2 has served the physiological community well for nearly 80 years, but it is clearly no longer applicable to Western populations, as can be seen from Table 17.5. As early as 1951, Homer W. Smith noted that there was a problem with the value 1.73 m^2. "The figure of 1.73 m^2 is of course arbitrary. The writer has averaged the surface areas reported by 11 groups of investigators… and obtains 1.85 m^2 for 263 men and 1.81 m^2 for 164 women." If we accept the basic premise that the index of normalisation should be the average BSA of US 25-year-old males and females, then a new index of normalisation 1.92 m^2 should be adopted. The approach is, however, problematic. Periodic adjustments, e.g., once every decade, would be required for the foreseeable future. Some physicians might be horrified by the implication that an average BMI of 26.7 kg/m^2 would now be defined as "normal". One possible solution could be to choose a less overtly obese population, such as the European Union. This would improve, but not remove, the normative problem, but might just provide a short respite. Another possible approach follows from the observation that 1.73 m^2 corresponds to a BMI of 22.3, a figure which both then and now, is associated with the lowest mortality. Thus, serendipity has given us an "optimal" value for BSA, which should be preserved for posterity regardless of present and future developments of the reference interval. While accepting that the choice of 1.73 m^2 is arbitrary, the political decision to permanently retain the value will permit comparisons of different populations, separated both by geography and time. Again, to quote Homer Smith: "It is immaterial which figure is used so long as all investigators use the same figure, and since innumerable data are now reported in terms of 1.73 m^2, we may accept this usage as established." A suitable symbol of the decision to create this new fundamental physiological constant could be the deposition of a square platinum-iridium plate of exactly 1.73 m^2 at the Bureau International des Poids et Mesures, Sèvres, Paris.

Fig. 17.4. A new fundamental constant?. A suitable symbol of the decision to create a new fundamental physiological constant, viz. a BSA of 1.73 m^2 could be the deposition of a square platinum-iridium plate of exactly 1.73 m^2 at the Bureau International des Poids et Mesures, Sèvres, Paris

Table 17.5 Evolution of body dimensions 1927–2002

	25-year-olds	USA 1927	USA 2002	EU 2002
Male	Weight (kg)	68.9	83.2	78.6
	Height (cm)	172.7	176.8	177.2
	BSA (m^2)	1.80	2.04	1.98
Female	Weight (kg)	58.5	71.0	64.8
	Height (cm)	162.6	163.1	165.4
	BSA (m^2)	1.62	1.81	1.74
All	BSA (m^2)	1.72	1.92	1.86
	BMI (kg/m^2)	22.3	26.7	24.3

17.6 Applications to Other Areas of Health and Disease

17.6.1 Glomerular Filtration Rate (GFR)

The indexing of GFR is an excellent example of the above discussion. All advanced species require the ability to excrete excess and toxic products that enter the body. Water soluble products diffuse from the TBW to the blood. The blood is filtered in the renal glomerulus, the GFR being the amount of blood water filtered per unit time. Providing there is no tubular absorption or excretion of the product, its clearance is identical to the GFR. Conventional measures of renal function are inaccurate

in this respect. For instance, since creatinine is excreted in the tubules, creatinine clearance will be about 25% higher than GFR. Even slightly reduced GFR (and, in some instances also increased GFR, e.g., early diabetic nephropathy) is associated with increased morbidity and mortality. GFR is correlated to body size; thus, the definition of a normal indexed GFR is of great medical importance. The choice of BSA as the optimal index factor was based on a small study (McIntosh et al. 1928, *vide supra*), and has since been virtually unchallenged. Several studies have now reanalyzed the choice and shown that it does not fulfill the criteria mentioned above. Inter-species comparisons show that GFR scales to $W^{0.72–0.79}$ (Singer 2001), higher than the value expected for BSA ($W^{0.67}$), but similar to the power index for BMR ($W^{0.75}$). The use of BSA for GFR indexation results in low values for children aged 1–5 (Kurtin 1988), a finding which has no obvious physiological explanation. Indeed, the optimal scaling index for babies (<12 months) is $W^{1.30}$, making the BSA assumption wildly inaccurate. On the other hand, while some studies have shown a lower GFR in females, other studies have shown no difference. Thus, BSA correction is probably valid for inter-sexual comparisons, but is inappropriate for children.

The criterion of a linear correlation to BSA passing through the origin is not fulfilled. The correlation between GFR and BSA is low. If GFR is corrected for height, the correlation to BSA is absent. Adjusting for BSA in obese groups results in artificially low values for GFR.

17.6.2 Cardiac Physiology

Cardiac function is assessed by a number of static and dynamic variables: left ventricular mass (LVM), left atrium diameter (LAD), cardiac output (Q) and stroke volume (SV). Traditionally, they have been indexed using BSA. This is a somewhat surprising assumption. Blood flow in adipose tissue is poor and accounts for only 5% of Q, so a priori FFM would be expected to be the optimal index. Inter-species comparisons show that Q scales to $W^{0.78–0.81}$, similar to the measured value for BMR, but higher than the figure for BSA ($W^{0.67}$), while SV scales to $W^{1.05}$. De Simone investigated 970 adults and children, and found BSA appropriate for adults, but not for children. The most accurate indexing factor was, however, $H^{2.7}$. In contrast, Turley et al. (2006) investigating 759 adults found BSA, height, weight and FFM all inapplicable for both Q and SV. Similarly, Neilan et al. (2008), in 15,667 adults, found that simple isometric indices to actually increase the variability of LAD, and found the optimal indexing parameter to be $W^{0.262}$. George et al. (2001) showed that BSA indexing is inappropriate for LVM in 464 junior athletes, the optimal indexing parameter being $W^{0.91}$, while Daniels et al. (1995) found H^{3} to be the appropriate index in 192 children. A study of 254 dialysis patients showed that correcting LVM using the de Simone index of $H^{2.7}$ was superior to BSA in predicting mortality and cardiovascular outcomes. Using BSA instead of LBM to normalize LVM results in an inappropriate difference between men and women. The Framingham Heart Study (Vasan et al. 2000) proposed a simple height and sex based indexing for all echocardiographic variables.

17.6.3 Pulmonary Physiology

Vital capacity is proportional to height, and is 20–25% lower in women than men of the same height. Nevill and Holder (1999) found that forced expiratory volume in 1 s (FEV1) was related to body weight and height in a logarithmic fashion, peaking at 90 kg for men and 84 kg for women, and even declining thereafter for women. Traditionally, peak oxygen uptake has been indexed to weight, but

there is overwhelming evidence that a power function is preferable. Most studies show values between $W^{0.71}$ and $W^{0.80}$, again significantly different for the value if BSA was the correct index. Interspecies studies show that the elastic work of breathing scales to $W^{0.78}$, minute volume to $W^{0.80}$, pulmonary surface area to $W^{0.76}$ and mean expiratory flow rate to $W^{0.77}$ (Singer 2001). All these power values are similar to that for BMR (*vide supra*).

17.6.4 Hepatic Physiology

Surprisingly little research has been performed on size adjustment for dynamic liver function variables. Variables are either not adjusted, or weight or BSA is arbitrarily chosen as the indexing parameter. For instance, the lowest acceptable value for the Indocyanine green clearance is variably reported as 5.2 mL/min/kg or 9%/min. Where investigated (Leevy et al. 1962), variation in hepatic blood flow actually increases when corrected for BSA. An indirect method of assessing the correct indexing factor for liver function is to study the hepatic clearance of drugs. These generally show that LBM indexing gives the best results (Morgan and Bray 1994; Green and Duffull 2004). One notable exception is the clearance of alcohol, which is more closely related to BSA than LBM.

17.6.5 Hematology

A priori, one would expect blood volume to be more closely related to weight than BSA, since both blood volume and weight are three-dimensional variables. However, blood-volume measurements correlate better to BSA than weight. Feldschuh and Enson (1977) confirmed this, but also noted a major negative impact of body fat on the result, with grossly obese patients (defined as a high W/IBW) having less than half the blood volume predicted by BSA. This implies that blood volume is a function of TBW or LBM rather than BSA. The authors recommended scaling for IBW, but LBM indexing would be equally appropriate in this setting.

17.6.6 Drug Therapy

BSA is commonly used for adjusting drug dose to prevent toxicity, particularly for anti-cancer drugs. Previously to 1990, it was presumed that clearance would be a function of BMR and thus BSA. A recent review (Felici et al. 2002) noted, however, that in only 5/23 anti-neoplastic drugs where the relationship had been investigated could one find a significant relationship between BSA and clearance or toxicity. A 5–20-fold variation in pharmacokinetics is common even after adjusting for BSA. The correlation was relevant for highly protein-bound drugs confined to the blood compartment, which is a function of BSA (*vide supra*). The presence of adipose tissue must a priori be expected to influence pharmacokinetics in a number of complex ways: lipophilic drugs will have lower peak concentrations and slower elimination; adipose tissue in the liver will reduce hepatic metabolism. In contrast, the distribution volume of hydrophilic drugs will be unaffected by obesity. Many oncologists have reacted to these findings by capping doses at an arbitrary BSA of e.g., 2 m^2, but there is evidence that this may reduce drug efficacy in the obese. Green and Duffull (2004) found that weight was the best predictor of drug volume of distribution, while clearance was best described by LBM.

Thus, in the absence of pharmacokinetic studies, or sophisticated assessments of hepatic enzyme function, weight is the appropriate index for acute treatments, e.g., anaesthetics, while LBM is the appropriate index for chronic administration.

17.6.7 Obesity

Obesity has traditionally been defined as a BMI > 30 kg^2/m, and the concept of anthropometric correction would seem tautological. However, the physiological concept of obesity is that of a raised body fat percentage (%BF), which is not a linear function of BMI. Body fat percentage is largely independent of height. More advanced models include abdominal girth or waist-hip ratio. Abdominal girth >102 cm (male) and 88 cm (female), and wait-hip ratios >0.9 (male) and 0.85 (female) are associated with increased morbidity. The most sophisticated assessment of abnormal fat accumulation uses DEXA (Gallagher et al. 2000). Here, "unhealthy" was defined as a %BF >25 (male) and >33 (female). Anthropometric formulae for estimating %BF were derived (Table 17.3).

17.7 Conclusion

While the physiologist has a mission to define the underlying principles governing physiological processes, the practising physician pursues more prosaic questions. Is an abnormal value pathological, or just an expression of deviation in body size and obesity? What is the correct dose of medicine? The widespread use of BSA is a consequence of the historical dogma that BMR is proportional to BSA, which is untrue, and that bodily functions are linearly correlated to BMR. This is partly or wholly untrue for a number of variables. The above review shows that, in many cases, FFM, LBM or TBW are better choices, in accordance with basic physiological principles. The medical community needs, therefore, to return to a more empiric approach consisting of two steps:

1. Define the background population. Who is the patient to be compared with? For some purposes, e.g., the prediction of complications, a comparison to a young, healthy population is to be preferred; in others, e.g., the diagnosis of pathological conditions, the comparison should be to a group of the same age and sex. For some questions, "healthy" obese and cachectic individuals should be excluded from the background population, and perhaps supplied with their own anthropometric analysis.
2. The basic model for anthropometric correction is:

$$\text{Scaled variable} = \text{Variable} \cdot \left(A + B \cdot \text{Weight}^{C} \cdot \text{Height}^{D}\right) \cdot f_1(\text{Sex}) \cdot f_2(\text{Ethnicity})$$

where A, B, C and D are constants, and f are defined optional functions of sex and ethnicity. More complex equations can be used where relevant (Nevill et al. 2005). If paediatric populations are included the constant A should be equal to 0, but otherwise no prior assumptions of the constants are made, and their optimal value is measured. Simplified versions of the resulting equation are to be empirically justified, but are hardly required in a computerised age.

Similarly, use of more complex indices, e.g., total body water is to be justified. Different equations for different populations, e.g., children versus adults are acceptable. More complex functions, e.g., logarithmic, are acceptable if empirically more correct. BMI and BSA, being derived functions of weight and height are not included. Previous equations, based on a priori use of BSA, that have been shown not to accord with the facts, e.g., the currently used adjustment for GFR, are to be abolished. It is left to physiologists to determine whether the resulting equations are compatible with existing physiological theories or not.

Summary Points

- Body surface area is indefinable.
- Body surface area is difficult to measure.
- The choice of 1.73 m^2 as the norm for body surface area is inapplicable to modern Western populations.
- Basal metabolic rate is not a linear function of body surface area.
- Body surface area is not the optimal scaling index for most physiological variables.
- Alternatives include total body water, fat-free mass and lean body mass.
- Body surface area does not predict drug toxicity.
- Optimal scaling indices should be empirically determined.
- Complex formulae are not a problem in a computerised age.
- The usual formula for assumption-free modelling is:

$$\text{Scaled variable} = \text{Variable} \cdot \left(A + B \cdot \text{Weight}^{C} \cdot \text{Height}^{D}\right) \cdot f_1(\text{Sex}) \cdot f_2(\text{Ethnicity})$$

  where A, B, C and D are constants, and f are defined optional functions of sex and ethnicity.
- The background population for the reference interval should be defined.

Key Features of Body Surface Area in Medicine

1. Since the nineteenth century, dividing physiological variables by body surface area has been a popular method of adjusting measurements for differences in body size.
2. Body surface area is also used for adjusting medicine dose, larger doses being given to patients with a larger surface area.
3. The reason for this is that BMR, and thus most physiological processes, are assumed to be proportional to body surface area.
4. Body surface area has traditionally been measured by encasing subjects in wax paper, and subsequently measuring the area of the paper. This process is laborious, and numerous equations for calculating body surface area using patient weight and height have been devised.
5. Physiological variables are often adjusted to a "normal" body surface area of 1.73 m^2, the calculated average area of life insurance applicants in the USA during the 1920s.

Part III
Tools and Techniques in Anthropometry: Muscle

Chapter 18
Anthropometry of Human Muscle Using Segmentation Techniques and 3D Modelling: Applications to Lower Motor Neuron Denervated Muscle in Spinal Cord Injury

Paolo Gargiulo, Ugo Carraro, Thomas Mandl, Helmut Kern, Sandra Zampieri, Winfried Mayr, and Thordur Helgason

Abstract This chapter describes a novel approach to determining muscle anthropometry using medical imaging and processing techniques to evaluate and quantify: (1) progression of atrophy in permanent muscle lower motor neuron (LMN) denervation in humans and (2) muscle recovery as induced by functional electrical stimulation (FES). Briefly, we used three-dimensional reconstruction of muscle belly and bone images to study the structural changes occurring in these tissues in paralyzed subjects after complete lumbar-ischiatic spinal cord injury (SCI). These subjects were recruited through the European project RISE, an endeavour designed to establish a novel clinical rehabilitation method for patients who have permanent and non-recoverable muscle LMN denervation in the lower extremities. This chapter describes the use of anthropometric techniques to study muscles in several states: healthy, LMN denervated-degenerated not stimulated, and LMN denervated-stimulated. Here, we have used medical images to develop three-dimensional models, including computational models of activation patterns induced by FES. Shape, volume and density changes were measured on each part of the muscles studied. Changes in tissue composition within both normal and atrophic muscle were visualized by associating the Hounsfield unit values of fat and connective tissue with different colours. The minimal volumetric element (voxel) is approximately ten times smaller than the volume analyzed by needle muscle biopsy. The results of this microstructural analysis are presented as the percentage of different tissues (muscle, loose and fibrous connective tissue, fat) in the total volume of the rectus femoris muscle; the results display the first cortical layer of voxels that describe the muscle epimisium directly on the three-dimensional reconstruction of the muscle.

These analyses show restoration of the muscular structure after FES. The three-dimensional approach used in this work also allows measurement of geometric changes in LMN denervated muscle. The computational methods developed allow us to calculate curvature indices along the muscle's central line in order to quantify changes in muscle shape during the treatment. The results show a correlation between degeneration status and changes in shape; the differences in curvature between control and LMN denervated muscle diminish with the growth of the latter. Bone mineral density of the femur is also measured in order to study the structural changes induced by muscle contraction and current flow. Importantly, we show how segmented data can be used to build numerical models of the stimulated LMN denervated muscle. These models are used to study the distribution of the electrical field during stimulation and the activation patterns.

SCI	Spinal Cord Injury
UMN	Upper motor neuron

18.1 Introduction

18.1.1 Medical Anthropometry

Computer simulation and modelling of the human body and its behaviour are very useful tools in situations where it is either too risky to perform an invasive procedure or too costly for in vivo experiments or simply impossible for ethical reasons. However, the modelling of these systems may be seriously complex because of the large number of potential variables. Indeed, a system may have such a large number of parameters that they cannot all be identified and considered. Therefore, the modelling approach, especially in biological systems, is designed according to established criteria and objectives and is usually constrained to accurately consider or describe only certain characteristics while approximating or ignoring others. Medical modelling of biological systems is generally applied under certain conditions: (1) to describe mechanical and/or electrical behaviour; (2) to evaluate normal and abnormal morphologies for three-dimensional (3D) visualization of animal anatomy; (3) to simulate biological conditions and surgical treatments; and (4) to study tissue properties or to correlate different tissue characteristics.

An emerging field of anthropometry is the so-called biomodelling, which is the creation of highly accurate physical models of human anatomy directly from medical image data. The process involves capturing human anatomy images, processing these data to isolate individual tissue or organs and then using rapid prototyping techniques (automatic manufacturing of physical items directly from 3D computer data) to provide a physical model.

The main stages of medical modelling process are:

- Medical imaging
  - Select the optimal modality such as CT or MRI
  - Set the appropriate protocol which enables a proper visualization of the region of interest
  - Scan the patient

- Export the data from the scanner in an appropriate format
- Process the data: segmentation of the organs or tissue to be modelled
- Further processing to analyse and model other biological characteristics and properties (such as tissue composition, fibre activation and bone mineral density [BMD]) or rapid prototyping to produce a physical model

18.1.2 Anthropometric Techniques in Clinical Research: Muscle Denervation After Spinal Cord Injury (SCI)

Anthropometry is proving to be an extremely useful tool in medical research and, indeed, has the potential to be very valuable in the evaluation and comparison of anatomic structures in both normal and pathological conditions. One area of specific interest to us is the use of anthropometric techniques in the study of muscle degeneration after denervation. It is known that alterations of functional and structural properties of muscle fibres result from the lack of permanent innervation in SCI patients; however, the specifics vary dependent upon the location of the lesion. The literature offers a good knowledge base concerning the progression of muscle atrophy in response to upper motor neuron (UMN) lesions in human patients; however, much less is known about the time-course of transition from atrophy to degeneration in irreversible lower motor neuron (LMN) muscle denervation. For example, much research shows that muscle mass decreases significantly during the first few months after UMN damage (Lotta et al. 1991) with ultrasound revealing a loss of up to 40% of the mass in the first month post injury (Gorgey 2007; Taylor et al. 1993). After the first few months post injury, the atrophy process slows down, resulting in a stable atrophy (50% of initial muscle mass) with the onset of spastic incomplete paralysis for up to 2 years after SCI (Andersen et al. 1996; Giangregorio et al. 2006). Stable muscle atrophy occurs in long-term paraplegics with complete UMN lesion from 3 to 20 years post SCI (Kern et al. 2007; Biral et al. 2008). Interestingly, most of these studies were related to FES in thoracic level paraplegics and demonstrate that UMN denervated muscles can respond with tetanic muscle contraction when stimulated with commercial electrical stimulators even 20 years after SCI (Kern et al. 2007; Mohr et al. 1997). These features are in sharp contrast, however, to SCI that involve LMN lesions. These injuries generally involve a complete disconnect between the muscle fibres and the nervous system; the accompanying atrophy and degeneration processes are particularly severe when a complete transverse SCI involves all the LMNs of the affected muscles. Complete LMN denervated muscles degenerate quickly and are soon unable to sustain tension during tetanic contractions induced by electrical stimulation (Dulhunty and Gage 1985). Over time, unstimulated muscles become unexcitable with commercial electrical stimulators, so that the long-lasting severe atrophy of the permanently inactive muscles is irreversibly exacerbated by the substitution of myofibres with adipocytes and collagen (Kern et al. 2004; Biral et al. 2008). It is known that in LMN denervated human muscles the degeneration occurs over years; however, the time course is not clear.

18.1.3 Restoration of LMN Denervated Muscle: EU Project RISE

Loss of muscle mass occurs with many pathological conditions and is linked to increased patient disability, morbidity and mortality (Janssen et al. 2002; Fisher 2004) thus, it is important to discover how to deter muscle degeneration. Empirical clinical observations (Kern 1995; Kern et al. 1999) revealed that LMN denervated-degenerated muscle can recover by a specific variation of home-based

daily FES therapy. This is in contradiction to earlier data which suggested that FES was effective only when started immediately after LMN lesion. The observations led to the founding of the European funded project RISE in November 2001. The project aim was to establish the biological basis for a clinical rehabilitation treatment for patients who have permanent muscle LMN denervation in the legs. To this end, it funded research designed to reverse muscle degeneration produced by the permanent lack of innervation in SCI patients using muscle FES. Some of the funding has been used to fund research in rehabilitative centres in Vienna (Austria), Heidelberg (Germany), Hamburg (Germany), Tuebingen (Germany), Reykjavik (Iceland) and Vicenza (Italy). The RISE project has achieved its goal using a multidisciplinary approach to optimize technology to stimulate LMN denervated muscle with custom-designed electrodes and stimulators developed in Vienna, Austria (Mayr et al. 2001). The project encompassed a clinical trial with over 20 voluntary patients and additional animal experiments to research the muscle restoration process by combining physiological, histological, immunohistochemical and biochemical analyses with anthropometric techniques (Kern et al. 2009; Mödlin et al. 2005). Many of the tissue analyses employed to study structural changes occurring in LMN denervated muscle (both after long-term LMN denervation and during electrical stimulation) were performed with biopsies which meant that only a few grams of muscle could be analyzed. Complementary imaging techniques, such as CT scan, were also employed in order to assess and validate histological information. The value of the imaging methods demonstrates that the development and use of non-invasive anthropometric techniques is critical to this area of research.

18.1.4 Objectives

In this chapter, modelling tools and a 3D approach are used to study, display and quantify the structural changes occurring on the quadriceps muscle during long-term denervation and electrical stimulation treatment. In previous studies, the effects on cross-sectional area (CSA) of LMN denervated muscle in SCI patients were monitored by means of CT scans of the thigh, using the top of the trochanter major muscle as the individual reference point. By distally scanning four further cross-sectional (axial) areas at increments of 10 cm, robust morphometric data of the patient's thigh were collected in the course of the EU project RISE. Cross-sectional areas of the left and right thigh muscles, before and after 2 years of h-b FES-training, are reported in Fig. 18.1. The average CSA of *quadriceps muscle* was 27.5 ± 8.2 cm² in the group (n = 25) before FES training (1, red lines), whereas in the FES-trained group (n = 20) it was 36.6 ± 13.8 cm² (2, blue lines). This variation corresponded to the +33% increase in CSA of the h-b FES-trained thigh muscles; this difference was highly significant ($p < 0{\cdot}001$, Mann–Whitney U-test). The CSA values measured by CT scan were very similar in the right (thin lines) and left (bold lines) legs both before and after 2 years of training (red and blue lines, respectively, in Fig. 18.1). This approach provides valuable clinical information, but its limitation is that 5–10 scans over a volume of interest of 40–60 cm are not enough to give comprehensive information on volume, shape and density of the whole muscle.

Here, medical imaging routines, segmentation techniques and special computational tools are developed and used to quantify volumes and tissue characteristics and classify physiological conditions in normal, LMN denervated, LMN denervated-degenerated and LMN denervated muscles treated with FES (in Paragraphs 4 and 5). The results from the segmentation work are used as input to simulate and study activation patterns in muscle to optimize the stimulation techniques (in Paragraph 6). Finally, the induced effects of FES on the quadriceps muscle are measured and displayed on the patella bone (in Paragraph 7).

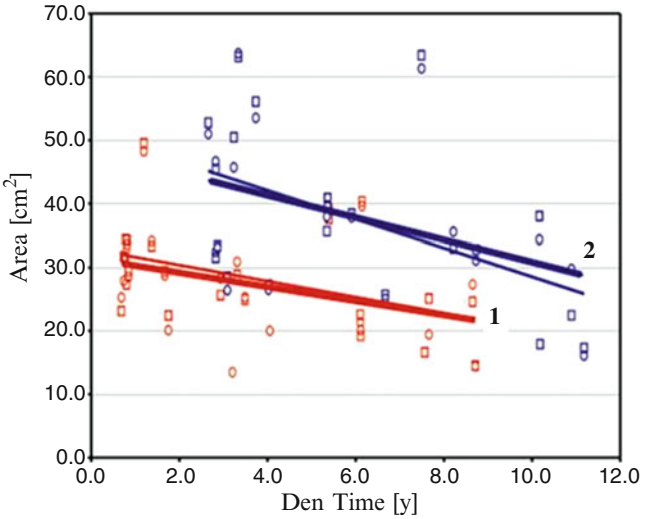

Fig. 18.1 Two years of home-based functional electrical stimulation (h-b FES) of lower motor neuron (LMN) denervated human muscle. Correlation of time spent from spinal cord injury to computer tomography scan area. Muscle cross-section area before (*labeled with 1*) and after functional electrical stimulation (FES) (*labeled with 2*). After FES results are shifted to the right because the values are plotted with respect to the time elapsed from spinal cord injury to computer tomography scans. The medical images are very similar in the right (*displayed with thin lines*) and left legs (*displayed with bold lines*), both before (*labeled with 1*) and after FES (labeled with 2)

18.2 CT Data, 3-D Reconstruction and Segmentation of Muscle and Bone

18.2.1 DataSet Source

X-ray computed tomography (CT) is an imaging method that uses X-rays to produce images of structures 'inside' the body. Patients are scanned slice-per-slice and each slice is scanned several times from different angles.[1] Each imaged volume element (voxel) is traversed, during the scan, by numerous X-ray photons and the intensity of the transmitted radiation is measured by detectors. The measured intensity profile contains information on the densities the beam encountered on its path through the body (i.e. the denser the regions the weaker the signal). With suitable mathematical methods the measured profiles of each slice are transformed into an image of the structures inside – the image is reconstructed, the grey value corresponding to the linear attenuation coefficient.

Three-dimensional data are gathered scanning the patient's lower limbs with spiral CT. The scan starts above the head of the femur and continues down to the knee joint, both legs being covered by one scan. Slice increment is set to 0.625 mm resulting in a total of about 750–900 CT slices, depending on the patient's size.

Every acquired CT slice is subdivided into a matrix of different size, from a minimum of 128 × 128 up to 1024 × 1024 volume elements (voxels). The average linear attenuation coefficient μ of the tissue contained in each voxel is represented by floating numbers in the computer which range from 0.0 up to values equal to 1.0.

Once the image is calculated from the 3D dataset it is converted into a matrix of picture elements (pixels) with each pixel assigned the attenuation value of the corresponding voxel. Linear attenuation

[1]Modern CT scanners might use broader beams and sensor arrays to scan larger regions of the body at once.

Table 18.1 Hounsfield threshold sets for the displaying and the segmentation of main human tissues scanned with Computer Tomography technique

	Threshold sets for computer tomography (HU)	
Anatomical tissues	Min	Max
Bone	226	3,071
Compact bone	662	1,988
Spongial bone	148	661
Muscle	–5	135
Fat Tissue	–205	–10
Skin Tissue	–30	60
Tooth	1,200	3,071

Different intervals of Hounsfield unit (HU) values are associated to main human tissues scanned with Computer Tomography (CT) or spiral CT technique. The intervals are established after experimental experience. The HU value range are set large in order to include, from the same tissue type, HU values from different physiological conditions such as: well trained muscle (displayed with high HU values), atrophic muscle (medium–low HU values), degenerate muscle (low HU values), osteoporosis bone (low HU values) and skin in different dermatological conditions

coefficients are rescaled to an integer range that encompasses 4,096 values, between –1,000 and 3,095. From these intensity readings, the density or attenuation value of the tissue at each point in the slice can be calculated. This scale is called CT number or Hounsfield unit (HU) and it is expressed by the following formula:

$$\text{CT Number} = 1{,}000 \cdot \frac{\mu_{\text{pixel}} - \mu_{\text{water}}}{\mu_{\text{water}}} \tag{18.1}$$

With this scaling, if the linear attenuation coefficient of a given pixel (μ_{pixel}) is equal to that of water, the CT number will be 0. If μ_{pixel} is less than μ_{water} the CT number will be negative which is typical for air spaces, lung tissues and fatty tissues. Values of μ_{pixel} greater than μ_{water} will result in positive CT numbers. Very dense tissue such as bone has large positive numbers.

Table 18.1 is a display of main organic tissues and respective HU intervals.

In the datasets used in this work, each slice consists of 512 × 512 pixels, and each pixel has a grey value in the Hounsfield unit (HU) scale of 4,096 grey-scale values, represented by a 12-bit value. A total dataset from a single scan (for instance of 750 slices) is therefore 512 × 512 × 750 × 12 = 2.36 Giga Bits (ca. 300 MB). This dataset allows a complete high resolution 3D description of the tissue, including the muscles and bones in both upper legs.

18.2.2 Quantitative CT and Calibration

In order to be able to monitor the volume of a patient's muscle in the course of electrical stimulation therapy it is obvious that the volume measurements, which are performed with an interval of several months, have to be comparable and precise, since the smallest change in volume indicates the result of the therapy and answers the question: Is the muscle still degenerating or is it growing in size?

For the volume measurement of the muscle this means that the imaged region must be the same in every scan (i.e. cover the whole thigh in our case) and that the image segmentation scheme applied must not differ either. For the bone density measurements, corresponding areas of the bone have to be identified.

Absolute quantification of muscle density and BMD requires that the CT scans made at different time points be comparable. To achieve this reproducibility, the CT scanner has to be calibrated regularly or even better before each scan. If data are acquired on different CT scanners the standardisation of the scanning protocol and calibration method is essential as well.

In addition to a calibration of the device it is important for the reproducibility to choose the same region of interest. Other factors to take care of are the use of the exact same scanning protocol: slice thickness, X-ray tube voltage and reconstruction algorithm. Selecting the same parameters is essential when the datasets are to be comparable.

Calibration is normally done with a standard phantom. The phantom, typically a circular disk about 5 cm thick and 35 cm diameter, is made up of several different components to estimate spatial and density resolutions. Spatial resolution is tested using decreasing circular rods and density resolutions using rods that gradually decrease in density. These phantoms are also used for testing constancy, that is, to detect possible drift of the scanners' sensors and/or other changes in the scanning instrumentation. If necessary, corrective measures are taken.

In this work we performed phantom measurements for quality assurance of the device once a year. Hydroxylapatite rods are used for single calibration and to determine the BMD equivalent. Additionally, in each scan of the patient's leg, three rods are placed in parallel with the thigh. The rods have a circular cross-section, are different in diameter and one is a pipe containing water. They cover the total length of the scanned region and therefore are present in every CT cross-sectional image. This enables a statistical evaluation and calibration of the density values in all scans.

18.2.3 Image Processing Tools: Segmentation

In the analysis of the objects in images it is essential that we can distinguish between the objects of interest and "the rest." This latter group is also referred to as the *background*. The techniques used to find the objects of interest are usually referred to as segmentation techniques: segmenting the foreground from background. Any segmentation result is a set of pixels that are related to each other in some sense, that is they belong to the same class (e.g. tissue class or an object in an image). This set of pixels is usually called segm*entation mask* or simply *mask*.

In computer vision, segmentation refers to the process of partitioning a digital image into multiple regions (sets of pixels). The goal of segmenting an image is to produce a binary mask image which fulfils the segmentation criteria.

The software environment in which the medical images shown in this chapter were processed and segmented is *MIMICS* (www.materialise.com). The main goal is to reconstruct – from spiral CT data – 3D models of muscle and bones and to isolate RF from other quadriceps muscle in order to study their anthropometrical characteristics in different physiological conditions. The first step in the segmentation process is to establish a threshold, which discriminates the region of interest from the rest by grey value.[2] From the visual point of view, thresholding allows pixels to be highlighted (e.g. in different colours), thereby distinguishing pixels with certain grey values from others. In an M × N CT scan slice, each element in the image matrix *a[m,n]* displays a level of brightness coded by a HU value which varies from

[2]In the case of thresholding, segments (i.e. pixel classes) are defined by ranges of grey values. Spatial information is not used to determine class membership of pixels.

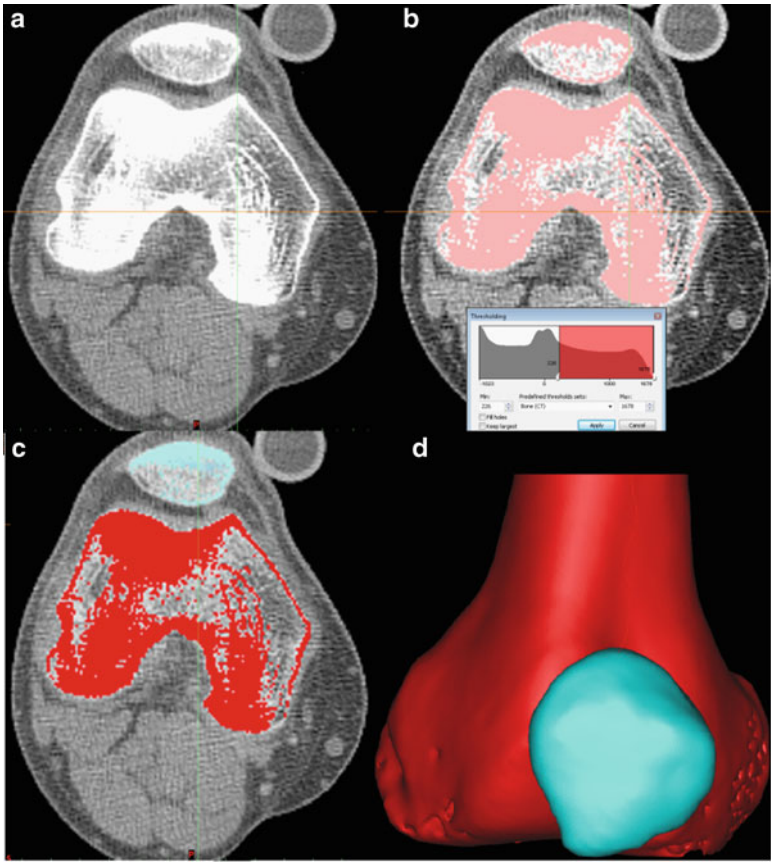

Fig. 18.2 Basic steps to segment medical images: displaying (**a**), thresholding (**b**), region-growing to isolate the region of interest from its surroundings (**c**) and reconstruction and visualization in three dimensions (**d**). Knee cross-section from Computer Tomography scan (**a**). Bones thresholding: 600–2,000 HU (**b**). Selection of the knee cap (patella bone) using region-growing (**c**). Three–dimensional (3D) views from the patella and the femur segment (**d**)

–1024 to 3072. If, for instance, the (HU-) region of interest to be visualized is compact bone in adults (ranging in value between 600 and 2,000 HU), then the threshold test condition will appear as follows:

If $600 \geq a[m,n] \geq 2000$ *then* $a[m,n]$ = *object* = *colour*
Else $a[m,n]$ = *background*

The dataset after thresholding will display only certain information: the pixels having HU values (or more generally grey values when data are not CT scans) within the defined interval are selected and highlighted in color while the others having HU values outside the threshold remain black (Fig. 18.2a, b).

The second segmentation tool which typically follows thresholding is *region growing*. Region growing is an image segmentation approach in which neighbouring pixels of the current region's boundaries are examined and added to the region class if no edges are detected (or more generally some inclusion-criteria is met). This process is iterated for each boundary pixel in the region. An arbitrary *pixel seed* is chosen and compared with neighbouring pixels. The region is grown from the pixel seed by adding neighbouring pixels that are similar, increasing the size of the region. This whole process is continued until all pixels belong to a region.[3] Thus, if in the dataset there are several compact bones not connected

[3]Region growing uses spatial information when determining pixel class membership: pixels that belong to the same region are connected.

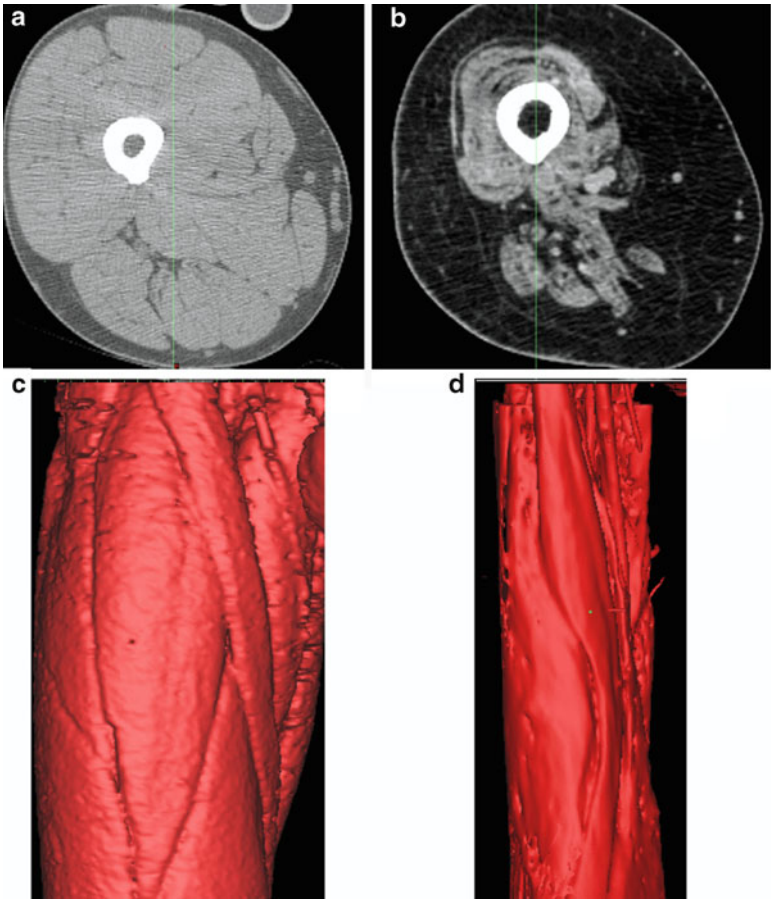

Fig. 18.3 Comparison between muscle morphology in healthy and denervated–degenerated lower extremities. Computerized tomography data from healthy and long-term denervated thigh showing the dramatic muscle volume loss due to degeneration of the muscle tissue: Cross-section healthy thigh (**a**). Cross-section of 4-year-old spinal cord injured thigh (**b**). Three-dimensional model of healthy thigh (**c**). Three-dimensional model 4 years spinal cord injured thigh (**d**)

directly to each other, then using region growing it is possible to display these bones individually though they have the same threshold (600–2,000) (Fig. 18.2c). The region growing condition appears as follows:

If $600 \geq a[m,n] \geq 2000$ *then* $a[m,n] \in$ *pixel seed*
Else $a[m,n] =$ *background*

Typically, the two segmentation techniques described deliver good quality segmentation of the CT images used in this work, sometimes requiring minor manual editing to correct misclassified pixels. After successful segmentation the regions can be converted to and visualized as 3D objects, as seen in Fig. 18.2d.

The main target in this work is to segment and compare quadriceps femoris in normal, long-term LMN denervated, LMN denervated and stimulated muscles. The quadriceps includes four muscles on the anterior side of the thigh: RF, vastus lateralis, vastus medialis and vastus intermedius.

As a consequence of long-term denervation the muscle degenerates dramatically. This can be observed in the cross-sectional areas and the 3D reconstruction of right thighs from normal-innervated after SCI subjects (Fig. 18.3). The muscles become very thin and the single bellies are no longer recognizable in their shape. Only RF remains recognizable among the quadriceps muscles

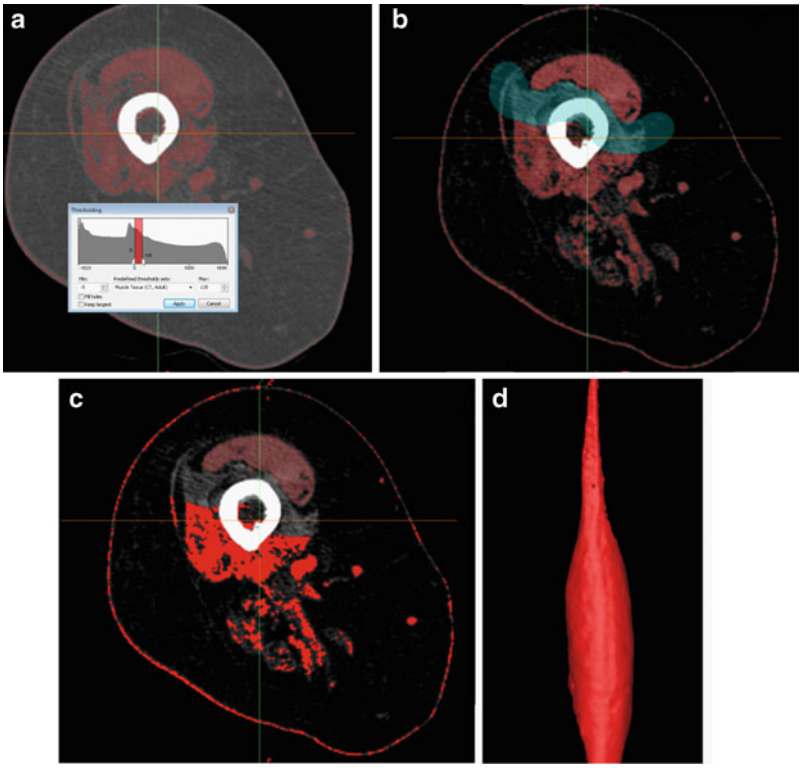

Fig. 18.4 Segmentation of rectus femoris muscle (RF) in lower motor neuron (LMN) denervated muscle. Segmentation of rectus femoris (RF): the muscle threshold is set to –5, 135 HU (**a**); this interval allows a good visualisation of the degenerate muscle belly. Editing contours are used to delete muscle tissues surrounding RF (**b**). Region-growing applied on RF (**c**). Reconstruction and –3D visualization of RF (**d**)

though it is severely degenerated compared to the normal situation. Therefore, 3D modelling and segmentation techniques are used to isolate RF from other bellies and to monitor changes occurring during the degeneration and restoration process.

Besides, accurately measuring changes in RF during electrical stimulation treatment is important to evaluate treatment effectiveness; indeed, surface electrodes are placed on top of the quadriceps and since RF occupies the middle of the thigh it is especially exposed to the current distribution (Mandl et al. 2008). RF is thus the optimal target for monitoring therapeutic effects and morphological changes with a 3D approach (Gargiulo et al. 2007, 2008, 2009).

18.2.4 Segmentation of RF

The threshold interval chosen to segment RF is: [–5, 135] HU. A wide interval is chosen because it must display muscle tissue and allow monitoring of changes, particularly the restoration–degeneration process. Within the selected interval the displayed pixels represent both normal and degenerated muscles, connective tissue and water, but subcutaneous fat is excluded. Thus the surrounding fat in RF is automatically excluded from the segmentation mask (Fig. 18.4a). After thresholding, the next step for the segmentation is to isolate RF from the other muscles. For this purpose special editing tools are used.

The process starts from a cross-section where the muscle boundaries are visible (usually in the middle, along the length of the muscle). A contour is manually drawn around the muscle and projected to the next cross-sections in both directions. If the contour fits the new cross-sectional area well, it is projected ahead unchanged to the next slice, otherwise it is adapted[4] and then projected ahead. The process continues until all cross-sections containing RF cross-sections are edited (Fig. 18.4b). The contour areas are then erased, creating a gap between segmentation target and its surrounding areas. Finally, a new segmentation mask representing RF is created applying a region growing procedure which creates a new mask separating the edited structure that is no longer connected to the surrounding (Fig. 18.4c). The result of the segmentation process and a 3D rendering thereof is shown in Fig. 18.4d.

18.3 Measurement of Volume and Density

Modelling is a unique way to visualize morphological changes occurring due to the degenerative process in LMN denervated muscles and to display electrical stimulation effects on shape and geometry. In addition, the 3D file provides information on muscle density and volume which would otherwise be difficult to access.

Muscle density and volume are immediately available from the segmentation object; these parameters depend on pixel number, size and intensity (generally grey value or HU value in CT scans).

18.3.1 Measurement of Volume

In digital imaging, a pixel or picture element is the smallest piece of information in an image. A voxel instead, is a volume element representing a value on a regular grid in –3D space. The voxel datasets have a limited resolution, as their position is only exact in the centre of each voxel. The value of a voxel may represent various properties; in CT scans it accounts for the opacity of the material to X-rays (the Hounsfield units).

The volume in a 3D file can be generally obtained through the voxel size and number of voxels in the 3D object. In biological tissues this is more complicated and there are additional issues to consider. The image that results from the assumption that a voxel within a dataset is occupied by one single material is an approximation of the reality because of real dimensions involved in biological tissue. As the voxels are not infinitesimal in size, the result is a measured value that is a mean attenuation value for the different materials or tissue types in each voxel. This will be the case especially for the voxels lying at the border of the object or voxels covering objects thinner than the voxel's dimensions. This lack of resolution can be somewhat overcome by assigning mean values to these voxels and then using interpolation algorithms.

In *Mimics* which we use for segmentation and modelling, there are two different algorithms that can be used to compensate partial volume effects. The first is called *contour interpolation* and compensates partial volume effects in 2D (i.e. in each cross-section). The second method is *grey value interpolation* which uses also consider neighbouring voxels in the above and below slices. The latter algorithm is more accurate but tends to deliver noisy 3D models, which makes it less useable for medical images. Incorporating partial volume effect compensation greatly improves 3D model rendering accuracy.

[4]Assuming that shapes change little from one slice to the next the adaptation necessary is small. It is done with active contours that "snap" to boundaries.

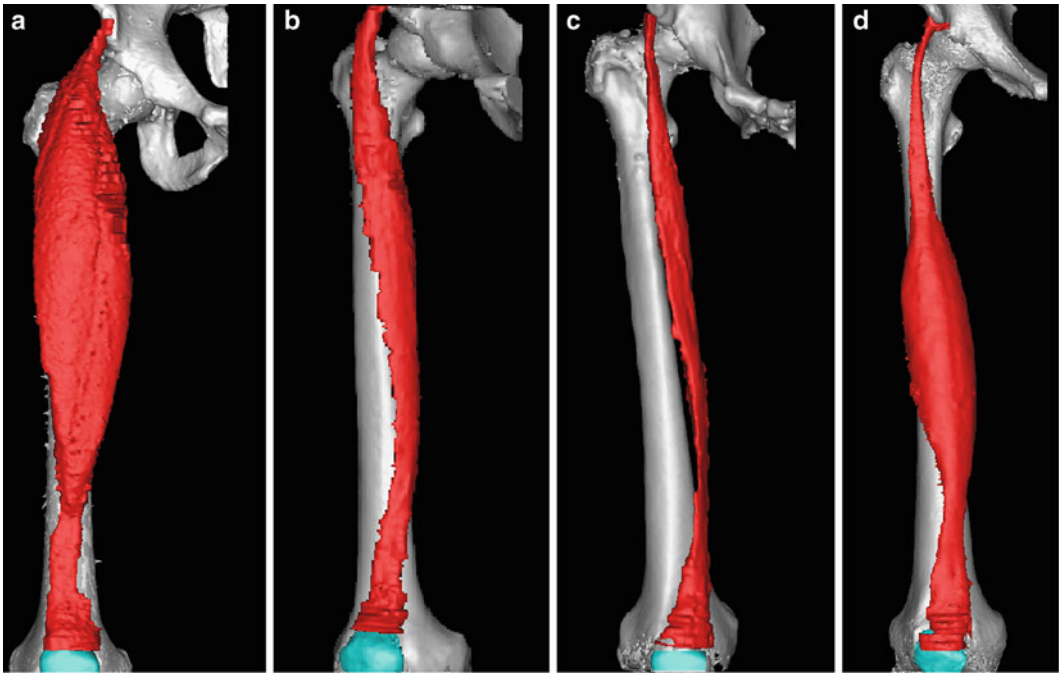

Fig. 18.5 Rectus femoris (RF) in different physiological conditions: reconstruction and –3D visualization. Rectus femoris volume in different physiological conditions: healthy, volume: 354,000 mm^3 (**a**). Ten months after spinal cord injury (SCI), volume: 106,000 mm^3 (**b**). Seven years after SCI, volume: 86,000 mm^3 (**c**). Seven years after SCI with 4 years home-based functional electrical stimulation treatment (h-b FES), volume: 145,000 mm^3 (**d**)

In this work the contour interpolation algorithm was used to visualize the 3D model of RF and the grey value interpolation algorithm to calculate and measure the muscle volume. Figure 18.5 depicts the 3D reconstruction and the volume measurement in: normal, short-term LMN denervated, long-term LMN denervated and LMN denervated-restored RF, while the restoration process is seen in Fig. 18.6.

18.3.1.1 3D Reconstruction and Volume Measurement in: Normal, Short-Term Denervated, Long-Term Denervated and Denervated-Restored RF

Anthropometric techniques have allowed us to follow the degeneration of denervated muscle in terms of muscle volume over a long time course. In Fig. 18.4, we show muscle thresholding of four different RF muscles. The 3D reconstruction of these muscles is shown in Fig. 18.5. The first, in Fig. 18.5a, is a normal RF muscle with a volume of 354,000 mm^3. It is the biggest one of the four with a characteristic distribution of the tissue mass. It has reached considerable diameter already at the height of the trochanter but is slimmer in its lowest one third part. In Fig. 18.5b is a RF muscle 10 months after flaccid paralysis. Its volume is reduced to 106,000 mm^3 in a relatively muscular individual. The upper part of the muscle shows considerable loss of diameter. It can be seen in Fig. 18.5c how the degeneration process continues. The volume of the muscle is reduced to 86,000 mm^3 and it is slim along its entire length. Figure 18.5d shows a denervated-restored RF muscle. After a 4-year period of degeneration, FES was applied for 4 years. In response, the muscle volume increased to 145,000 mm^3 but the tissue distribution in not the same as in a normal RF muscle as can be seen by comparing Fig. 18.5a, d. In Fig. 18.5d the muscle is slim until well

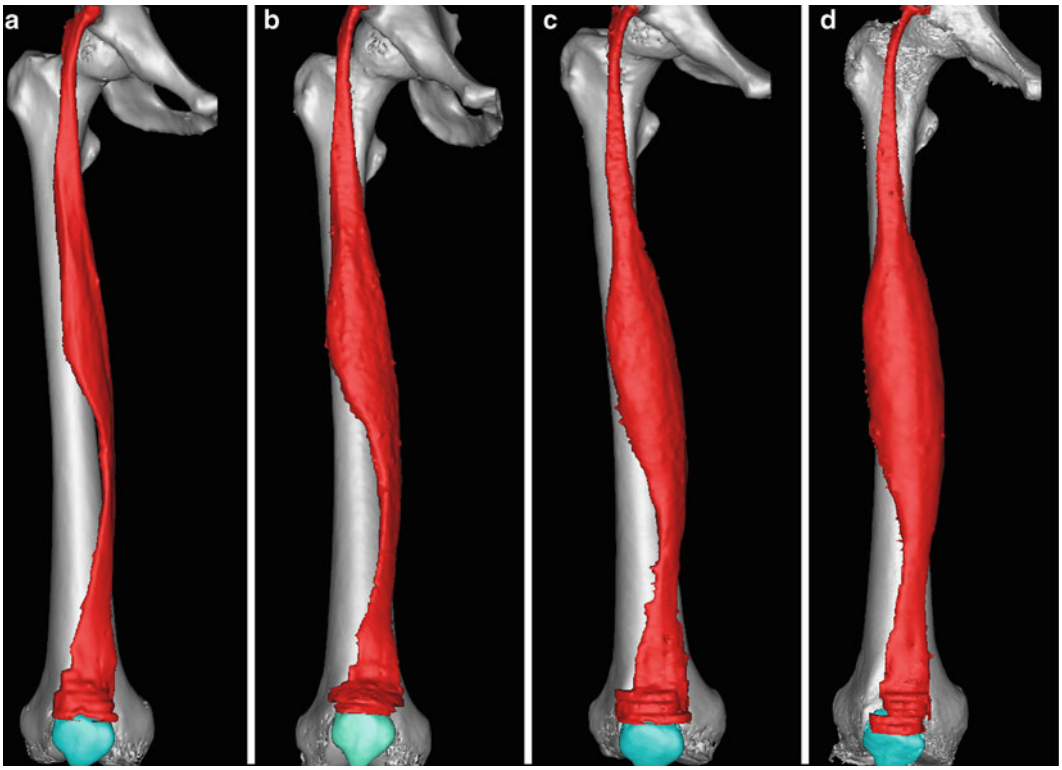

Fig. 18.6 Rectus femoris growth during 4 years of h-b FES treatment: reconstruction and –3D visualization. Changes in muscle volume (RF) during 4 years of h-b FES. The patient started the treatment 4 years after spinal cord injury with RF volume of 93,000 mm^3 (**a**). Muscle volume: 140,000 mm^3 after 1 year h-b FES (**b**). Muscle volume: 165,000 mm^3 after 3 years h-b FES (**c**). Muscle volume: 167,000 mm^3 after 4 years h-b FES (**d**)

below the trochanter and has its biggest diameter in the middle to lower part of the muscle. The explanation of this is probably that the stimulation is not reaching all the muscle fibres in the muscle which is of the pennatus form.

18.3.1.2 Restoration Process: Muscle Volume Measurements Reveal Positive Effect of FES

Volumetric data have allowed us to strongly demonstrate the highly restorative effects of FES. Electrical stimulation treatment is known to increase the volume of spastic muscles (i.e. muscles with an intact LMN). In that case, the neuron connected to the muscle is stimulated, as it has a lower stimulation threshold than the muscle fibres. Each nerve axon is connected to many muscle fibres and by stimulating those axons all connected muscle fibres contract and are "trained". Because this can be done with a stimulating pulse frequency causing tetanic contraction in the muscle fibre, the muscle can be trained effectively.

In a denervated muscle where there is no LMN, the muscle fibres have to be stimulated directly. In a degenerated stage, for example, after 2 years of inactivity, the stimulating threshold of het muscles has risen and the diameter diminished. Activating these muscle fibres requires stimulating currents of two to three orders of magnitude higher than those used for spastic muscles. This means that the duration of the stimulating pulses approach 100 ms limiting the frequency to values below 10 Hz, which is not enough for a tetanic contraction of the muscle fibre.

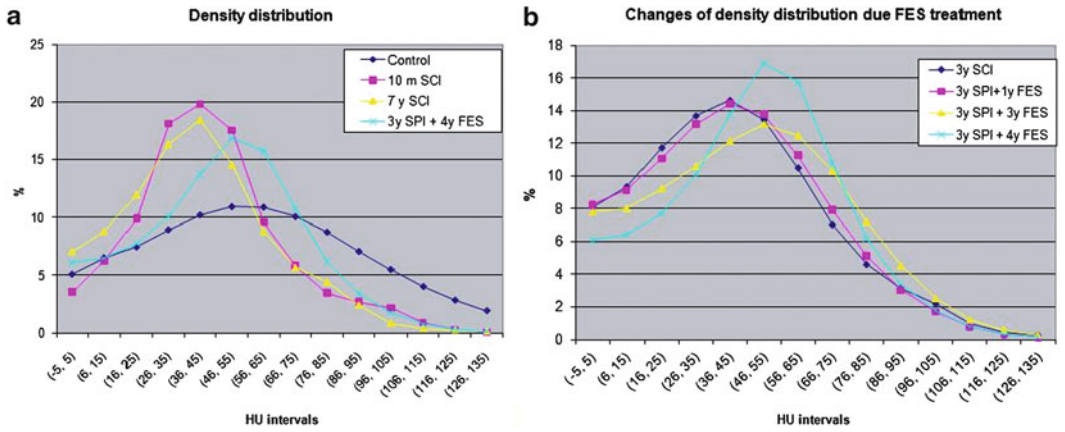

Fig. 18.7 Density distribution from rectus femoris (RF) in different physiological conditions (**a**). Changes of RF density due to h-b FES treatment (**b**). Density distributions from RF in different physiological conditions: control (*circular dots*), 10 months after spinal cord injury (SCI) (*rectangular dots*), 7 years after SCI (*triangular dots*) and 7 years after SCI with 4 years h-b FES treatment (*converging arrow dots*) (a). Density distributions during h-b FES treatment: patient 3 years after SCI at beginning of the h-b FES (*circular dots*), after 1 year h-b FES (*rectangular dots*), after 3 years h-b FES (*triangular dots*) and after 4 years h-b FES (*converging arrow dots*) (**b**)

The initial effect of the electrical stimulation treatment of the muscle fibres is to lower the stimulating threshold, meaning that stimulating pulses can be shortened to values below 40 ms thus enabling frequencies up to 20 Hz. As the stimulation threshold is lowered, training with tetanic contraction of the muscle can begin (Kern et al. 1999). The effect of the tetanic electrical stimulation treatment is a recovery in muscle fibre diameter up to normal values and a rise in muscle force which, however, does not reach normal values (Kern et al. 2005).

Because the action potential is not conducted from one muscle fibre to another, each and every fibre has to be stimulated by the electrical current. This has to be considered when designing the stimulating electrode geometry. If the muscle fibres are lying parallel in the longitudinal direction of the muscle (fusiformis) then they can be more easily stimulated that if they are placed like fibres in a feather (pennatus form).

18.3.2 Measurement of Density

Muscle density is a parameter describing the structural integrity of the tissue. The anthropometric techniques we have applied here, have allowed us to obtain a more accurate measure of muscle density and to better gauge the effects of FES to denervated muscle. To measure muscle density, it was necessary for us to determine the voxel intensity within the muscle volume. In this work, we evaluated the RF muscle density by monitoring the number of voxels in the interval [–5 to 135] HU. To visualize and analyze the distribution, the HU interval is divided into 14 sub-intervals with 10 HU values each and changes are measured between these intervals from datasets taken from the same subject at different points in time.

The number of voxels in each interval is displayed as a percentage of the overall distribution.

Figure 18.7a displays the density distribution in normal, LMN denervated, LMN denervated-degeneration and LMN denervated electrically restored RF. The number of voxels (percentage of

total) is on the ordinate axes and the HU intervals are located on the abscissa. Muscle density distributions from normal, LMN denervated, LMN denervated-degenerated and LMN denervated-restored muscle are displayed in the same panel.

The control distribution shows that in normal muscle most of the values are distributed between 26 and 85 HU with a mean value of 54.5 HU. The situation is completely different in degenerated muscles where, depending on the degree of degeneration, the muscle density is decreased. Density mean values for RF after 10 months and 7 years from SCI are 45 and 40 HU, respectively. A patient who has been injured for 8 years but receives FES for only 4 years shows a mean density value of 47 HU.

The restoration process as change in muscle density is displayed in Fig. 18.7b. The density restoration process induced through the stimulation treatment is qualitatively represented by the shifting of the distribution towards denser values (Fig. 18.7b). The mean density 4 years post SCI is 37 HU. In response to FES treatment, it changes as follows: 36 HU after 1 year, 42 HU after 3 years and 47 HU after 4 years of electrical stimulation treatment.

18.4 Quantitative Analysis of Muscle Tissue by Quantitative Colour 3D Imaging

18.4.1 Muscle Biopsy Versus 3D Modelling

In order to study the changes in tissue composition on a larger muscle section, with the intent of supporting and validating histological analyses from minute tissue biopsies, a new non-invasive method was developed to analyze macroscopic and microscopic structural changes of human skeletal muscle. The advantages of using segmentation technique and 3D modelling are mainly two: (1) the analysis of whole muscle and (2) the potential to isolate single muscle bellies such as RF. We applied the technique to our studies of degenerating muscle as described here.

The degeneration process completely changes muscle physiology and fibre structure. Fig. 18.8a shows the light microscopy aspects of a biopsy harvested from normal human muscle, which is characterized by large, well packed muscle fibres with minimal inter-fibre space. In normal muscle, some loose connective tissue could be observed around the vessels only if the biopsy contained some endomysial tissue. On the other hand, muscle tissue harvested from thigh muscles of paraplegic subjects 4 years after a severe conus cauda lesion is characterized by a patent degeneration of the tissue, which presents as severely atrophied muscle fibres, prevalent areas of loose connective tissue and some adipocytes (Fig. 18.8b). After an additional 3 years of LMN denervation, during which time the subjects performed home-based FES training, the light microscopy specimen of the muscle biopsy shows numerous large muscle fibres despite the still abundant intermyofibre fibrous tissue. The biopsy area covered by muscle fibre transverse sections are indeed more than 95% in the normal muscle, decreased to 14% after 4 years of LMN denervation and recovered to 37% during the 3 years of FES training.

This approach gives important indication of the changes occurring in the muscle tissue but on a very restricted volume. Further, the method is invasive and, therefore, only a limited region can be analyzed and no more than two time points are typically studied in SCI patients.

The size of the volumetric element (a voxel) in the dataset presented in the previous paragraphs is approximately 0.7 mm^3; therefore the CT number assigned to the voxel represents an average of

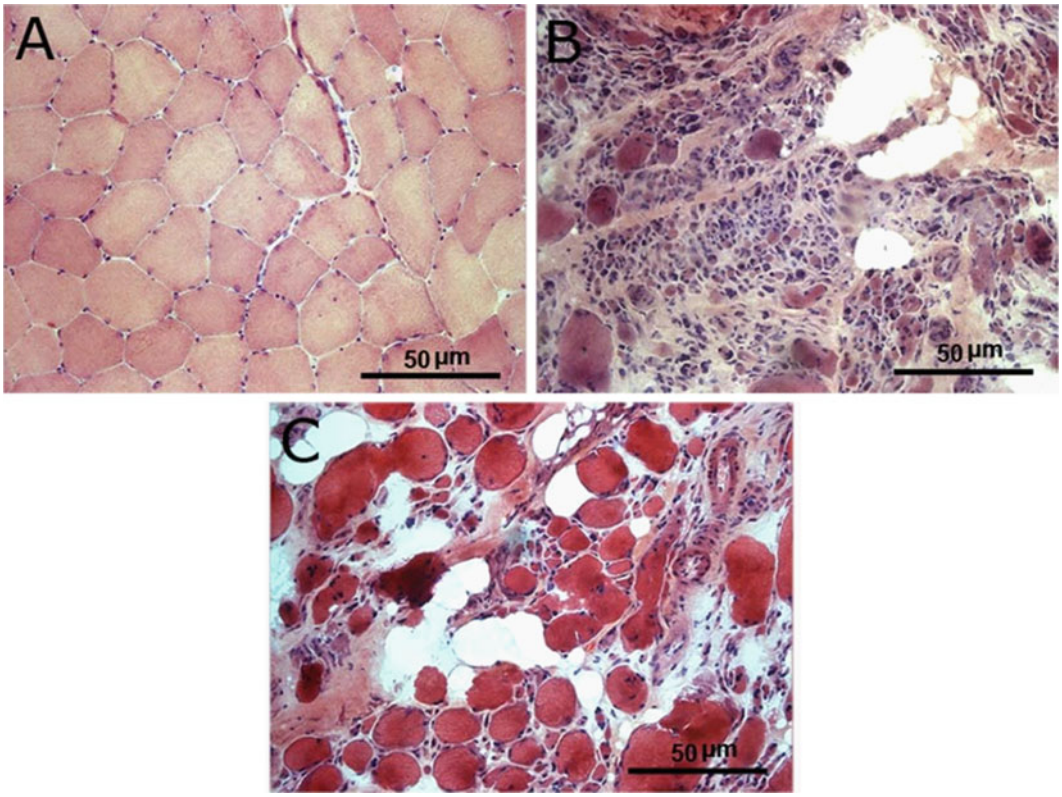

Fig. 18.8 Muscle biopsy from muscle tissue in different physiological conditions. Biopsies harvested from different human muscles: normal-innervated (**a**). Muscle tissue harvested from thigh muscles of a paraplegic subject 4 years after a severe conus cauda lesion (**b**). Biopsies harvested from the same subject after 7 years of LMN denervation, but who underwent home-based FES training during the last 3 years (**c**)

the different biological elements, which may be present within a single elementary volume. For instance, in the case of normal muscle tissue, a voxel would contain the transverse section of 20–50 muscle fibres, which is approximately one tenth of the volume analyzed with the typical needle muscle biopsy (Kern et al. 2004) as displayed in Fig. 18.7 (where a section of around 0.02 mm² presents the cross-sections areas of about 50 fibres).

Muscles are normally displayed with CT number between 40 and 90 HU, though within a normal muscle belly there are also other tissue elements such as connective tissue and fat, which are coded with much lower CT numbers. The different tissue elements express their specific CT number if such tissue completely occupies the voxel volume; otherwise the CT number will be an average of different values. This fact explains the wide range of values present inside a dataset and suggests the definition of various intervals to study muscle structural changes. Therefore, to estimate the tissue composition in the muscle volume, the CT numbers present within the segmented volume are subdivided in four HU intervals and displayed with different colours. Thresholds: [–200; –10], [–9; 20], [21; 40] and [41; 135] representing, respectively, fat (yellow), connective tissue (cyan), low dense/atrophic (pink) and normal muscle tissue (red) (Fig. 18.9). The muscle tissues are generally coded with HU values between 40 and 80 although, in the muscle belly region, a minimum amount of voxels are coded with higher HU values. We account for these values (81–135 HU) as muscle tissue in order to improve segmentation and 3D visualization. Table 18.2 is a display of the percentage values of tissues in RF volume in different clinical conditions.

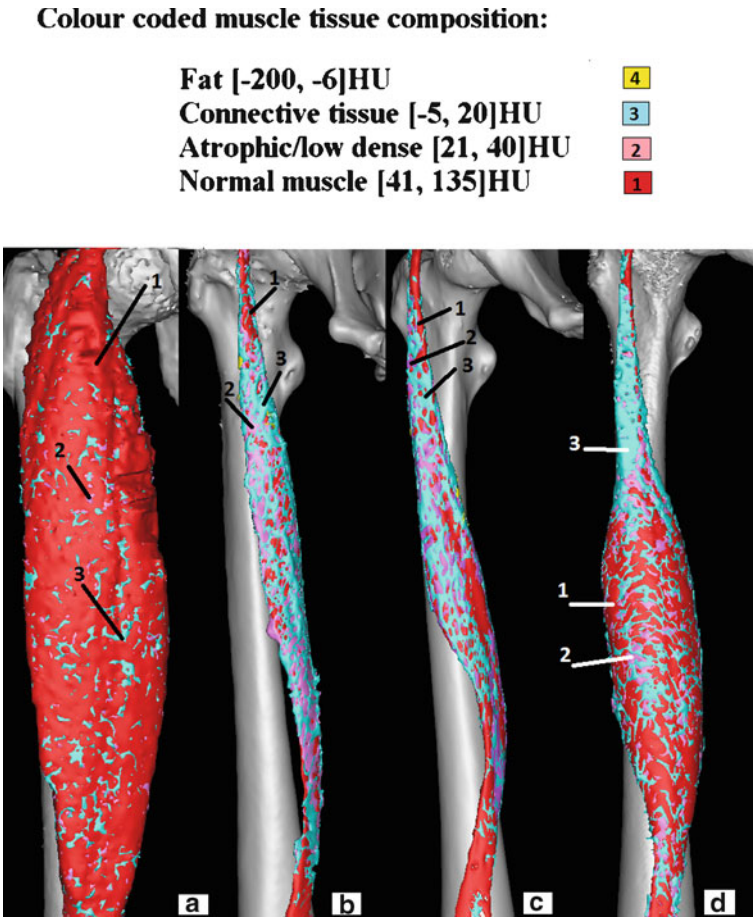

Fig. 18.9 Quantitative muscle tissue composition. Quantitative colour –3D model displaying tissue composition from control-innervated RF according to the muscle tissue composition colour coding legend above: normal muscle fibres (*labeled with 1*) 64%, atrophic muscle fibres 17% (*labeled with 2*), connective tissue 14% (*labeled with 3*) and fat 5% (*labeled with 4 but not visibile on the surface of the 3D-model*) (a). Seven years of muscle LMN denervation without FES: normal muscle fibres 41%, atrophic muscle fibres 31%, connective tissue 20% and fat 8% (b). 4 years of muscle LMN denervation without FES normal muscle 45%, atrophic 24%, connective 23% and fat 8% (c). The same muscle displayed in (c) after 4 years of electrical stimulation treatment: normal muscle fibres 60%, atrophic muscle fibres 20%, connective tissue 16% and fat 4% (D)

Table 18.2 Tissue composition from rectus femoris muscles (RFM) in different physiological conditions

	Percentage of tissue in RF volume			
Subjects	High dense muscle tissue	Atrophic-low dense muscle tissue	Connective tissue	Fat
Healthy Control	64	17	14	5
Patient 1 at 4-years denervation -Before FES	45	24	23	8
Patient 1 at 8-years denervation, with 4 -years FES	60	20	16	5
Patient 2 at 7-years denervation without FES	41	31	20	8

Percentage of tissues in RF volume measured on subjects in different physiological conditions: healthy, 4 years LMN injury (patient 1), 4 years LMN injury and 4 years h-b FES treatment (patient 1) and finally 7 years LMN injury (patient 2)

18.4.2 Quantitative Colour 3D CT Imaging of Normal, Long-Term LMN Denervated and FES Treated Muscle

Quantitative colour 3D analysis is an extremely valuable tool, enabling researchers to evaluate the specific tissue content of muscle structures. This is extremely important because the ratio of muscle to adipose to connective tissues is an invaluable indicator of muscle health. Here, we apply colour 3D CT imaging to the evaluation of FES treatment on normal and denervated muscles.

Figure 18.9a shows the 3D reconstruction of a control-innervated RF and its muscle tissue composition. Although the majority of RF volume has CT numbers above 40 HU, there is still a considerable amount of pixels displaying low density muscle tissues (which are 17% of the total) and different tissues such as fibrous and loose connective tissue and fat (which are 19% of the total). The effects of long-term muscle LMN denervation were evaluated performing Quantitative Colour 3D analysis on two patients in different clinical conditions: (1) 7 years and (2) 4 years after SCI and consequent muscle LMN denervation in the lower limbs (respectively displayed in Fig. 18.9b, c). Both muscles appear to be surrounded with connective tissue and atrophic fibres, suggesting that the fibrous content of the cortical layer of these long-term LMN denervated muscles substantially contributes to the physical properties of the 3D voxels of the muscle external layer (epimisium).

For the second patient, the analysis was performed 4 years after SCI, just before starting the electrical stimulation treatment (Fig. 18.9c). In Fig. 18.9c, d are displayed, respectively, the quantitative colour 3D reconstructions of the same RF with its cortical tissue composition before home-based FES training and 4 years after treatment. It has to be emphasized that clinically speaking, the latter presents a state of additional 4 years of LMN denervation, but 4 years during which the patient was submitted to daily electrical stimulation. The improvement in the muscle volume is clearly visible. The restoration process induced through electrical stimulation treatment is also unquestionable. Indeed as a result of FES treatment, the high density muscle fibres increased from 45% to 60% of the whole volume while connective and adipose tissues were reduced by 30% and 50%, respectively, after the 4 years of treatment. The fact that very large cutaneous electrodes and high energy are needed to stimulate these muscles demonstrates that the recovery is not a result of late reinnervation (which would be very unusual 5 years post LMN SCI).

18.5 Computational Models to Simulate and Study Activation Patterns

The model for FES of degenerated LMN denervated human skeletal muscle consists of four parts:

- Membrane model
- Fibre model
- Electrical model of the external electrical field
- Coupling between external field and fibre

The membrane model is a modified Hodgkin–Huxley model that accounts for changed membrane properties due to denervation (Reichel et al. 1999), e.g. reduced excitability due to an inclined number of ion channels. For the fibre, a compartment model is used that describes the propagation of action potentials along the fibres. In the case of LMN denervated fibres, the muscle tissue is excited directly without the mediation of a nerve. The electrical field created by the electrodes is modelled as a quasi static volume conductor problem and the coupling between the field and the fibre, i.e. the

reaction of the fibre to the externally applied field is described by two activating functions, which are a consequence of the compartment model. The classical, or second order activating function (AF2) allows estimation of the excitation process in the middle of a fibre (Rattay 1990), whereas the terminal or first order activating function is suited for describing activation at the locations of fibre endings (Reichel et al. 2002).

This paragraph illustrates a typical data processing pipeline and the steps involved in the creation of two computational models: a finite element (FE) model and a finite difference (FD) model of the spatial distribution of the electrical potential in human lower extremities during FES. Activation patterns can then be estimated from the potential distribution with the application of the concept of activating functions and fibre models. Membrane model parameters can be varied after the computation of the electrical field: studying activation patterns is therefore decoupled from the electrical field distribution.

The processing pipeline described assumes a properly segmented 3D volume dataset as the starting point; the origin of the data has thus no influence on the model design process: it can be of any 3D capable imaging modality. (See Fig. 18.10 for an illustration of the processing pipeline.) The stimulation electrodes are added to the segmented images as additional segments.

18.5.1 FE Model

The first step in the creation of the FE model is the extraction of the surfaces of the segments with standard image processing methods, i.e. identifying border voxels and subsequent triangularization. The extracted surfaces are represented in the form of triangular surface meshes (Fig. 18.11) and serve as the starting point for subsequent volume meshing. The result is a 3D tetrahedral quality Delaunay mesh (see Fig. 18.12).

The success of the meshing task depends very much on the geometry and topology of the domain in consideration (see below for detailed discussion).

Another approach would be to use all the voxels of the 3D dataset to produce a trivial mesh of the complete region (i.e. mesh every single voxel) and try to simplify the mesh afterwards. Memory consumption of the trivial mesh has to be considered when taking this trail.

There are a number of commercial and open source software packages available for meshing. A prominent and popular package with a free licence for research and non-commercial use is Tetgen (http://tetgen.berlios.de), which was used for all models shown in this paragraph.

After assignment of electrical properties to the segments the FE model is solved. For the distribution of the electrical field in LMN denervated muscle, see Fig. 18.13. The results shown here were produced with COMSOL Multiphysics (COMSOL, Inc. Burlington, MA USA, www.comsol.com)

18.5.2 FD Model

Assigning electrical properties (conductance) to voxels is the first step required for the buildup of the FD model. The actual (large, but sparse) system of linear equations describing the model is then built by considering a discrete formulation of the conductor problem

$$\operatorname{div} \vec{j} = \vec{\nabla} \cdot \left(\vec{\sigma} \vec{E} \right) = \vec{\nabla} \cdot \left(\vec{\sigma} \left(-\vec{\nabla} \phi \right) \right) = 0 \tag{18.2}$$

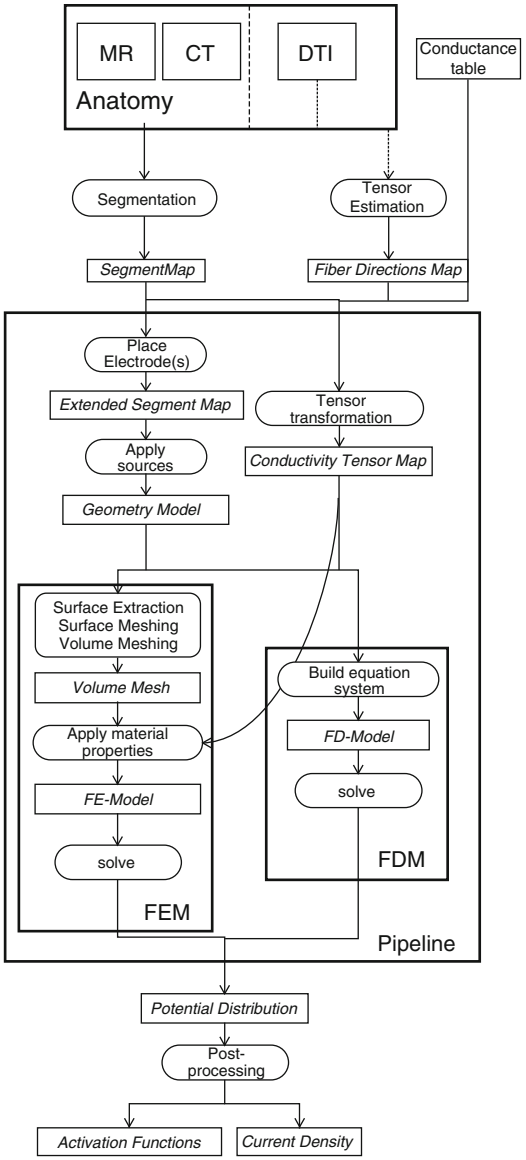

Fig. 18.10 Illustration of a typical Data Processing Pipeline. In the Data Processing Pipeline rectangles represent data, whereas round nodes stand for processing steps. The dotted line shows a possible dataflow that is currently not implemented

for each voxel in the domain. The discrete formulation establishes a relation between a center voxel and its neighbours that leads to the description with a system of linear equations. The result is a number of Voxels x number of Voxels sized matrix that needs to be inverted, which can be done with any suitable solver. All FD models shown in this paragraph were solved with the MATLAB implementation of the minimal residuum method (Barrett et al. 1994; Paige and Saunders 1975).

See Fig. 18.13 for the distribution of the electrical potential.

All calculations and figures shown in this subsection were produced with MATLAB (The MathWorks, Inc, Natick, MA, USA).

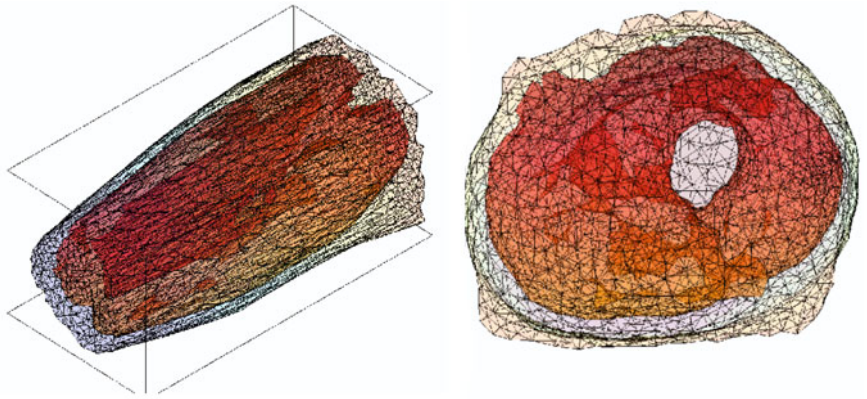

Fig. 18.11 Surface mesh of the fat and the muscle segment in axial (*top*) and general 3D (*bottom*) perspectives. The images illustrate the intersection-free containment hierarchy: the (*inner*) muscle surface is entirely within the surface of the fat segment. The colours used have no significance. For illustration purposes, the dataset was meshed with a lower resolution

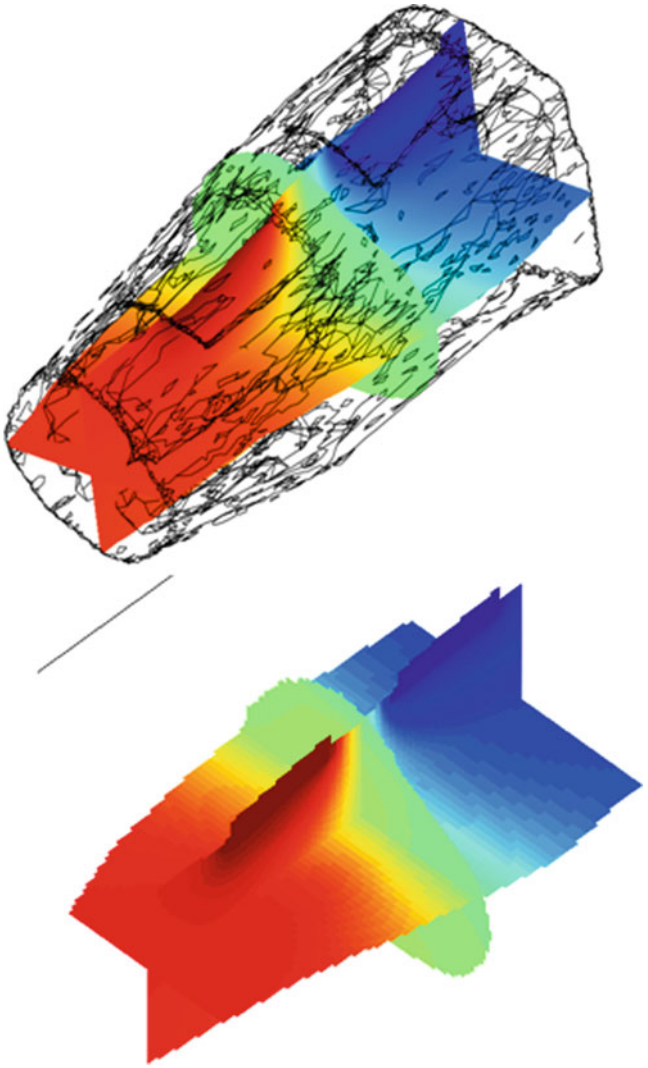

Fig. 18.12 Results of finite element FE (*top*) and a finite difference FD (*bottom*) simulation of the same Geometry Model. The electrodes are modelled as voltage sources (+/–1 V). The first step in the creation of the FE model is the extraction of the surfaces of the segments with standard image processing methods, i.e. identifying border voxels and subsequent triangularization. The extracted surfaces are represented in the form of triangular surface meshes and serve as the starting point for subsequent volume meshing. The figure shows the result which is a 3D tetrahedral quality Delaunay mesh

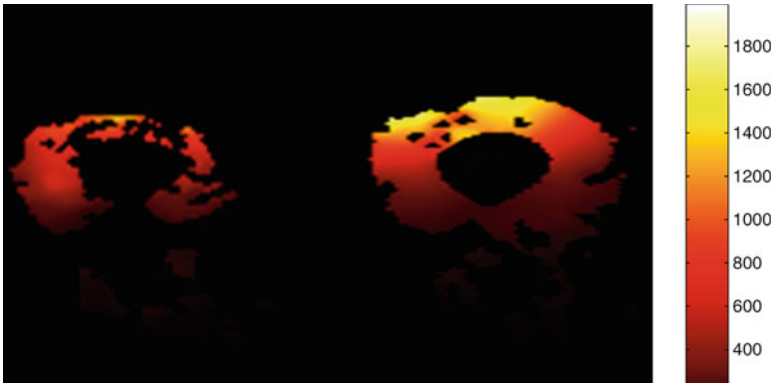

Fig. 18.13 Terminal activation function in a cross-section between the stimulation electrodes of the same patient after 2 years of denervation (*left*) and after another 2 years of FES (*right*). Note how activation extends into the hamstrings, which leads to the experimentally observed co-contractions in well-trained patients as well as the increased spread of activation after FES training

18.5.3 Post Processing

Once the distribution of the electric potential is calculated with either the FE or the FD model, a number of interesting quantities can be calculated with computational software such as MATLAB or octave (www.gnu.org/software/octave). Quantities of interest include the electrical field, current density and the two activating functions. For an illustration see Fig. 18.13. Note how the activation extends into the hamstring muscles, which leads to the experimentally observed co-contractions in well trained patients as well as the increased spread of activation after FES training.

18.5.4 FE Versus FD

The data processing pipeline discussed illustrates the steps typically involved in the creation of two computational models for FES. Similar steps are necessary for other bioelectric problems such as deep brain stimulation. The most difficult or rather sensitive step is the creation of the volume mesh for the FE model. This is because the geometry and topology of biological structures are far from regular and "well behaved" in a geometrical sense. Segments are often broken apart into several regions; especially in LMN denervated patients, there are small and thin structures present as well as more complex topologies, i.e. regions with holes and three-segment borders, e.g. between bone, muscle and fat. All this leads to complications that make the volume meshing process somewhat unstable and challenging. It can, however, be resolved by simplifying the given geometry, e.g. application of erosion or other morphological operations (to the segmented images) to further separate close borders between segments or eliminate small or thin structures entirely. To achieve an intersection-free containment hierarchy of the segments (every closed border of a segment borders only with one other segment) it might be necessary to alter the geometry: dummy slices can be added to extend the domain further (where the influence on the electrical field between the electrodes is assumed to be negligible), thereby ensuring that, e.g., the bone segment is entirely contained within the muscle segment. As a last resort there is also manual mesh optimization and repair, a rather time consuming process.

These troubles should be overcome with the development widespread availability of methods for creating meshes from volumetric data without the intermediate step of surface meshing.

In comparison with the complex and time-consuming meshing process the creation of the FD model seems appealingly straightforward. Complex geometries and topologies pose no problem and do not jeopardize the creation process. However, FD models are less memory sufficient in the sense that high detail (number of elements) is present in areas where it would not be necessary given the geometry and complexity of the problem. In FE models one would start with a coarse mesh and refine the mesh in regions where more detail and accuracy is desirable. In FD models one would have to decrease the grid spacing globally (and thereby increase the number of elements drastically), which produces higher demands on the machinery in terms of memory.

Further, model quality depends heavily on the segmentation it uses as a starting point – this aspect has been discussed elsewhere. However, we might add that a rigorous and robust solution to the automatic segmentation task should lead to significant improvement once it is available. Looking even further upstream in the pipeline, to the source of the medical image data, it seems likely that with higher resolutions, less (or better controllable) artifacts and more advanced imaging technologies the models will improve at the same time. Inclusion of fibre directions with the help of Diffusion Tensor Imaging (DTI) as it is already almost routinely performed in white brain matter will add important aspects and realism to the FES models as well. DTI has already been applied to human skeletal muscle; however, the validity of the information obtained in LMN denervated, degenerated muscle has not yet been verified or validated.

18.6 Effects of Electrical Stimulation on Bone Density

18.6.1 Bone Mineral Loss in Paraplegic

Shortly after the SCI the bones of the paralyzed extremities atrophy and lose minerals. Osteoporosis is one of the major complications in patients with SCI. Immobilization of paraplegic patientsinduces severe bone loss: the bone becomes more and more fragile and there is a dramatic increase in the risk of fracture. SCI causes immediate and permanent gravitational unloading. The result is a disuse structural change with associated metabolic consequences.

Alternative to the medications other treatment like electrical stimulation has been showing beneficial effects on bone strength. Indeed electrical stimulation for bone repair has been used for three decades to treat inadequate healing of the fracture (pseudoarthrosis) and bone non-union (Lind 2001). Mechanical or electrical stimuli of relatively low amplitude and high frequency can influence bone formation and resorption in vitro and in vivo, suggesting that these modalities can be used clinically to inhibit or reverse loss in bone density.

In this section bone density on the patella (knee cap) is measured in different clinical conditions in order to study bone structural changes as secondary effect of the electrical stimulation treatment.

18.6.2 Modelling Patella Bone

The patella bone is chosen as study volume to monitor changes in BMD during FES treatment. The patella bone is a good sample to study changes in density; it is a small bone with triangular shape which articulates with the femur and covers and protects the knee joint from external applied force.

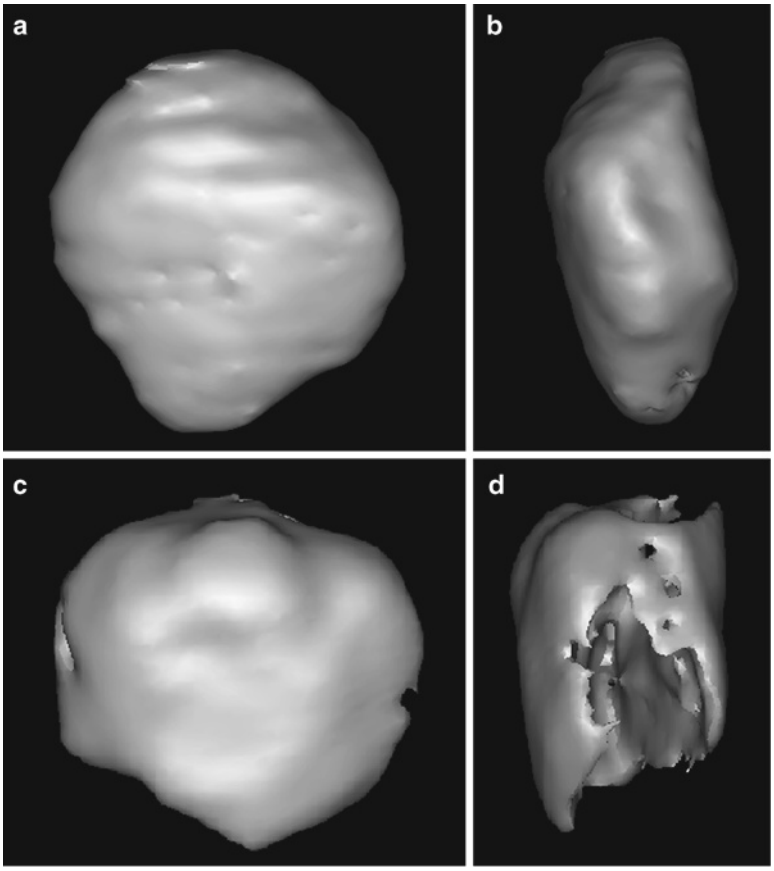

Fig. 18.14 Three-dimensional reconstruction of patella bone: healthy versus 4 years LMN spinal cord injury. Three-dimensional reconstructions of patella bone in normal condition from a healthy subject: front view (**a**) and lateral view (**b**). In spinal cord injured subject, 7 years of LMN paraplegia: front view (**c**) and lateral view (**d**)

Besides, since all four parts of the quadriceps muscle attach to the patella via the quadriceps tendon, the patella bone is a perfect candidate to study structural changes induced by quadriceps contraction. Vastus intermediaus and RF muscle are attached to the base of the patella while vastus lateralis and vastus medialis are attached to the lateral and medial borders of the patella, respectively. The patella bone is attached to the tendon of the quadriceps femoris muscle, which in healthy subjects contracts to extend/straighten the knee.

In paraplegic patients with flaccid paralysis and therefore completely LMN denervated, the patella is unloaded; the only possible load is induced by the contractile activity generated in the muscle with FES treatment. Indeed the patella is outside the electrical field generated by the stimulation and therefore changes in density can be attributed exclusively to the contraction force transferred to the patella from the quadriceps muscle.

The information used to study the patella's bone are extracted from the CT data, in fact the patella is isolated from the surrounding using the segmentation techniques described in paragraph 3.

The dramatic effects of bone loss in SCI are seen in Fig. 18.14: the 3D model reconstruction of patella bones from a control-innervated subject are shown in Fig. 18.14a and 7 years SCI patients in Fig. 18.14b.

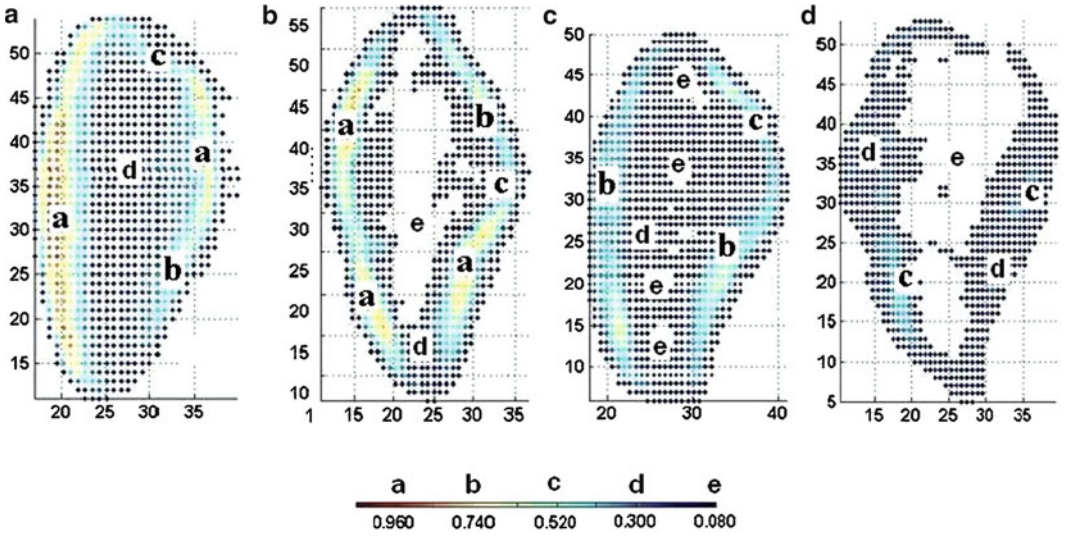

Fig. 18.15 Map the local bone mineral density (BMD) distribution on patellas in different physiological conditions. Axial view and associated mean bone mineral density (MBMD) value from patellas in different clinical conditions: Healthy MBMD = 0.281 g/cm³ (**a**), 6 years denervated with 5 years h-b FES MBMD = 0.193 g/cm³ (**b**), 4 years denervated MBMD = 0.144 g/cm³ (**c**) and 7 years denervated MBMD = 0.106 g/cm³ (**d**).The BMD values are mapped with letters: the pixels with the lowest BMD are marked with e while the pixels with the highest BMD are marked with a.

18.6.3 Bone Mineral Density Measurement on the Patella

Evaluation of the bone density is performed by a conversion of HU values contained in the segmentation masks to the respective BMD values. Bone density is the amount of bone tissue in a certain volume of bone (g/cm^3). Bone mineral density is a test that measures the amount of calcium in a special region of bones. From this information, an estimate of the strength of the bones can be made. BMD helps predicting the risk of a future fracture of the bone, measures the amount of bone mass, and also monitors the effectiveness of treatment. BMD was measured using a special X-ray technique called quantitative computed tomography (QCT) (Jóhannesdóttir 2006; Helgason 2005). The normal, average BMD is around 0.388 g/cm^3 in males and 0.290 g/cm^3 in females. Individuals with a BMD lower than 0.10 g/cm^3 need certain care (Donina 2002).

An algorithm was designed in Matlab (Jóhannesdóttir 2006; Gargiulo 2008) that scaled the data and converted it from HU to BMD. The BMD distributions are displayed in the three segmentation planes: coronal, axial and sagittal. The BMD distributions from patella in different physiological conditions are depicted in Fig. 18.15. The BMD values are colour coded and mapped with letters (Table 18.3): pixels with low BMD in blue (marked with **e**), and pixels with high BMD in red (marked with **a**).

In the control patella a less dense area on the cortical bone facing the knee joint (patella back side) can be noticed, when compared to the front side; this can be seen clearly in the axial and coronal planes. The probable explanation is the fact that the patella function is protecting the knee joint from external force and therefore the front side which is in general more exposed to these solicitations and to unexpected stress (e.g. fall or accident) develops stronger bone structure.

The other panels in Fig. 18.15 show changes in BMD distribution as a consequence of LMN injury and when the muscles are treated with FES. Fig. 18.15b depicted the BMD distribution of a

Table 18.3 Bone mineral density intervals

	Bone mineral density intervals	
Label	Min (g/cm³)	Max (g/cm³)
a	0.800	1.070
b	0.600	0.799
c	0.400	0.599
d	0.200	0.399
e	0	0.199

Letters from **a** to **e** are associated to different BMD intervals in order to localise on the patella's cross sectional areas displayed in Fig. 18.15 where are the regions with high, medium or low bone density

Table 18.4 Patella mean bone mineral density (MBMD) values from subjects in different clinical conditions

Patella's	Mean bone mineral density value (g/cm³)
Control, healthy	0.281
6 years LMN, 5 FES	0.193
4 years LMN, no FES	0.145
7 years LMN, no FES	0.106

The patella's MBMD values are calculated from subjects in different clinical conditions. The table shows that the MBMD value is better in the subject undergoing electrical stimulation treatment for his quadriceps muscle compared to the other two subjects in similar clinical conditions but not undergoing stimulation

patella from 6 years LMN denervated subject treated with FES; though the decrease in bone density is remarkable compared to the healthy subject (Fig. 18.15a) it is clear that the bone density is better here than in Fig. 18.15c, d, respectively, displaying patella's from 4 and 7 years LMN denervated subjects not treated with FES.

To quantify the overall bone mineral content in the patella, the mean bone mineral density value (**MBMD**) is calculated using the following formula:

$$\mathbf{MBMD} = \left(\frac{\sum \mathrm{BMD}}{N} \right) \tag{18.3}$$

where $\sum BMD$ is the sum of BMD values in all voxels in the dataset and N is the number of voxels in the dataset.

The quantitative measures of **MBMD** values for the patellas in Fig. 18.15 are summarised in Table 18.4.

18.7 Applications to Other Areas of Health Care: Medical Modelling for Planning of Maxillofacial Surgery

We demonstrate here that computer modelling techniques and rapid prototyping technologies can be used to enhance biological research, specifically in the area of muscle physiology. These anthropometric techniques are also invaluable to applied medicine. For example, these methods are being employed to develop computer and physical models which are used to plan and support different surgical treatments such as complex fractures, tumours, maxilla traumas and malformations. This present section reviews the use of segmentation techniques and modelling for planning maxilla facial surgery and particularly to support the treatment of retrognathia which is a malformation where the maxilla or the mandible is further posterior than normal. The surgical process in use to correct this malformation is called distraction osteogenesis. It involves gradual, controlled displacement of surgically created fractures which results in simultaneous expansion of soft tissue and bone volume. The procedure of mandibular osteogenic distraction involves sectioning cortical bone at the site of distraction. The distraction device (the distractor) is mounted on either side of the jaw. The distractor either may be attached directly to the bone or may be partially tooth borne. Gradual distraction is then performed at a rate of 1–2 mm/day, which is done incrementally. Distractors, for intraoral use, have been developed to eliminate extra oral scars. It is complicated and frustrating to position and manipulate these devices during surgery.

The use of 3D models makes the operation easier and more accurate; indeed it is possible to adjust the distractor on the physical model (Fig. 18.16) and use the device directly on the patient after a previous sterilization. Further, the mandibular nerve, which must be protected

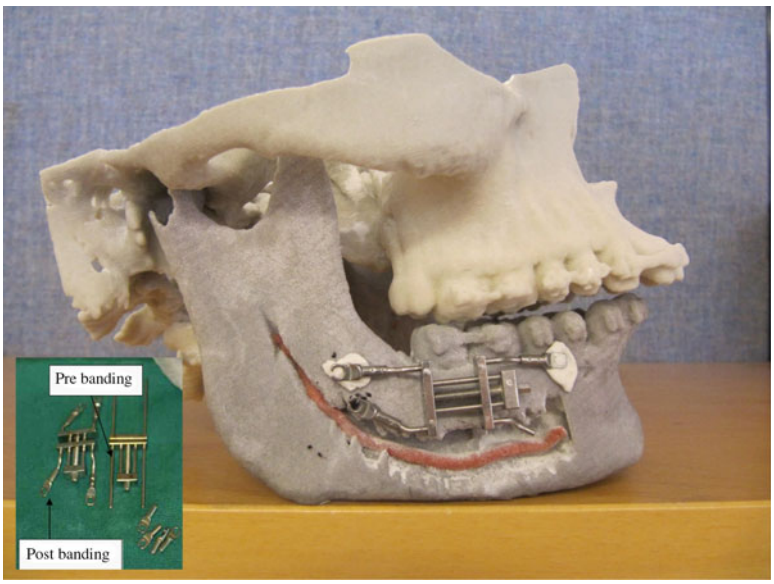

Fig. 18.16 Three-dimensional model used in surgery for the evaluation and planning of maxilla facial treatments. Three-dimensional model of a maxilla and the jaw previous operation; the model displays the mandibular nerve within the bone. The model is used for treatment planning and to bend the distractor device directly on the physical model of the previous surgery

from damage during the treatment, is rendered visible on the model (Fig. 18.16). Using it, the surgeon can check nerve position very accurately during the operation by placing the model in a sterilized bag.

A survey of over 20 surgeries of this type, where 3D models have been used to plan intraoral distraction in mandibular lengthening, shows that the length of time for the surgery was shortened by 25–35% (ca. 1–1.5 h).

18.8 Practical Methods and Technique

18.8.1 Measuring Volume of the Rectus Femoris Muscle

(a) Measuring the volume of the rectus femoris muscle (RFM) we start by taking a spiral computer tomogram (spiral CT) of the whole muscle. The subject is laid on the CT bench –a movable bench that can slide through the circular hole in the CT device – the legs towards the CT device. It is best to have the legs in a parallel position. If the person is paralysed it might be necessary to fix the position of the foot, the ankle joint and the knee with either strap or tape. The legs can be fastened to each other and/or to the bench.

(b) First an overview of the patient is taken with a single projection image to determine the position of the hip and knee joints. Then the spiral CT is taken starting from a tangent between the hip joint continuously down to below the knee joints. This covers the whole RFM including its tendons. By scanning one slice image after another is taken of both legs.

Typically the thickness of a slice is 1.25 mm and the distance between two adjacent slices is 1.25 mm. These parameters can be adjusted independently to some extent. Thinner slices mean higher spatial resolution, higher radiation dose and higher noise. Less distance between two adjacent slices, even less than the thickness of the slices, means not only higher resolution or less noise, but also higher radiation dose. For a 45 cm long scan and 1.25 mm distance between slices, the number of slices is 360. If the distance is reduced to 0.675 mm the number of slices is 667.

The scan data are stored on a CD disk in DICOM format to be read by software for post processing of the images.

(c) Post-processing of the CT scan images can be done with software independent of the CT scanners (e.g. Mimics from Materialise, Leuven, Belgium). CT images in DICOM format can be imported into most post-processing software. Once imported, the task is to isolate the RFM from the other tissue types. This is called segmentation and is done in a specific sequence. First, the upper and lower limits of the tissue density inside the muscle are determined (upper and lower threshold). Second, the computer searches for all voxels with density inside the limits (thresholding). Third, starting with an arbitrary voxel seed, neighbouring voxels of the current region's boundaries are examined and added to the region class if some inclusion-criteria are met. The region is grown from the voxel seed by adding in neighbouring voxels that are similar, increasing the size of the region. This whole process is continued until all pixels belong to some region (region growing). The last step of the segmentation is to separate the RFM from other muscles. This is done in an interactive way since the boundaries cannot

be detected automatically in all cases. A contour is drawn around the muscle and this shape projected to the next cross-section in both directions. This contour is modified to fit the next cross-section if necessary. This is done in all slices.

The contour areas are then erased, creating a gap between segmentation target and its surroundings. Finally, a new segmentation mask representing RF is created applying a region-growing procedure which creates a new mask separating the edited structure that is no longer connected to the surrounding. Now we have segmented the RFM and the volume can be determined, i.e. measured automatically by the software.

Summary Points

- Anthropometry is the study of human body measurements. It can be applied in numerous fields, including engineering, sociology, psychology, physics, biology and medicine. It has a huge potential to improve the quality of human life in many areas, specifically in medicine.
- In this work, anthropometry techniques are applied to research in muscle physiology, with the aim of evaluating long-term changes in denervated human muscle and the therapeutic effects of FES treatment.
- Image processing and segmentation techniques are used to construct (from spiral computer tomography data) –3D models of muscle and bone and to isolate RF from other quadriceps muscles in order to study the anthropometrical characteristics in different physiopathological conditions.
- Segmentation techniques are capable of measuring volumes and density of specific regions of interest.
- Anthropometric techniques demonstrate that the LMN denervation–degeneration process can result in: (1) reduction of muscle volume to 1/5 of a normal muscle; (2) loss of electrical stimulation excitability using commercial devices; and (3) reduction in tissue density.
- Advanced medical imaging tools are used to monitor macrostructural changes occurring in human skeletal muscle undergoing LMN denervation–degeneration. Detailed tissue composition and large muscle surface characteristics are measured and used to support and validate typical histological analyses.
- Image processing and segmentation techniques show that LMN denervated–degenerated muscle can recover in terms of volume and density by home-based daily FES (h-b FES) using large electrodes and high-energy electrical currents.
- Properly segmented medical image data are used to construct patient-specific numerical models in several fields. With a numerical model of FES, the activation patterns of LMN denervated muscle can be simulated, studied, and, most importantly, optimized to establish more efficient training set-ups for the benefit of patients
- Tissue composition analysis by quantitative colour –3D imaging on the whole RF shows increased content of muscle fibres and decrease of connective and fat tissues, the effect of electrical stimulation treatment
- Bone mineral loss measured on knee cap (patella) seems to be decreased in subjects performing home-based electrical stimulation treatment of thigh muscles.

Key Features

Tables 18.5–18.7.

Table 18.5 Key features of image segmentation and medical modelling for LMN denervated muscles

1. Image segmentation and 3D modelling are anthropometric techniques which have broad applications in numerous fields, including physiological research and medicine.
2. Medical modelling is defined as the creation of highly accurate physical and/or computational models of human anatomy and its functions directly from medical scan data.
3. In computer vision, segmentation refers to the process of partitioning a digital image into multiple regions. The goal of segmentation is to extract information about the region of interest from the dataset of a scan.
4. The main stages of the medical modelling process are: (1) to determine the protocol that enables an appropriate visualization of the region of interest; (2) to gather medical images from CT or MRI; (3) to import the data into special image processing software; (4) to segment organs or tissue; and (5) to develop the information to be modelled.
5. Segmentation techniques enable the isolation of anatomic structures (e.g. muscle bellies) and the subsequent study of normal and abnormal morphologies (e.g. the morphology of normal and denervated muscles).
6. Image segmentation and 3D modelling can be used to monitor the effects of medical treatment on anatomic structures and their function (e.g. the effect of FES on muscle size, force and function).
7. Modelling the function and behaviour of biological structures (e.g. LMN denervated muscles) can allow for the improvement of treatment technology and protocols.

This table lists the key facts of image segmentation and medical modelling for LMN denervated muscles, including definitions methods and uses

Table 18.6 Key feature of X-ray and spiral computer tomography

1. Clinical X-ray CT is the measurement of an object's X-ray absorption along straight lines.
2. Clinical CT scanners have an X-ray focal spot that rotates continuously around the patient while a cylindrical detector positioned on the opposing side of the X-ray tube records the absorbed radiation.
3. In spiral CT, data acquisition is performed continuously while the patient moves at constant speed through the gantry.
4. No discontinuities between adjacent images (absence of interscan delay) will result in a spiral CT.
5. Spiral scans provide better image quality than conventional scans. This, however, requires more computational work for optimal image reconstruction.

This table lists the key features of X-ray and spiral computer tomography

Table 18.7 Key facts on DTI and fiber tracking

1. DTI is a Magnetic Resonance Imaging Method based on the MR method of Diffusion Weighted Imaging (DWI).
2. Image contrast in DWI contains information on the diffusion of water[a] in a certain direction specified by the orientation of additional gradients during acquisition.
3. DTI is the acquisition of a series of DWI of several different diffusion directions with the purpose of estimating a diffusion tensor for every voxel. From this tensor, the main diffusion directions of water can be calculated.
4. In highly directional tissue such as brain or muscle tissue the main diffusion direction corresponds to the fibre direction.
5. A method called Fiber Tracking can be employed to estimate fibre paths in tissue from DTIs.
6. Since the diffusion information is a loss of signal (in the DWI images, when compared to non-DWIs) several acquisitions are often necessary for a sufficient signal to noise ratio (SNR). This and the fact that DWIs need to be acquired for several different directions in order to be able to estimate the diffusion tensor with sufficient accuracy makes this a time-consuming method.
7. DTI and Fiber-Tracking methods are applied to estimate fibre tracts in the brain.

This table lists the key facts of Diffusion Tensor Imaging

[a] When the imaged nucleus is ^{1}H, and other ^{1}H-containing compounds are neglected

Chapter 19
Upper Limb Muscle Volumes in Adults

Katherine R. Saul, Scott L. Delp, Garry E. Gold, and Wendy M. Murray

Abstract Muscle force-generating properties used in models are derived from measurements of muscle architecture, such as volume, cross-section, and fiber length. While the peak force a muscle can produce is related to its physiological cross-sectional area, several studies of muscle architecture have shown that muscle volume is an excellent predictor of joint moment-generating capacity, and is an important parameter for evaluating strength in the upper limb and for model development. Researchers have classically relied on dissection of cadavers to assess architectural properties of the muscles of the upper limb, including muscle volume, fiber length, sarcomere length, and pennation angle. Medical imaging approaches, including computed tomography, magnetic resonance imaging, and ultrasound have also been used to assess muscle force-generating properties in living subjects. In this review, the strengths and weaknesses of these approaches for assessing muscle volume in the upper limb are discussed. The volumes of muscles in the upper limb as measured by a number of researchers are summarized and compared. A study in which a magnetic resonance imaging approach is used to assess the muscle volumes of all the muscles crossing the shoulder, elbow, and wrist in living subjects is highlighted. It has been shown that the distribution of muscle volume in the upper limb is highly conserved across these subjects with a threefold variation in total muscle volumes (1,427–4,426 cm^3). The studies discussed in this review provide normative data that form the basis for investigating muscle volumes in other populations, and for scaling computer models to more accurately represent the muscle volume of a specific individual.

19.1 Introduction

Humans vary greatly in size and shape, yet biomechanists often use generic musculoskeletal models with average parameters to evaluate muscle function and coordination. While this approach allows researchers to investigate general principles underlying human movement, it is unclear how conclusions derived from studies of generic models apply to individuals of different sizes.

Muscle force-generating properties used in models are derived from measurements of muscle architecture, such as muscle volume, physiological cross-sectional area, and optimal fiber length (Zajac 1989). While the peak force a muscle can produce is related to its physiological cross-sectional area (defined in more detail below), several studies of muscle architecture have shown that muscle volume is also an excellent predictor of joint moment-generating capacity (Fukunaga et al. 2001; Holzbaur et al. 2007a). When compared to an anatomical cross-sectional area, muscle volume is a better predictor of strength in the upper limb (Akagi et al. 2009). Therefore, muscle volume is an important parameter for evaluating the strength of upper limb muscles and for developing models of the upper limb.

Frequently these parameters are determined via cadaveric studies of muscle architecture. However, cadaveric specimens may not accurately reflect the absolute or relative sizes of muscles in young, healthy subjects. Cadaveric studies of muscle architecture often focus on individual muscle groups; this is especially true for the upper limb, where muscle parameters have been measured separately for the shoulder (Langenderfer et al. 2004), elbow (An et al. 1981; Murray et al. 2000), and forearm and wrist (Jacobson et al. 1992; Lieber et al. 1990, 1992). Thus, there are excellent data describing the relative size of muscles acting about a single joint in cadaveric specimens, but the relative sizes of muscle across joints in living subjects has not been evaluated in many studies.

Several fundamental questions must be answered. What are the relative sizes of muscles in the upper extremity? Are the relative sizes of muscles consistent across subjects with different total muscle volume? How is muscle volume distributed among muscles crossing the shoulder, elbow, and wrist? In this review, we describe measurements of upper limb muscle size using dissection and various imaging techniques. In addition, we focus on a study in which these questions were addressed by measuring volumes of 32 muscles of the upper limb in young healthy subjects using magnetic resonance imaging (MRI) (Holzbaur et al. 2007b). This review provides a comprehensive evaluation of muscle volumes in the entire upper extremity.

19.2 Physiological Cross-Sectional Area

The isometric force a muscle can generate depends on the number of fibers in a muscle, the lengths of the fibers, and the orientation of the fibers relative to the tendon (Gans 1982). Physiological cross-sectional area (PCSA) is just one of a number of quantitative measures that are used to characterize the structural design of a muscle, often referred to as muscle architecture (Lieber and Friden 2000; Zajac 1989). PCSA is a measure of the muscle's total volume, normalized so that the maximum isometric force-generating capability of muscles with different numbers, lengths, and orientations of fibers can be directly compared based only on anatomical measurements.

The relationship of PCSA to the maximum isometric force a muscle can produce has been established experimentally. Of particular interest is a study by Spector et al. (1980) that quantified the forces produced by the soleus and the gastrocnemius in adult cats *in situ* and also characterized the architectural design of the contralateral muscles in the same animals. This study demonstrated that if the total volume of a muscle was normalized by optimal fiber length (the fiber length at which

maximum isometric force is produced), and this normalized volume was corrected for the pennation angle of the fibers (the orientation of the fibers relative to the tendon), the resulting "physiological cross-sectional area" was directly proportional to maximum isometric force. Thus, PCSA provides an anatomically based, quantitative measure of the relative force-generating capacity of muscles of different sizes and architectural design. In fact, if PCSA is scaled by the specific tension of individual muscle fibers (the force generated per unit area), which can be considered to be a constant for all muscles (Zajac 1989), maximum isometric force can be accurately predicted.

Important points to keep in mind are embedded in the definition of PCSA. First, calculated PCSA is only proportional to the maximum force a muscle can produce if volume is normalized by *optimal* fiber length (Lieber 1993). This caveat about optimal fiber length is an important point because the force a muscle can produce varies with fiber length and muscles are capable of producing force over a large range of fiber lengths (Gordon et al. 1966). In addition, the traditional definition of PCSA incorporates a correction factor for pennation angle; specifically, the normalized volume is multiplied by the cosine of the pennation angle. This was critical in the study described above because the forces produced by the cat muscles were quantified by attaching their tendons to a force transducer. The force transmitted through the tendon differs from the force developed by the muscle fibers when the fibers are not oriented along the line of pull of the tendon.

Comparing PCSAs among muscles with different architectural designs allows researchers to quantitatively understand differences in force-generating capacity between muscles. However, when comparing the same muscle (i.e., the triceps brachii from a small female to the triceps brachii of a large male) or muscle groups across individuals, it seems that differences in muscle volume dominate the observed variability across subjects. For example, while in one study the relative variance (standard deviation/mean) of triceps volume was 47% (Holzbaur et al. 2007b), optimal fascicle length in triceps long head has been shown to have a relative variance of only 17% (Murray et al. 2000). It is for this reason that muscle volume is an excellent predictor of joint moment-generating capacity (Fukunaga et al. 2001; Holzbaur et al. 2007a), and why muscle volume is of such importance for researchers interested in understanding upper limb function from the context of *in vivo* anatomy.

19.3 Cadaveric Approach

The most common method by which the distribution and architecture of muscle has been assessed has been via dissection of cadaveric specimens. Typically, fresh frozen upper limbs are thawed and the muscles dissected and fixed in formalin, after which the architectural measurements can be made. This approach has the advantage of allowing detailed characterization of the volume, cross section, muscle belly and fiber length, tendon length, pennation angle, and sarcomere length of muscle. It is straightforward to combine these measurements to calculate PCSAs of individual muscles, which can then be scaled by specific tension to calculate the maximum isometric muscle force human muscles can produce. Because muscle forces cannot be directly measured in human subjects noninvasively, these results are of general interest. In addition, maximum isometric force is also an important parameter in biomechanical models (Zajac 1989).

Several studies have characterized the muscles of the upper limb using a cadaveric approach. Architecture of the forearm and hand muscles have been measured by Brand et al. (1981), Lieber et al. (1990, 1992), and Jacobson et al. (1992). The architecture of muscles crossing the elbow (An et al. 1981; Murray et al. 2000) and shoulder (Bassett et al. 1990; Langenderfer et al. 2004; Veeger et al. 1991; Wood et al. 1989) have also been measured. It is notable, however, that none of these studies assessed all of the muscles of the arm in the same specimens. In addition, while dissection of cadaveric specimens permits

characterization of architectural details of muscle, it has some important limitations. The demographics of the specimen population are generally uncontrolled, and therefore may not be typical of the population at large. In particular, as described below, muscle volumes of cadaveric specimens do not represent those of young, healthy adults. In addition, dehydration effects may further underestimate muscle volume by 4–9% (Ward and Lieber 2005). Thus, while cadaveric dissection provides access to all of the parameters necessary to calculate PCSA, and therefore, maximum isometric force, the force magnitudes calculated using this approach are only valid for subjects with comparable muscle volumes to the cadaveric specimens.

19.4 Imaging Approaches

Medical imaging techniques, such as computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound, allow researchers to study muscle volume, fiber arrangement, and cross-sectional areas of muscle in living subjects. All of the modalities have been used to quantify muscle volumes, and have demonstrated accuracies for volumetric measurements between 1% and 5% (Audenaert et al. 2009; Berg et al. 2007; Tingart et al. 2003).

CT is a valuable modality for its speed of acquisition and its capacity to readily distinguish among bone, fat, and muscle. For that reason, it has been used to evaluate the infiltration of fat into muscle, for example in the gluteal muscles (Jolivet et al. 2008). It has been rarely used to characterize the upper limb, though it has been used to analyze the muscle, fat, and bone composition of the forearm in the trained and untrained limbs of male tennis players (Maughan et al. 1986). The difficulty associated with determining borders among individual muscles, as well as the radiation dosage, has limited its use in studies of this type when MRI is available.

MRI has been shown to provide enhanced contrast between anatomical borders of individual muscles while avoiding the radiation exposure of CT (Juul-Kristensen et al. 2000a; Lehtinen et al. 2003). The accuracy of estimating muscle volume from MRI has been established by Tingart et al. (2003); they measured the volume of rotator cuff muscles in cadavers using MRI of the intact shoulder and water displacement of the dissected muscles, and reported differences of less than 4%. While MRI allows one to capture information about a large number of muscles in an acquisition, it is extremely time consuming to manually identify the borders of the muscles to calculate muscle volumes, and reliable tools for automated segmentation of individual muscles have proven difficult to develop despite the enhancement of borders inherent to the imaging technique. In addition, the high clinical costs, long imaging times, and limited access associated with the modality limit its use in large studies. For this reason, cheaper and faster alternatives have been explored.

Ultrasound has also been considered as an alternative to either MRI or CT, as an inexpensive, portable method (Teefey et al. 1999) to accurately image muscle and fat (Juul-Kristensen et al. 2000b; Miyatani et al. 2000, 2004). However, because of the relatively limited field of view of ultrasound, estimates of muscle volume must be made from measurements of muscle thickness, limb length, and knowledge of the approximate shape of the muscle of interest (e.g. cylindrical, Miyatani et al. (2004) or triangular, Audenaert et al. (2009)). This approach has been used to successfully determine the volumes of deltoid (Audenaert et al. 2009), extensor digitorum communis (Brorsson et al. 2008), and elbow flexor and extensor muscles (Fukunaga et al. 2001; Miyatani et al. 2004), as well as fiber length and pennation angle (Fukunaga et al. 2001).

As compared to the cadaveric approach, medical imaging techniques have the benefit of providing a means to quantify important muscle architectural parameters in living human subjects. Thus, these valuable data can be acquired for populations of subjects for whom cadaveric specimens are not

generally available. These populations include young, healthy adults, children, and persons with physical disabilities or musculoskeletal impairments. In contrast, an important limitation to imaging methods is that no imaging technique successfully quantifies all of the parameters necessary to calculate PCSA as traditionally defined (muscle volume normalized by optimal fiber length, corrected for pennation angle). A particularly important limitation is the inability to easily quantify optimal fiber length via imaging techniques. MRI provides a means to accurately quantify muscle belly lengths (e.g. Holzbaur et al. 2007b), and ultrasound is frequently used to quantify muscle fiber lengths (Maganaris et al. 2001). However, how these measured lengths relate to the optimal fiber length of a given muscle in a given subject cannot be quantified using either MRI or ultrasound. Thus, most imaging studies that estimate PCSA from their data normalize the measured muscle volumes by muscle belly lengths or fiber lengths measured from imaging, and scaled to better approximate optimum lengths using ratios of optimal fiber length to fascicle length measured in cadaveric experiments (Holzbaur et al. 2007b; Klein et al. 2001). However, these approximated fiber lengths may not correspond to optimum lengths for the particular subjects. Importantly, exciting advances in imaging techniques include methods that can track fiber architecture using MRI (Sinha et al. 2006), will may ultimately enable measurement of muscle volume, muscle belly length, muscle fiber length, and pennation angle using the same modality. Also, new methods have been developed that allow imaging of muscle at the sarcomere level (Llewellyn et al. 2008), which could ultimately allow fiber lengths measured using ultrasound to be normalized to fiber length.

19.5 Comprehensive Upper Limb Muscle Volume Assessment

One study (Holzbaur et al. 2007b) provides a comprehensive assessment of muscle volume in the upper limb for all muscles crossing the shoulder, elbow, and wrist in the same subjects. This study also presents calculated estimates of PCSAs for these muscles. While the accuracy of PCSA values determined from medical imaging has limitations (as we have described in this review), the authors demonstrated in a follow up study that the muscle volumes were strongly correlated to total isometric strength at the shoulder, elbow, and wrist (Holzbaur et al. 2007a). The strong relationship between muscle volume and joint strength has also been observed in other studies (Akagi et al. 2009; Fukunaga et al. 2001). As such, documentation of muscle volumes, and the variability in volume and distribution across different subjects and populations, is of interest to study.

The dominant arm of ten subjects (5 females, 5 male, 24–37 years, 158–188 cm tall, 50–86 kg) with no history of injury or pathology of the upper limb was studied. The subjects varied from a 20th percentile female to a 97th percentile male (Gordon et al. 1989), based on height (Table 19.1).

Each subject was imaged in a supine position within a 1.5 T MRI scanner (GE Healthcare, Milwaukee, WI). Axial images were acquired from shoulder to wrist using two three-dimensional spoiled gradient echo sequences with 3 mm sections. Images of the muscles crossing the shoulder were obtained with the body coil with TE = 3 ms, TR = 11.6 ms, flip angle (FA) = 30°, matrix = 512 × 192, bandwidth = ±31.25 kHz, and field of view (FOV) = 32 cm, resulting in a 16-min scan time. Elbow and forearm images were acquired using a flexed array long bone coil (Medical Advances, Milwaukee, WI) with TE = 5 ms, TR = 23 ms, FA = 45°, matrix = 320 × 192, bandwidth = ±15.63 kHz, and FOV = 16 cm, resulting in a 22-min scan time.

To calculate muscle volume, the three-dimensional geometries of the 32 upper limb muscles that cross the wrist, elbow, forearm, and shoulder (glenohumeral joint) were reconstructed (Fig. 19.1). Muscle boundaries were identified and manually outlined, or segmented, in the axial images, and a three-dimensional polygonal surface was created for each muscle from the outlines (3D-Doctor,

Table 19.1 Subject characteristics

This table presents important anthropometric measurements for the subjects studied in Holzbaur et al. (2007), including height, weight, and length and circumference of the upper limb.

[a] The letter in the subject designation indicates the gender of the subject.

[b] Percentile values based on height and weight are based on Gordon et al. (1989)

[c] Arm length was calculated from the image data as the sum of the length of the radius and humerus.

[d] Forearm and arm circumference was measured from the image data as the largest circumference measured on any axial slice.

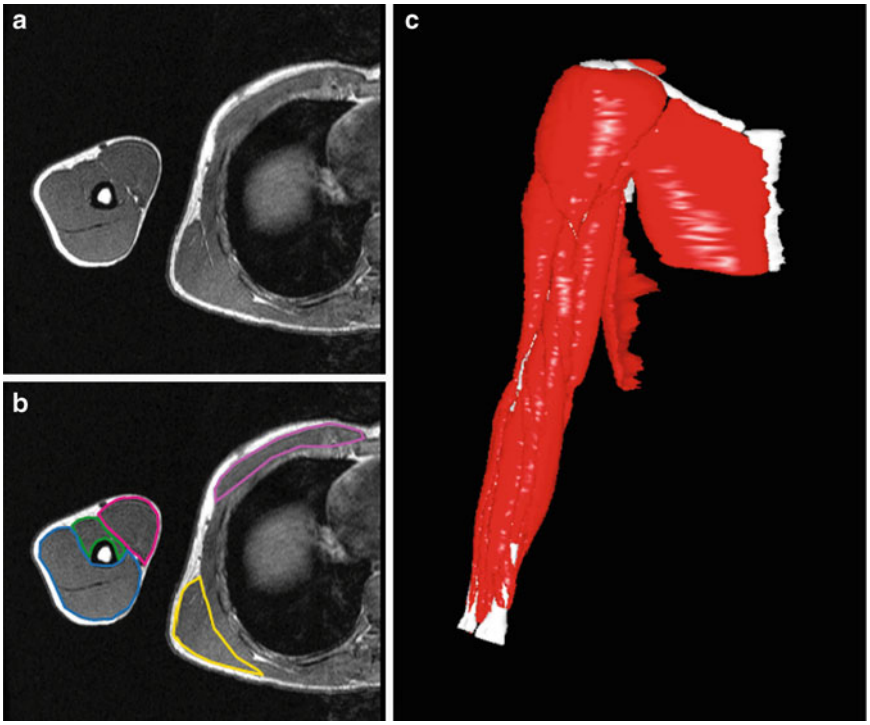

Fig. 19.1 Reconstructed muscle volumes for a representative subject. On each axial image (**a**) muscle structures were identified and the boundaries were manually outlined (**b**). The boundaries were used to create three-dimensional surfaces (**c**), from which volume and length were measured for each muscle. (Reprinted from Holzbaur et al. (2007b). With permission)

Able Software Corp., Lexington, MA). Thirty-two muscles were segmented in 4 subjects; 31 were segmented in 6 subjects. The palmaris longus was not identified in six subjects; this muscle is absent in some individuals (Dalley and Moore 1999).

Muscle volume was determined for each of the 314 muscles from 10 subjects. Total muscle volume of the upper limb was determined for each subject as a sum of all their individual muscle volumes (31 or 32 muscles). The mean volume for each muscle across all ten subjects was calculated, as was the mean total muscle volume.

To determine the distribution of muscle volume among the muscles of a given subject, the volume fraction (Fraction_m), expressed as a percentage of total muscle volume, was calculated for each muscle:

$$\text{Fraction}_m = 100 \times V_m / V_{total}, \tag{19.1}$$

where V_m is the individual muscle volume and V_{total} is the total upper limb muscle volume for a given subject. The mean volume fraction for each muscle across the ten subjects was also calculated. The subject-specific volume fraction across all ten subjects was compared, and the degree to which the mean volume fraction for each muscle represented the volume fraction for an individual subject was examined by comparing the measured muscle volumes to the volumes predicted by multiplying the mean volume fraction by the total muscle volume of a subject.

To determine how muscle is distributed among the shoulder, elbow, and wrist the total volume of muscle crossing each joint for each subject were compared across subjects. Muscles that cross more than one joint were considered with the joint of their primary action (groups indicated in Fig. 19.2).

Physiological cross-sectional area (PCSA), an important parameter in maximal muscle force estimation, was estimated for all muscles based on the measured volumes (V_m), measured muscle length (L_m^{meas}), and muscle length to optimal fiber length ratios $\left(L_m / L_m^o\right)$ available in the literature (An et al. 1981; Jacobson et al. 1992; Langenderfer et al. 2004; Lieber et al. 1990, 1992; Murray et al. 2000) according to the following equation:

$$\text{PCSA} = \left(\frac{V_m}{L_m^{meas}}\right)\left(\frac{L_m}{L_m^o}\right) \tag{19.2}$$

Muscle length was measured from the reconstructed volumes as the length of the centroidal path of each volume from most proximal appearance of the muscle to the most distal (Lieber et al. 1992). Tendon length was not included in this calculation. Some muscles have architectural parameters measured separately for multiple compartments or heads. For these muscles (deltoid, latissimus dorsi, pectoralis major, biceps brachii, triceps brachii, extensor digitorum communis, flexor digitorum profundus, and extensor digitorum superficialis) average ratios of muscle length to optimal fiber length (Langenderfer et al. 2004; Lieber et al. 1992; Murray et al. 2000) were used. Calculations of PCSA for each muscle, PCSA fraction as a percentage of total PCSA of the upper limb, and total PCSA at each joint, and means for these values across the ten subjects were calculated in the same manner as described for the volume calculations above. PCSA fraction was compared to volume fraction for each muscle using a paired *T* test.

Anthropometric measures, including humerus length, radius length, ulna length, total arm length, arm circumference, and forearm circumference, were measured on each subject. Arm length was calculated from the image data as the sum of the length of the radius and humerus. Forearm and arm circumference were measured from the image data as the largest circumference measured on any axial slice. The length of each muscle was compared to the radius length of that subject using linear regression to determine if muscle lengths scale with bone lengths.

19.6 Muscle Distribution in the Upper Limb

As reported by Holzbaur et al. (2007b), the muscles with the largest volume fractions are the deltoid and triceps. The deltoid (DELT) has the largest mean volume fraction of the muscles crossing the shoulder (15.2% ± 1.0%) and coracobrachialis (CORACO) has the smallest (0.9% ± 0.3%) (Fig. 19.2). The triceps (TRI) (combined three heads) has the largest volume fraction of muscles crossing the elbow (14.5% ± 0.7%) and anconeus (ANC) has the smallest (0.4% ± 0.08%). For muscles crossing the wrist, flexor digitorum profundus (FDP) has the largest volume fraction (3.7% ± 0.45%) and extensor indicis propius (EIP) has the smallest (0.2% ± 0.05%).

The distribution of muscle in the upper limb was consistent across the 10 subjects, despite a threefold variation in total muscle volumes (1,427–4,426 cm^3) (Table 19.2). Pectoralis major showed the largest variation, with a standard deviation of 2.0% of total muscle volume, and extensor pollicis longus showed the least with 0.04% standard deviation. The average standard deviation for all muscles was 0.4% of total muscle volume. The individual volume for a given muscle falls close to a line with a slope representing the average volume fraction for that muscle across all 10 subjects (Fig. 19.3). When the volume of an individual muscle was predicted using the mean volume fraction, on average 85% of the variation among subjects was accounted for (average $p = 0.0008$). For all muscles, more than 70% of the variation was accounted for ($p < 0.001$), except for extensor pollicis brevis ($r^2 = 0.52$, $p = 0.015$), supinator ($r^2 = 0.68$, $p = 0.002$), and extensor indicis propius ($r^2 = 0.67$, $p = 0.003$).

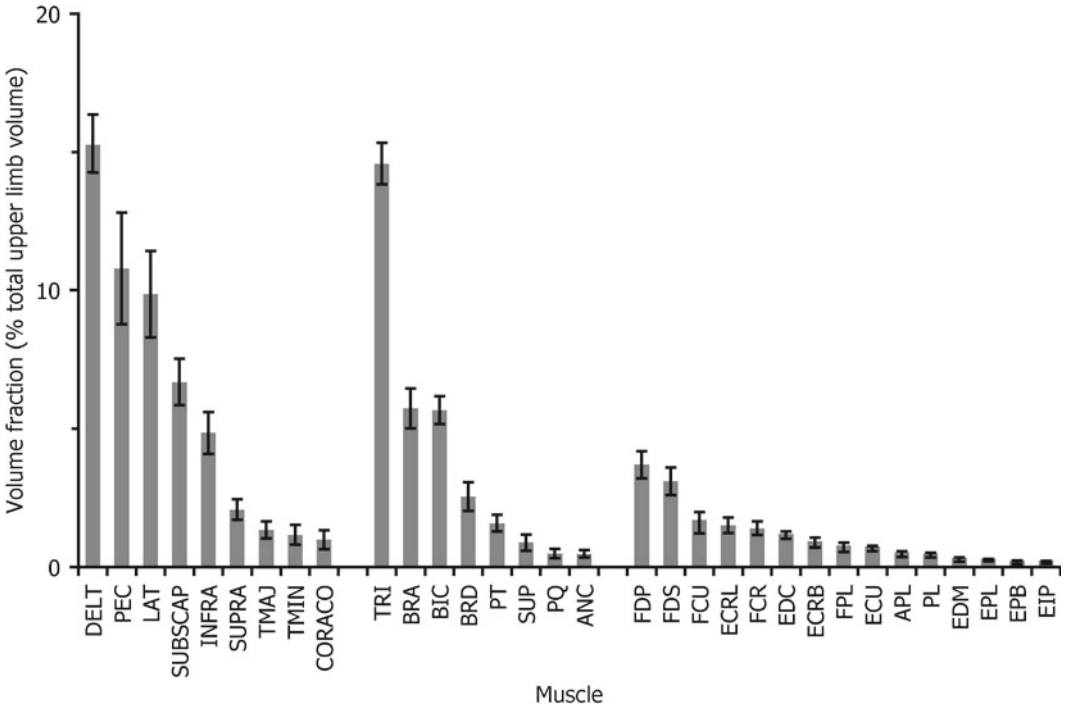

Fig. 19.2 Volume fractions for upper limb muscles. Muscles are grouped by anatomical region (shoulder, elbow and forearm, and wrist) and ordered within each group from largest volume fraction to smallest. The bar for each muscle represents the mean volume fraction with error bars representing one standard deviation for ten subjects. The abbreviations for muscle names are defined in Table 19.2. Reprinted from Holzbaur et al. (2007b). With permission)

The shoulder muscles comprise 52.5% of the total muscle volume, the elbow muscles comprise 31.4%, and the wrist muscles comprise 16.0% (Fig. 19.4). Shoulder adductors made up 28.3% of total muscle volume, while abductors comprised 24.0%. At the elbow, flexors and extensors both made up approximately 15% of total muscle volume (15.3% and 15.0%, respectively). At the wrist, flexors (11.0%) had more than twice the muscle volume of the extensors (5.0%).

On average, the length of the radius accounted for 48% of the variability in muscle length across subjects, although the relationship between bone length and muscle length varied among muscles. For deltoid, teres major, triceps, biceps, extensor carpi ulnaris, flexor carpi ulnaris, extensor pollicis longus, flexor digitorum superficialis, and flexor digitorum profundus, more than 70% of the variability in muscle length was explained by the length of the radius ($r > 0.84$, $p < 0.0008$) (Fig. 19.5). The variability in the lengths of other muscles (pectoralis major, infraspinatus, extensor carpi radialis longus, and abductor pollicis longus) was less explained by radius length, but still had a significant correlation ($r > 0.74$, $p < 0.01$) between these two lengths. Less than 30% of the variability in muscle length was explained by changes in radius length for subscapularis, coracobrachialis, brachioradialis, anconeous, supinator, pronator quadratus, flexor carpi radialis, palmaris longus, flexor pollicis longus, and extensor pollicis brevis ($r < 0.55$, $p > 0.07$).

The PCSA fraction calculated for each muscle was consistent across subjects (Table 19.2). Triceps had the largest PCSA fraction with 18.2% (±0.75%), and extensor pollicis brevis had the smallest

Table 19.2 Muscle characteristics

Muscle	Abbreviation	Average volume (cm^3) (±SD)	Volume fraction (%) (±SD)	PCSA (cm^2) (±SD)	PCSA fraction (%) (±SD)	Length (cm) (±SD)

Total muscle volume		2554.0 (1166.7)				

Reprinted from Holzbaur et al. (2007b). With permission

This table summarizes the mean values for muscle volume, PCSA, volume and PCSA fraction, and muscle length for the 32 muscles of the upper limb.

(0.28% ± 0.07%). At the shoulder, deltoid, pectoralis major, and latissimus dorsi had PCSA fractions that were significantly smaller than the volume fraction for the same muscles ($p < 0.001$). At the elbow, triceps, pronator teres, and pronator quadratus were significantly larger for PCSA fraction than for volume fraction ($p < 0.001$), and biceps and brachioradialis had significantly smaller PCSA fraction than volume fraction ($p < 0.001$). At the wrist, flexor carpi ulnaris, flexor pollicis longus, extensor carpi ulnaris, extensor pollicis longus, and extensor indicis propius had a significantly larger PCSA fraction than volume fraction ($p < 0.001$).

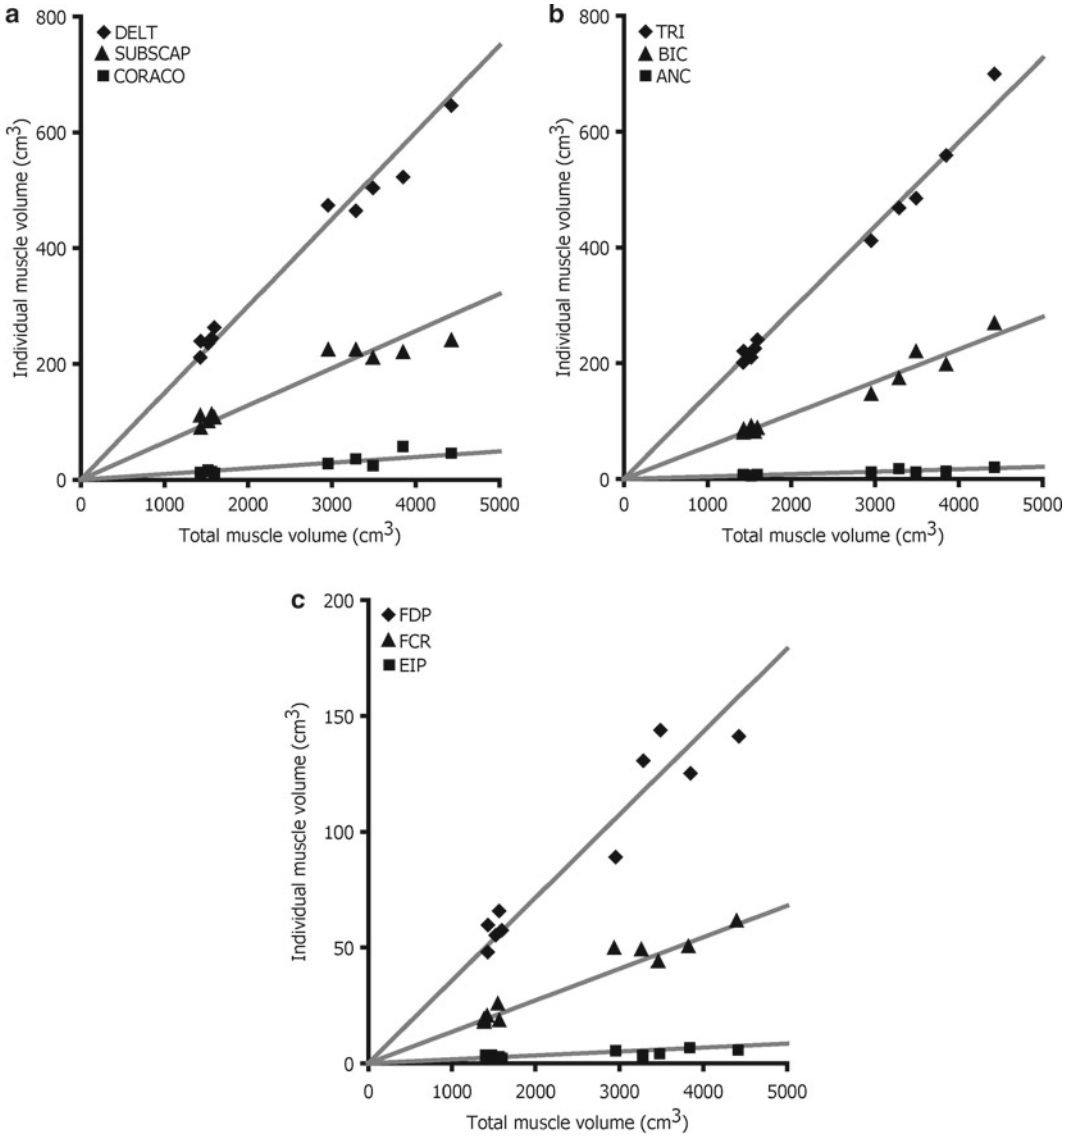

Fig. 19.3 Individual muscle volumes compared to total muscle volume for muscle crossing the shoulder (**a**), elbow (**b**), and wrist (**c**). The muscles with the largest volume fraction (*diamonds*), smallest fraction (*squares*), and an average fraction (*triangles*) for each muscle group are shown. For each muscle, the slope of the corresponding line is the average volume fraction calculated for ten subjects. For all the representative muscles shown, the volumes fall close to the appropriate average line, demonstrating consistent muscle distribution across all subjects. (Reprinted from Holzbaur et al. (2007b). With permission)

Pectoralis major had the largest variation of PCSA fraction across subjects, with a standard deviation of 1.4% of total muscle PCSA, and extensor pollicis longus had the least variation (standard deviation of 0.06%). The average standard deviation was 0.4% of total muscle PCSA.

Measurements of volume fraction have also been made for muscles of the forearm and hand by Brand et al. (1981). Substantial agreement was observed between the volume fractions measured for muscles common to both the Brand et al. and Holzbaur et al. studies ($r^2 = 0.9381$, $p < 0.00001$).

A summary of muscle volumes reported by a number of studies is included in Table 19.3.

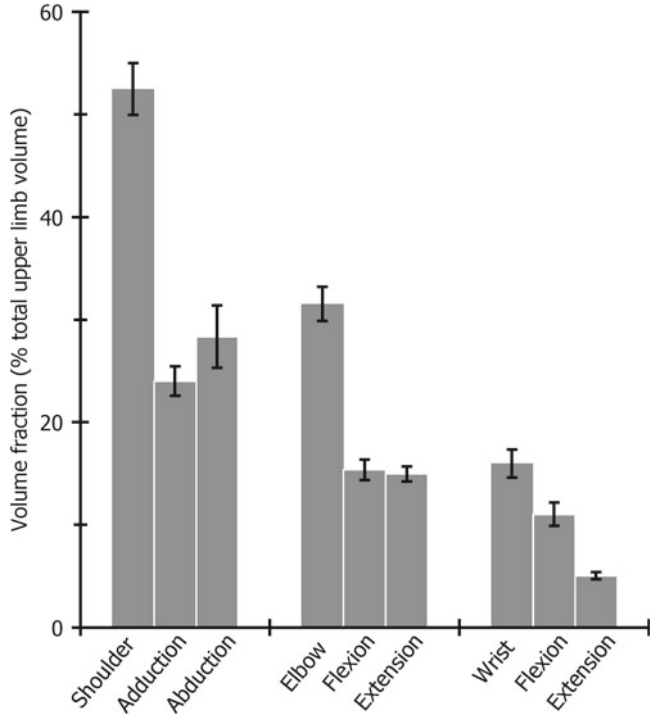

Fig. 19.4 Volume fraction for muscles crossing the shoulder, elbow and forearm, and wrist. Muscles are grouped with the joint of primary action (largest moment arm). The first bar in each group indicates the total volume fraction of all muscles crossing the joint of interest. The second and third bars in each group indicate volume fraction of muscles at a joint capable of creating abduction or adduction of the shoulder, flexion or extension of the elbow, and flexion or extension of the wrist. (Reprinted from Holzbaur et al. (2007b). With permission)

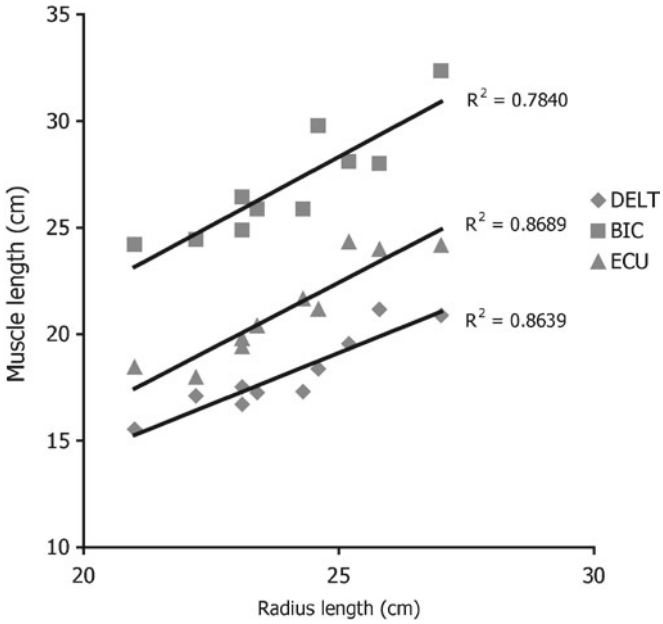

Fig. 19.5 Muscle length compared to radius length. The length of several muscles, including the deltoid (DELT, *diamonds*), biceps (BIC, *squares*), and extensor carpi ulnaris (ECU, *triangles*), correlated well ($r^2 > 0.7$) with radius length. (Reprinted from Holzbaur et al. (2007b). With permission)

This table summarizes the mean muscle volume measurements for several representative studies of upper limb muscle volume (An et al. 1981; Garner and Pandy 2003; Holzbaur et al. 2007b; Langenderfer et al. 2004; Lieber et al. 1990; Lieber et al. 1992; Murray et al. 2000; Veeger et al. 1991, 1997).

[a]The value for ECRL represents the combined ECRL and ECRB (Garner and Pandy, 2003).

19.7 Distribution of Muscle Across Joints

It has been shown that volume fraction and PCSA fraction were consistent across individuals with different total muscle volumes. A number of interesting observations about the way muscle is distributed across joints with respect to their function can be made. Interestingly, the muscle volume crossing the wrist on the flexor side is twice as large as the extensor side (Fig. 19.4). The wrist has the largest imbalance between antagonist muscle groups of any joint in the upper limb. In addition, the two largest muscles crossing the wrist are the flexor digitorum profundus and flexor digitorum superficialis, two muscles that flex the fingers. This highlights the importance of considering the role of the finger muscles when examining the function of the wrist (Gonzalez et al. 1997).

19.8 Physiological Cross-Sectional Area Distribution

By comparing the PCSA fraction and the volume fraction for muscles of the upper limb, one can observe the possible effects of including a muscle length measurement on the distribution of muscle. At the shoulder, the muscles for which the volume fraction and PCSA fraction were statistically different always had a reduced PCSA fraction. This is consistent with the fact that muscles crossing the shoulder have relatively long optimal fiber lengths (average = 12.9 cm) (Langenderfer et al. 2004). At the wrist, the muscles for which the PCSA and volume fractions were different demonstrated increased PCSA fraction. This indicates that these muscles had relatively short optimal fiber lengths (average = 6.5 cm) (Jacobson et al. 1992; Lieber et al. 1990, 1992). There was no distinct trend for muscles crossing the elbow.

It should be noted that in the calculations of PCSA made by Holzbaur et al. (2007b), scaling by the cosine of pennation angle was not performed. In this case, only the force-generating capability of the fibers themselves is considered; scaling by pennation can be incorporated by researchers as a separate step. Further, an estimate of fiber length was used rather than optimal fiber length in the PCSA calculation because measures of sarcomere length were unavailable. As discussed above, to date, medical imaging approaches are not able to capture information about optimal fiber length in living subjects.

19.9 Gender Differences

The Holzbaur et al. (2007b) study included both male and female subjects, and was able to note some differences in the subject groups. Male subjects were observed to have a stronger relationship between height and weight and total muscle volume than did the female subjects. There was very little difference in total muscle volume among the five female subjects, despite the large range in their height and weight. For the male subjects, there was a trend toward increased muscle volume with height ($r^2 = 0.77$, $p = 0.05$) and weight ($r^2 = 0.40$, $p = 0.25$). Further study is necessary to determine if these relationships are observed in a larger group of subjects.

Though there were observed differences between genders with respect to total muscle volume, a difference between genders with respect to the distribution of muscle was not observed. Therefore, these data suggest that once the total muscle volume of a subject is known, individual muscle volume

can be estimated without regard to gender. No strong relationships between total or individual muscle volumes and the other anthropometric measurements were observed.

19.10 Scaling of Muscle Volume

The strong scaling of individual muscles and muscle groups with total muscle volume can be highlighted by normalizing the subject-specific volumes by the corresponding mean volumes for all ten subjects (Fig. 19.6). When the normalized total volume for a subject is compared to the normalized volume of muscle crossing each joint, all points fall near a line of unity slope with r^2 = 0.9818. This indicates that, for each subject, the size of individual muscles relative to the mean muscle volumes is the same as the ratio of total upper limb muscle volume to the mean total upper limb volume. For example, the tallest subject in the Holzbaur et al. study had a total muscle volume that was approximately 1.7 times the mean found in that study. This subject also had a volume of muscle crossing the shoulder that was approximately 1.7 the mean volume of muscle crossing the shoulder. That is, a single number, the scaling ratio, can be used to represent the total and individual muscle volume of a subject. For a given muscle, a ratio greater than 1 indicates that its volume is larger than the mean. By assessing the volume of just a few muscles, the size of any subject can be estimated and the volume of all muscles can be determined using the volume distributions reported in this study.

To facilitate comparison of muscle volumes measured from a number of the studies discussed in this review documenting muscle volumes at the shoulder (Langenderfer et al. 2004), elbow (An et al. 1981; Murray et al. 2000), and wrist (Jacobson et al. 1992; Lieber et al. 1990, 1992), the volumes measured in these studies were normalized by the corresponding mean muscle volume measured in the Holzbaur et al. study (Fig. 19.6). In this way, scaling ratios from all of these studies could be readily compared. The distribution of muscle measured in cadaveric studies of muscles crossing the shoulder, elbow, and wrist was the same as the distribution measured in the Holzbaur et al. study in living subjects, as evidenced by the fact that the average scaling ratios for these studies also fall on the unity line. However, the total muscle volume reported by these previous studies is consistent with the smallest female subjects. One previous study used the volumes of the Visible Human Male (from the National Library of Medicine, National Institutes of Health) to investigate muscle architecture and force-generating capabilities (Garner and Pandy 2001). This individual exhibits less constant scaling ratios among the muscles crossing different joints than did the subjects in the other studies; the volume of muscle crossing the shoulder was relatively larger than that crossing the elbow, and the volume of muscle crossing the wrist was relatively smaller. Only muscles common to the Garner and Pandy and Holzbaur et al studies were considered in this analysis. In addition, the total muscle volume of the Visible Human Male was very large compared to that of the other subjects and specimens in the literature. The difference in muscle distribution in the Visible Human Male may be due to exercise related adaptation. Comparing the mean muscle volumes from cadaveric studies and imaging based studies also reinforces the conclusion that muscle volumes in younger subjects are much larger than those measured in cadavers (Table 19.3).

This review summarizes a wealth of data regarding the range of total muscle volume in normal adults of both genders and the distribution of this volume among the muscles. Given the mean volume fractions reported here, it has been shown that a single parameter is sufficient to scale all of the muscles in the upper limb to represent a typical individual with different total muscle volume. This is powerful information for understanding the relationship among muscles of the upper limb and for supporting the results of modeling and simulation that use mean muscle properties to understand muscle function.

19.11 Applications to Other Areas of Health and Disease

In this review, muscle volumes and PCSAs and how they scale for individuals of different size have been presented. Muscle fiber length, optimal fiber length, and moment arms may also scale with an individual's size. For example, there is evidence that moment arms for muscles crossing the elbow may scale with bone length or other bone dimensions, and that the degree of this scaling varies across muscles (Murray et al. 2002). It is unknown how moment arms may scale for muscles crossing other

Table 19.4 Key features of upper limb muscle volume in young adults

1. Muscle volume and fiber arrangement, also called muscle architecture, are the major determinants of the force-generating capacity of muscle.
2. Imaging and dissection methods are both useful for characterizing muscle volume and architecture.
3. PCSA is an important measurement for predicting individual muscle force-generating capacity, while muscle volume can be used to evaluate differences in overall strength between individuals.
4. Volume fraction is consistent among healthy adults with different total muscle volumes.
5. Total muscle volumes vary substantially among individuals, and between studies of cadavers and living subjects.
6. The wrist has the largest volume imbalance between antagonist muscle groups of any joint in the upper limb.

This table lists the key facts regarding upper limb muscle volume, including how it is assessed, how it is distributed in the upper limb, and how it varies among individuals.

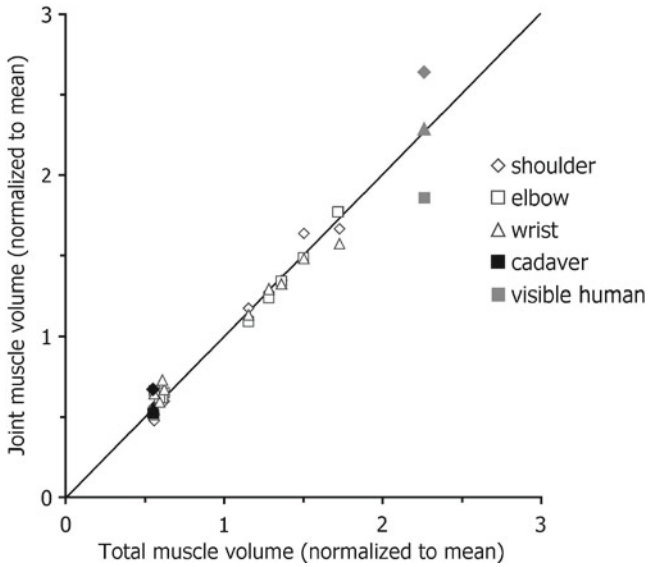

Fig. 19.6 Volume of muscles crossing a joint (normalized by mean muscle volume crossing the joint) compared to total muscle volume (normalized by mean total muscle volume). The subjects in the Holzbaur et al. (2007b) study (*open data points*) demonstrated uniform scaling of individual muscle volume with total muscle volume, as demonstrated by the points falling on the unity line. Data from cadaveric studies (An et al. 1981; Jacobson et al. 1992; Langenderfer et al. 2004; Lieber et al. 1990; Lieber et al. 1992; Murray et al. 2000) (*black data points*), when normalized by the corresponding mean volumes from this study, also fall on this line, indicating muscle volume distribution equivalent to that found in Holzbaur et al. Muscle volumes from cadaver studies are equivalent to the smallest females in Holzbaur et al. Muscle volumes from the Visible Human Dataset (from the National Library of Medicine, National Institutes of Health) (*grey data points*, Garner and Pandy 2001), when normalized by the means from Holzbaur et al. do not fall on the unity line, indicating that the shoulder muscles are relatively larger and the elbow muscles are relatively smaller than those found in other studies. In addition, the volumes from the Visible Human Dataset are almost 2.5 times the mean found in Holzbaur et al. (Reprinted from Holzbaur et al. (2007b). With permission)

joints. Future work to determine scaling rules for moment arm and fiber length is necessary to create subject specific models that account for variations in these parameters.

The studies presented in this review provide a normative data set that allows for investigation of other populations. Many researchers study populations that may have different distributions of muscle, such as children, athletes, or patients following spinal cord injury or stroke. We may now be able to detect differences in muscle proportions from healthy adult subjects, which may help researchers uncover changes in muscle function with training or disease.

Summary points

- Physiological cross-sectional area is an important measurement for predicting individual muscle force-generating capacity, while muscle volume can be used to evaluate differences in overall strength between individuals.
- Imaging and dissection methods are both useful for characterizing muscle volume and architecture.
- Dissection methods allow researchers to obtain measurements of muscle volume, optimal fiber length, and pennation angle in the same specimens, and permit accurate calculations of PCSA.
- Volumes in young healthy subjects are much larger than cadaveric specimens, so forces calculated from PCSAs measured in cadavers may be of limited applicability.
- Muscle volumes measured with medical imaging approaches are strongly correlated with strength in living subjects.
- Volume fraction is consistent among healthy adults with different total muscle volumes.
- Various studies of upper limb muscle show consistent volume fraction measurements; however, magnitudes of muscle volume can vary widely across individuals and studies.
- The wrist has the largest volume imbalance between antagonist muscle groups of any joint in the upper limb, with approximately twice as much as muscle volume on the flexor side.

Chapter 20
Bioelectrical Impedance to Predict Muscle Mass in the Elderly

Lars Ellegård and Marja Tengvall

Abstract In ageing, body composition changes gradually and will ultimately reduce function and health. In healthy elderly, deterioration of muscle mass and development of sarcopenia may be masked by weight stability. There is an increasing interest in specific estimation of skeletal muscle mass, as it may better reflect the body protein reserves and nutritional status in disease and aging.

Bioelectrical impedance analysis is an easily performed and non-invasive indirect method to measure body composition based on the different conductive/resistive properties of body tissues. There are several prediction equations to estimate skeletal muscle mass by BIA. In the elderly, some of the assumptions in the impedance technique may be violated, and thus their validity must be assessed by a reference method in the population under study.

Reference values for muscle mass in the elderly have been published based on both single-frequency and impedance spectroscopy data. Impedance methods are suitable for measurement of muscle mass in the elderly because they are convenient and precise. This chapter presents various aspects of bioimpedance techniques to estimate muscle mass or muscle function in the elderly.

20.1 Introduction

In ageing, body composition changes gradually and will ultimately reduce function and health (Woodrow 2009). In general, the proportion of fat free mass falls in people of older age (Chumlea et al. 2002; Dey et al. 2003; Ding et al. 2007). More specifically, there are reductions in bone mass, body cell mass (BCM) and muscle mass (Gallagher et al. 1997; Kyle et al. 2003). Initially in senescence, fat mass may increase but over the years total body fat tends to decrease. In healthy elderly, deterioration of muscle mass and the development of sarcopenia may be masked by weight stability (Gallagher et al. 1997). Thus, body weight measurements do not accurately detect such changes, and other measures of body composition will be of interest. However, it must be kept in mind that most body composition methods are based on assumptions that, although relevant for healthy adults, might lead to errors when applied to an elderly population (Woodrow. 2009). Many body composition methods are applications of the two-compartment model, where the body is divided into fat mass (FM) and fat free mass (FFM). Fat free mass consists of body cell mass, including muscles and internal organs, as well as bone and extracellular water (ECW). In order to discriminate between these entities, additional techniques or combinations of techniques are necessary, as outlined below. Body cell mass (BCM) has been proposed as a more specific marker for nutrition and wasting, but there is a lack of normal reference range data for the ageing individual (Woodrow. 2009).

There is an increasing interest to specifically estimate skeletal muscle mass (SMM), as it may better reflect the body protein reserves and nutritional status in disease and ageing (Kyle et al. 2003). Muscle wasting or muscle loss, often termed sarcopenia, is a process associated with ageing as well as with several diseases (Kyle et al. 2003). Sarcopenia has been found to be associated with functional impairment (Janssen et al. 2002). The prevalence of sarcopenia is obviously dependent on age classification, but has been reported to apply to 50% of men and 72% of women over 80 years of age in a large US population study (Janssen et al. 2002). This chapter presents various aspects of bioimpedance techniques to estimate muscle mass or muscle function in the elderly, defined as persons above 65 years of age.

20.2 Spectrum of Bioimpedance Techniques

Bioelectrical impedance analysis (BIA) is an easily performed and non-invasive method to measure body composition based on different conductive/resistive properties of body tissues. The theory, practice and clinical application of bioimpedance analysis have recently been extensively reviewed (Kyle et al. 2004a, b). Single frequency-BIA (SF-BIA) is commonly used to estimate total body water and fat free mass (FFM). Multifrequency-BIA (MF-BIA) and bioelectrical impedance spectroscopy (BIS) estimate both intracellular water (ICW) and extracellular water (ECW) and from

them fat free mass (FFM) (Kyle et al. 2004a). Body fat (BF) is generally calculated as the difference between body weight (BW) and FFM. Bioimpedance vector analysis (BIVA) does not primarily predict volumes or quantify muscle mass but instead plots resistance and reactance against reference values to estimate hydration status and body cell mass (Piccoli et al. 1996).

Skeletal muscle mass forms the largest proportion of the fat free mass, and as it is a tissue rich in electrolytes it has low resistance and hence is a dominant conductor. Thus, bioimpedance analysis might be especially suitable for the clinical estimation of muscle mass. However, as impedance methods are only indirect methods, they have to be validated by direct methods (Kyle et al. 2004a). Dual-energy X-ray absorptiometry (DXA) is increasingly accepted as a reference method to evaluate bioimpedance methods (Kyle et al. 2004a). DXA yields information on body fat, lean soft tissue (LST) and bone mineral content (BMC). The extremities consist primarily of three components: skeleton, fat and muscle mass (Heymsfield et al. 1990). The sum of lean soft tissue in the extremities, sometimes referred to as appendicular lean soft tissue (ALST), has also been termed appendicular skeletal muscle mass (ASMM) (Kyle et al. 2003). Appendicular skeletal muscle mass forms the major proportion of total body muscle mass and the ratio ASMM/0.75 has been proposed to represent total body muscle mass (Heymsfield et al. 1990). DXA has successfully been validated both by total body potassium and total body nitrogen (Hansen et al. 1999) and by MRI (Kim et al. 2002, 2004) for the estimation of total body skeletal muscle mass (TBSMM or SMM), both with and without correction for intra-muscular fat.

20.3 Single-Frequency Bioimpedance Analysis (SF-BIA)

There are several prediction equations to estimate skeletal muscle mass by BIA (Table 20.1). A single-frequency BIA equation was suggested by Janssen to predict whole body skeletal muscle mass among healthy Caucasians aged 18–86 years, validated against MRI (Janssen et al. 2000). The large US National Health and Nutrition Examination Survey (NHANES III) study included 4449 subjects older than 60 years of age screened by single-frequency BIA, and later reanalyzed for the determination of muscle mass calculated according to the Janssen equation, without validation (Janssen et al. 2004) (Table 20.2).

The Janssen equation has recently been reported to be accurate also for Asians, although only subjects 20–40 years of age were included in the validation (Chien et al. 2008). When applied to community dwelling elderly Taiwanese volunteers with a mean age close to 75 years, the predicted height-adjusted skeletal muscle mass indexes were actually higher than reported for US citizens (Table 20.2).

Another single-frequency BIA equation used data from healthy volunteers aged 22–94 years to predict appendicular skeletal muscle mass validated by DXA (Kyle et al. 2003). However, a recent authoritative review has not recommended the use of general BIA prediction equations across different ages and ethnic groups without prior testing of their validity (Kyle et al. 2004a). This is underlined by our experience where we found the equations of Janssen and Kyle to overestimate skeletal muscle mass in non-institutionalized subjects aged 75. The overestimations were larger for men than for women for both equations. This could be due to the fact that both muscle mass estimates were developed to include a wide range of ages, perhaps at the cost of less accuracy among the elderly. Hence, we found it necessary to develop an age-specific prediction equation. We developed an equation for the assessment of skeletal muscle mass based on 50 kHz measurements extracted from Xitron 4200 Hydra data using the same independent predictors as Kyle and Janssen.

Table 20.1 Muscle mass equations in impedance analysis

Equation	Entity	Reference	#
(height^2/*R* * 0,401) + (sex(men = 1, women = 0) * 3,825) + (age * –0,071)+5,102	TBSMM	BIA (Janssen et al. 2000)	**1**
–4,211 + (0,267 * height^2/*R*) + (0,095 * weight) + (1,909 * sex (men = 1, women = 0)) + (–0,012 * age) + (0,058 * Xc)	ALST	BIA (Kyle et al. 2003)	**2**
–24,021 + 0,33 * Ht – 0,031 * *R* + 0,083 * Xc – 1,58 * gender + 0,046 * weight	TBSMM	BIS (Tengvall et al. 2009)	**3**
–23,953 + 0,333 * Ht – 0,004 * Ri – 0,010 * Re – 1,727 * gender + 0,042 * weight	TBSMM	BIS (Tengvall et al. 2009)	**4**
–24,05 + 0,365 * Ht – 0,005 * Ri – 0,012 * Re – 1,337 * gender	TBSMM	BIS (Tengvall et al. 2009)	**5**

Predictive equations to estimate total body skeletal muscle mass (TBSMM) or appendicular lean soft tissue mass (ALST) from bioelectrical impedance, both by single-frequency data (BIA) and impedance spectroscopy data (BIS)
Ht height in cm, *R* Resistance at 50 kHz, *Xc* Reactance at 50 kHz, *Ri* Resistance of intracellular fluid, *Re* Resistance of extracellular fluid
Sex (eq 1–2) women = 0, men = 1
Gender (eq 3–5): women = 1, men = 0

Table 20.2 Muscle mass in elderly populations

Australia *n* **= 119**	**6,3 (1,0)**	156	75	**7,9 (1,3)**	170	75

Total body skeletal muscle mass index (SMMI) in elderly populations estimated by predictive equations from bioimpedance analysis

This equation has been successfully validated by DXA in an Australian population of 119 elderly subjects referred for body composition analysis, while the Janssen and the Kyle equations were both shown to overestimate muscle mass as compared to DXA (Bosaeus Strauss 2009). All three equations are presented in Table 20.1, and the resulting muscle mass values are presented in Table 20.2. The muscle mass indexes in different populations of elderly are remarkably similar, when estimated by identical equations. However, the high SMMI for the Taiwanese population might be an overestimate as the equation was validated only in a younger population. The difference between the Swedish and the Australian populations in muscle mass estimated by the same equation might be explained by the different recruitment approaches, as the Swedish elderly was a population-representative sample whereas the Australian elderly were all individually referred for body composition examination.

20.4 Multifrequency-Bioimpedance Analysis (MF-BIA)

Multifrequency bioimpedance analysis uses at least two different frequencies for the alternating current in order to assess both intra- and extracellular volumes. No equations based on multifrequency bioimpedance analysis explicitly designed for muscle mass in the elderly have been derived. However, equations have been published for the assessment of body cell mass in apparently healthy,

well nourished but non-obese elderly, validated by total body potassium (Dittmar and Reber. 2001). The authors failed to find any advantage of multiple as compared to single frequency BIA for the prediction of body cell mass.

20.5 Bioimpedance Vector Analysis (BIVA)

In bioimpedance vector analysis (BIVA) plots of height adjusted resistance and reactance are compared with gender-specific bivariate tolerance intervals for the impedance vector to estimate hydration status and body cell mass (Piccoli et al. 1996). Bioimpedance vector analysis is suggested to give a qualitative measure of body tissues, where vector length indicates hydration status and sideways migration in the diagram indicates changes in tissue structure and mass (Norman et al. 2009). Bioimpedance vector analysis does not predict any volumes, and thus does not require any data on body weight, which would be valuable in many clinical settings, especially among the elderly. Recently bioimpedance vector analysis was reported to correlate strongly (r^2=0.71) with hand grip strength and its development over time in late middle age Europeans (mean age 63 years) (Norman et al. 2009).

20.6 Bioelectrical Impedance Spectroscopy (BIS)

We have reported BIS, using Xitron equations, to be valid for estimating average FFM in non-institutionalized elderly Swedes when compared to DXA (Tengvall et al. 2009). However, previously published BIA prediction equations (Janssen et al. 2000; Kyle et al. 2003) for skeletal muscle mass applied on the 50 kHz data both tended to overestimate muscle mass when compared to DXA.

Based on DXA-measurements of skeletal muscle mass we developed two new predictive equations applicable for BIS data; with and without body weight as a predictor (Table 20.1). The trunk has limited impact on whole body impedance because of its large cross-sectional area although it constitutes at least half of total body weight (Kyle et al. 2004a). Thus, changes in fat free mass in the trunk are probably inadequately detected by whole body impedance, although it contributes to body weight. In addition, the relative proportions of trunk and extremities may vary between subjects, and especially so in the elderly due to compression of the axial skeleton. Hence, excluding body weight as a muscle mass predictor may reduce that source of bias. Average differences for total skeletal muscle mass from the BIS-equations compared to DXA were less than ¼ kg without any significant systematic bias (Tengvall et al. 2009).

These muscle mass equations could successfully predict average total body skeletal muscle mass, with 85% of the individual predictions within ±10% of the reference method, as demonstrated in Fig. 20.1. 91% of the variation in muscle mass could be attributed to the BIS-data (Tengvall et al. 2009).

Based on a DXA-validated subsample we constructed reference values and ranges for total body skeletal muscle mass in elderly non-institutionalized Caucasians, as presented in Table 20.3. In institutionalized elderly in residential care facilities, muscle mass appears to be lower as judged by ICW from BIS, although without any validation from reference methods (Carlsson et al. 2009). Reported ICW was only 2/3 of our reference values, with some extremely low values, again raising doubts as to the feasibility of bioimpedance spectroscopy in extreme situations without proper validation.

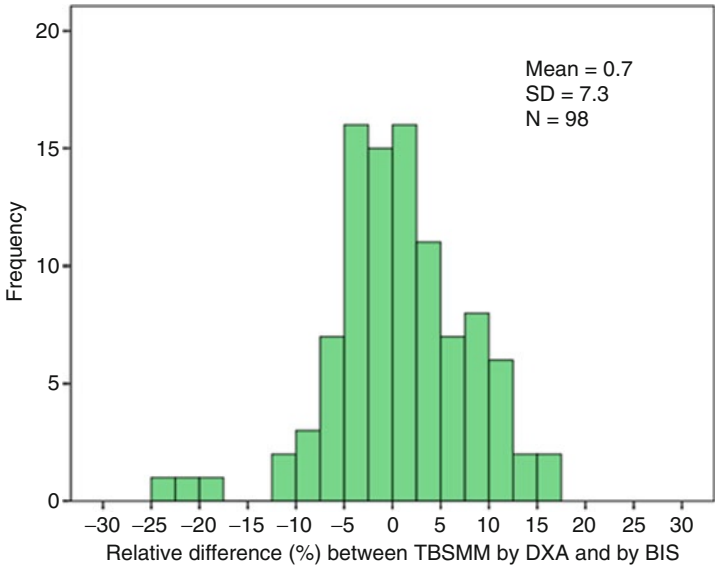

Fig. 20.1 Relative variation in muscle mass prediction. Relative difference (%) between muscle mass predicted by BIS-equation #5 and muscle mass quantified by DXA in 98 free-living elderly subjects. 85% of the individual predictions were within ±10% of the reference method (Adapted from Tengvall et al. 2009)

Table 20.3 Body composition by BIS in the elderly

	Women n = 345			Men n = 229		
	Mean (SD)	Perc. 5	Perc. 95	Mean (SD)	Perc. 5	Perc. 95
TBSMM (kg)	**17,4 (2,9)**	12,4	21,7	**26,3 (3,0)**	20,8	31,0
SMMI (kg/m²)	**6,6 (0,9)**	5,1	7,9	**8,6 (0,7)**	7,5	9,6

Reference values for BIS-derived body composition parameters including total body skeletal muscle mass in non-institutionalized elderly Caucasians (Tengvall et al. 2009)

20.7 Application to Other Areas of Health and Disease

Comparison of the equations to predict muscle mass, based on either 50 kHz single frequency BIA or impedance spectroscopy, resulted in small average differences. Thus, in our experience, there seems to be neither any advantage nor any disadvantage to predict muscle mass from single-frequency BIA compared to BIS. Two equations that included BIS measurements with or without body weight gave only slightly different results. Thus, the inclusion of body weight as an independent predictor of total body skeletal muscle mass will only slightly increase the explanatory power. Hence, we suggest the use of muscle mass predictive equations without body weight in future studies.

Bioelectrical impedance analysis offers, in general, good opportunities to study changes in muscle mass over time, thanks to high reproducibility. However, in ageing, violations of the

assumptions used in the method software presumably increase, and thus such violations must be checked by validation of BIA results with reference methods in the specific population under study.

Summary Points

- Impedance methods are convenient to use and show good precision
- Impedance is only indirectly associated with muscle mass; thus, predictive equations are required
- In the elderly some of the assumptions in the impedance technique may be violated
- Impedance methods must be validated in the population under study
- Reference values for muscle mass in the elderly have been published, based on both single-frequency and impedance spectroscopy data

Key Facts of the Elderly

- Elderly people are defined as those 65 years of age or older
- Almost 1 in 5 citizens belong to this group
- The prevalence (proportion) of elderly in the society is steadily increasing, being 18% in Sweden in 2008
- Women tend to live longer than men, thus the proportion of women among the elderly is approximately 55%, and the proportion increases with age
- In the elderly, bone mass, body cell mass, muscle mass and fat mass gradually decrease with age

Key Points on Impedance and Muscle Mass in the Elderly

- Bioimpedance methods are suitable for measurement of muscle mass in the elderly because they are convenient and precise
- The validity must be assessed by a reference method in the population under study

Tools and Techniques in Anthropometry: Adipose Tissue, Other Compartments and Relationships

Chapter 21
Anthropometry of Body Fat: How Anthropometric Measures Predict Mortality and Especially Cardiovascular Mortality

Eddy Mizrahi-Lehrer, Beatriz Cepeda-Valery, and Abel Romero-Corral

Abstract The World Health Organization defines overweight and obesity as an abnormal or excessive fat accumulation that impairs health. However, there are no well established cut-offs to define obesity based on body fat. The NIH, WHO, the American Association of Clinical Endocrinologist, and the American College of Endocrinology define obesity as an excess of total body fat, specifically body fat that is 20–25% of total body weight in men, and 30–35% in women. But there are not enough data supporting these cut-offs as predictors of adverse outcomes. Furthermore, because direct body fat is difficult to measure, more widely available and easier to perform anthropometric measurements are used in clinical practice.

Body mass index is the most commonly used and accepted anthropometric measure to define obesity. It is a well known conditional risk factor for the development of several cardiovascular risk factors, such as diabetes mellitus type 2, metabolic syndrome, systemic hypertension, dyslipidemia, obstructive sleep apnea, etc. However, recently scientists have questioned its usefulness as slightly increased body mass index (overweight and mild obesity range) has been related to improved survival and fewer cardiovascular events when compared to subjects with a normal body mass index, a phenomenon known as the "obesity paradox".

Anthropometric measures of obesity that take into consideration body fat distribution, mainly truncal and/or abdominal obesity, such as waist circumference and specially waist-to-hip ratio appear to better predict cardiovascular risk than BMI alone, but this remains to be proven. Interestingly, despite body fat being the gold standard to define obesity, very little is known regarding its impact as a predictor of all-cause and cardiovascular mortality. The following chapter will analyze the different anthropometric measurements including body fat and lean mass and their impact on mortality with a focus on cardiovascular mortality, the leading cause of death worldwide.

21.1 Introduction

In the US the prevalence of obesity is estimated to affect 34% of adults over the age of 20, according to an analysis released by the Center for Disease Control and Prevention (CDC 2007). This translates roughly to more than 70 million Americans having a body mass index (BMI) >/= 30 kg/m^2. The World Health Organization (WHO) estimates that obesity rates have tripled over the last two decades in developing countries (WHO 2006). Asian-Pacific countries are not immune to this epidemic either: countries like Japan, with historically low rates of obesity, are now facing a challenge of increased prevalence: a twofold increase in the age group 20–29 years (Gill 2001). Unfortunately, the future doesn't seem very bright, as estimates project 2.3 billion overweight adults and 700 million obese children by 2015 (WHO 2006).

The National Institute of Health (NIH), WHO, American Association of Clinical Endocrinologist, and American College of Endocrinology define obesity as an excess of total body fat, specifically body fat that is 20–25% of total body weight in men, and 30–35% in women (WHO 2006, NIDDK-NIH 2008, AACE/ACE 1998). However, there are poor data to justify these cut-offs, which are somehow arbitrary. Moreover, measurement of body fat is neither a common procedure nor easy to perform on a routine basis. That is why in clinical practice and epidemiologic studies, other measurements are more widely used. These measurements reflect either general obesity, such as weight, BMI, body surface area or more recently central adiposity, such as waist circumference (WC) or waist-to-hip ratio (WHR).

BMI remains the most widely used measurement to quantify obesity. Its simple calculation has allowed clinicians and scientists to compare body habits, body weight changes and the impact of obesity on several diseases, with special emphasis on cardiovascular (CV) diseases (Poirier et al. 2006). However, recent evidence suggests that BMI might not be the best measure of obesity to predict total and CV mortality. Other anthropometric measures of obesity, including those taking into account body fat distribution or even body fat or lean mass, might be necessary for better risk prediction. Despite the increasing prevalence of obesity, the impact of anthropometric measures and their prognostic impact on total and CV mortality remains unclear, and this is the main theme of this chapter (Table 21.1).

Table 21.1 Key facts of sensitivity (%), specificity (%), positive predictive value (%) and negative predictive value (%) (Rao 2004)

1. Sensitivity, specificity, positive predictive value and negative predictive value are collectively known as the test characteristics and are important ways to determine the usefulness of diagnostic test.
2. Sensitivity is the capacity of the test to correctly identify diseased individuals in a population, also known as the "true positive". The greater the sensitivity, the smaller the number of unidentified cases or "false negatives".
3. Specificity is the capacity of the test to correctly identify individuals who are free of disease in a population, also known as the "true negatives". The greater the specificity, the smaller the number of "false positives".
4. Positive Predictive Value is the probability of the disease being present among those with a positive test result.
5. Negative Predictive Value is the probability that the disease was absent among those whose diagnostic test results were negative.

21.2 Body Mass Index, Waist Circumference and Waist-to-Hip Ratio and Its Relationship to Cardiovascular Risk Factors

The negative impact of increased BMI on health has largely been studied, especially for CV disease. In fact, the American Heart Association and the American College of Cardiology guidelines list obesity as a major modifiable risk factor for CV disease (Smith et al. 2001). Whether obesity is an independent risk factor for CV disease or only acts as a conditional risk factor for developing CV risk is still matter of ongoing research (Krauss et al. 1998).

There are overwhelming data suggesting that obesity plays a significant role in the development of several CV risk factors, the better established being links with systemic hypertension (Barret-Connor and Khaw 1985, Lewis et al. 2009), diabetes mellitus type 2 (Sharper et al. 1997), dyslipidemia (Poirier et al. 2006), and obstructive sleep apnea (Somers et al. 2008).

Most of the studies assessing the impact of obesity on CV risk rely on BMI. But recently, anthropometric measures that take into account body fat distribution, such as WC and WHR have also been associated with CV risk. Moreover, in some studies, these measures appear to be more closely related to cardiometabolic dysregulation than BMI and may be the reason why they could be better predictors of total and CV mortality.

For instance, abdominal obesity, as measured by WC, is associated with, increased triglyceride levels and lower HDL-cholesterol concentrations. It seems that WC has a higher degree of correlation with lipid variables than BMI, HC or WHR (Reeder et al. 1997; Després et al. 1998). Interestingly, not only accumulation of fat in the waist but also around the hip may play an important role in the development of CV disease. Heitmann and colleagues (Heitman 2004), have shown that in a random subset of ~3,000 adult Danes, a large hip circumference seems to have independent and positive effects on CV disease, especially in women. This could be explained by studies that have shown that fat located around the hip is associated with better lipid profile (Snijder et al. 2003).

Another example of the usefulness of central obesity measures to assess CV risk is the study conducted by Ito and colleagues. In this study researchers recorded different anthropometric measurements among 2,728 Japanese individuals and studied their relationships with different CV risk factors. They concluded that WHR and fat mass-trunk-legs ratio predicted CV risk factors like hypertension, dyslipidemia and diabetes mellitus more accurately than BMI alone (Ito et al. 2003).

Many other studies worldwide have confirmed the utility of central obesity measures in assessing CV risk but are beyond the scope of this book chapter. Nonetheless, it is clear that health care providers and researchers need to complement their body weight assessment with anthropometric measures that take into account body fat distribution to adequately assess the effects of obesity on CV disease.

21.3 Anthropometric Measures of Obesity as Predictors of Total and Cardiovascular Mortality

Although there is a clear association between obesity and increased mortality, there is an ongoing controversy regarding which measure of obesity is the best to assess and predict CV risk. The following paragraphs will discuss in greater detail the association between anthropometric measures of obesity and their relationship with total and CV mortality.

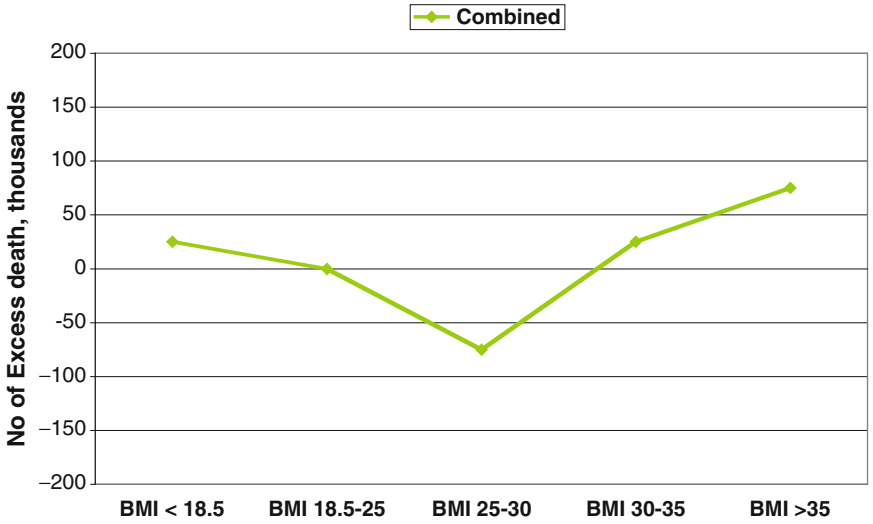

Fig. 21.1 Estimated numbers of excess deaths in 2000 in the United States relative to the Healthy Reference BMI Category of 18.5 to <25 kg/m^2, *BMI* Body Mass Index. All estimates are based on the covariate distribution from National Health and Nutrition Examination Survey (NHANES) 1999–2002, the number of deaths in 2000 from US vital statistics data. Relative risks estimated from combined data from National Health and Nutrition Examination Surveys I, II, and III (Adapted from Flegal et al. 2005)

21.3.1 BMI and Its Association with Total and Cardiovascular Mortality

Till date, most of the studies assessing obesity and mortality have relied on BMI as the defining marker. Emerging data has prompted scientists to question BMI's ability to predict total and CV mortality (Romero-Corral et al. 2008a). This controversy is mainly due to large epidemiologic studies showing that the relationship between BMI and mortality and CV mortality follows a U or J-shaped association with the lowest mortality in the BMI range corresponding to overweight and mildly obese subjects (Allison et al. 2002; Flegal et al. 2005; McGee et al. 2005; Romero-Corral et al. 2006; Adams et al. 2006; Flegal et al. 2007). These unexpected results are now known as the "obesity paradox".

The U or J-shape relationship between BMI and total (Fig. 21.1) and CV mortality has been described in many other studies (Allison et al. 2002; Flegal et al. 2005; McGee et al. 2005; Adams KF et al. 2006; Flegal et al. 2007). Interestingly, even in subjects who theoretically should be at higher risk for total and CV death, such as those with established coronary artery disease, this U-shape (Fig. 21.2a, b) association has been reported (Romero-Corral et al. 2006). Several theories have been proposed to explain these unexpected results relating overweight and mild obesity to improved survival, and they will be discussed below.

Reverse causality is a term referring to data confounded by a previous medical condition not identified. An example would be a patient who had cancer at the time or before the study resulting in weight loss and consequently relating low BMI to increased mortality. This increased mortality in the low BMI group could then be attributed to similar medical conditions associated with chronic wasting diseases rather than having a low BMI per se. On the other end of the curve, in the overweight/obese population, there is the possibility of bias due to a more aggressive implementation of effective secondary prevention therapies, such as healthy diets, exercise programs, etc. as compared to the groups with normal or low BMI, thus resulting in improved survival.

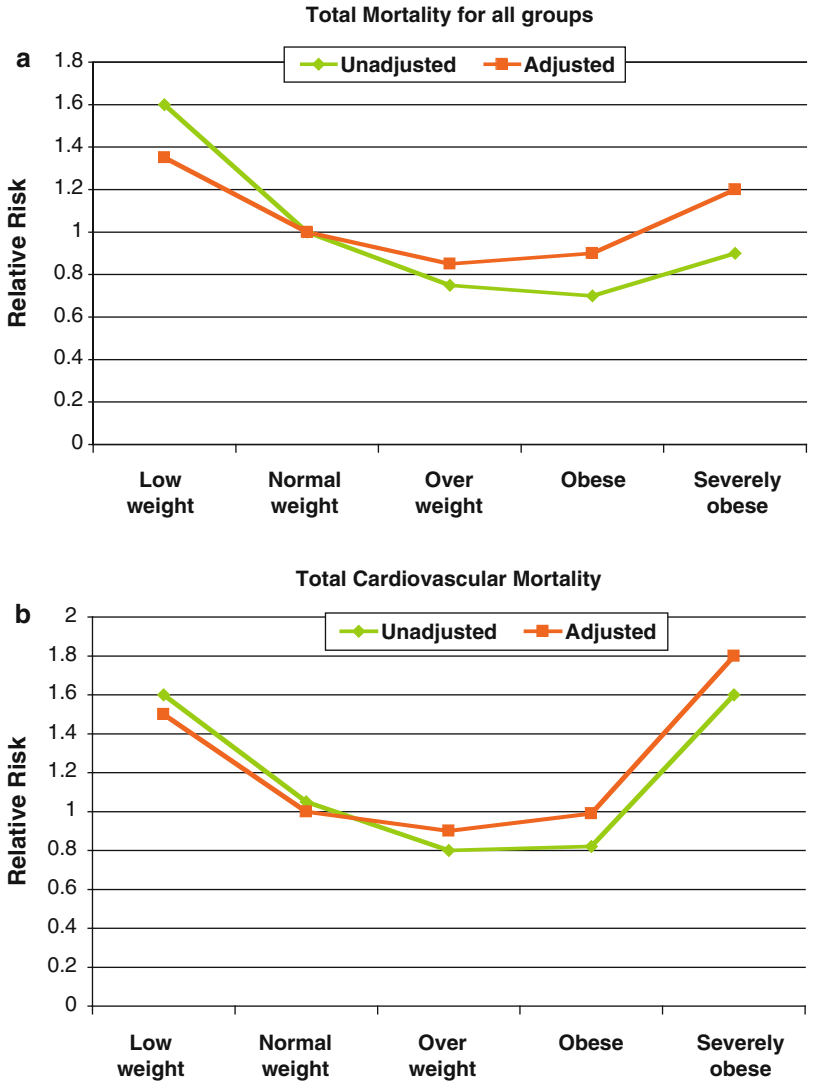

Fig. 21.2 (**a**) Unadjusted and adjusted relative risk for total (**a**) and cardiovascular (**b**) mortality according to body mass index groups in patients with coronary artery disease. (**b**) Unadjusted and adjusted relative risk for total mortality in patients with coronary artery disease by body mass index groups (Adapted from Romero-Corral et al. 2006)

Another potential bias is reclassification. During the follow-up of the study, subjects might shift from one group of BMI to another. For example: an obese man who lost weight due to diet and/or exercise. The opposite might also apply: a normal weight subject who became obese due to poor diet and inactivity. Both scenarios could theoretically result in "shifting" their risk of dying based on their body weight. Regretfully, this "change in body weight" is not accounted for in most of the studies, as only baseline weight/BMI is used to perform analyses.

Over-adjustment of confounders has also been listed as a potential explanation to the obesity paradox. This issue could be exemplified by the following example: if BMI contributes to the development of diabetes, systemic hypertension, dyslipidemia, obstructive sleep apnea, etc., all of which are potential risk factors for CV death, then adjusting for all these confounders could "dilute" or "modify" the effect of BMI on total and CV mortality. An example of this could be the Munster

Heart Study (PROCAM) (Schulte et al. 1999). In this study, the researchers followed 16,288 men and 7,328 women for up to 7 years, and concluded that the increased mortality in the higher BMI group was completely accounted for by other risk factors measured in the study, suggesting that an increased BMI had no relationship with total mortality, but the results could also be potentially due to over-adjustment of the risk models.

Lack of statistical power is extremely common in studies exploring the association between obesity and mortality, as most of the studies have few patients and/or short follow-ups. This may be a conceivable explanation, as very large studies have shown a gradual increase in mortality as BMI increases. An example of this is the prospective studies collaboration. These analyses included ~900,000 patients with 66,552 all-cause deaths and 30,416 vascular deaths with a follow-up of ~13 years (first 5 years were not used in analyses trying to avoid reverse causality). This study did not show a lower all-cause or vascular mortality in the overweight group defined by BMI. In fact, for every 5 points of increment in BMI were associated with a 30% increased risk in all-cause mortality and a 40% increased risk in vascular mortality (Prospective Studies Collaboration 2009).

Another study, conducted by Calle and colleagues, supports the usefulness of BMI in very large samples of over a million people (457,785 men and 588,369 women), with 201,622 deaths that occurred during 14 years of follow-up. This study showed that an elevated BMI, including the overweight range, was associated with higher rate of deaths among both men and women in all age groups (Calle et al. 1999). However, requiring such large numbers for BMI to demonstrate its impact on mortality speaks against its usefulness, and suggests that more reliable anthropometric measures to assess total and CV mortality are needed, especially when trying to individualize risk.

Another possible explanation for the inconsistent results between BMI and outcomes, that has recently gained attention, is that BMI by itself is a poor anthropometric measure to diagnose obesity (Romero-Corral et al. 2008b). When BMI was first introduced in the nineteenth century by Adolphe Quetelet, he described body weight as being proportional to the squared height in adults *with normal body frames*. What seemed to be an accurate equation then may not be valid now as the obesity epidemic rises, as what was considered a normal/standard body frame may no longer apply.

To test the hypothesis that BMI performs poorly as a measure of obesity, mainly due to its inability to differentiate between body fat and lean mass, Romero-Corral and colleagues used data from 13,601 subjects from the Third National Health and Nutrition Examination Survey (NHANES III) in whom body fat was estimated using bioimpedance. The diagnostic performance of BMI was assessed in relationship to the gold standard definition of obesity (excess in body fat), using as cut-offs >/= 25% in men and >/= 35% in women. Table 21.2 shows that BMI >/= 30 kg/m^2 has a high specificity but a poor sensitivity in detecting an excess in body fat and misses more than half of subjects with increased body fat. On the other hand, a BMI >/= 25 kg/m^2 has a good sensitivity but poor specificity, resulting in misclassification of subjects as obese when in fact they may have an increased lean mass.

Interestingly, in subjects with a BMI in the normal to overweight range, where most of the disagreement in results have been generated, BMI has its worst diagnostic performance. Figure 21.3 illustrates that men and women with a BMI of 25 kg/m^2 have a very wide range in the amount of body fat. The variability in body fat is so great that based on body fat subjects could be classified as malnourished or even obese, despite all of them having a "normal BMI". Authors conclude that the poor diagnostic performance of BMI as an anthropometric measure of obesity might be explained by BMI's inability to differentiate between body fat and lean mass, as shown by the similar correlation between BMI and both body fat and lean mass (r = ~0.75 between BMI and body fat and r = ~0.73 between BMI and lean mass).

Based on all of the above, it is clear that although BMI might be useful in large epidemiological studies, it has important limitations, especially at the intermediate range (normal to overweight) and on an individual basis. This becomes highly relevant, if we take into consideration that one third of the US population is overweight and another third has a normal BMI. In fact, the American Heart

Table 21.2 Diagnostic performance of body mass index in detecting excess in body fat* using body mass index cut-off points of >/= 30 kg/m^2 and >/= 25 kg/m^2 by sex (Adapted from Romero-Corral et al. 2008)

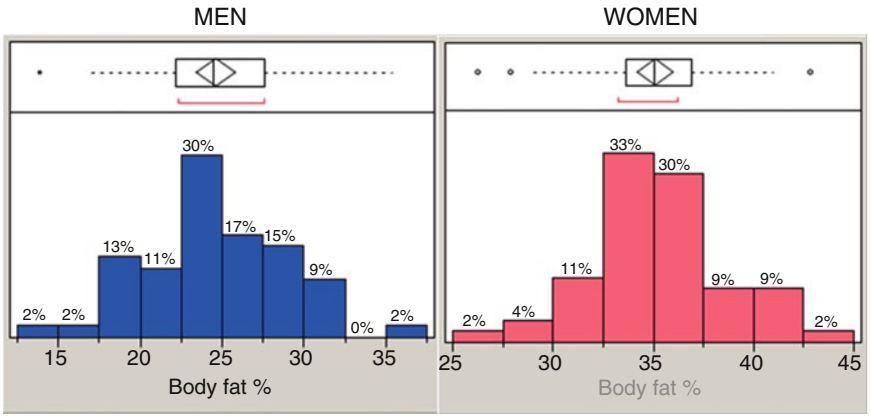

Fig. 21.3 Variability in body fat % among men and women with a BMI of 25 kg/m^2. Variability of body fat for men and women with a BMI of 25 kg/m^2. Percentages above bars show to the percentage of patients with that amount of body fat (Adapted from Romero-Corral et al. 2008)

Association released a Science Advisory statement in June 2009 regarding the conflicting results about mortality in overweight subjects (Lewis et al. 2009). Although they clearly state that there is insufficient evidence to assess if overweight subjects have a lower mortality of not, they are clear that the adverse effects of having an excess in body weight are not limited to mortality. It is well established that overweight subjects are at increased risk for the development of diabetes, dyslipidemia and systemic hypertension, thus blood pressure as well as glucose and lipid profile should be carefully monitored in this group. Moreover, both healthy eating and physical activity are advisable to lower CV risk regardless of bodyweight and should still be encouraged.

21.3.2 Waist Circumference and Waist-to-Hip Ratio and Their Association with Total and Cardiovascular Mortality

Recently, it has been proposed that central measures of obesity might correlate better with the development of adverse CV events and death than BMI. Data of large epidemiologic studies like the one conducted by Pischon and colleagues are now being published more often. This study followed

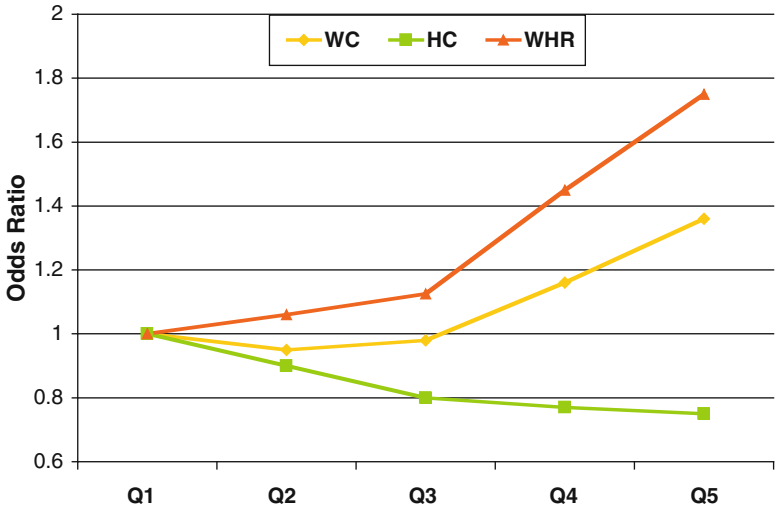

Fig. 21.4 Risk of myocardial infarction associated with increasing waist circumference, hip circumference and waist-to-hip ratio. Association of increasing waist circumference (WC), hip circumference (HC) and waist-to-hip ratio (WHR) with myocardial infarction risk. Odds ratios adjusted for all risk factors identified in INTERHEART (Adapted from Yusuf et al. 2005)

359,387 participants from nine European countries from the European Prospective Investigation into Cancer and Nutrition (EPIC) group for almost 10 years. BMI, WC and WHR were recorded. The study concluded that general (BMI) and abdominal (WC and WHR) adiposity were independently associated with the risk of death (Pischon et al. 2008). As previous studies, the relationship between BMI and risk of death followed a J-shaped curve, whereas once general adiposity was adjusted for, abdominal obesity remained positively associated with the risk of death. Although, this study was not designed to demonstrate which anthropometric measure is a better predictor for mortality, the fact that mortality increased among participants with normal weight but abdominal obesity, demonstrates the need to perform these measurements.

Another study assessing not only the relationship between measures of total and central obesity with acute myocardial infarction, but also how prevalent they are in the population is the INTERHEART study. This is a large case–control study of 27,098 participants with acute myocardial infarction conducted in 52 countries (12,461 cases and 14,637 control) exploring the relationship between BMI, WC, hip circumference, and WHR with myocardial infarction risk. This study confirmed the J-shaped association between BMI with myocardial infarction. Interestingly, WC also showed a J-shape association, but increased hip circumference was associated with lower risk of myocardial infarction. After adjustment for age, sex, region of study and smoking, WHR showed a dose–response relationship with myocardial infarction (Fig. 21.4). More importantly, the population-attributable risks (which speaks of the prevalence of a condition in a population) of myocardial infarction for increased WHR in the top two quintiles was 24.3% as compared with only 7.7% for the top two quintiles of BMI (Yusuf et al. 2005). Authors concluded that WHR ratio increases the population attributable risk resulting from obesity by over three-fold when compared to BMI.

Whether obesity measures that take into account central obesity are better associated with CV risk factors remains controversial, but based on recent data it is clear that they are needed to better estimate the risk for CV events. In a recent meta-analysis, de Koning et al., included 15 prospective studies with >250,000 subjects to assess the effect of WC and WHR on CV risk. For every centimeter increase in WC, the risk for CV events increased by 2%, while it increased by 5% for each 0.01 increment on

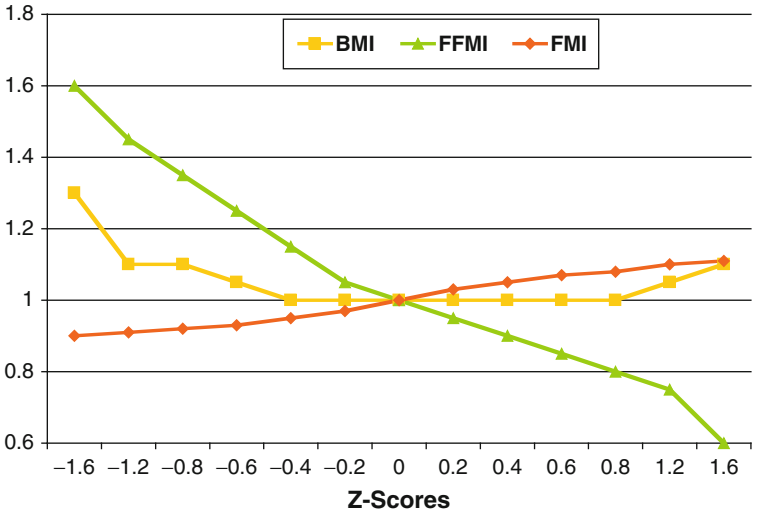

Fig. 21.5 Hazard ratios relative to *Z*-scores of zero for body mass index, body fat and lean mass. BMI shows a J-shaped association with all-cause mortality. Body fat shows (FMI) a positive relationship with all-cause mortality. Lean mass (FFMI) shows a negative relationship with all-cause mortality (Adapted from Allison et al. 2002)

WHR. Notably, besides central obesity measures being useful to predict risk, data suggest that it might also help to identify subjects at risk that could be missed by measuring total obesity alone. Zeller et al. followed for 1 year 2,229 subjects who suffered a myocardial infarction. In this study, even in subjects with a low BMI, increased WC was associated with higher mortality after a year of follow-up, stressing the need to account for measures of central obesity even when having a low or normal BMI (Zeller et al. 2008).

Regretfully, despite WC and WHR proving their value in predicting all-cause and CV mortality, most of the times are not measured in clinical practice. It is imperative to educate not only physicians, but all health personnel, and stress the importance of performing and adequate anthropometry in every patient to help establishing an adequate prognosis for many common medical conditions.

21.3.3 Body Fat and Lean Mass and Their Association with Total and Cardiovascular Mortality

Despite body fat being the gold standard definition of obesity, very little is known regarding its association with total and CV mortality. To our knowledge, there is only one large epidemiologic study conducted by Allison and colleagues addressing this question. This longitudinal prospective cohort study evaluated whether all-cause mortality is dependent on body fat (estimated by skinfold thickness) or lean mass rather than BMI or weight alone. A total of 10,169 male subjects aged 25–75 years old were followed for a mean of 12 years. After adjusting for age, smoking, race and educational level, BMI had a J–shaped association with mortality. Nevertheless, body fat (measured as fat mass index) showed a positive and significant relationship with all-cause mortality (HR = 1.03, $p = 0.02$) whereas lean mass (measured as fat free mass index) showed a significant negative linear relationship with all-cause mortality (HR = 0.93, $p < 0.0001$) (Fig. 21.5) (Allison et al. 2002). Based on these results, we can speculate that that the J-shape relationship between

BMI and mortality may be the result of the inverse and independent effects of body fat and lean mass on mortality.

Allison DB and colleagues study, also supports the notion that at least part of BMI's inability to accurately predict mortality is be due to its inability to differentiate between body fat and lean mass. It also highlights that studies to assess the relationship between mortality and body fat and its distribution measured by other more accurate techniques, such as dual energy X-ray absorptiometry are needed. In addition, the possible effect of visceral fat measured by MRI and or CT on predicting adverse events are also largely unknown, and research is still needed to answer these important questions.

The relationship between obesity as an independent risk factor for CV disease is still not absolutely clear. The quest for an anthropometric measure that accurately predicts total and CV mortality independently of other CV risk factors is far from over and requires extensive research. More data should be analyzed to answer this difficult and controversial topic.

What seems to be intuitively beneficial is leading a healthy lifestyle where diet and exercise play a key role. The impact of different diets and exercises, and the more extreme, pharmacological and surgical therapies for weight control and their impact on morbidity and overall mortality are being studied worldwide.

Summary Points

- There is a clear association between obesity and total and CV mortality.
- There is controversy regarding which anthropometric measure of obesity better predict total and CV mortality.
- BMI association with total and CV mortality is conflicting as it has shown that overweight subjects might have better survival and fewer CV events.
- Anthropometric measures of obesity that take into account central obesity, such as WC and especially WHR appear to better predict total and CV mortality than BMI alone.
- Although body fat is the gold standard definition of obesity, little is known regarding its impact on mortality. However, body fat and lean mass appear to play a key role in predicting mortality.

Key Points

Anthropometric measures of obesity in predicting total and cardiovascular mortality.

1. BMI association with total and CV mortality is controversial, as it follows a U-shape association with lowest mortality in overweight subjects.
2. Measures of central obesity, such as WC and WHR appear to better predict total and CV mortality but this remains to be proven.
3. Despite body fat being the gold standard to define obesity, little is known regarding its relationship with mortality. However, data suggests that body fat increases mortality while lean mass is related to improved survival.

Chapter 22
Body Fat Measurement by Air Displacement Plethysmography: Theory, Practice, Procedures, and Applications

Mauro E. Valencia and Rosa C. Villegas-Valle

Abstract The importance of measuring body composition has increased because of the need to evaluate changes in nutritional status that can affect body reserves differentially. These changes can be detected only by using valid body composition measurement techniques. Air displacement plethysmography (ADP) has proved to be a valid method for determining body composition in adults and children. ADP measures body volume using a subtraction technique in which body volume equals reduction in the volume of a chamber resulting from the introduction of the individual into the chamber. There are two versions of the plethysmograph, one for adults and children, the BOD POD, and another version for infants, the PEA POD. Both versions correct the raw body volume measurement for the isothermal effect of skin on air and thoracic gas volume. The body volume is then converted to mass and density relationships for body fat and fat-free masses, and body fat percentage is calculated. In both formats, ADP has good reliability in terms of body volume and fat percentage and has been validated against three-compartment (3C) and four-compartment (4C) models. It has also been used to develop body composition prediction equations for methods like bioimpedance analysis (BIA) and anthropometry in a wide range of populations. Among other applications, ADP has been applied successfully to determine the relationship between body size and adiposity, to evaluate intervention programs based on diet or physical activity, and in athletes, to evaluate body composition changes related to training in different sports.

Abbreviations

2C, 3C, 4C	Two-, three-, and four-compartment models
% fat	Percentage of fat mass
ADP	Air displacement plethysmography
BIA	Bioimpedance analysis
BMI	Body mass index
CV	Coefficient of variation
D_2O	Deuterium oxide
DXA	Dual X-ray absorptiometry
FFM	Fat-free mass

22.1 Introduction

The importance of measuring body composition has increased because of the need to evaluate changes in nutritional status that can affect body reserves differentially. Individuals can gain or lose body fat, fat-free mass (FFM), bone mineral mass, or cellular mass components as a result of disease, overeating, sports, or undernutrition (anorexia nervosa), or as a result of nutritional intervention programs. These changes can be detected only by using valid body composition measurement techniques. In addition, the worldwide epidemic of obesity and its association with chronic disease has also contributed to the need to study body composition and the distribution of body components. The definition of obesity based on body size has been challenged in the context of different populations because of the different relationships of percent (%) body fat at the same body mass index (BMI) levels (Gallagher et al. 2000). Therefore, a definition of obesity based on body composition terms could help to clarify this issue.

22.2 Measurement of the Density of the Body

Air displacement plethysmography (ADP) is a valid method for determining body composition compared with hydrodensitometry and the four-compartment (4C) model in adults (Demerath et al. 2002; Fields et al. 2002), in elderly adults (Alemán-Mateo et al. 2007), and in babies (Ellis et al. 2007). Body density measurement by hydrostatic weighing (HW or hydrodensitometry) originally outlined by Behnke et al. (1942) uses Archimedes' principle to determine body volume by measuring an individual's weight in water compared with that in air (Fig. 22.1). This procedure requires the person to be submerged completely under water, exhaling maximally to measure the residual lung volume (V_r). This V_r has been commonly measured using the O_2-dilution method of Wilmore (1969), with nitrogen analyzers.

In spite of having been a reference standard for many years, HW is time consuming, laborious, and difficult to perform in the elderly, disabled, obese, and in infants. To overcome these limitations, alternative methods to HW that measure whole-body volume have been developed, including ADP, acoustic plethysmography, helium displacement, photogrammetry, and the more recent 3-dimensional photonic scanning and sulfur hexafluoride dilution (Fields et al. 2002). Some of these methods have unsatisfactory reliability and validity because of technical and practical problems (McCrory et al. 1998). This chapter focuses on ADP, which measures body volume by a subtraction technique in which body volume is equal to the reduction in chamber volume caused by the introduction of the individual to be measured. The main features of the method are described in Table 22.1.

The earliest attempts to use ADP yielded results that were not very useful for measurement of body composition. The volume measurement errors were high, and body fat changes ranged from 20% to 32%, mainly because of difficulties with temperature, pressure, and relative humidity in the enclosed chamber (Gnaedinger et al. 1963). Later, Gundlach and Visscher (1986), in an effort to

Fig. 22.1 Measurement of hydrostatic weight (courtesy of INCAP, Guatemala). This figure shows a person being introduced in a water tank to calculate body density by the hydrostatic weight method, while the technician prepares for the measurement of residual lung volume (courtesy of INCAP, Guatemala)

Table 22.1 Important features of air displacement plethysmography (ADP) by the BOD POD

1. Solid physical principles are the basis of this method
2. It has been validated against its predecessor, hydrodensitometry, for determining body volume and body density, including the corrections for lung volume
3. There have been many reliability studies both in the calibration procedure with phantoms and humans, and repeated measurements taken with respect to volume, density, and percent body fat.
4. The validation has been done against other reference methods like isotopic dilution, DXA, and the 4C Model
5. It is a potential reference for validating field methods like BIA and anthropometry through the development of age–sex–ethnicity-specific algorithms for the estimation of fat mass and fat-free mass.
6. It is useful in a wide range of populations: from infants to the elderly, malnourished and obese individuals, athletes, and patients under different conditions, and/or diseases.
7. With proper training, it is fast and easy to perform

This table lists some important characteristics of air displacement plethysmography (ADP) by the BOD POD, referring to its general uses and advantages
Abbreviations: *DXA* dual X-ray absorptiometry; *4C* four-compartment model; *BIA* bioimpedance analysis

maintain isothermal and adiabatic conditions, measured ADP and compared it to HW in a group of 88 people. Although they experienced practical difficulties, the prediction of % body fat from ADP showed an $R^2 = 0.93$ and a standard error of the estimate (SEE) = 6.7%.

A new air displacement plethysmograph, the BOD POD (Body Composition System; Life Measurement Inc., Concord, California now a part of COSMED srl.Italy), has been recently developed and appears to overcome previous problems. There are two versions, the BOD POD for adults and children and the PEA POD for infants. For the BOD POD, a new pediatric option accesory for children as small as 12kg and between 2 and 6 years of age is now available (COSMED srl, 2011).

22.3 Description of the BOD POD and Principles of Operation

The BOD POD is based on physical principles to measure whole-body volume (V_b) of an individual. It uses the relationship between pressure and volume (the gas laws), to calculate the V_b, which, along with the measurement of body mass (M_b) permits calculation of body density (D_b) and subsequently the estimation of % body fat and FFM (Dempster and Aitkens 1995). Table 22.2 explains the main gas laws involved in the performance of the measurement.

The BOD POD is made out of fiberglass. There are two chambers, separated by a seat where the individual sits and the volume is measured. A door with an acrylic window is the entrance for the individual into the chamber and closes tightly by a series of electromagnets that reduce the sensation of being in a closed environment. Instruments, circuits, valves, air circulation system, pressure transducers, and other electronic devices are located in the rear chamber. Figure 22.2 shows the main system components of the BOD POD.

Table 22.2 Key facts in air displacement plethysmography (ADP): the gas laws

Boyle's Law states that the pressure of a fixed amount of gas maintained at constant temperature (isothermal condition) is inversely proportional to the volume of the gas (Chang 2000). Thus, a quantity of air compressed under isothermal conditions will decrease its volume in proportion to the increasing pressure, or

$$P_1 / P_2 = V_2 / V_1$$

where P_1 and V_1 represent one paired condition of pressure and volume and P_2 and V_2 represent a second condition. In contrast to isothermal conditions, under adiabatic conditions, air is more compressible. Poisson's Law describes the relationship between pressure and volume under adiabatic conditions as

$$(P_1 / P_2 = V_2 / V_1)^{\gamma}$$

where γ is the ratio of the specific heat of the gas at constant pressure to that at constant volume (Sly et al 1990). The value of γ is approximately 1.4 for air and 1.3 for CO_2 (Daniels and Alberty 1967).

The system maintains the equivalency of gas composition in the two chambers and constancy of the γ in the pressure–volume relationship.

This table explains the basic concepts of the gas laws involved in the accurate measurement of body volume by air displacement plethysmography (ADP)

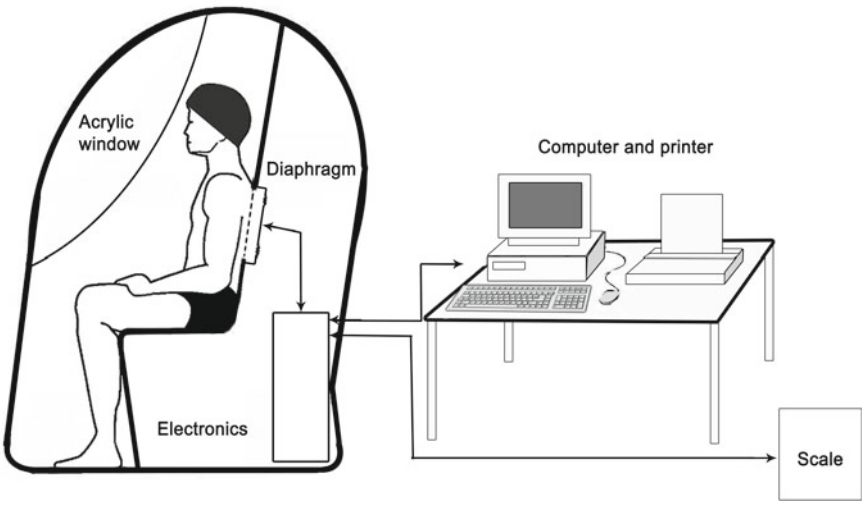

Fig. 22.2 Main system components of the BOD POD (Life Measurement Inc., Concord, CA). The figure shows the general system components of the BOD POD (Life Measurement Inc., Concord, CA), including the fiberglass chambers and electronic components. It also shows the position of the individual inside the equipment for the measurement of body density (adapted from Dempster and Aitkens 1995 under permission of Wolters Klower Health, Lippincot Williams & Wilkins, Baltimore, MD, USA)

The body volume is measured through an air displacement method. A moveable diaphragm mounted on a common wall separates the external and internal chambers. This diaphragm is controlled by a computer integrated into the system and oscillates to produce complementary volume perturbations (approximately 350 mL) in the two chambers that are equal in magnitude but opposite in sign. These volume perturbations lead to small complementary pressure fluctuations in the two chambers of approximately ±1 cm H_2O.

The results from the pressure fluctuations allow calculation of the chamber's air volume. After this, the individual enters the chamber and the same procedure is repeated. The volume of the chamber is reduced and the raw body volume (V_{br}) is calculated by difference:

$$V_{br} = (\text{Empty chamber volume}) - (\text{Chamber volume with individual inside.})$$

22.4 Practical Methods and Techniques

22.4.1 Calibration, Corrections, and Technical Aspects of the Measurement

Calibration of the BOD POD is done by a two-point system measuring the pressure of the ratio of the empty test chamber and the chamber with a 50-L cylinder. After the calibration procedure, the unit is ready for measuring people.

The difference in the behavior of gases under isothermal and adiabatic conditions is important for the accurate measurement of volumes by plethysmography. When an individual enters the chamber, air close to the skin and clothing will not maintain adiabatic conditions, but air in the lungs is maintained at body temperature (isothermal conditions). Air under these circumstances is more compressible than that under adiabatic conditions, and hair, clothing, and skin can show an apparent negative volume while measured in the chamber. To eliminate the effects of clothing and hair, the person must wear minimal and tight clothing (bathing suit), and the hair must be compressed with a swimming cap. Finally, to account for an apparent negative volume caused by the isothermal effects of the skin, a surface area artifact (SAA) is computed automatically and applied for this correction (Dempster and Aitkens 1995).

As in HW, residual gas volume in the lungs must be accounted for. In ADP, thoracic gas volume (V_{TG}) (volume of air in the lungs and air trapped in the thorax) is measured as a part of the procedure. Because the individual is breathing normally, the variable of interest is the average V_{TG}. This technique is similar to the plethysmographic measurement of V_{TG} used in pulmonary function testing (Ruppel 1995).

As Dempster and Aitkens (1995) described, the measurement of V_{TG} in the BOD POD includes the use of a single-use disposable filter and tubing attached to a port in the front chamber that passes to a breathing circuit housed in the rear chamber. With the door open, the person, with a nose clip attached, connects to the system and proceeds with quiet tidal breathing. The door is then closed. Pressure transducers in the two chambers monitor the person's body volume change due to breathing, producing a real-time record of tidal breathing. After 2–3 cycles, the airway is occluded at approximately average lung volume (mid-exhalation), at which point the individual puffs against the closed airway at about 1 Hz, producing pressure changes in the lungs that are measured by a transducer in the breathing circuit. During this occlusion, airflow is essentially zero, so there is little difference between pressure in the alveoli and the airway. Time-correlated analysis of airway pressure and tidal breathing record yields V_{TG} at the point in the breathing cycle when the airway is occluded. The V_{TG} at occlusion is

$$V_{TG} = \left(m / 1.4\right) - \text{dead space of the breathing apparatus}$$

where m is a slope and the constant 1.4 may be interpreted by considering the air in the thorax (mainly lungs) as isothermal while air in the chamber is adiabatic. As such, V_{TG} would be overestimated by 40% if m were not divided by 1.4.

A complete test involves measurement of the uncorrected body volume, computation of the surface area artifact (SAA), and measurement of V_{TG}. The latter two items serve to correct the original measurement of body volume (V_{br}) as follows:

$$V_b(L) = V_{br}(L) - \mathrm{SSA}(L) + 40\% V_{TG}(L)$$

where V_b (L) is the corrected body volume.

It is important to mention that the equipment can also predict V_{TG} with the entered data for the individual based on gender, age and height (Crapo et al. 1982; Fields et al. 2004).

22.4.2 Measurement Procedure

The measurement of V_b by the BOD POD begins with the calibration of the equipment with a "phantom" of previously known volume. After the calibration is completed, the person is weighed wearing tight clothing and swimming cap. Then the individual sits inside the chamber and remains still, and the measurement of V_b is performed by duplicate. The V_{TG} is either measured using a plastic tube attached inside the instrument and a nose clip, or predicted by the equipment. The total time of the measurement is approximately 15 min. Figure 22.3 shows an explanatory sequence for the measurement procedure in the BOD POD.

22.5 Reliability

Reliability is a general term denoting repeatability or consistency between ≥2 measurements. The reliability of the BOD POD in measuring the body volume of inanimate objects is reported to be very good. Twenty consecutive measurements of a 50.039-L aluminum cylinder resulted in a mean ± SD, (standard deviation) volume of 50.027 ± 0.00127 L and a corresponding coefficient of variation (CV) of 0.025% (Dempster and Aitkens 1995).

Reliability in terms of % of body fat has also been explored. Fields et al. (2002) reported mean within-subject CVs for % body fat ranging from 1.7% to 4.5% within a day and from 2% to 2.3% between days. According to their review, these CVs are within the range of those measured previously by HW and dual X-ray absorptiometry (DXA).

Reliability of body volume measurements compared to hydrostatic weighing should be compared based on the combined measurements of body volume and lung volumes rather than on estimating the lung volume. Dewit et al. (2000) and Wells et al. (2000) reported that the precision of V_b in children aged 7–14 years was 0.07 and 0.08 L in the two studies, respectively, which was similar to the precision in adults in the same studies (0.07 and 0.11 L, respectively). In our laboratory, we tested the reproducibility of the ADP system using duplicate measurements in 91 adults. The duplicate measurements were both performed during the same session, with duplicated mean body density measurements of 1.0292 ± 0.019 and 1.0296 ± 0.019 and a mean difference in body density of 0.00007. In terms of % body fat, the technical error of measurement was 0.066% fat units, assessed as $\left(\sum d^2 / 2n\right)^{1/2}$, where d is the difference between repeated measurements and n is

Fig. 22.3 Sequence for the measurement of body volume using ADP (courtesy of CIAD, Mexico). (**a**) The instrument is calibrated before a series of measurements using a known volume or "phantom." (**b**) The individual is weighed in the calibrated scale. Note that the person is wearing tight clothing and a swimming cap, with no jewelry. (**c**) After a second calibration with the phantom, the individual enters the instrument and sits still. The measurement starts after closing the chamber and is performed twice. (**d**) To measure the lung volume, the person is instructed to breathe normally through the tube attached inside the instrument. The measurement is performed twice after the chamber is closed. The instrument will then calculate the final results

the number of paired repeated measurements (Macias et al. 2007). In another study (Ramírez et al. 2009) involving 60 children 6–14 years of age with a 4C model using the BOD POD, we found that the mean V_b within individuals was 0.0212 L and 0.23% fat (data not shown in that paper).

22.6 Validation Studies and Body Composition Prediction Equations

Just as HW once served as a reference method, ADP with the BOD POD is becoming a single-body composition reference method, especially thanks to the validation studies that have compared ADP to 3C and 4C models (Durenberg-Yap et al. 2001; Alemán-Mateo et al. 2007). In these multicompartment models, total body water was determined by deuterium oxide (D_2O) dilution and bone mineral content by DXA. Among these studies is a wide variation of age groups in both male and female individuals from children to the elderly, in ethnicity (Caucasians from North America and Europe, Latinos from Mexico, and Asians from Japan, Malaysia, and India), and in nutritional status, including individuals with overweight and obesity.

In obese individuals, ADP by the BOD POD has proved to be valid for measuring D_b compared with HW. Ginde et al. (2005) measured a wide range of individuals (n = 123; 42.4–190.2 kg) of which 70 were obese (BMI: 30.4–38.8) and 10 were very obese (BMI: 40.6–58.4). ADP was found to be accurate for measuring % body fat by D_b, with no significant bias attributable to the method up to a BMI of 58.4.

The BOD POD has also been used based on its own merits in multicompartment models to develop body composition prediction equations, using either bioimpedance analysis (BIA) (Macias et al. 2007) or anthropometry (Huerta et al. 2007). These equations usually arise from cross-validated studies in which the main sample is randomly split into two groups; one for developing the algorithm and the other for validating it.

Example. In our laboratory, we developed a simple BIA equation:

$$\mathrm{FFM}\left(\mathrm{kg}\right) = 0.7374 * (\mathrm{Ht}^2 / R) + 0.1763 * (\mathrm{BW}) - 0.1773 * (\mathrm{Age}) + 0.1198 * (\mathrm{Xc}) - 2.4658$$

based on the BOD POD by a 2C model. This study included 155 men and women from northern Mexico, 20–50 years of age, from low, middle, and upper income levels. In the equation, Ht^2 is height in centimeters, R is resistance in ohms, BW is body weight in kilograms, age is in years, and Xc is reactance in ohms.

The mean values of FFM predicted by this new BIA equation and measured by ADP in the validation sample were 48.57 ± 10.9 kg and 48.43 ± 11.3 kg, respectively. The limits of agreement, defined as mean ± 2 SD, were from -6.56 to + 4.82 kg of FFM. The new BIA equation based on a 2C model method was accurate, precise, and free of bias. The prediction-validated equation can be used to assess body composition and nutritional status in populations having anthropometric and physical characteristics similar to this sample.

22.7 Validity of Equations Based on Anthropometry to Estimate Body Fat in Older Adults

With the same ADP approach using the BOD POD, we also developed a prediction equation to estimate body fat mass from anthropometry in the healthy elderly using a 4C model as the criterion method. This study included 202 participants, 60 years of age and over. The measurements of total

body water, bone mineral content, and body density were included in the 4C model equation. The best model included body mass, sex, and the calf and triceps skinfold thicknesses, with an $R^2 = 0.85$ and a SEE of 3.2. The new equation was accurate and precise as well as free of significant bias in men and women together or separately. This equation can be a good option to estimate fat mass in elderly men and women with similar physical characteristics and ethnicity to participants in this study for use in clinical and epidemiological applications in this age group (Huerta et al. 2007).

$$\text{Fat mass (kg)} = (0.165 \times \text{Calf SFT}) + (0.355 \times \text{Biceps SFT}) + (0.521 \times \text{Body weight}) - (6.054 \times \text{Sex}) - 13.171$$

where SFT is skinfold thickness and for sex, female = 0 and male = 1.0.

22.8 New Developments: The Use of Plethysmography in Infants

Recently, a new ADP system has been developed for use in infants because of the need for body composition methods that help researchers clarify the link between infant development and childhood obesity. This system is called PEA POD (Life Measurement Inc., Concord, California, USA). The main features of this method are presented in Table 22.3.

22.9 Principles of Operation and Design

As described by Urlando et al. (2003), the PEA POD operation principles are based on Boyle's Law and Poisson's Law (described in Table 22.2), similar to the BOD POD system. Although the main components of the system are the same, the physical design of the apparatus differs.

The main system components of the PEA POD are shown in Fig. 22.4. All the system components are all placed in a moveable cart. These components are either located in the bottom section (reference chamber, calibration volume, electronic components, central process unit, and printer) or on the top of the cart (test chamber, scale, and monitor).

The PEA POD has two chambers (test and reference), both constructed with the same material, design, and volume (37 L). Both chambers are connected by a manifold that houses the volume-perturbing diaphragm, which is placed between the chambers and thus prevents their direct contact.

Table 22.3 Important features of air displacement plethysmography (ADP) for infants (PEA POD)

1. Solid physical principles are the basis of this method
2. It has been validated against tissue phantoms and against 4C models in vivo.
3. The lung volume is not measured; it is estimated based on previous work (Stick 1996; Stocks et al. 1996; National Center for Health Statistics 2000)
4. There are very few studies both in the calibration procedure with phantoms and humans with repeated measurements with respect to volume, density, and percent body fat.
5. Useful in a wide range of infant behaviors: awake, crying, asleep, etc.
6. Very fast and easy to perform with proper training

This table lists some important characteristics of air displacement plethysmography (ADP) by the PEA POD, referring to its general uses and advantages

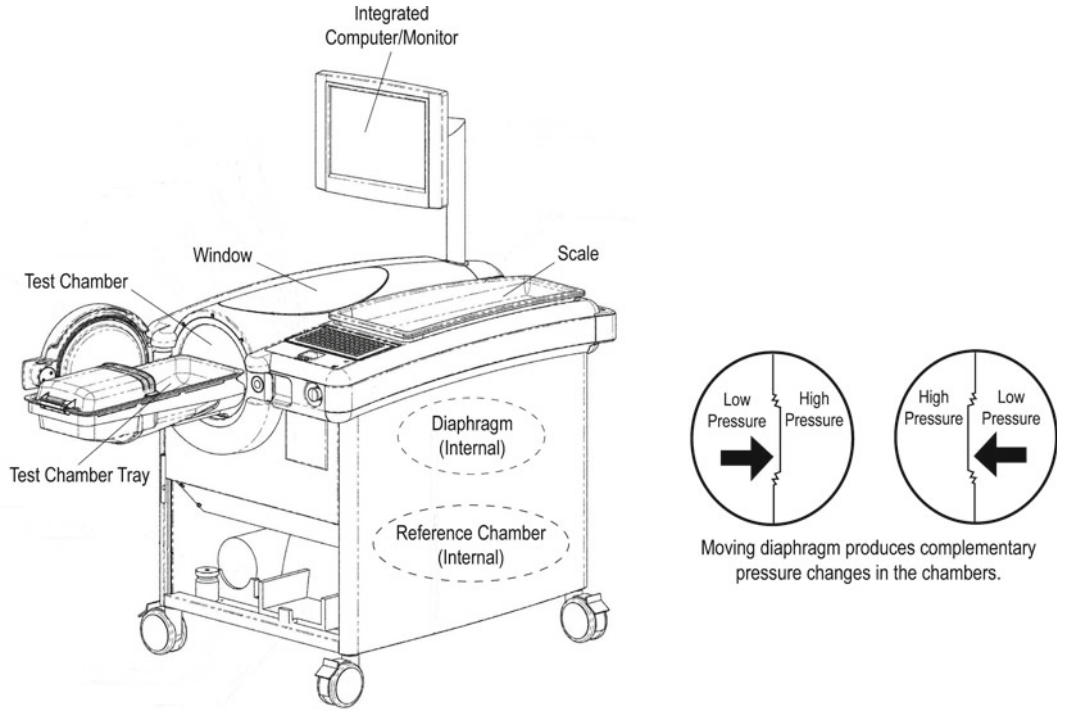

Fig. 22.4 General design and operation of the PEA POD Body Composition System (Used under license of Life Measurement Inc., Concord, CA, USA). The figure shows the general mechanical and electronic system components of the PEA POD (Life Measurement Inc., Concord, CA), mounted in a moveable cart, as well as an schematic representation of the pressure changes that occur in the chambers as the equipment performs the calibration or measurement

The test chamber consists of an acrylic cylinder containing a sliding plastic tray where the infant is placed. A pneumatic valve (calibration valve) connects the test chamber with the calibration volume container. Electromagnets close the aluminum door of the chamber during the calibration and test. A special characteristic of the test chamber is that it has a heating system to maintain a constant temperature between 31°C and 37°C.

As with the BOD POD, when the system is operating, the diaphragm creates equal volume changes in both chambers, but opposite in sign. These perturbations change the pressure in the chambers less than ±0.5 cm H_2O and make it possible to maintain a linear relationship between pressure and volume.

22.10 Practical Methods and Techniques

22.10.1 Corrections and Technical Aspects of the Measurement

Every measurement is corrected automatically for the isothermal behavior of air near the infant and inside the lungs. As in the BOD POD, the correction for the air near the infant is the SAA and is the result of the difference between the volume measured by the PEA POD and the actual volume of an object or person.

For the air inside the lungs, the thoracic gas volume (V_{TG}) of infants is predicted based on previous work (Stick 1996; Stocks et al. 1996; National Center for Health Statistics, 2000). As with the BOD POD, 40% of the V_{TG} is added to the infant's body volume measured by the PEA POD, accounting for the higher compressibility of air under isothermal conditions. Similar to what happens with larger individuals in the BOD POD, without this correction, the lung volume would be overestimated by 40%, which would therefore underestimate the person's volume. Each correction represents approximately 1.5% of the final volume of the individual (V_b).

The V_b is then calculated as follows:

$$V_b(L) = V_{br}(L) - \mathrm{SSA}(L) + 40\% V_{TG}(L)$$

where V_{br} corresponds to the raw volume directly measured by the apparatus.

In ADP testing, hair and clothes can cause a significant difference in the final fat percentage results. In the PEA POD, baby oil has been used to flatten the hair of infants closer to their heads, and the measurement has been performed without clothes (Ma et al. 2004; Ellis et al. 2007).

22.10.2 Measurement Procedure

The PEA POD accommodates infants ranging in size from 2.2 lbs (1 kg) to 17.6 lbs (8 kg) (Life Measurement Inc. 2009). Figure 22.5 summarizes the measurement sequence of body volume by ADP in the PEA POD. The first step of the actual measurement is the weighing of the infant to the nearest 0.1 g. At the same time, the volume of the chambers is calibrated automatically. This two-point calibration is made while the calibration valve is opened and closed, and the pressure changes are registered. The calibration lasts 50 s, although some have reported up to 2 min (Ma et al. 2004).

After the calibration, the test chamber door opens, the infant is placed in the sliding tray, which is pushed into the chamber, and the door is closed. When the measurement begins, air is exchanged between the chamber and the environment, and the pressure changes are collected. After 2 min, the door opens and the test is completed. This procedure is performed twice. The mean of the two measurements is used to calculate % body fat if the two volume measurements are within 5 mL of each other, or 0.25% of the mean of the two measurements, whichever is larger. If this requirement is not met, a third measurement is taken.

It has been observed that the behavioral state of the infant (quiet, alert, awake and active, crying, etc.) does not affect the fat % estimate (Ma et al. 2004).

22.11 Accuracy and Precision

Regarding the measurement of weight, it has been reported that the mean values of repeated measurements differ by ≤0.1 g to the actual mass values (Urlando et al. 2003), with a precision of 0.12% CV (Sainz and Urlando 2003). Regarding the precision of the volume measurement, reported mean SDs and CVs have varied from 1.7 to 2.3 mL and 0.03–0.08%, respectively, for several known volume levels (Urlando et al. 2003). A study performed in tissue phantoms found that in the repeated measurement of fat %, the SDs ranged from 0.2% to 1.7% for several fat percentages (Sainz and Urlando 2003), and in humans the mean within-subject SD and CV were 0.7% body fat and 7.9%, respectively (Ellis et al. 2007).

Fig. 22.5 Sequence for the measurement of body volume in infants using ADP (used under license of LMI Inc., Concord, California). (**a**) The infant is weighed, and at the same time, the volume of the chambers is calibrated automatically. (**b**) The test chamber door opens; the infant is placed in the sliding tray, and pushed into the chamber. (**c**) The measurement begins when the door is closed. After 2 min, the door opens and the test is completed. This procedure is performed twice. (**d**) The acrylic window allows the infant to be observed at all times. The behavioral state of the infant (quiet, alert, awake and active, crying, etc.) does not affect the fat % estimate (Ma et al. 2004)

The accuracy of the fat % results from ADP has been compared with several other body composition methods, in frozen animal tissue and in humans. The comparison of the ADP with chemical analysis of bovine tissue phantoms found that both methods gave virtually the same result for fat %, with a mean CV of 3.21% and 3.50%, respectively, in a range of fat percentages (Sainz and Urlando 2003). Another study performed in humans compared the PEA POD with D_2O dilution to calculate % fat. The mean difference and SD between the two methods, –0.07 ± 3.30% body fat, was not significant, and the differences were not related to body mass (Ma et al. 2004). Moreover, the comparison of infant ADP with a 4C model showed that the PEA POD estimates for % body fat were not significantly different from the values obtained with the 4C reference model (Ellis et al. 2007).

22.12 Reliability

The reliability of the PEA POD has also been evaluated. The mean difference in % body fat between days (–0.5 ± 1.21) and within days (0.16 ± 1.44) was not significant (Ma et al. 2004).

22.13 Future of the Method

Only a few studies have used the PEA POD to measure body composition in infants; however, it is in good agreement with the 4C model. Because the ADP has been used extensively in other populations and the PEA POD presents good accuracy, precision, and reliability, more studies could be useful to confirm that the infant ADP is not only easy to perform but also reliable and convenient in this population group.

22.14 Calculation of Body Density and % Body Fat by ADP

Using the corrected volume measured by the apparatus (V_b), the whole-body density (D_b), either in the BOD POD or PEA POD, is calculated using the following formula (Urlando et al. 2003):

$$D_b = M_b / V_b$$

where M_b is the body mass.

Then, the V_b is converted into:

$$M_b / D_b = M_f / D_f + M_{ffm} / D_{ffm}$$

where M_f is the fat mass, D_f is the density of the fat mass, M_{ffm} is the fat-free mass, and D_{ffm} is the density of fat-free mass. In adults, D_{fm} is mostly constant (approximately 1.100 g/mL) (Sopher et al. 2005). Because D_{fm} changes during growth, the PEA POD uses specific values for age and gender (Butte et al. 2000), which are shown in Table 22.4.

The fat percentage is then calculated as follows:

$$\%\text{fat} = (M_f / M_b)(100)$$

22.15 Application of ADP to Other Areas of Health and Disease

The worldwide obesity epidemic has brought about the necessity for looking at the nature of the disease beyond body size (BMI), which is most commonly used for the definition and classification of obesity. Different populations can show important differences in body fat content at the same body size, a phenomenon that can be related to ethnicity, environment, or both.

Intervention programs based on diet and/or physical activity for tackling overweight and obesity is probably one of the most practical applications of ADP. By contrast, malnutrition recovery in conditions like anorexia nervosa or other types of malnutrition can use this method to monitor changes in time.

Table 22.4 Fat-free mass (FFM) density according to age ($n = 76$) (adapted from Butte et al. 2000) under permission of WOHers Kluwer Health, Lippincot Williams & Wilkins, Baltimore, MD, USA).

Age (mo)	FFM density (g/mL)
Boys	
0.5	1.054 ± 0.006
3	1.061 ± 0.005
6	1.062 ± 0.004
9	1.066 ± 0.004
12	1.068 ± 0.005
18	1.072 ± 0.004
24	1.077 ± 0.005
Girls	
0.5	1.053 ± 0.005
3	1.060 ± 0.006
6	1.062 ± 0.006
9	1.066 ± 0.006
12	1.070 ± 0.005
18	1.072 ± 0.005
24	1.073 ± 0.005

Values are mean ± SD

Table 22.3 shows the densities of fat-free mass (FFM) according to age, and separated by sex ($n = 76$). Note that the density of FFM increases with age (adapted from Butte et al. 2000). Values shown are means ± standard deviation.

It is not easy to study body composition in infancy with a scientifically solid methodology. Alternatives like isotopic dilution by D_2O or oxygen-18 have to be analyzed by isotope ratio mass spectrometry (IRMS), which is not readily available to many hospital facilities as ADP could be. There are practically no studies of D_2O dilution in infants using Fourier transform infrared spectroscopy (FTIR). Also, the application of BIA and anthropometry estimation methods has its own technical difficulties and insufficiently validated algorithms for the calculation of FFM and fat mass components. The PEA POD can be a simple noninvasive and rapid method for evaluating body composition changes in time as indicators of nutritional status in infants that either by primary or secondary cause can be malnourished or require intervention for recovery. ADP in infants has been more recently used to evaluate the accuracy of some fetal parameters calculated from ultrasound (2D and 3D) for prediction of body fat percentage in newborns. The PEA POD is well tolerated by the infant. They do not have to be asleep, and there is no problem if they are crying during the procedure. Results are immediately available and the procedure can be repeated as needed. The PEA POD has shown good agreement with the 4C model.

There is a lot of interest in using ADP to evaluate changes in body composition in relation to the effect of training in different sports. It has also been used to measure the effect of several types of exercise on body fat loss, either total or regional, and to measure the effect of different supplements during training. In addition, ADP is useful in determining if the methods commonly used to measure body composition in athletes are accurate enough to assess changes over time due to training.

ADP has also been applied in the evaluation of body composition in patients suffering from different diseases. For example, it has been used to validate other methods of measuring body fat in pediatric cancer patients (White et al. 2008) and to evaluate body composition in patients with Huntington disease (Gaba et al. 2005).

Summary Points

- Valid body composition measurements help evaluate changes in body fat, fat-free mass, bone mineral mass, or cellular mass as a result of changes in nutritional status, exercise, or disease.
- Air displacement plethysmography (ADP) measures body volume by a subtraction technique in which body volume is equal to the reduction in the volume of a chamber caused by the introduction of the individual.
- Derivation of body volume, along with measurement of body mass, permits calculation of body density and subsequently the estimation of percent fat and fat-free mass.
- The final volume measured by the equipment is corrected for the effect of air near the skin and for the thoracic lung volume (air contained in the lungs).
- Two types of apparatus (plethysmographs) are available to date: the BOD POD for children and adults and the PEA POD for infants up to 17.6 lb (8 kg).
- The measurement of humans in the BOD POD involves the calibration of the apparatus with a "phantom" of known volume, weighing of the individual, duplicate measurement of body volume, and measurement (or prediction) of lung volume. The total time of the measurement is approximately 15 min.
- Measurement in the PEA POD involves the simultaneous weighing of the infant and calibration of the equipment. The infant is then placed on a sliding tray and pushed inside the chamber, where the body volume is measured twice.
- ADP has been extensively validated against 3C and 4C models in a wide range of populations (from infants to the elderly), and is reliable and accurate.
- Body composition prediction equations for field methods like bioimpedance and anthropometry have been developed with ADP.
- Applications of ADP include evaluation of changes in body composition due to intervention or training programs based on diet or physical activity, to evaluate associations between fetus size and newborn adiposity, and to evaluate the effect on body composition of supplements or drugs in patients suffering from different diseases.

Acknowledgments We thank the Centro de Investigacion en Alimentacion y Desarrollo (CIAD, A.C.) (Research Center for Food and Development) in Hermosillo, Mexico, for providing the equipment and facilities for the illustration of the BOD POD human measurement procedure. We specially thank Erika Ibarra and Alma Robles, for their assistance and participation in the photographic procedures, and Aida Espinosa for her assistance with drawings and graphics. We thank Cruz Teros, official photographer of the University of Sonora for taking the pictures of the BOD POD measurement procedure. We also thank Manuel Ramirez and Karen Schlosser from the Instituto de Nutricion de Centro America y Panama (Institute of Nutrition of Central America and Panama, INCAP) in Guatemala City, Guatemala, for providing the photographs of the hydrostatic weight measurement. Thanks also to Life Measurement Inc. (LMI), California, USA, for allowing us to use their images.

Chapter 23
Selected Applications of Bioelectrical Impedance Analysis: Body Fluids, Blood Volume, Body Cell Mass and Fat Mass

Alexander Stahn, Elmarie Terblanche, and Hanns-Christian Gunga

Abstract This chapter is intended as a practice-oriented complement to the introduction of the basic concepts of bioimpedance measurements in the chapter *Use of bioelectrical impedance: general principles and overview*. The present chapter focuses on selected applications of bioelectrical impedance analysis (BIA) for body composition analysis in health and disease. Various techniques and models are introduced in detail and summarized in a discussion about the potentials and limits of BIA. The chapter begins with a brief overview of the historical developments of BIA applications. The following section introduces a range of body composition applications such as measurements of intra- and extracellular water as well as fat mass, body cell mass, and blood volume. In addition to discussing the role of the basic BIA model in these applications, recent alternative developments that show promise for future research are addressed wherever applicable. This includes a discussion underlying the developments from single-frequency to multi-frequency BIA to finally bioimpedance spectroscopy (BIS). It also covers the potential advances of purely descriptive models that are statistically derived compared to rather explanatory, biophysical models that do not rely on calibrations of the target quantity by regression techniques. The most popular approach of the latter is the use of Hanai's mixture theory and its original approach plus its most recent advances are therefore discussed in detail. This is written in an accessible way, so that also the novice reader will be provided with a basic understanding of the technique to implement it in future applications. The chapter finally discusses the potentials and limits of the applications and models introduced, gives an outlook for future research, and concludes with recommendations regarding the use of BIA/BIS in practice.

Abbreviations

Latin letters (boldface letters denote complex numbers)

A	Area (m^2)
BCM	Body cell mass (kg)
BIA	Bioelectrical impedance analysis
BIS	Bioelectrical impedance spectroscopy
BM	Body mass (kg)

ρ	Resistivity (Ω·m)
Ω	Ohm

23.1 Introduction

As early as 1888 the French psychiatrist Vigouroux suggested that bioimpedance measurements of the clinically ill might provide interesting diagnostic information. However, it was not until half a century later that the technique first made the transition from theory into practice. In 1929 Lueg and Grassheim demonstrated the first clinical application of bioimpedance analysis. They were able to show that electro-cardiographic changes in myxedema were partly due to modifications in the electrical properties of the skin and that these changes were related to the basal metabolic rate in both hypo- and hyperthyroid states. A few years later, Brazier (1935) improved the technique and provided a rapid and easy method for monitoring thyroid function based on measurements of phase angle. During these early studies, some of the major problems of bioimpedance monitoring such as stray cable capacitance, polarization potentials between electrodes or tissue interfaces, and surface conduction already became transparent. To minimize the errors due to polarization effects of the electrode–skin interface, Horton and Van Ravensway (1935) introduced a tetrapolar electrode arrangement which is still used today in a similar way. Nearly 25 years later Nyboer achieved measuring physiological and pathological volume changes in body segments based on continuous bioimpedance monitoring. Since the 1960s, electrical bioimpedance research has developed in several areas. In 1962, the Frenchman A. Thomasset demonstrated the potential of the technique to determine total body water. In the following years, his research group managed to differentiate intra- and extracellular fluid volumes using high and low frequencies (Jenin et al.1975; Thomasset 1963). Almost at the same time Hoffer (1969) compensated for the weakness of the bipolar technique

employed by Thomasset, by slightly modifying the tetrapolar arrangement originally suggested by Horton and Van Ravensway. This approach was then extended by Nyboer (1981) to quantifying fat-free mass and fat mass, which is still one of the most widely used applications today. In fact, its portability, quick and easy operation, financial attractiveness, and non-invasive nature affirm that his method is one of the most widely used techniques for determining body composition. Furthermore, the technological explosion of computers and electronics and the appearance of a number of commercial instruments have substantially supported the expansion of bioelectrical impedance applications in a number of clinical settings, including the assessment of hydration during dialysis (Chertow et al. 1997), the determination of nutritional status (Barbosa-Silva et al. 2003), abdominal fat (Scharfetter et al. 2001), body cell mass (De Lorenzo et al. 1997), skeletal muscle mass (Janssen et al. 2000) and blood volume (Siconolfi et al. 1996), the prediction of survival in human immunodeficiency virus-infected patients (Ott et al. 1995), the quantification of muscular activity during exercise (Cornish and Fallah 2001), and the assessment of neuromuscular disease (Tarulli et al. 2005).

23.2 Body Fluids

Based on the relationships underlying the basic biophysical model of BIA (for details see the chapter *Use of bioelectrical impedance: general principles and overview*), Thomasset (1962) first presented the potential of bioimpedance measurements for determining total body water (TBW). Since then an overwhelming number of regression equations have been published which relate bioimpedance and sometimes additional covariates such as anthropometry, age, and gender to different body fluid compartments. An overview of published regression equations is provided by Baumgartner (1996) and more recently by Kyle et al. (2004a, b). These types of equations can be classified as either single- or multi-frequency methods, whereas the latter usually employ two to four frequencies. To differentiate multi-frequency methods from approaches employing a much higher range of frequencies (between 15 and 500), the term bioimpedance spectroscopy (BIS) is commonly used.

23.2.1 Single-Frequency BIA

Single-frequency methods most commonly employ frequencies at 50 kHz. Impedance (Z) or resistance (R) corrected for conductive length (l), is then used to predict TBW. This is the simplest implementation of the basic biophysical model underlying bioimpedance measurements. The major criticism pertaining to single-frequency bioimpedance measurements at 50 kHz is that only a portion of the intracellular space is measured (Cornish et al. 1993; Matthie et al. 1998; Schoeller 2000). In fact, full penetration of the extra- and intracellular compartments requires frequencies of 10 MHz (Schwan 1957). Consequently, the strong relationship between TBW and bioimpedance indices at 50 kHz might be due to the high intercorrelations between extracellular water (ECW), intracellular water (ICW) and TBW in normal hydration states (Van Marken Lichtenbelt et al. 1994; De Lorenzo et al. 1997; Gudivaka et al. 1999; Schoeller 2000). Interestingly, some studies also suggested that reactance (X_c) obtained at 50 kHz is useful for estimating ECW (Lukaski and Bolonchuk 1988; McDougall and Shizgal 1986). However, according to Segal et al. (1991) it is likely that this finding is a function of the linear dependence between ECW and TBW in the samples studied. Furthermore, since the ratio between ECW and ICW is tightly regulated and the two compartments reflect TBW, any single-frequency measurement in the β-frequency range (frequency spectrum between a few kHz and 100 MHz) will predict ECW, ICW,

or TBW equally well during normohydration. Given that the characteristic frequency (f_c) can vary substantially between individuals – average frequencies ranging between 30 kHz and 60 khz with values up to 130 kHz have been reported for healthy adults (Baumgartner 1996; De Lorenzo et al. 1997; Matthie et al. 1998; Ward and Stroud 2001) – different amounts of volume of the extra- and intracellular compartments are measured. Furthermore, disruptions in the ratio of ECW to ICW or basically any changes in intracellular resistance (R_i), extracellular resistance (R_e) or membrane capacitance (C_m) can affect f_c. Thus, f_c varies not only between, but also within individuals, and the respective measured volume fractions can be highly variable (Matthie et al. 1998). This might at least in part explain the population specificity as well as the poorer performance of single-frequency measurements in subjects with illness and/or obesity or generally when fluid status is altered (De Lorenzo et al. 1997; Matthie et al. 1998; Gudivaka et al. 1999; National Institutes of Health 1996; Schoeller 2000).

23.2.2 Multi-Frequency BIA

A number of remedies have been suggested to address the drawbacks underlying single-frequency measurements. A frequently employed approach is to measure *Z* or *R* at relatively high frequencies (200–500 kHz) and assume that both the extra- and intracellular compartments are penetrated entirely. Usually, this approach is coupled with an additional measurement at relatively low frequencies (1–5 kHz) and thus allows the separation of fluid compartments. This method is usually referred to as multi-frequency BIA and was first introduced by Thomasset and colleagues (Jenin et al. 1975). At low frequencies, the current is assumed to flow through the extracellular space only, and the resulting *Z* or *R* is regressed against water determined by ECW-specific dilution tracers, yielding a prediction algorithm for the extracellular fluid compartment. In contrast, at high frequencies, *Z* or *R* is supposed to reflect both the extra- and intracellular compartments and can therefore be used to determine TBW. Finally, ICW can then be derived by subtraction of ECW from TBW. Yet, if f_c changes, the problem of measuring different water volumes still remains (Matthie et al. 1998). Extending the lower and higher frequency limits poses technical problems. Even if measurements at very low frequencies (< 1 kHz) and at very high frequencies (> 5 MHz) were possible, the limiting resistances of ECW and TBW would not be reached as relaxation mechanisms in living tissue (delay in polarization of the cell membrane or between tissue interfaces) would prevent the impedance locus (see chapter *Use of bioelectrical impedance: general principles and overview* for details) to reach the x-axis (Jaffrin and Morel 2008). To overcome these difficulties and extrapolate resistance at zero and infinite frequency, bioimpedance spectroscopy can be employed.

23.2.3 Bioimpedance Spectroscopy

An extension of the high–low frequency approach is to extrapolate resistance at zero frequency (R_0) and infinite frequency (R_∞) by fitting measured data to the Cole equation (see chapter *Use of bioelectrical impedance: general principles and overview* for details). The advantage is that R_0 and R_∞ are independent of f_c, and any errors related to inconsistent f_c are removed. However, it should be noted that R_∞ is not a measure of TBW, but rather two fluid compartments with different electrical resistivities. Using R_∞ for the determination of TBW requires the resistivity of TBW (ρ_{tbw}) to be constant across fluid compartments. However, the resistivity of ECW (ρ_{ecw}) differs from the resistivity of ICW (ρ_{icw}) by a factor of 3–4. Hence, ρ_{tbw} can be significantly altered, simply when the ratio of ECW to ICW changes, even though ion concentration and other influences remain constant (Matthie et al. 1998).

A straightforward alternative for removing the error related to assuming a constant ρ_{tbw}, in cases when fluid distribution is altered, is to determine intracellular resistance (R_i) and extracellular resistance (R_e) separately (for details on determining R_i and R_e see the chapter *Use of bioelectrical impedance: general principles and overview*), and subsequently employ compartment-specific resistivities for separately determining ECW and ICW. Presently, BIS is performed using measurements from 15 to 500 frequencies ranging between 1 kHz and 1 MHz. Given that each measurement as well as fitting by Cole-Cole modeling are not without error and BIS instruments are still relatively expensive, the use of impedance at four frequencies for the derivation of resistance at zero and infinite frequencies has also been suggested (Ward et al. 2006). Irrespective of the number of frequencies employed, once R_i and R_e have been determined regression analysis can be used to derive prediction equations for ICW and ECW. Finally, TBW can be calculated as the sum of ICW and ECW.

23.2.4 Use of Hanai's Mixture Theory

A general drawback of regression equations is, however, that they are based on statistical rather than causal relationships, and are therefore highly population-specific. Specifically, the underlying biophysical model does not account for the non-linear effect of the mixture of non-conductors and conductors in human body tissue. Therefore, Van Loan and coworkers (1993) introduced the application of Hanai's mixture theory to whole-body bioimpedance measurements. This approach is based on Hanai's mixture theory which describes the effects on conductivity of a suspension of non-conductive spheres in a conducting medium (Hanai 1968). Originally, this theory was developed by Maxwell (1873) for dilute suspension of spherical particles. Hanai later extended the theory to high-volume fractions. Hanai's theory corrects the actual resistivity of a suspension for its non-conducting spheres. The apparent resistivity is therefore given by

$$\rho_a = \frac{\rho_0}{(1-c)^{3/2}} \quad (\Omega \cdot \mathrm{m}). \tag{23.1}$$

where ρ_a (Ω·m) is the apparent resistivity, ρ_0 (Ω·m) is the actual resistivity, and c (dimensionless) is the volumetric concentration of non-conducting spheres of the suspension. With regard to bioimpedance measurements the resistivity of blood can therefore be modeled as non-conducting particles, i.e. red blood cells, in the ECW which increase resistance as the current must flow around the cells (see also Fig. 3.7 in chapter *Use of bioelectrical impedance: general principles and overview*). Similarly, fat and bones can be thought of as non-conducting tissues assuming that they draw negligible current (Jaffrin and Morel 2009). An extensive theory of applying Hanai's model to bioimpedance measurements been described elsewhere (De Lorenzo et al. 1997).

23.2.4.1 Determination of ECW

At low frequency the volume fraction c for extracellular fluid is given by

$$c = 1 - \frac{V_{ecw}}{V_{wb}}. \tag{23.2}$$

where V_{ecw} (m^3) is the extracellular fluid volume, and V_{wb} (m^3) is the volume of the body. V_{wb} can be obtained by dividing body mass (kg) by mean whole-body density (δ_{wb}), which is assumed to be a constant (≈1.05 kg·m^{-3}). Combining (23.1) and (23.2) with regard to ECW yields to ECW) and substituting pa,ecw for pa and pecw for p0 (yields)

$$\rho_{a,ecw} = \rho_{ecw}\left(\frac{V_{wb}}{V_{ecw}}\right)^{3/2} \quad (\Omega \cdot m). \tag{23.3}$$

where $\rho_{a,ecw}$ (Ω·m) is the apparent resistivity of ECW, and ρ_{ecw} (Ω·m) is the resistivity of ECW. Resistance R can be expressed as

$$R = \frac{\rho l^2}{V} \quad (\Omega). \tag{23.4}$$

where ρ (Ω·m) is resistivity, V is volume (m^3), and l (m) is length. In order to account for the geometrical relations of the body, De Lorenzo et al. (1997) calculated a dimensionless correction factor K_{wb} for whole-body measurements, scaling the relative proportions of the leg, arm, and trunk. Details for the derivation of K_{wb} are given by De Lorenzo et al. (1997). Adding K_{wb} to (23.4) and substituting height H (m) for general conductor length yields

$$R = \frac{K_{wb}\rho H^2}{V_{wb}} \quad (\Omega). \tag{23.5}$$

Substituting $\rho_{a,ecw}$ for ρ and R_e for R in (23.5), yields

$$R_e = \frac{K_{wb}\rho_{ecw}H^2V_{wb}^{1/2}}{V_{ecw}^{3/2}} \quad (\Omega). \tag{23.6}$$

and solving for V_{ecw} yields

$$V_{ecw} = \left(K_{wb}\rho_{ecw}\frac{H^2}{R_e}V_{wb}^{1/2}\right)^{2/3} \quad (m^3). \tag{23.7}$$

V_{wb} can be replaced by δ_{wb} ($kg \cdot m^{-3}$) and BM (kg), yielding

$$V_{ecw} = \left(K_{wb}\rho_{ecw}\frac{H^2BM^{1/2}}{R_e\,\delta_{wb}^{1/2}}\right)^{2/3} \quad (m^3). \tag{23.8}$$

It should be noted that ρ_{ecw} and H are often expressed in Ω·cm and cm, respectively. Similarly, deltawb is expressed as kg/L or kg/cm^3. Hence, simple calculation of the units shows that the formula needs to be corrected by 10^{-2} (kg/dm^3) or 10^{-3} (kg/cm^3). Considering this unit correction factor and rewriting (23.8) according to De Lorenzo et al. (1997) finally gives

$$V_{ecw} = k_{ecw}\left(\frac{H^2\sqrt{BM}}{R_e}\right)^{2/3} \quad (dm^3), \tag{23.9}$$

with

$$k_{ecw} = 10^{-3}\left(\frac{K_{wb}^2\rho_{ecw}^2}{\delta_{wb}}\right)^{1/3} \tag{23.10}$$

23.2.4.2 Determination of ICW

Applying the Hanai theory to bioimpedance measurements at high frequencies, the volumetric concentration c is given by

$$c = 1 - \frac{V_{ecw} + V_{icw}}{V_{wb}}, \tag{23.11}$$

where V_{icw} (m^3) is the intracellular fluid volume.

Based on equation 23.1 the apparent resistivity of TBW $\rho_{a,tbw}$ ($\Omega \cdot m$) can be calculated as

$$\rho_{a,tbw} = \rho_{tbw}\left(\frac{V_{wb}}{V_{ecw} + V_{icw}}\right)^{3/2} = \rho_{tbw}\left(\frac{V_{ecw} + V_{icw}}{V_{wb}}\right)^{-3/2} \quad (\Omega \cdot m) \tag{23.12}$$

Assuming that the mean ρ_{tbw} is dependent on the volumes of ECW and ICW and their resistivities ρ_{ecw} and ρ_{icw} it follows that

$$\rho_{tbw}\left(V_{ecw} + V_{icw}\right) = \rho_{ecw}V_{ecw} + \rho_{icw}V_{icw}, \tag{23.13}$$

Accordingly, mean ρ_{tbw} is given by

$$\rho_{tbw} = \frac{\rho_{ecw}V_{ecw} + \rho_{icw}V_{icw}}{\left(V_{icw} + V_{ecw}\right)} \quad (\Omega \cdot m). \tag{23.14}$$

and can be used to replace ρ_{tbw} in (23.12). Hence,

$$\begin{aligned}\rho_{a,tbw} &= \left(\frac{\rho_{ecw}V_{ecw} + \rho_{icw}V_{icw}}{\left(V_{icw} + V_{ecw}\right)}\right)\left(\frac{V_{ecw} + V_{icw}}{V_{wb}}\right)^{-3/2} \\ &= \frac{\rho_{ecw}V_{ecw} + \rho_{icw}V_{icw}}{\left(V_{icw} + V_{ecw}\right)^{5/2}}V_{wb}^{3/2} \quad (\Omega \cdot m).\end{aligned} \tag{23.15}$$

Rewriting (23.4) with regard to high-frequency measurements gives

$$R_{tbw} = \frac{K_{wb}\rho H^2}{V_{wb}} \quad (\Omega). \tag{23.16}$$

where R_{tbw} (Ω) is the resistance of total body water. Replacing $\rho_{a,tbw}$ for ρ yields

$$R_{tbw} = \frac{\rho_{ecw}V_{ecw} + \rho_{icw}V_{icw}}{\left(V_{icw} + V_{ecw}\right)^{5/2}}V_{wb}^{1/2}K_{wb}H^2 \quad (\Omega). \tag{23.17}$$

Since R_{tbw} can be assumed equal to infinite resistance (R_∞), R_{tbw} can be replaced by infinite resistance using intracellular resistance R_i and extracellular resistance R_e (see chapter *Use of bioelectrical impedance: general principles and overview* for details). Thus,

$$\frac{R_iR_e}{R_i + R_e} = \frac{\rho_{ecw}V_{ecw} + \rho_{icw}V_{icw}}{\left(V_{icw} + V_{ecw}\right)^{5/2}}V_{wb}^{1/2}K_{wb}H^2. \tag{23.18}$$

Substituting (23.6) for R_e in the numerator of the left-hand side of (23.18) gives

$$\frac{\left(\frac{\rho_{ecw}}{V_{ecw}^{3/2}}V_{wb}^{1/2}K_{wb}H^2\right)R_i}{R_e + R_i} = \frac{\rho_{ecw}V_{ecw} + \rho_{icw}V_{icw}}{\left(V_{icw} + V_{ecw}\right)^{5/2}}V_{wb}^{1/2}K_{wb}H^2, \tag{23.19}$$

and after simplification

$$\frac{R_i}{R_e + R_i}\left(\frac{\rho_{ecw}}{V_{ecw}^{3/2}}\right) = \frac{\rho_{ecw}V_{ecw} + \rho_{icw}V_{icw}}{\left(V_{icw} + V_{ecw}\right)^{5/2}}. \tag{23.20}$$

Finally, (23.20) can be rearranged as

$$\left(1 + \frac{V_{icw}}{V_{ecw}}\right)^{5/2} = \left(\frac{R_e + R_i}{R_i}\right)\left(1 + \frac{k_\rho V_{icw}}{V_{ecw}}\right), \tag{23.21}$$

Where k_ρ is a dimensionless parameter given by ρ_{icw}/ρ_{ecw}. Eventually, V_{icw} can be calculated by an iterative procedure. k_{ecw} in (23.10) and k_ρ in (23.21) can be obtained analytically but are usually derived statistically using tracer dilution reference methods. De Lorenzo et al. (1997) reported values of 0.306 and 0.316 for k_{ecw} and 3.82 and 3.4 for k_ρ in men and women, respectively. Assuming values of 4.3 and 1,050 kg·m^{-3} for K_{wb} and δ_{wb}, respectively, corresponding actual resistivities become 40.3 Ω·cm for men and 42.3 Ω·cm for women. These values are close to that of saline (Jaffrin and Morel 2008). It should be noted that the actual resistivities, which should be clearly distinguished from apparent resistivities, are also sometimes reported as reference values. Generally, conversion from one to the other is possible via (23.1), but then the concentration of nonconductive material should be known, which is determined by the ratios between the fluid volume compartments (see 23.2 and 23.11). Frequently, resistivities for ECW and ICW are not explicitly reported, but lumped into the k_{ecw} and k_ρ terms.

23.2.4.3 Hanai's Second Generation Mixture Theory

Matthie (2005) recently argued that the above-mentioned determination of V_{icw} is based on the assumption that the relationship between ρ_{tbw} and the V_{ecw} to V_{icw} ratio is linear. As he suggests that the effect of changes in the V_{ecw} to V_{icw} ratio are highly nonlinear due to the three- to fourfold higher resistivity of V_{icw}, a new V_{icw} equation was proposed taking into account the mixture of two conducting fluids, termed the second-generation mixture theory equation. Since at low frequencies it is still assumed that the relationship between impedance and V_{ecw} involves a simple nonlinear mixture effect between two spaces (conductor and non-conductor), the Vecw-equation (see equation 23.8) remains unchanged. For V_{tbw} and V_{icw}, however, it is now suggested that an additional mixture effect needs to be accounted for due to the nonlinear relationship between V_{ecw}, V_{icw}, and non-conductors (Matthie 2005). Accordingly, the resistivity of total body fluid ptbw is given by

$$V_{icw} = V_{ecw}\left\{\left(\frac{\rho_{tbw}\left(R_e + R_i\right)}{\rho_{ecw}R_i}\right)^{2/3} - 1\right\} \quad (m^3). \tag{23.22}$$

where V_{icw} (m^3) is the intracellular fluid volume, V_{ecw} (m^3) is the extracellular fluid volume, R_i (Ω) is intracellular resistance and R_e (Ω) is extracellular resistance, and ρ_{ewc} (Ω·m) and ρ_{tbw} (Ω·m)are the mean resistivities of the extracellular and total body fluid volume, respectively.

$$\rho_{tbw} = \rho_{icw} - \left(\rho_{icw} - \rho_{ecw}\right)\left(\frac{R_i}{R_e + R_i}\right) \quad (\Omega\cdot m). \tag{23.23}$$

where ρ_{icw} (Ω·m) and ρ_{ecw} (Ω·m) are the resistivities of V_{icw} and V_{ecw}, respectively. As the calculation for V_{ecw} (see equation 23.8) remains unchanged, V_{tbw} can be expressed in SI units as

Listed are the parameters reported in various studies for k_{ecw} and k_ρ used to obtain estimates of TBW, ECW, and ICW by Hanai modeling. k_{ecw} and k_ρ are statistically derived from regression techniques. While k_ρ is a dimensionless parameter given by ρ_{icw}/ρ_{ecw}, k_{ecw} comprises the resistivity of ECW, whole-body density as well as a shape factor scaling the relative proportions of the leg, arm, and trunk. Most notably k_{ecw} varies between 0.238 and 0.370, and k_ρ can be as low as 2.827 and as high as 6.469. Accordingly, despite its appeal the Hanai approach might also suffer from the same drawbacks as regression-based estimations because different populations might also require very specific parameter values. Thus, the accuracy of estimations will largely depend on choosing the correct parameters

$$V_{tbw} = \left(\frac{\rho_{tbw} K_{wb} H^2 \sqrt{BM}}{\sqrt{\delta_{wb}} R_\infty} \right)^{2/3} \quad (m^3). \tag{23.24}$$

where R_∞ (Ω) is infinite resistance. The second-generation mixture equation has been shown to be superior compared to the original version (Matthie 2005). Further validation studies in different populations and under different conditions are, however, needed to confirm these findings.

23.2.4.4 Limitations and Future Directions of Hanai's Mixture

A quite recent advancement of the use of mixture theory for bioimpedance applications is to correct the parameters of the Hanai equation for differences in body composition by the body mass index (Moissl et al. 2006). This idea is related to the assumption that body density, resistivity, and the shape factor are not constant across diverse populations. In fact, the often observed differences in resistivity (and regression weights) between men and women might simply be an expression of gender-related differences in body composition. Consequently, various authors have suggested different values for

resistivity (ρ_{ecw} and ρ_{icw}), body geometry correction factor (K_{wb}) and whole-body density (δ_{wb}) related to their sample under study. Table 23.1 gives an indication of the range of parameter values employed in bioimpedance modeling using Hanai's mixture theory.

It is shown that k_{ecw} varies between 0.238 and 0.370, and k_{ρ} can be as low as 2.827 and as high as 6.469. Furthermore, it is worth noting that Ellis and Wong (1998) observed a high degree of variation between subjects for both k_{ecw} and k_{ρ} in a large sample of 469 healthy men and women, ranging in age between 3 and 29 years. Using tracer dilution techniques they reported coefficients of variation for k_{ecw} and k_{ρ} exceeding 19% and 25%, respectively. This dispersion by far exceeds the limits generally considered for defining constants in body composition analysis (Wang et al. 1992). In a subsequent reanalysis of the pediatric subsample (subjects aged 3–18 years only), the authors found that the coefficients of variations k_{ecw} and k_{ρ} were only about ±8%, when estimates of fluid volumes were derived from dual-energy X-ray absorptiometry (DEXA) and total body potassium counting (Ellis et al. 1999a). In spite of methodical aspects underpinning the reliability of dilution techniques that might have inflated the observed variability, it is apparent that ρ_{ecw} and ρ_{icw} used to calculate k_{ecw} and k_{ρ}, as well as the body geometry correction factor (K_{wb}) and whole-body density (δ_{wb}), might not be constant across age and gender. At least some of these differences might be associated with body composition. This is also supported by findings indicating that fluid volume estimations are affected by body composition (Carter et al. 2005). Furthermore, Cox-Reijven and Soeters (2000) observed that body mass index (BMI) is negatively correlated to k_{ecw}. Given this inverse relationship, it is unlikely that the body density and shape factor might account for this observation, as both these factors would be expected to be positively associated to BMI. In addition, since body density (δ_{wb}) varies relatively little between subjects, typically ranging between 0.95 and 1.1 kg·dm^{-3} (Keys and Brozek 1953) the impact on k_{ecw} is substantially less compared to the body geometry correction factor (K_{wb}) or ρ_{ecw}. This is also in line with the finding by Moissel et al. (2006). They found that replacing the fixed constant of 1.05 kg·m^{-3} by the true body density as determined by air displacement plethysmography did not decrease the variation in k_{ecw}. Further support attributing the variation of k_{ecw} to ρ_{ecw} and ρ_{icw} is given by Cox-Reijven and Soeters (2000), who reported that both ρ_{ecw} and ρ_{icw} are highly correlated to BMI ($r = -0.641$ and -0.683 for ρ_{ecw} and ρ_{icw}, respectively). In summary, given these findings the idea to adjust resistivity for body composition seems to be clearly appealing. Yet, it remains to be established whether this can be effectively achieved by the use of the BMI. In summary, it should be kept in mind that strictly speaking, the Hanai model is only valid for blood but not for other tissues. In addition, application of the model assumes that the body consists of five cylindrical segments with homogeneous electrical properties. While this may be true for the arms and legs, the trunk is clearly anisotropic (see also chapter *Use of bioelectrical impedance: general principles and overview*). These discrepancies can be corrected by different shape factors, fluid resistivities and body densities. Accordingly, when applying the Hanai model one needs to be aware of the pitfall of simply shifting from population-specific regression equations to population-specific resistivities, body densities and shape factors.

23.2.5 Alternative Approaches

Another suggestion to alleviate the problems of single-frequency bioimpedance approaches was proposed by Cornish et al. (1993). This approach is based on the fact X_c is maximal midway between R_0 and R_∞ at f_c. In particular, they hypothesized that since R at f_c is defined as $(R_0 + R_\infty)/2$ and given that R_0 as well as R_∞ are proportional to ECW and TBW, the same water volumes (or

proportion of water volumes relative to R_∞ and R_0) should be measured across and within individuals. However, the problem of assuming a constant ρ_{tbw} still remains. Thus, any single-frequency measurement including R at f_c as well as R_∞ is prone to errors as long as ρ_{tbw} is assumed to be constant.

Finally, Piccoli et al. (1994) suggested a qualitative evaluation of body hydration based on the measurements of R and X_c at 50 kHz. The principal component of this graphical method is the RX_c graph, which plots X_c vs. R standardized for height, respectively, and compares their resulting impedance vector with bivariate tolerance limits obtained in reference populations. According to Piccoli and colleagues, the impedance vector reflects body hydration. Basically, a shortening and downsloping of the impedance vector is assumed to indicate fluid overloading, while a lengthening and steepening is attributed to fluid removal. Thus, a comparison of the impedance vector with 50%, 75%, and 95% tolerance limits allows the distinction between different hydration levels between subjects. If the subject's impedance vector lies within the 75% tolerance ellipse, the authors suggest that normal hydration can be assumed and regression equations for estimating body fluids can be applied with confidence.

A similar approach employing phase angle spectrum analysis has been suggested by Chumlea et al. (1994, 1998). The basic idea is to plot the phase angle (φ) as a function of frequency, and compare and describe differences among individuals in levels of hydration. The difficulty with using φ or the RX_c-graph is that they are directly related to fluid distribution. However, as already indicated by Löfgren et al. (1951) and outlined by De Lorenzo et al. (1997), changes in body fluid distribution affect f_c, which, in turn changes X_c and φ. Since changes in f_c can be related to R_e, R_i, and C_m, or any combination of them (De Lorenzo et al. 1997), X_c and φ are affected by all these elements. Thus, it remains questionable to attribute the change in X_c or φ to unique alterations in body fluids only.

23.3 Fat Mass

23.3.1 Conventional Approach

The majority o f bioimpedance models for the estimation of body fat rely on the determination of FFM and the computation of fat mass (FM) by subtraction. Since BM is the sum of FM and FFM and FFM can be related to R and conductor length according to (23.4), percent FM (%FM) can be calculated as

$$\%\mathrm{FM} = 100\left(1 - \rho_{\mathrm{ffm}}\frac{H^2}{R\ \mathrm{BM}}\right)\quad(\%). \tag{23.25}$$

where ρ_{ffm} (Ω·m) refers to resistivity of FFM, R (Ω) to resistance, H (m) to height and BM (kg) to body mass. However, most %FM prediction equations are based on multiple regression analysis that lumps the best predictors into a single prediction algorithm without a sound physical basis. A review of the equations is provided by Kyle et al. (2004a, b). Some studies have also suggested regressing the impedance index directly against FM or %FM. This approach, however, clearly lacks physical meaning and any predictive potential is likely to be due to the association between height and/or weight and FM rather than by the assumption that the impedance index accounts for a substantial amount of variance in FM or %FM.

23.3.2 A Specific Resistivity Approach to Determine Segmental FM

To provide a straightforward estimate of FM that does not rely on statistical relationships, and has clear physical meaning, Fuller and coworkers (1999, 2002a, b) suggested a model for determining segmental fat mass taking into consideration that the flow of current might not be limited to skeletal muscle tissue and blood. Accordingly, the basic biophysical bioimpedance model can be extended by taking into account that the introduced current is not only drawn by skeletal muscle, but also by fat, neurovascular, bone, and skin tissue. Hence, after some algebraic rearrangement skeletal muscle volume ($V_{seg,sm}$) can be computed as

$$V_{seg,sm} = \frac{l_{seg}^2}{R_{seg,tot}} - \frac{V_{seg,tot}}{\rho_{fat}} + \frac{V_{seg,neu}}{\rho_{fat}} + \frac{V_{seg,bo}}{\rho_{fat}} + \frac{V_{seg,sk}}{\rho_{fat}} - \frac{V_{seg,neu}}{\rho_{neu}} - \frac{V_{seg,bo}}{\rho_{bo}} - \frac{V_{seg,sk}}{\rho_{sk}}\left(\frac{\rho_{sm}\rho_{fat}}{\rho_{fat} - \rho_{sm}}\right) \quad (m^3) \tag{23.26}$$

where $R_{seg,tot}$ (Ω) is the total segmental resistance. Values for ρ_{fat}, ρ_{neu}, ρ_{bo}, ρ_{sk}, and ρ_{sm} at 50 kHz are assumed to be respectively. Analogously, an estimate of segmental fat volume ($V_{seg,fat}$) is given by

$$V_{seg,fat} = V_{seg,tot} - V_{seg,sm} - V_{neu} - V_{seg,sk} - V_{seg,bo} \quad (m^3). \tag{23.27}$$

where the subscripts tot, sm, neu, sk, and bo refer to total tissue, skeletal muscle, neurovascular, skin, and bone tissue, respectively. $V_{seg,tot}$, $V_{seg,sm}$, $V_{seg,neu}$, $V_{seg,sk}$ and $V_{seg,bo}$ are calculated as the product of their respective segmental area (A_{seg}) and segment length (l_{seg}). $A_{seg,tot}$ is determined from measurements of circumference. $A_{seg,sk}$ is approximated by measurements of circumference and by assuming a skin thickness of 0.16 cm for men and 0.12 cm for women. In addition, it is assumed that neurovascular tissue contributes about 1% to total $A_{seg,tot}$, and $A_{seg,bo}$ can be approximated by about 6 cm^2. Hence, (23.27) can be rewritten as

$$V_{seg,fat} = V_{seg,tot} - V_{seg,sm} - V_{seg,tot} \times 0.01 - V_{seg,sk} - 0.0006 l_{seg} \quad (m^3). \tag{23.28}$$

Fuller and colleagues tested for leg and calf sections in both children and adults. While for skeletal muscle volume, the approach seemed to outperform anthropometry, the superiority was less clear for fat tissue. In addition, both methods showed substantial deviations for individual measurements as indicated by large limits of agreement. The authors suggested that part of the error regarding BIA could be attributed to disparities between the locations for circumference measurements and electrode positions, the violation of the assumption that the cross-sectional areas of the tissue are uniform, and uncertainties about the resistivities. The latter pertains to skeletal muscle in particular, as it has a substantial impact in the equations presented above. In addition, it should also be noted that the approach is based on a single-frequency measurement and generally any criticism that has been raised concerning such approaches for fluid volume estimations (see Sect. 23.2.1) also pertain to any other body compartment. In conclusion, it seems as if this approach seems to be the most advantageous for skeletal muscle volume determinations and it will be interesting to see how further research can address the choice and the development of resistivity constants.

23.3.3 A Three-Compartmental Model of Body Mass and Segment Resistivity to Predict Whole-Body Fat Mass

Another interesting approach for determining fat mass of the total body using segmental measurements and anthropometry has been suggested by Biggs et al (2001). Given its innovative character

and potential it will be presented in detail. Basically, the model assumes that both skeletal muscle and fat are conductive, while the remaining tissues such as bone, ligaments, and tendons are non-conductive. Thus, total mass (BM_{tot}) of the body can be described as the sum of the following distinctive masses by

$$BM_{tot} = BM_{con} + BM_{non} = BM_{sm} + BM_{fat} + BM_{non} \quad (kg). \tag{23.29}$$

where BM refers to mass (kg) and the subscripts sm, fat, and non denote skeletal muscle, fat, and non-conductive tissue, respectively. Furthermore, the total cross-sectional area for any specific body segment ($A_{seg,tot}$) is given by

$$A_{seg,tot} = A_{seg,con} + A_{seg,non} = A_{seg,sm} + A_{seg,fat} + A_{seg,non} \quad (m^2). \tag{23.30}$$

where A is the cross-sectional area (m^2), and the subscripts con, non, sm, and fat indicate conductive and non-conductive, skeletal muscle and fat, tissue, respectively. Accordingly, the conductive path can be modeled by two resistors in parallel, one representing the muscle compartment, the other indicating the fat compartment. Based on Kirchhoff's law, total resistance ($R_{seg,tot}$) of any body segment can be calculated as

$$\frac{1}{R_{seg,tot}} = \frac{1}{R_{seg,sm}} + \frac{1}{R_{seg,fat}} \quad (\Omega^{-1}). \tag{23.31}$$

where $R_{seg,sm}$ (Ω) and $R_{seg,fat}$ (Ω) refer to the resistance of skeletal muscle and fat tissue, respectively.

Given the relationship between resistance, length, area, and resistivity, (23.31) can be rewritten as

$$\frac{1}{R_{seg,tot}} = \frac{A_{seg,sm}}{\rho_{sm} l_{seg}} + \frac{A_{seg,fat}}{\rho_{fat} l_{seg}} \quad (\Omega^{-1}). \tag{23.32}$$

where ρ_{sm} (Ω·m) and ρ_{fat} (Ω·m) are the resistivities of skeletal muscle and fat, respectively, and l_{seg} (m) refers to the conductor length. Arranging the right-hand side term on a common denominator yields

$$\frac{1}{R_{seg,tot}} = \frac{A_{seg,sm}\rho_{fat} + A_{seg,fat}\rho_{sm}}{\rho_{sm}\rho_{fat} l_{seg}} \quad (\Omega^{-1}). \tag{23.33}$$

According to (23.30), $A_{seg,sm}$ can be replaced by the term $A_{seg,con} - A_{seg,fat}$. Hence, (23.33) can become

$$\frac{1}{R_{seg,tot}} = \frac{A_{seg,con}\rho_{fat} - A_{seg,fat}\rho_{fat} + A_{seg,fat}\rho_{sm}}{\rho_{sm}\rho_{fat} l_{seg}} \quad (\Omega^{-1}). \tag{23.34}$$

For clarity, $A_{seg,fat}$ can be grouped so that

$$\frac{1}{R_{seg,tot}} = \frac{A_{seg,con}\rho_{fat} + A_{seg,fat}\left(\rho_{sm} - \rho_{fat}\right)}{\rho_{sm}\rho_{fat} l_{seg}} \quad (\Omega^{-1}). \tag{23.35}$$

Multiplying (23.35) by he right-hand side denominator gives

$$\frac{\rho_{sm}\rho_{fat} l_{seg}}{R_{seg,tot}} = A_{seg,con}\rho_{fat} + A_{seg,fat}\left(\rho_{sm} - \rho_{fat}\right) \quad (\Omega \cdot m^3). \tag{23.36}$$

and solving for terms with $A_{seg,fat}$ yields

$$A_{\text{seg,fat}}\left(\rho_{\text{sm}}-\rho_{\text{fat}}\right)=\frac{\rho_{\text{sm}}\rho_{\text{fat}}\,l_{\text{seg}}}{R_{\text{seg,tot}}}-A_{\text{seg,con}}\rho_{\text{fat}}\quad(\Omega\cdot\text{m}^3). \tag{23.37}$$

Dividing both sides by $A_{\text{seg,con}}$, and then by $(\rho_{\text{sm}} - \rho_{\text{fat}})$ gives

$$\frac{A_{\text{seg,fat}}}{A_{\text{seg,con}}}=\frac{\rho_{\text{sm}}\rho_{\text{fat}}\,l_{\text{seg}}}{A_{\text{seg,con}}R_{\text{seg,tot}}\left(\rho_{\text{sm}}-\rho_{\text{fat}}\right)}-\frac{\rho_{\text{fat}}}{\left(\rho_{\text{sm}}-\rho_{\text{fat}}\right)}. \tag{23.38}$$

The left-hand side in (23.38) can be extended by l_{seg}, which gives

$$\frac{A_{\text{seg,fat}}\,l_{\text{seg}}}{A_{\text{seg,con}}\,l_{\text{seg}}}=\frac{V_{\text{seg,fat}}}{V_{\text{seg,con}}}=\frac{V_{\text{seg,fat}}}{V_{\text{seg,fat}}+V_{\text{seg,sm}}}\equiv Q_{\text{seg}}. \tag{23.39}$$

where V is the volume (m^3), and the subscripts sm, fat, and con refer to skeletal muscle, fat, and conductive tissue of the body segment, respectively. Thus, Q_{seg} can be understood as a fat quotient as it relates the segmental fat to the sum of fat and skeletal muscle. Substituting Q_{seg} for the left-hand side in (23.38), allows the calculation of the fat quotient Q_{seg} for an arbitrary number of body segments from measurements of resistance, length, and circumference.

$$Q_{\text{seg}}=\frac{\rho_{\text{sm}}\rho_{\text{fat}}\,l_{\text{seg}}}{A_{\text{seg,con}}R_{\text{seg,tot}}\left(\rho_{\text{sm}}-\rho_{\text{fat}}\right)}-\frac{\rho_{\text{fat}}}{\left(\rho_{\text{sm}}-\rho_{\text{fat}}\right)}. \tag{23.40}$$

Biggs et al. (2001) suggested deriving ρ_{sm} by nonlinear parameter estimation. Results in a calibration sample (n = 10) yielded an average value of 1.37 ± 0.11 Ω·m, which was not significantly different from values for muscle and blood determined ex vivo. ρ_{fat} (50 Ω·m) was taken from the literature data (Foster and Schwan 1989). $A_{\text{seg,con}}$ can be determined as follows. First, $A_{\text{seg,tot}}$ is simply calculated as

$$A_{\text{seg,tot}}=\frac{C_{\text{seg}}^2}{4\pi}\quad(\text{m}^2). \tag{23.41}$$

where C_{seg} (m) refers to the segmental circumference. Given that the area of any object generally scales with the square of its length (McMahon and Bonner 1983), $A_{\text{seg,non}}$ can be estimated from segment length squared after adjusting for different tissue compartments by a scaling coefficient (k_{a}). Hence,

$$A_{\text{seg,non}}\cong k_{\text{a}}l_{\text{seg}}^2\quad(\text{m}^2). \tag{23.42}$$

where l_{seg} (m) is the segmental length. k_{a} can be derived from converting the length of a typical upper-leg segment to a cross-sectional area approximating the shaft of an adult femur (Biggs et al. 2001). These computations were based on data for upper-leg cross-sections by Netter (1989). Subsequently, $A_{\text{seg,con}}$, can be calculated from the difference of $A_{\text{seg,tot}}$ and $A_{\text{seg,non}}$.

After obtaining the fat quotient Q_{seg} for different body segments such as the upper arm, lower arm, trunk, upper leg, and lower leg, these estimates can be combined to quantify total body %FM. Combining the body segments, however, requires that the body segments are weighted according to volume. This is achieved by first computing total conductive volume ($V_{\text{tot,con}}$) as the sum of all conductive volumes of each segment ($V_{\text{seg,con}}$).

$$V_{\text{tot,con}}=V_{\text{seg-1,con}}+\ldots+V_{\text{seg-n,con}}=A_{\text{seg-1,con}}l_{\text{seg-1}}^2+\ldots+A_{\text{seg-n,con}}l_{\text{seg-n}}^2\quad(\text{m}^3). \tag{23.43}$$

where the subscripts -1 and *n* refer to the first and *n*th segment, respectively. The weighing factors (w_{seg}) of each segment can then be calculated as

$$w_{\text{seg-n}} = \frac{V_{\text{seg-n,con}}}{V_{\text{tot,con}}}. \tag{23.44}$$

Finally, the overall fat quotient can be derived from

$$\hat{Q}_{\text{tot}} = w_{\text{seg-1}} Q_{\text{seg-1}} + \ldots + w_{\text{seg-n}} Q_{\text{seg-n}}. \tag{23.45}$$

Irrespective of whether $\hat{Q}_{\text{tot}}$ is obtained for single or multiple body segments, they need to be converted to %FM. This is achieved as follows. According to (23.39), $\hat{Q}_{\text{tot}}$ can be expressed as

$$\hat{Q}_{\text{tot}} = \frac{V_{\text{tot,fat}}}{V_{\text{tot,fat}} + V_{\text{tot,sm}}} = \frac{\frac{BM_{\text{fat}}}{\delta_{\text{fat}}}}{\frac{BM_{\text{fat}}}{\delta_{\text{fat}}} + \frac{BM_{\text{sm}}}{\delta_{\text{sm}}}}. \tag{23.46}$$

where $V_{\text{tot,fat}}$ (m^3), $V_{\text{tot,sm}}$ (m^3), δ_{fat} ($kg \cdot m^{-3}$) and δ_{sm} ($kg \cdot m^{-3}$) refer to total whole-body volume and density of fat and skeletal muscle, respectively. After simplification by finding a common denominator, (23.46) can be rewritten as

$$\hat{Q} = \frac{BM_{\text{fat}} \delta_{\text{sm}}}{\delta_{\text{sm}} BM_{\text{fat}} + \delta_{\text{fat}} BM_{\text{sm}}}. \tag{23.47}$$

According to (23.29), BM_{sm} can be expressed as

$$\text{BM}_{\text{sm}} = \text{BM}_{\text{tot}} - \text{BM}_{\text{fat}} - \text{BM}_{\text{non}} \quad \text{(kg)}. \tag{23.48}$$

Thus, substituting BM_{sm} in (23.47) yields

$$\hat{Q} = \frac{\text{BM}_{\text{fat}} \delta_{\text{sm}}}{\delta_{\text{sm}} \text{BM}_{\text{fat}} + \delta_{\text{fat}} \left(\text{BM}_{\text{tot}} - \text{BM}_{\text{fat}} - \text{BM}_{\text{non}}\right)}. \tag{23.49}$$

Multiplication with the right-hand side denominator and distribution of Q over terms give

$$\hat{Q}\delta_{\text{sm}} \text{BM}_{\text{fat}} + \hat{Q}\delta_{\text{fat}} \text{BM}_{\text{tot}} - \hat{Q}\delta_{\text{fat}} \text{BM}_{\text{fat}} - \hat{Q}\delta_{\text{fat}} \text{BM}_{\text{non}} = \text{BM}_{\text{fat}} \delta_{\text{sm}}. \tag{23.50}$$

Regrouping terms containing BM_{fat} and factoring lead to

$$\hat{Q}\delta_{\text{fat}} \text{BM}_{\text{tot}} - \hat{Q}\delta_{\text{fat}} \text{BM}_{\text{non}} = \text{BM}_{\text{fat}} \left(\delta_{\text{fat}} \hat{Q} + \delta_{\text{sm}} \left(1 - \hat{Q}\right)\right) \tag{23.51}$$

For clarity, the right-hand side terms in brackets are replaced by K. For isolation of BM_{fat} both sides are then divided by K.

$$\frac{\hat{Q}\delta_{\text{fat}} \text{BM}_{\text{tot}}}{K} - \frac{\hat{Q}\delta_{\text{fat}} \text{BM}_{\text{non}}}{K} = \text{BM}_{\text{fat}} \quad (kg). \tag{23.52}$$

Subsequently, both sides are divided by BM_{tot}, giving

$$\frac{\hat{Q}\delta_{\text{fat}}}{K} - \frac{\hat{Q}\delta_{\text{fat}} \text{BM}_{\text{non}}}{K \text{BM}_{\text{tot}}} = \frac{\text{BM}_{\text{fat}}}{\text{BM}_{\text{tot}}}. \tag{23.53}$$

Then, common terms can be factored out on the left-hand side and multiplied by 100 to convert proportion to percent:

$$100\frac{\hat{Q}\delta_{\text{fat}}}{K}\left(\frac{1-\text{BM}_{\text{non}}}{\text{BM}_{\text{tot}}}\right)=100\frac{\text{BM}_{\text{fat}}}{\text{BM}_{\text{tot}}}=\%\text{FM}\quad(\%).\tag{23.54}$$

Finally, K can be again substituted back, so that

$$100\frac{\hat{Q}\delta_{\text{fat}}}{\delta_{\text{fat}}\hat{Q}+\delta_{\text{sm}}\left(1-\hat{Q}\right)}\left(\frac{1-\text{BM}_{\text{non}}}{\text{BM}_{\text{tot}}}\right)=100\frac{\text{BM}_{\text{fat}}}{\text{BM}_{\text{tot}}}=\%\text{FM}\quad(\%).\tag{23.55}$$

δ_{fat} (900 kg·m^{-3}) and δ_{sm} (1,340 kg·m^{-3}) are assumed to be fixed and taken from the literature data (Brozek et al. 1963). Since the mass of any object generally scales with the cube of its length, BM_{non} can be estimated as

$$\text{BM}_{\text{non}}\cong k_{\text{m}}H^3\quad(\text{m}^3).\tag{23.56}$$

where k_{m} is a constant which scales the non-conductive compartment with subject height H (m) cubed. The value of k_{m} (3.90 ± 1.37) was also derived from parameter estimation in a calibration sample.

Biggs et al. (2001) determined fat quotients according to (23.40) for trunk and upper and lower arm and leg, respectively. The best prediction accuracy for %FM was achieved by simply combining Q obtained from the upper arm and upper leg. The root mean square error for FM was 2.65 kg and approaches the error inherent to the reference method, i.e. densitometry (Biggs et al. 2001). Furthermore, the values of the two calibrated parameters, i.e. ρ_{sm} and k_{m} are well in agreement with data theoretically expected based on the data obtained in vitro, substantiating the validity of the model. In addition, it is noteworthy that the sample under study comprised 21 men and 9 women aged 21–44 years from a variety of ethnic backgrounds. The subjects included descendents from North America, Asia, Middle East, Europe, and Africa. Accordingly, the model might not require population-specific adjustments as its accuracy might not be limited by age, gender, and ethnic background. It could be argued that the estimation of the scaling coefficient k_{a} in (23.42) is prone to substantial error. However, it should be noted that the impact of k_{a} on %FM is rather marginal. Biggs et al. (2001) showed that increasing or decreasing k_{a} changed the root mean square error of %FM about 0.02-fold. In summary, a unique feature of the approach is that each parameter of the model is inspired by a real physical parameter instead of lumping a variety of predictors such as age, weight, gender, and the resistance index into a multiple regression equation. In addition, the estimated parameters in fact show reasonable agreement with tissue properties measured in vitro, thus independently substantiating the biophysical validity of the model. The model therefore seems to be very promising. Future research should address testing the validity of the model in larger cohorts with a variety of body composition levels and different hydration states. Such research should also address the relevance of using multi-frequency BIA and BIS to quantify the potential error underlying single-frequency BIA (see also Sect. 23.2.1).

23.3.4 Local Fat Tissue Measurements

Another innovative approach that provides a rather direct determination of FM was proposed by Ward and associates (Elia and Ward 1999). The so-called electronic skinfold caliper is supposed to provide estimates of skinfold thickness at specific body sites by measuring Z via both a tetrapolar

and bipolar electrode arrangements. The difference between the two is assumed to be the combined Z of skin and subcutaneous adipose tissue and can therefore be used to compute skinfold thickness if the resistivities of skin and subcutaneous adipose tissue are known. Correlations with skinfold thickness measured by using a caliper yielded correlations as high as 0.94 with a standard error of the estimate (SEE) of 4.3%. The major advantage of this technique is an improved intra- and inter-observer reliability as well as the application of skinfold measurements in very obese subjects in whom measurements of skinfold by anthropometry may be difficult or impossible. This approach seems to be promising, and needs to be investigated in further studies. A similar technique was extensively investigated by Scharfetter (1999) for assessing abdominal fatness. By positioning voltage-sensing electrodes in close vicinity of current injecting electrodes, it was also assumed that measured voltage potentials mainly reflect the subcutaneous fat layer. Z was highly and significantly correlated with subcutaneous fat-layer thickness determined by magnetic resonance imaging ($r = 0.992$). Since the narrowest prediction intervals were obtained at 50 kHz, and no differences were found for the regression models between men and women at this frequency, the authors concluded that 50 kHz is well suited for this technique (Scharfetter et al. 2001).

23.4 Body Cell Mass

Body cell mass (BCM) represents the active metabolic component of the body and is thus an important component of body composition. BCM consists of intracellular fluid and solids. Hence, bioimpedance can also be expected to be associated with BCM. Lukaski et al. (1985) reported that the l^2/R at 50 kHz was highly related to total body potassium. Similarly, Pietrobelli et al. (2002) found arm potassium content to be highly related to arm impedance adjusted for a segment length. There was a slight trend for prediction accuracy to increase with frequency with the best model fit obtained at the highest frequency measured (300 kHz).

In addition to covariates such as age, gender, and anthropometry, some authors have also reported X_c to be highly related to BCM (Kotler et al. 1996; Gudivaka et al. 1999; Dittmar and Reber 2001). A clear theoretical explanation for the inclusion of X_c in predicting BCM is, however, lacking. Moreover, the zero-order correlation between fat-free mass (FFM) and X_c is as low as 0.23 (Kyle et al. 2001). It seems as if the predictive potential of X_c is only achieved when X_c is expressed as its parallel equivalent (Kotler et al. 1996; Lukaski 1996; Gudivaka et al. 1999). However, transforming measured series X_c to parallel X_c shows that the latter is inherently related to series R, which itself is associated with ICW due to the interdependence between TBW and ICW (see Sect. 23.2). Irrespective of the use of R and/or X_c for the estimation of BCM, it should be considered that analogue to the determination of body fluids, any prediction based on a single-frequency measurement will be prone to errors associated with assuming a constant characteristic frequency and/or a constant resistivity (Matthie et al. 1998). At least theoretically, a straightforward alternative is therefore to first determine ICW based on R_i and the use of Hanai's mixture theory, and subsequently derive BCM by dividing ICW by an assumed cell hydration (Wang et al. 2004).

23.5 Blood Volume

Siconolfi and coworkers (1994, 1996) suggested a technique termed bioelectrical response spectroscopy (BERS) to estimate blood volume (V_{bl}). Based on multiple regression analysis V_{bl} is predicted from resistance, capacitance, inductance, height, and body mass.

$$V_{bl} = 591.607 + 55.292 \times \left\{ 2.584 + 0.379 \times \left(\frac{l^2}{R_{tot}} \right) + 0.168 \times BM \right\}$$
$$+ 6.011 \times 10^{-6} \times \left(\frac{l^2}{L} \right) - 2.308 \times 1010 \times C \quad (mL). \tag{23.57}$$

where l (cm) is the height, R_{tot} (Ω) is the total resistance of the body and theoretically similar to R_{∞}, BM (kg) is the body mass, L (H) is the inductance, and C (F) is the capacitance. According to the authors, correlation coefficients exceeding 0.92, low SEE (>7.7%), and Bland–Altman comparisons between V_{bl} determined by BERS and V_{bl} measured by a radioactive dilution technique (^{125}I-albumin) verified the validity of the new approach. Though the results of this technique seem to be promising, a number of researchers have raised concerns both about the inclusion of an inductor in the underlying biological electrical equivalent circuit (Gluskin 2003; Riu 2004) and the viability of modeling total circuit resistance as suggested by Siconolfi and coworkers (Ward et al. 1999). Stahn et al. (2004) therefore also investigated the potential of conventional whole-body impedance measurements to predict V_{bl}. It was found that blood volume, erythrocyte volume, and plasma volume were highly associated with impedance (r = 0.89, 0.87, 0.85 for blood, erythrocyte, and plasma volume, respectively). In spite of these promising findings, substantiating the findings by Siconolfi and coworkers (1994, 1996), it should be noted that measurements were obtained in a sample of young, healthy men and women (n = 67). Consequently, given tightly regulated fluid compartments, the results are to some extent simply a reflection of the underlying relationship between body size and blood volume. This could be confirmed by statistically correcting the influence of body mass, the correlations were reduced to 0.65, 0.60, and 0.57 for blood, plasma, and erythrocyte volume, respectively. Nonetheless, impedance seems to be independently related to hematological parameters, and might also explain to some extent the relationships found between bioimpedance and measures of physical work capacity (Varlet-Marie et al. 1997) and cardiorespiratory fitness (Varlet-Marie et al. 2003; Stahn et al. 2006, 2008)

23.6 Concluding Remarks

23.6.1 Lack of a Single Dominant Approach

Since the introduction of bioimpedance for measuring body fluids in the 1960s, a number of approaches and applications have been extensively investigated. Due to the complexity of assumptions underlying all bioimpedance techniques and concomitant error sources, a clear superiority of a single technique remains uncertain and is still being discussed (Hannan et al.1994, 1998; Paton et al. 1998; Ward et al. 1998; Ellis et al. 1999b; Schoeller 2000).

For instance, segmental measurements have not always shown to be superior to whole-body measurements. The segmental approach might therefore only reveal its full potential in subjects with altered fluid distributions (Thomas et al. 2003). Similarly, BIS seems to be advantageous over single- and multi-frequency BIA only when the relationship between ECW and ICW is changed. In fact, in a review study by Martinoli et al. (2003) it was observed that multi-frequency BIA was more accurate for estimating TBW than BIS. Furthermore, the benefit of additional modeling compared to BIS through the use of Hanai's mixture theory remains unclear.

The reasons for these observations are multifold. First, it should be noted that all approaches, some more, some less, violate the basic biophysical model underlying BIA and BIS. The human body is

neither an isotropic conductor, nor is its cross-sectional area always homogeneous. In addition, the tissues are neither fully aligned in parallel, nor is the current distribution uniform. Another grave simplification is that the FM draws negligible current and therefore does not significantly contribute to bioimpedance. In obese subjects, however, body geometry, the increased amount of adipose tissue and hydration of the latter might all affect bioimpedance measurements (Baumgartner et al. 1998). These alterations might explain the often observed overestimations of FFM in people with moderate to severe obesity. For these reasons, in addition to account anthropometrically for excess fat mass (De Lorenzo et al. 1999), new biophysical models distinguishing the separate contribution of adipose tissue, muscle, and body fluids have been proposed (Van Kreel et al. 1998; Fuller et al. 1999; Zhu et al. 2005). Furthermore, intra- and interindividual variations in the hydration of non-adipose and adipose tissue might further bias the relationship between bioimpedance and FFM. This led to a huge collection of regression equations, and the accuracy of BIA might often depend on the choice of the correct equation. Moreover, multiple regression analysis is often employed to allow for additional predictors expected to improve prediction accuracy. This, however, will further decrease equation stability across different populations. For instance, whereas age might generally be inversely related to TBW and FFM, this relationship might be less prevalent in older subjects engaging in regular physical activity, thus leading to underestimations of TBW and FFM, when regression equations are employed that additionally use age as a covariate.

The idea to replace these purely statistical, descriptive bioimpedance models by an explanatory, biophysical approach using Hanai's mixture theory is certainly appealing. Yet, it should be noted that the same violations underpinning BIA also pertain to Hanai modeling. In addition, neither R_i nor R_e are directly measured, but approximated by a fitting algorithm. Even assuming well-fitted predictions, errors in R_i can be high since it is the difference between $R_¥$ and R_0 and therefore errors involved in each parameter will affect R_i. Furthermore, Hanai's theory was originally based on suspensions of cells. It is, however, highly questionable to apply this theory to the entire human body including adipose tissue and bone. Finally, the existence of several different values for the parameters of the Hanai equation highlights the vulnerable point of the approach. Presently, it seems as if the choice of resistivity, shape factor, and body density depends on the investigators' preference rather than experimental data. As a result, the discussion will simply shift from sample-specific regression equations to sample-specific resistivity constants.

23.6.2 Validity and Reliability of Bioimpedance Measurements for Body Composition Analysis

Irrespective of the controversy of the best bioimpedance model, the majority of studies support the use of bioimpedance measurements for the determination of body composition. BIA seems to be reasonably valid and reliable (for a review of reliability studies see chapter *Use of bioelectrical impedance: general principles and overview*). Correlations between l^2/Z (l^2/R) and *FFM*, and between l^2/Z (l^2/R) and TBW exceed 0.9 in most studies. Kushner (1992) reviewed five studies for TBW and eight studies for FFM reporting regression models solely based on l^2/R. The unstandardized regression coefficients were quite similar between equations with coefficients of variation (CV) of ≈5% for TBW, and 7% for FFM. Furthermore, a single study seemed to substantially bias the results. Recalculating CV for the remaining seven studies reduced the variation to less than 3%. The small variation between regression coefficients indicates that different investigators obtained similar relationships between independent and dependent variables in samples diverse in age (0.4–83 years), underpinning the empirical stability of the model. Furthermore, dividing the mean regression coef-

Table 23.2 Key points on the accuracy of selected bioimpedance applications in health and disease

	Health		Disease	
	R^2	SEE	R^2	SEE
FFM	**0.86** (0.71–0.97)	**2.75** (1.6–3.9)	**0.81** (0.26–0.94)	**2.7** (1.9–3.3)
TBW	**0.87** (0.41–0.97)	**2.3** (0.9–3.8)	**0.77** (0.53–0.94)	**2.1** (0.8–3.4)
ECW	**0.78** (0.39–0.92)	**1.6** (0.9–2.2)	**0.76** (0.54–0.89)	**1.5** (0.7–2.4)
ICW	**0.73** (0.20–0.93)	**1.8** (0.9–3.5)	**0.51** (0.32–0.77)	**1.7** (1.4–1.9)

Data are reported as mean values (bold) and ranges (in brackets). Estimates are based on validation studies since 1990 as reported by Kyle et al. (2004a, b) and cover a variety of instruments of bioimpedance models, including single- and multi-frequency BIA, BIS, and Hanai modeling. Data for healthy subjects include children and the elderly between 12 and 94 years as well as studies where hydration was altered. Data for 'Disease' cohorts include a broad range of disease, including cancer, COPD, HIV, cirrhosis, congestive heart failure, hemodialysis patients, and different surgical patients
R^2 coefficient of determination; *SEE* standard error of the estimate

ficient for TBW by the generally assumed hydration constant of 0.73, yielded a value expected that from the slope of the FFM equations (0.82 for FFM equation vs. 0.89 for expected regression coefficient). Reported precision in terms of prediction errors expressed as SEE usually range between 0.8 and 3.8 L for TBW, 0.7–2.4 L for ECW, 0.9–1.9 L for ICW, 1.6–3.9 kg for FFM, 1.71–1.73 kg for BCM, and 1.9–5% for %FM. Accuracy expressed as total error (TE) combining SEE with the residuals observed in cross-validation samples are similar, ranging between 1.59 and 4.79 kg for FFM and 0.23–3.3 L for TBW. The small differences between SEE and TE further substantiate the validity of BIA models. However, in spite of the similarity of regression equations solely based on l^2/Z (l^2/R) in healthy subjects, the diversity of published prediction equations during disease and states in which the fluid compartments are altered highlight the importance of choosing appropriate equations for individual subjects. Optimal accuracy will only be achieved for a given subject if the employed prediction equation was validated for subjects comparable to the subject being assessed.

A confounding difficulty of all validation studies is that the so-called gold-standards used as a reference are not error-free, and therefore restrict the degree of precision and accuracy that can be achieved.

According to Houtkooper et al. (1996) prediction error (SEE) for FFM of 2.0–2.5 kg in men and 1.5–1.8 kg in women is considered as ideal with an actual error of up to 1.8 kg. Hence, precision increases if the dependent variable is determined by a multi-compartment model.

Recently, the feasibility of BIA to determine FFM and TBW was confirmed in a representative multicenter study (Sun et al. 2003). The total sample consisted of 1,829 ethnically diverse men and women, who were split into a validation (n = 1,304) and cross-validation sample (n = 525). Whereas TBW was measured by deuterium dilution, FFM was obtained from a four-compartment model. SEE was 3.6 and 2.6 L for TBW and 3.7 and 2.8 kg for FFM for men and women, respectively. TE slightly increased to 4.2 and 3.2 L for TBW and 4.5 and 3.4 kg for FFM for men and women, respectively. These data are summarized in Table 23.2.

Considering the size and characteristic of some of the samples underlying these validation studies (e.g., n = 1,829 ethnically diverse men and women in Sun et al. 2003), the results can be considered as excellent and confirm the potential of bioimpedance measurements in determining body composition as repeatedly reported in recent years (for review see Kyle et al. 2004a, b). Finally, it should be considered that a confounding difficulty of all validation studies is that the so-called gold standards used as a reference are not error-free, and therefore restrict the degree of precision and accuracy that can be achieved. In a recent review Armstrong reports the accuracy of

TBW by isotope dilution to be within 1% and 5%. For the Reference Man this corresponds to an absolute error of 0.42–2.1 L. Thus, the criterion method also contributes to the error observed for the new method. According to Lohman (1992) this contribution ranges between 20% and 50% as long as accuracy and precision of the reference method exceed 1%, respectively. Thus, the actual errors reported for BIS applications might actually be much smaller. Consequently, in comparison to isotope dilution the accuracy of 0.23–3.3 L for TBW based on bioimpedance measurements can be considered as very good, if not excellent.

Finally, precision needs to be taken into account to assess the usefulness of a technique. Dilution techniques have a precision of 1–4%, depending on the analytical method employed (Schoeller 2005). It is, however, not clear whether those values also include subject preparation and tracer administration or refer to repeated sample collection and analysis only. Even considering ideal conditions with a precision of 1.5% for TBW and ECW, respectively, the error for ICW will be as large as 2.5% as the errors are propagated if ICW is calculated from the difference of TBW and ECW (Schoeller 2005). In contrast, under ideal conditions the variation for repeated measurements of bioimpedance during a single testing session has been reported to be lower than 1% (Elsen et al. 1987; Turner and Bouffard 1998). While the intraindividual variability obviously increases over days or weeks to about 1–4% (see Chap. 3), a corresponding inflation of errors due to biological variation is expected for dilution techniques or any other body composition method. Accordingly, though any systematic bias might confound absolute estimations of body composition by bioimpedance techniques, they might well be sensitive to detecting small changes in body composition, and particularly fluid volumes. Consequently, at least under standardized conditions the technology might be most useful for determining changes in fluid volumes and body composition.

23.6.3 Final Notes

It should be noted though that the validity of bioimpedance rises and falls with the quality control of its performance. Its main advantages such as accessibility, non-invasiveness, low costs, and ease of operation might sometimes mask the complexity underlying the measurement. Each measurement should therefore precisely follow standardization procedures in accordance with ESPEN guidelines (Kyle et al. 2004b). Awareness for these aspects is promoted by a basic understanding of the raw data obtained from bioimpedance measurements and the biophysical model underlying BIA (see also Chap. 3). Furthermore, valid results will only be obtained if the bioimpedance models (i.e. regression equations or Hanai parameters) are carefully chosen in accordance with the subjects under study. In healthy subjects this minimally implies consideration of gender, age, and race, but might include factors such as physical activity levels or degree of obesity. Additionally, in the clinical setting, the type of disease might also be taken into consideration by the choice of specific regression equations. Cautious interpretation is even more important when hydration and/or electrolyte balance is altered. This particularly pertains to subjects in which body composition and/or body shape are at the extremes such as in highly obese people or in subjects with abnormal limb length to height ratios. Presently, bioimpedance measurements cannot be recommended in these situations. Further validation studies will show whether specific regression equations are needed for these conditions. The general concept of an explanatory biophysical model using Hanai's mixture theory is certainly promising and needs to be further investigated. It would be clearly extremely valuable to develop a universal model that can be applied for a range of populations, hydration states, and clinical conditions. Future research will show if, and to what extent, mixture theory can reveal the true underlying potential of bioimpedance applications.

Summary Points

- Technological advances and the commercial availability of instruments have promoted the use of bioimpedance measurements in various clinical and research settings. Applications include the determination of whole-body hydration and body composition, abdominal fat, predicting survival in human immunodeficiency virus-infected patients, monitoring muscular activity during exercise, and the assessment of neuromuscular disease.
- BIA is presently one of the most widely used techniques for determining body composition.
- Most BIA instruments perform measurements at a single frequency of 50 kHz. As only a portion of the intracellular space is penetrated at this frequency, any body composition estimations of this approach are based on a constant ECW to ICW ratio.
- Multi-frequency (at least one high and one low frequency) as well bioimpedance spectroscopy (BIS), i.e. the measurement of up to 500 frequencies, and the subsequent extrapolation of resistance at zero and infinite frequencies have been proposed to overcome the drawbacks associated with single-frequency measurements and to differentiate TBW, ECW, and ICW.
- Due to substantial differences between the resistivity of ICW and ECW, BIS has been extended by the use of Hanai's mixture theory. This approach determines the resistances of ICW and ECW separately, and employs fluid compartment specific resistivities to obtain estimates of ICW and ECW.
- Further advantage of the Hanai approach is that it is based on an explanatory, biophysical model compared to purely statistically derived descriptive models relying on multiple regression analysis.
- Given the complexity of assumptions underlying all bioimpedance techniques, models, and their concomitant error sources, a clear superiority of a single technique remains to be established.
- BIA/BIS should only be performed under highly standardized conditions. In addition, regression equations or respective model parameters need to be carefully chosen with regard to the physiologic characteristics of the subject under study.
- If hydration and/or electrolyte balance is altered, results need to be interpreted with caution. This pertains particularly to the highly obese populations as well as subjects with abnormal body shapes and/or abnormal limb length to height ratios. Currently, the use of BIA/BIS under these conditions cannot be recommended in the clinical setting.

Chapter 24
Physiological Basis of Regression Relationship Between Body Mass Index (BMI) and Body Fat Fraction

David G. Levitt, Dympna Gallagher, and Steven B. Heymsfield

Abstract The body mass index (BMI) is the standard parameter for predicting body fat fraction (fat weight/total weight) and for classifying degrees of obesity. A large number of regression relations have been derived for predicting fat fraction from BMI. These regressions usually include age, sex and ethnicity. Most of these regressions are based on standard linear or non-linear fits. A recent approach is described in which the regression equation is derived from a physiological model of body composition. This model assumes that obese subjects can be represented by the sum of a standard lean reference subject plus an extra weight that has a constant adipose, bone and muscle fraction.

The optimal regression parameters are derived by fitting the equations to a large data set of three compartment (density and total body water) measurements of body fat. The data were collected at the New York Obesity Research Center, Body Composition Unit as part of ongoing studies. A total of 1,356 subjects were included, with a *BMI* range of 17–50 kg/m^2 for males and 17–65 for females.

There are large age and sex dependences of the regression relations. No significant difference was found for Caucasians, Blacks and Hispanics (excluding Puerto Ricans). Asians and Puerto Ricans have significantly different regressions. For the highly obese subjects (*BMI* > 45 kg/m^2), the non-linear physiological regression provides a significantly better prediction of fat fraction than the standard linear regression.

Abbreviations

BMC	Bone mineral mass
BMI	Body mass index
2C, 3C, and 4C	2-, 3-, and 4-compartment model of fat measurement
DXA	Dual energy X-ray absorptiometry
MSR	Mean square residual error
TBW	Total Body water

24.1 Introduction

The body mass index (BMI), defined as weight (kg)/height $(m)^2$, is the closest universal indicator of body fat in the social sciences (Burkhauser and Cawley 2008). Although the limitations of BMI as a predictor of body fat are well recognized (Prentice and Jebb 2001; Garn et al. 1986), BMI has become widely accepted because of its simple dependence on commonly measured parameters. A large number of regression relations relating body fat fraction (fat weight/total weight, dimensionless) to BMI has been published (see Table 24.9 for a partial listing). Although the accuracy of the prediction is clearly improved by adding other measurements to the regression relation (e.g., skinfold thickness (Goel et al. 2008)), this review will be limited to a discussion of the dependence of the body fat fraction on the standard parameters, namely BMI, age, sex, and ethnicity. In addition, only the adult regression relations (≥18 years) will be considered (Table 24.1).

24.2 Physiological Models of Body Composition

Until recently, these regression relations were regarded simply as mathematical fits to the data (either linear or non-linear). However, if one wants to extend the regression to the highly obese (i.e., $BMI > 45$), it is important to use an expression that has the correct physiological relationship between BMI and body fat. Another advantage of using a physiological regression relation is that it becomes possible to interpret the regression parameters in terms of body composition, and to analyze the assumptions in the model.

In a recently described physiological model (Levitt et al. 2009), it has been assumed that the total body weight is equal to the sum of the standard lean reference subject (W_0) and the additional weight (W_1) of the obese subject, with each component, respectively, having fat weight F_0 and F_1, with fat fractions f_0 and f_1:

$$W = W_0 + W_1 = \frac{F_0}{f_0} + \frac{F_1}{f_1} \tag{24.1}$$

The additional weight W_1 includes the extra adipose tissue plus the additional muscle and bone, etc., that is required to support this extra adipose tissue. Assuming that W_0 scales as the square of the height ($W_0 = bH^2$), using $BMI = W/H^2$ and defining $BMI_0 = W_0/H^2$, (24.1) is solved for the total body fat fraction:

$$\begin{aligned} F = F_0 + F_1 = f_0 W_0 + f_1 W_1 = f_1 W + W_0 \left(f_0 - f_1\right) \rightarrow \\ \text{Fat Fraction}\left(BMI\right) = \frac{F}{W} = f_1 + \left(f_0 - f_1\right)\frac{BMI_0}{BMI} \end{aligned} \tag{24.2}$$

Table 24.1 Key features of Body Mass Index (BMI) regression equations

1. The *BMI* is defined as weight(kg)/height $(m)^2$
2. The regression equation predicts the body fat fraction given the subject's *BMI*, age, and ethnicity
3. A regression is derived based on a physiological model of body composition. This non-linear equation provides predictions of fat fraction at high *BMI* that are more accurate than the standard linear regressions
4. The *BMI* regression relations provide predictions of fat fraction that are within about ± 0.05 of the true value. The predicted fat fraction significantly overestimates the true fat fraction for subjects with very low fat fractions

This table lists the important features of the BMI, including how it is defined, its physiological basis, and its validity

Two different regression models will be considered. For Model I, it is assumed that the standard reference state is the zero-fat condition ($f_0 = 0$):

$$\text{Fat Fraction I}(BMI) = f_1 - f_1 \frac{BMI_0}{BMI} \tag{24.3}$$

For Model II, it will be assumed that lean subjects, who have a *BMI* less than the standard lean reference value of BMI_0, have a constant fat fraction of f_0:

$$\text{Fat Fraction II}(BMI) = \begin{cases} f_1 + (BMI_0 / BMI)[f_0 - f_1] & BMI >= BMI_0 \\ f_0 & BMI < BMI_0 \end{cases} \tag{24.4}$$

The fat fraction for Model II (24.4) depends on three adjustable parameters: (1) BMI_0, the *BMI* of the lean reference subject; (2) f_0, the fat fraction of the lean reference subject; and (3) f_1, the fat fraction of the extra weight in obese subjects.

It can be seen from (24.3) and (24.4) that the fat fraction has a non-linear dependence on *BMI*, with the fat fraction asymptotically approaching f_1 as *BMI* tends to infinity. For simplicity, it will be assumed that the age dependence is linear, and the age-dependent regression will be included only for Model I:

$$\text{Fat Fraction I}(BMI, \text{Age}) = f_1 - f_1 \frac{BMI_0}{BMI} + c\ \text{Age} \tag{24.5}$$

The regression dependence on sex and ethnicity will be implemented simply by deriving separate regression parameter sets for different conditions. Finally, the non-linear relations will be compared with the commonly used linear regression:

$$Fat\,Fraction(BMI, Age) = a + b\,BMI + c\,Age \tag{24.6}$$

Both the linear (24.6) and non-linear (24.5) age-dependent regressions depend on the three adjustable parameters.

For comparison, these BMI regression relations will be compared with the regression, where height and weight are regarded as independent variables.

$$\text{Fat Fraction}(\text{Height}, \text{Weight}, \text{Age}) = a + b\text{Height} + c\ \text{Weight} + d\,\text{Age} \tag{24.7}$$

This regression has four adjustable parameters.

24.3 Measurement of Body Fat Fraction

In order to estimate the regression parameters, it is necessary to have accurate measurements of the fat fraction over a wide range of *BMI* and age. Although the most commonly used method is dual-energy X-ray absorptiometry (DXA), this approach cannot be used for the highly obese subjects ($BMI > 45$) because they are too large to fit the commonly available scanner tables. In addition, the DXA software has not been calibrated for highly obese subjects, and there is evidence that DXA underestimates the body fat in obese subjects (Das et al. 2003; Evans et al. 1999; Schoeller et al. 2005; Strauss et al. 2003; Valentine et al. 2008). Thus, DXA is not a suitable approach for calibrating the regression parameters for a *BMI* range that includes the highly obese.

Table 24.2 Age (years) and *BMI* (kg/m^2) distribution for subjects in different ethnic groups

Ethnic	Male/Female	N	Age range; ave. (SD)	*BMI* range; ave. (SD)
Caucasian	Male	234	18–97; 39.9 (18.3)	18.59–50.3; 25.6 (4.3)
	Female	355	18–90; 45.97 (18.0)	17.07–65.75; 25.05 (6.34)
Black	Male	124	20–86; 48.6 (17.0)	17.27–41.9; 26.2 (3.9)
	Female	233	18–88; 50.15 (17.5)	17.07–61.02; 29.04 (6.48)
Hispanic	Male	30	20–74; 37.5 (17.4)	20.08–47.9; 26.6 (5.4)
	Female	57	20–87; 42.18 (16.8)	18.84–57.46; 27.31 (7.70)
Asian	Male	59	28–89; 53.3 (18.1)	17.79–30.25; 23.9 (3.0)
	Female	61	26–88; 54.26 (17.5)	17.18–28.44; 21.73 (2.83)
Puerto Rican	Male	105	20–79; 47.0 (14.9)	18.41–41.7; 27.3 (4.7)
	Female	98	20–85; 46.99 (15.5)	19.8–43.5; 28.48 (5.0)

The age, *BMI*, and sex distribution of the subjects used for most of the analysis discussed here

The gold standard method is the 4-compartment (4C) approach, which uses DXA to measure bone mineral content (BMC) along with measurements of body density by underwater-weighing- or air-displacement plethysmography and of total body water (TBW) by isotope dilution. Because of the stated limitations with DXA, BMC cannot be measured and one is limited to using the 3C model (Siri 1993). This requires an assumption for the value of D_{res}, the average density of the sum of the protein, glycogen, and the bone and soft-tissue minerals (determined from 4C measurements on normal weight subjects) (Silva et al. 2005). Because one cannot make 4C measurements on obese subjects, there is no information about the value of D_{res} here, and, by necessity, it is assumed in the 3C method that D_{res} is constant, independent of the fat fraction. Other studies have used 2C approaches based on either body density or TBW. These measurements are obviously somewhat less reliable than the 3C methods.

In this review, much of our focus will be on regression relations derived from fitting the 3C fat fraction measurements determined from ongoing clinical studies at the New York Obesity Research Center at St. Luke's-Roosevelt Hospital, New York (Levitt et al. 2009). This is the largest single set of 3C measurements over the widest *BMI* range currently available. The subjects were all ambulatory adults, age 18 years or over, without any clinically significant diagnosed medical conditions. A total of 1,356 subjects were included, with a *BMI* range of 17–50 kg/m^2 for males and 17–65 kg/m^2 for females. Table 24.2 summarizes the age and BMI distribution for the different ethnic groups. This is the same data set that was used in a recent publication (Levitt et al. 2009). That publication provides the details of the fat measurement methodologies and the statistical analysis. Recently, Mills et al. (2007) presented a detailed statistical analysis of the body fat–BMI relationships for a data set that includes much of the data used here.

24.4 Sex, Age, and Ethnic Dependence of BMI Versus Body Fat Fraction

Although numerous studies have clearly demonstrated the age, sex, and ethnic dependence of the relation between body fat fraction and *BMI*, the commonly used BMI calculators freely available on the Internet usually ignore this dependence. Although regression relations that directly include age will be derived below, the importance of this dependence can be more clearly seen by grouping the subjects into fixed age and BMI groups.

Tables 24.3 (males) and 24.4 (females) show the dependence of fat fraction on age for two or three different *BMI* ranges for Caucasians. The subjects in the different age brackets have been grouped so that they have nearly identical average *BMI* values and, thus, differences in fat fraction between the

Table 24.3 Caucasian males: dependence of fat fraction on age (years) for two *BMI* ranges

BMI range	Ave. age (year) (SD)	Age range	Ave. BMI	Ave. Fat Fraction	N
18–24	21.86 (2.44)	18–25	22.19 (1.08)	0.1193 (0.046)	29
	29.94 (2.36)	26–33	22.12 (1.34)	0.134 (0.048) (NS)	32
	52.83 (19.42)	34–84	22.39 (1.31)	0.173 (0.057) ($p < 0.01$)	30
24–44	25.94 (2.66)	21–30	27.64 (4.00)	0.188 (0.084)	47
	38.17 (5.07)	31–48	27.42 (3.96)	0.211 (0.072) (NS)	48

Asian	35	20–52 (36.6)	20–30 (23.97)	0.212 (0.069) ($p < 0.01$)

Fat fraction for males of different ethnic groups with similar age and BMI

groups is a direct measure of age dependence. For males, age dependence is dramatic and nearly linear, with the subjects in the oldest age group having about 50% more fat that those in the youngest with the same *BMI*. For females, the age dependence is not quite as large and is more complicated (non-linear). For subjects in the two lower *BMI* ranges, there is a roughly linear increase in fat fraction with age, with the oldest subjects having about 35% more fat than the youngest with the same *BMI*. However, there is no significant age dependence of the fat fraction for obese females in the highest *BMI* range (26–56). The sex dependence of the fat fraction is obvious from comparing Tables 24.3 and 24.4, with the fat fraction in females nearly 0.1 greater than men for the same value of *BMI*.

Tables 24.5 (males) and 24.6 (females) describe the ethnic dependence of the fat fraction for Caucasians, Blacks, Hispanics (not including Puerto Ricans), Puerto Ricans, and Asians. The age

Table 24.6 Ethnic dependence of BMI versus fat fraction for females as a function of age (years) and *BMI* (the *p* value refers to comparison to Caucasians)

	N	Age range (ave.)	*BMI* range (ave.)	Ave. fat fraction (SD)
Caucasian	129	20–57 (37.4)	22–34 (25.42)	0.321 (0.071)
Black	95	20–52 (37.8)	20–34 (26.57)	0.328 (0.074) (NS)
Hispanic	37	20–60 (36.1)	20–34 (25.40)	0.311 (0.09) (NS)
Puerto Rican	41	20–52 (35.7)	20–30 (26.18)	0.348 (0.058) ($p < 0.05$)
Caucasian	153	23–53 (35.41)	17–25 (21.72)	0.257 (0.061)
Asian	35	23–53 (36.7)	17–28 (21.25)	0.282 (0.066) ($p = 0.07$)

Fat fraction for females of different ethnic groups with similar age and *BMI*

and *BMI* ranges of the different ethnic groups have been selected so that the average age and *BMI* are similar to that for Caucasians and, thus, any difference in fat fraction is an indication of ethnic dependence. There is no significant difference among Caucasians, Blacks, and Hispanics and, in the following analysis, these subjects will be grouped together. This differs from some other studies that have found significant differences between Blacks and Caucasians (Ortiz et al. 1992; Schutte et al. 1984; Gallagher et al. 2000a; Deurenberg et al. 1998). There is a clear difference between Asians and Caucasians, with Asians having a fat fraction that is about 0.03 greater than Caucasians with the same average *BMI* and age. This is a consistent observation for Asians (Gallagher et al. 2000a; Deurenberg et al. 1998). This study group (Table 24.2). had a large Puerto Rican population that was distinguished from other Hispanics, and Puerto Ricans have a significantly different *BMI* versus fat fraction relation, with an average fat fraction about 0.025 greater than Caucasians with the same average age and *BMI*.

24.5 Comparison of Age-Independent Linear and Non-linear Regressions

Three different forms of the relationship between fat fraction and *BMI* are described above: the standard linear regression and the two non-linear regressions (Model I, (24.3) and Model II, (24.4)). Figures 24.1 (males) and 24.2 (females) compare these three regression relations for Caucasians, Blacks, and Hispanics (all ages). The scatter plot of the experimental fat fraction around the value predicted by the regression relation provides a graphic indication of the quality of the regression relation. The large scatter seen in Figs. 24.1 and 24.2 partially results from the fact that all ages are included in this plot. As seen in Figs. 24.3 and 24.4, if the age range is limited, the scatter is significantly reduced. A quantitative measure of the scatter is provided by the mean square residual error (MSR), which is defined as the sum $(X_{\text{model}} - X_{\text{exp}})^2/N$, where X_{model} and X_{exp} are the predicted and experimental fat fraction, respectively. The square root of MSR provides an estimate of the average error. Table 24.7 lists the values of the regression parameters and MSR for the three regression relations for the different age ranges.

For males, the simple linear regression provides a good fit to the data, and no significant improvement in the fit (i.e., decrease in MSR) is provided by the non-linear models (see Figs. 24.1 and 24.3 and Table 24.7). For females, where some have a *BMI* as high as 65 kg/m^2, the non-linear regression clearly provides a better fit than the linear regression for the highly obese (Figs. 24.2 and 24.4), with MSRs for the non-linear Models I and II, which are about 25% less than for the linear regression. For females, there is no significant difference in MSR between Models I and II.

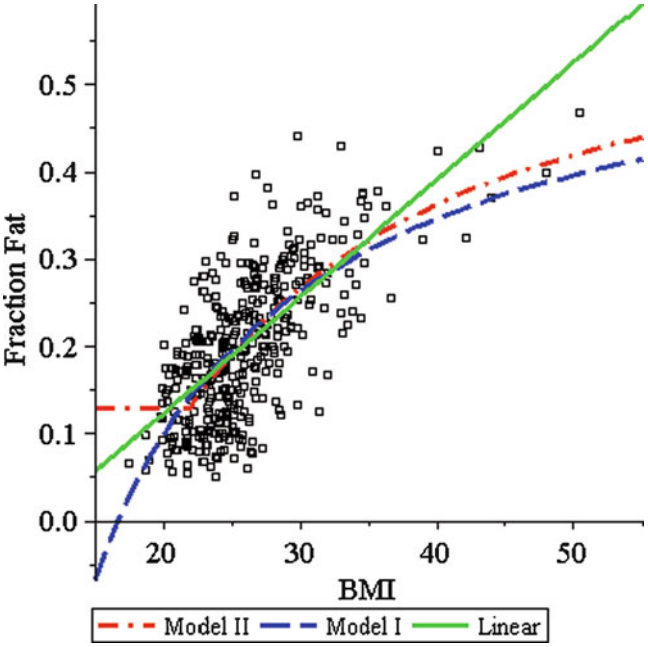

Fig. 24.1 Plot of the fat fraction as a function of *BMI* for Caucasian, Black, and Hispanic males of ages 18–89 years. The least-square fits to the data of the linear and the non-linear Models I and II are shown. The three lines show the fat fraction as a function of *BMI* predicted by the different regression relations for males. There is no significant difference in the accuracy of the different predictions

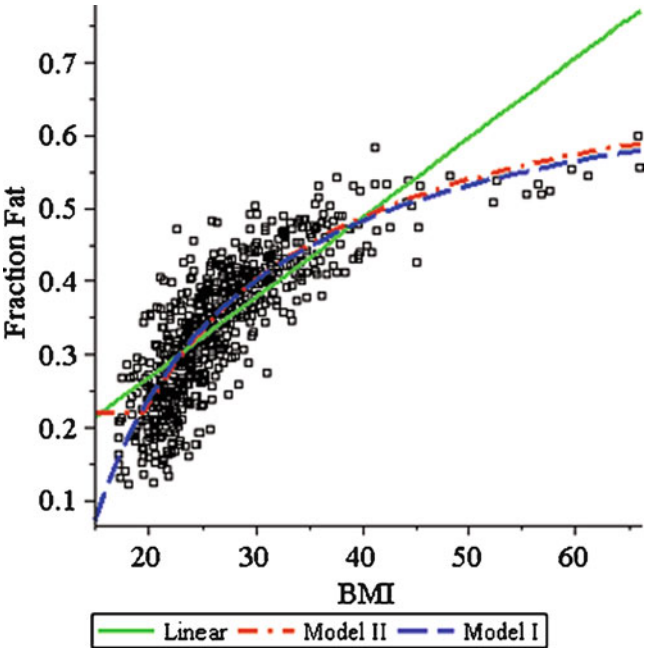

Fig. 24.2 Plot of the fat fraction as a function of *BMI* for Caucasian, Black, and Hispanic females of ages 18–90 years. The least-square fits to the data of the linear and the non-linear Models I and II are shown. The three lines show the faction fat as a function of *BMI* predicted by the different regression relations for females. The non-linear regressions (Models I and II) provide significantly better predictions, especially for the highly obese females

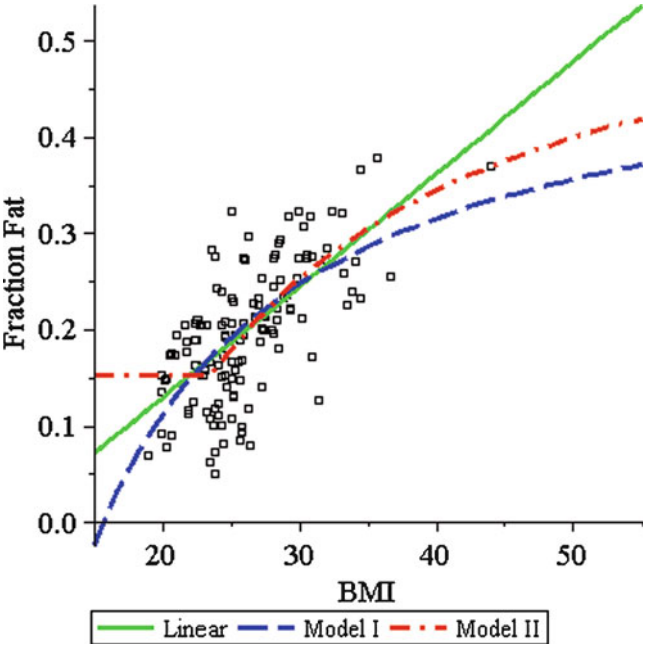

Fig. 24.3 Plot of the fat fraction as a function of *BMI* for Caucasian, Black, and Hispanic males of ages 32–50 years. The least-square fits to the data of the linear and the non-linear Models I and II are shown. This plot is similar to that of Fig. 24.1 except that only subjects in the age range 32–50 years are included

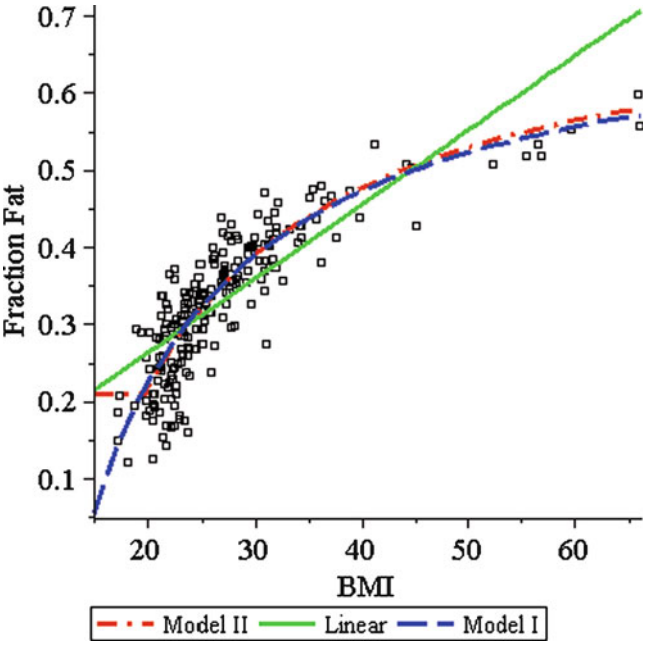

Fig. 24.4 Plot of the fat fraction as a function of *BMI* for Caucasian, Black, and Hispanic females of ages 32–50 years. The least-square fits to the data of the linear and the non-linear Models I and II are shown. This plot is similar to that of Fig. 24.2 except that only subjects in the age range 32–50 years are included

24.6 Comparison of Age-Dependent Linear and Non-linear Regressions

One approach for including age dependence in the regression is to use small age intervals and derive different sets of regression parameters for each interval (as was done in Table 24.7). However, this is complicated and it is simpler to directly include the age in the regression. Ideally, one would like to include age in a way that is based on the effects of age on the basic physiological model described

Table 24.7 Regression parameters and mean square residual error (MSR) for Caucasian, Black, and Hispanic subjects

Parameters for the linear and non-linear regression relations for the entire subject base (all ages), with and without and a linear age-dependent term

above. However, due to lack of such information, age is usually added as a linear term in the regression (see (24.5) and (24.6)). This is clearly an approximation because, as described above, the effect of age in females is non-linear (see Table 24.4).

Two different age-dependent regressions are considered: the standard linear (24.6) and the non-linear Model I (24.5). Table 24.8 summarizes the results of fitting these two equations to the New York Obesity Research Center data set (Levitt et al. 2009). The regression relations with and without the addition of the linear age term are listed. The ethnic dependence of the regression is incorporated by deriving separate sets of regression coefficients for each of the ethnic groups that differed significantly from Caucasians (see Tables 24.5 and 24.6).

Adding age dependence clearly improves the prediction of the regression relation, decreasing MSR by about 25%. The differences between the MSR for the linear and non-linear regressions are small. For males, the linear regression is slightly better, whereas for females with their larger *BMI* range, the non-linear regression is significantly better (e.g., an MSR of 0.00222 for non-linear vs 0.0026 for the linear regression). Also, the MSR when Caucasians, Blacks, and Hispanics are grouped is no worse than when the Caucasian regression is used separately, supporting the above conclusion that there is no significant difference among these three ethnic groups.

MSR provides a quantitative measure of the accuracy of the prediction of fat fraction from the regression relation, with the square root of the MSR being an approximate measure of the error in the prediction. For example, for female Caucasians, Blacks, and Hispanics, the square root of the MSR for the non-linear regression is 0.047 (units of fat fraction, dimensionless). That is, the error in the predicted fat fraction is 0.047 for the entire age and *BMI* range. Another way to visualize this error is as a scatter plot of the values of error in the predicted fat fraction. Figures 24.5 (males) and 24.6 (females) show plots of this error for the linear (24.6) and non-linear (24.5) regression as a function of the subject's BMI for Caucasian, Black, and Hispanic subjects. For males (Fig. 24.5), there is a small tendency for the predicted fat fraction at high *BMI* to be overestimated by the linear regression and underestimated by the non-linear regression. For females (Fig. 24.6), the linear regression dramatically overestimates the fat fraction at high *BMI* (>40), whereas there is no significant correlation of the error with *BMI* for the non-linear regression. Figures 24.7 (males) and 24.8 (females) show similar plots of the error as a function of the subject's true (experimental) fat fraction. For males, there is an obvious correlation of the error with fat fraction, with the predicted fat fraction overestimating the true experimental value at low fat fractions and underestimating it at high fat fractions. For females, the linear regression again overestimates the fat fraction at low fat values, whereas at high fat values, there are very large positive and negative errors. There is clearly less systematic error in the non-linear regression predictions for females.

Although the main focus of this review is *BMI* regression relations, the results for *BMI* in Table 24.8 were compared with the linear regression in which height, weight, and age were regarded as independent parameters (24.7). For Caucasian, Black, and Hispanic males, the MSR for this four-parameter regression was 0.00270, identical to that for the three-parameter *BMI* linear regression (24.6). For Caucasian, Black, and Hispanic females, the MSR for this four-parameter regression was 0.00260, identical to that for the three-parameter *BMI* linear regression and not as good as the non-linear three-parameter *BMI* regression (24.5). It is surprising that the addition of another independent parameter does not improve the prediction. This comparison provides additional support for the validity of the *BMI* as an indicator of fat fraction.

24.7 Accuracy of the *BMI* Regression Predictions of Fat Fraction

The accuracy of the prediction of body fat fraction from the *BMI* is graphically illustrated in Figs. 24.5–24.8, which show the scatter plots of the age-dependent regression error in fat fraction as a function of either *BMI* (Figs. 24.5 and 24.6) or experimental fat fraction (Figs. 24.7 and 24.8). The overall average error in the fat fraction (estimated from the square root of the RMS, Table 24.8) is 0.052 for men and 0.047 for women. As shown in Figs. 24.7 and 24.8, there is a systematic bias in the *BMI* estimate of fat fraction, with the regression overestimating the fat fraction for subjects with very low fat fractions. This probably results, in part, from the very low fat fractions in athletes, who commonly have higher muscle mass fractions than the general population.

A basic assumption underlying the use of *BMI* is that weight scales as height^N, where $N = 2$. In 2005, a large, extensive review of the height versus weight relationship found an average value of N of 1.92 for males and 1.45 for females. A recent study (Heymsfield et al. 2007) looked at the scaling of weight, adipose mass, skeletal mass, etc., with height, and found that weight scaled as 1.94, whereas fat mass scaled as only 1.43. One factor that was not considered by these analyses is that, according to the physiological model described above, it is only W_0, the weight of the lean reference subject, and not the total weight, that is assumed to scale as height^2. As a test of this

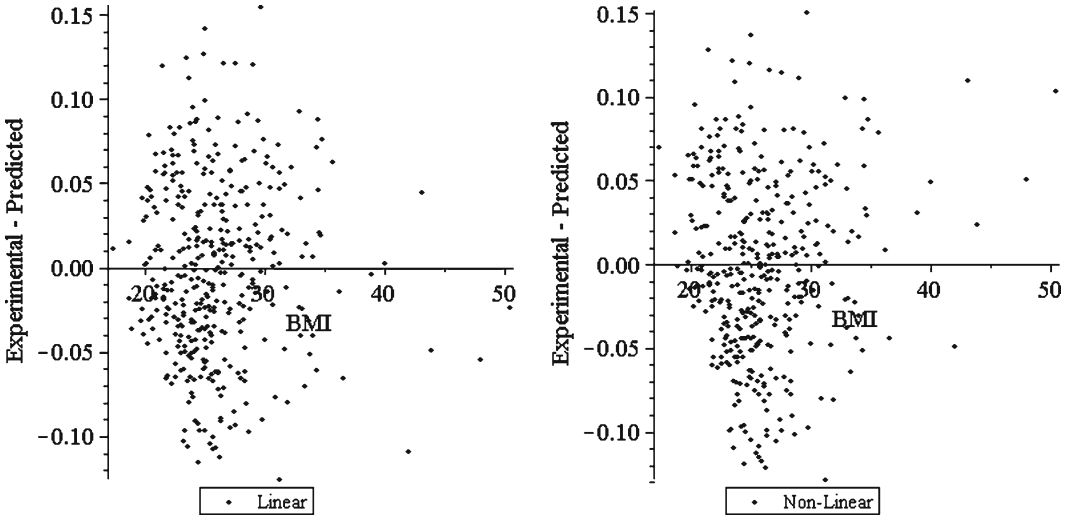

Fig. 24.5 Plot of the error in the fat fraction predicted from the age-dependent linear and non-linear regression equations (experimental vs predicted) as a function of *BMI* for Caucasian, Black, and Hispanic males. The scatter in the points represents the error in the fat fraction predicted by the linear (*left*) and non-linear (*right*) regression as a function of the subjects' *BMI*

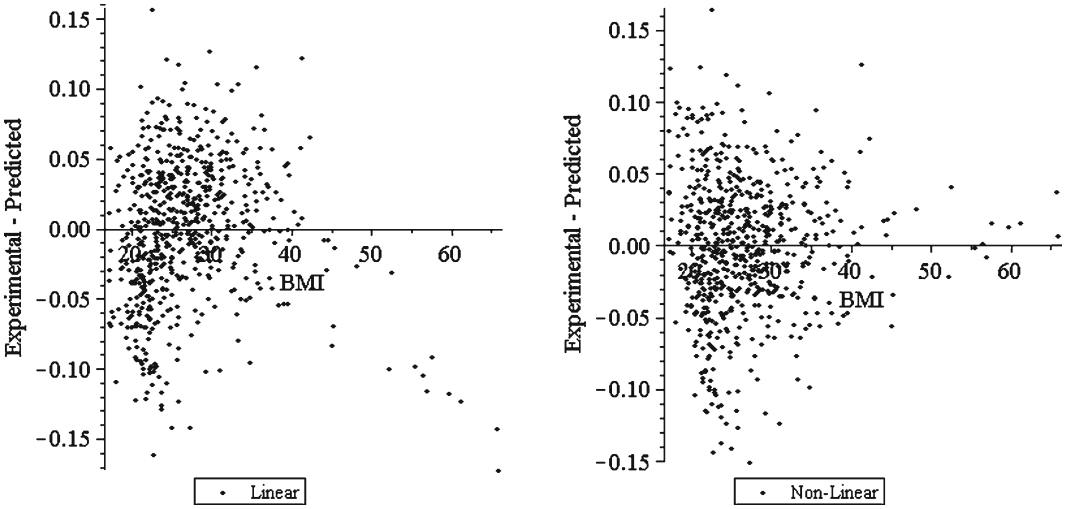

Fig. 24.6 Plot of the error in the fat fraction predicted from the age-dependent linear and non-linear regression equations (experimental vs. predicted) as a function of *BMI* for Caucasian, Black, and Hispanic females. The scatter in the points represents the error in the fat fraction predicted by the linear (*left*) and non-linear (*right*) regression as a function of the subjects' *BMI*

assumption, Fig. 24.9 shows a log–log plot of height versus weight for the lean males (fat fraction < 0.15) and females (fat fraction < 0.24) in the subject data set used in this analysis. This assumes that these subjects are representative of the hypothetical lean reference subject. For both males and females, the average value of N is close to 2 (1.96 for males and 1.95 for females), in support of this basic assumption.

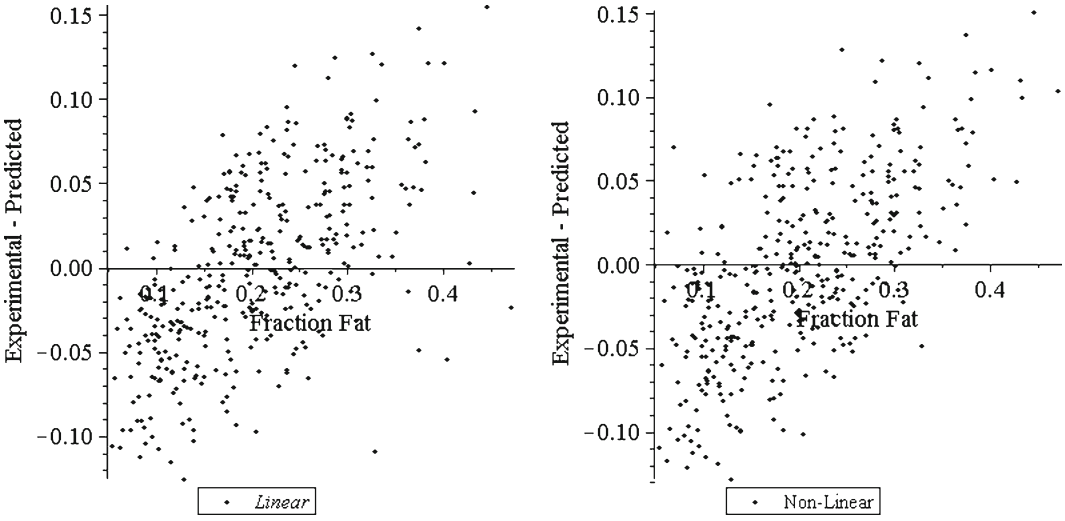

Fig. 24.7 Plot of the error in the fat fraction predicted from the age-dependent linear and non-linear regression equations (experimental vs. predicted) as a function of experimental fat fraction for Caucasian, Black, and Hispanic males. The scatter in the points represents the error in the fat fraction predicted by the linear (*left*) and non-linear (*right*) regression as a function of the subjects' fat fraction

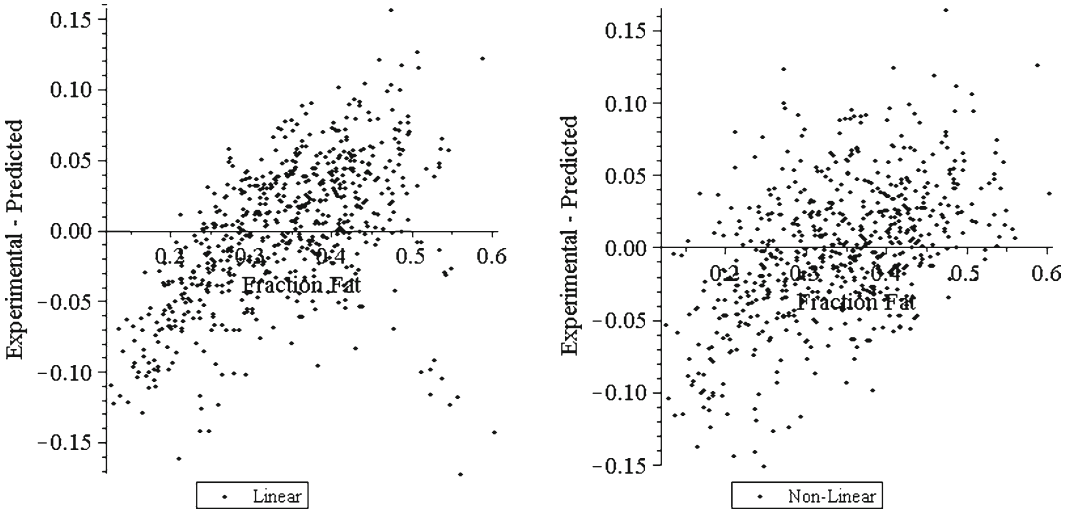

Fig. 24.8 Plot of the error in the fat fraction predicted from the age-dependent linear and non-linear regression equations (experimental vs. predicted) as a function of the experimental fat fraction for Caucasian, Black, and Hispanic females. Fig. 24.9 Log–log plot of height versus weight for lean Caucasian, Black, and Hispanic males (*top panel*) and females (*bottom panel*). The line is the least-squares linear fit. Test of the assumption in the non-linear model that weight scales as the square of the height of lean subjects

24.8 Summary of Recent Regression Relations

Table 24.9 lists some recent *BMI* regression relations and compares them with the regression results discussed here (Levitt et al. 2009). Two of these regressions (Gallagher et al. 2000a, 1996) are based on a subset of the data used in the present analysis. These regressions are plotted in Figs. 24.10 (males) and 24.11 (females), assuming an age of 40 years.

As can be seen in Figs. 24.10 and 24.11, for the *BMI* range of 25–35 kg/m^2, all the regressions are quite similar. The major differences occur when the regressions are extrapolated to very large *BMI* values, beyond the data range that was used to derive all the regressions except the one discussed here (Levitt et al. 2009; see Table 24.2). It is when applying these regressions to the very obese (up to *BMI* equal to 65 for females) that the non-linear form of the equation becomes important. For the two physiologically based relations derived here ((24.3) and (24.4), the fat fraction asymptotically approaches the fat fraction of the extra weight (f_1) as *BMI* approaches infinity. In contrast, for the linear regression, the fat fraction becomes greater than 1 at very high *BMI*, which is impossible. Both Jackson et al. (2002) and Larsson et al. (2006) use a non-linear regression formed by adding a term that varies as the square of the *BMI*. This arises simply from the standard curve fitting approach to non-linear data. This quadratic term is also non-physiological, as it predicts a decrease in fat fraction at large *BMI* values, as can be clearly seen in Fig. 24.11.

Table 24.9 Summary of recent *BMI* regression equations used to predict percent body fat for men and women. If the study found ethnic differences, only the Caucasian regression is listed

Reference	Regression equation		*BMI* range	Method
	Men (*N* subjects)	Women (*N* subjects)

Comparison of different regression relations recently used to predict fat fraction from *BMI* and age

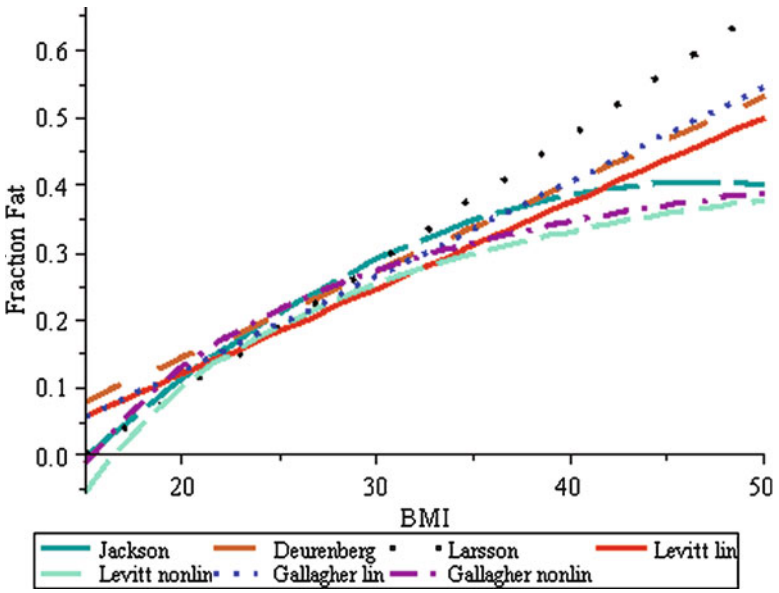

Fig. 24.10 Plot of the regression relations listed in Table 24.9 for men, age 40 years. Comparison of the different regression relations that have been recently proposed for predicting fat fraction from *BMI* for males

If the regression will be applied to the highly obese, then the non-linear form (24.3), (24.4) or (24.5) is clearly superior (this is the same form that was used by Gallagher et al. (2000a)). This is clearly seen in the data for females (Fig. 24.2), where the non-linear form diverges from the linear for $BMI > 45$ and the RMS of the non-linear relation is about 25% less than the linear for the entire female data set. For males (Fig. 24.1), the *BMI* does not reach high enough values in this data set to make the non-linear relation superior to the linear relation, with only two men having a $BMI > 43$.

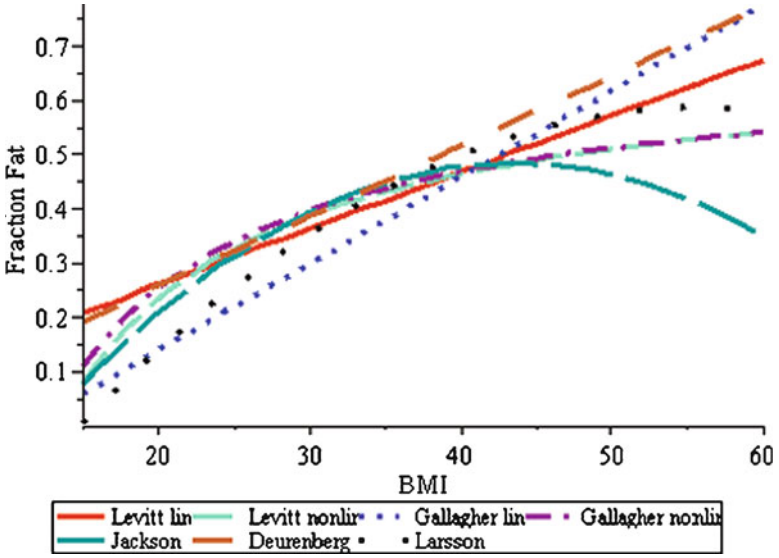

Fig. 24.11 Plot of the regression relations listed in Table 24.9 for women, age 40 years. Comparison of the different regression relations that have been recently proposed for predicting fat fraction from *BMI* for females

24.9 Applications to Other Areas of Health and Disease

An advantage of using a physiological model for BMI is that the regression parameters provide information about the body composition of both normal and highly obese subjects. The basic assumption used in the derivation of the physiological regression relations (24.3) and (24.4) is that, as a subject with a given height gains weight, the extra weight has a constant, fixed composition, with a fat fraction f_1. This is clearly an approximation because one would expect that, in severe obesity, as the subject becomes increasingly sedentary, there should be accompanying changes in both bone and muscle mass along with other pathological changes (Oppenheimer et al. 2006). However, the good fit of Model II for a *BMI* range of 17–65 (Fig. 24.2) suggests that this is an approximately valid supposition. For the two-parameter regression (Model I, (24.3)), the parameters correspond to BMI_0 (the *BMI* of the lean reference subject) and f_1 (the fat fraction of the extra weight). For the three-parameter regression (Model II, (24.4)), which is probably the most realistic, the parameters are BMI_0, f_1, and f_0 (the fat fraction of the lean reference subject). The values of these parameters for the different age ranges for men and women are listed in Table 24.7.

For males, the fat fraction of the lean reference subject is 0.129 and the fat fraction of the extra weight is 0.647. For females, the corresponding values are 0.22 and 0.745. Combining these results with body density measurements and some additional assumptions about body composition, one can estimate that the composition of the extra weight in men is 4.2% bone, 20% muscle, and 75.8% adipose, whereas in women it is 3.67% bone, 9.74% muscle, and 86.5% adipose (Levitt et al. 2009). This estimate of about 10% muscle in the extra weight for women is less than estimates of about 17%, based on direct MRI measurement of changes in muscle mass after dieting and weight loss (Gallagher et al. 2000b).

Summary Points

- The regression relation between body mass index (BMI) and fat fraction (fat weight/total weight) has a strong dependence on age. For males, subjects in the age range of 34–84 years have about 50% more fat than 18–25-year olds with the same *BMI*.
- The non-linear physiological regression relation should be used in place of the standard linear regression for highly obese subjects ($BMI > 45$ kg/m^2).
- The *BMI* regression relations provide predictions of fat fraction that are within about ±0.05 of the true value. The predicted fat fraction significantly overestimates the true fat fraction for subjects with very low fat fractions.
- For Caucasians, Blacks, and Hispanics, the following regression relations provide good estimates of fat fractions for a *BMI* range of 17–65 kg/m^2:

  Males: fat fraction = 0.496 – 9.29/*BMI* + 0.00172 age
  Females: fat fraction = 0.642 – 9.23/*BMI* + 0.00132 age

- Asians have a fat fraction that is about 0.03 greater than Caucasians for the same *BMI* and age and different regression equations should be used:

  Males: fat fraction = 0.438 – 6.885/*BMI* + 0.00169 age
  Females: fat fraction = 0.573 – 7.097/*BMI* + 0.00122 age

Chapter 25
Relationship Between Physical Measures of Anthropometry and Bioimpedance Measures

María Dolores Marrodán Serrano, Marisa González-Montero de Espinosa, and Estefanía Morales Zamorano

Abstract The purpose of this chapter is to compare the results of body composition obtained by anthropometry and by Bioelectrical Impedance Analysis (BIA). A brief review of the physical and biological bases of BIA is conducted and the main types of devices on the market are described. They are classified according to the range of frequencies (single or multiple frequencies) and the number of electrodes (bipolar, tetrapolar, octopolar). BIA equations for use in children and adults according to age and sex are offered and the statistical methods for checking agreement between the results obtained by BIA and by anthropometry. This point is illustrated with examples from two studies conducted by the authors. The first one corresponds to 106 young adults that were analyzed simultaneously by anthropometry, two BIA bipolar analyzers (OMRON BF-306 and LAICA EP1340) and one tetrapolar BIA analyzer (Holtain BC). The second example is based on a sample of 86 schoolchildren analyzed by anthropometry and a BIA tetrapolar device (Bodystat 1500).

The bipolar monitors, also called regional, produce results that depend on fat distribution in the individual. This means that results vary depending on fat location in the upper or lower segment of the body. In contrast, a tetrapolar analyzer offers values which are independent of the localization of fat deposits. The final result is a better match between fat percentage obtained by type scale BIA analyzer and anthropometry in females and between type hand BIA analyzer and anthropometry in males. Tetrapolar devices are more accurate in the paediatric age.

Abbreviations

BIA	Bioelectrical impedance analysis.
DEXA	Dual-Energy X-Ray Absorptiometry
FFM	Fat free mass
FM	Fat mass
ICC	Intraclass correlation coefficient
TBW	Total body water

25.1 Introduction

One of the methods used to evaluate nutritional status is body composition analysis. Several models can be established according to the number of elements into which the total weight is divided. One of the simplest and classic models is the bicompartmental model, which describes the body as the sum of two factors, the fat mass and the lean body mass. More complex models distinguish five or six compartments (Heymsfield et al. 1996; Pietrobelli and Tato 2005).

This fragmentation is determined by several indirect procedures, but one of the most commonly used is the anthropometric technique. Depending on the number of components to be estimated, different variables such as lengths, diameters, circumferences, skinfold thickness, weight and height are used. These measures are implemented in a mathematical formula that usually changes depending on ethnicity, gender, and age (Bellisari et al. 2007).

Another method for the analysis of body composition, called BIA (bioelectrical impedance analysis), was subsequently added. This technique was developed around the middle of the twentieth century, when it was shown that changes in impedance were associated with changes in blood volume (Nyober et al. 1940). At this time, apparatuses to determine body composition began to be used. Among the first were devices with electrodes arranged in a bipolar fashion – left hand and right foot (Thomaset et al. 1963). Then, Hoffer et al. (1969) used four electrodes using one or several frequencies. Finally, in the 1980s, several instruments became available in the market. Currently available devices are simple to operate and cheap and easy to transport; through an integrated program, these instruments are used to calculate the different body fractions immediately.

Anthropometry and BIA are two different means for analyzing body composition, and it is necessary to know how closely the results are correlated, and to what extent they may be equated. This chapter aims to establish the agreement that exists between these two analytical methods, which are now in use for nutritional status assessment.

25.2 BIA: Physical and Biological Bases

Impedance (Z) is defined as the response with which a cylinder filled with liquid opposes the passage of an electric current. For a cylindrical conductor of length L and cross section S, to which a potential difference is applied between its ends – at a particular intensity – the impedance is given by the following expression:

$$Z(\Omega) = \rho(\Omega \cdot \mathrm{m}) L(\mathrm{m}) / S(\mathrm{m}^2)$$

The resistivity (ρ) is a constant of proportionality that depends on the shape and size of the electric conductor. From this formula, we can ascertain the cylinder volume based on the impedance:

$$V(\mathrm{m}^3) = \rho(\Omega \cdot \mathrm{m}) L^2(\mathrm{m}^2) / Z(\Omega)$$

The BIA technique was developed by considering the human body as an irregular cylindrical conductor. If the above expression is interpolated to the case of humans, we can calculate the individual total body water (TBW) as follows (Houtkooper et al. 1996):

$$\mathrm{TBW}(\mathrm{m}^3) = \rho(\Omega \cdot \mathrm{m}) \mathrm{Height}^2(\mathrm{m}^2) / Z(\Omega)$$

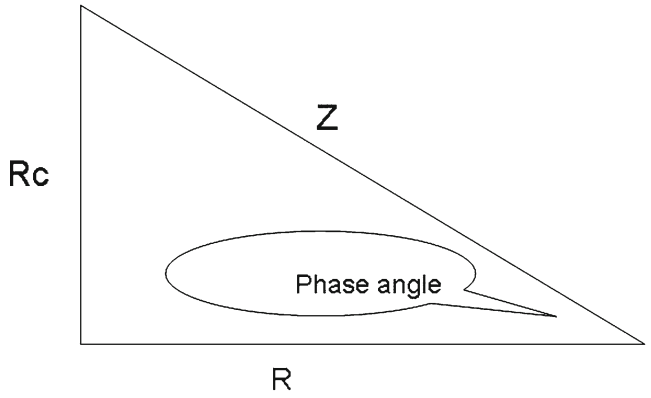

Fig. 25.1 Geometric relation among resistance (*R*), reactance (*Rc*), and the phase angle

The correlation between impedance (*Z*), resistance (*R*), and reactance (*Rc*) is observed in Fig. 25.1 (Brazier 1935). The reactance *Rc* varies with frequency. At very high or very low frequencies, Rc tends to zero and *Z* equals *R*. However, at intermediate frequencies,

$$Z = (R^2 + \mathrm{Rc}^2)^{1/2}$$

$$\text{Phase angle} = \operatorname{arctg}(\mathrm{Rc} / R)$$

The resistance *R* measures the opposition of biological materials to the flow of electric current and depends on both the physical nature and the section of the conductor. Consequently, if we accept that the human body consists of the sum of several cylinders connected in series, those that correspond to the extremities have a lower cross section than the trunk and, thus, the resistance will be higher in the former than in the latter.

Rc is determined either by the dielectric properties of tissues or by the temporary accumulation of charges on cell membranes, as the latter behave as capacitors. From an electrostatic viewpoint, this means that the lipid bilayer prevents the passage of alternating current. If frequency is high, the current will cause a change in polarity in membranes, pass through them, and flow through both the extra- and intracellular liquids. Conversely, if we apply a low-frequency current (50 kHz), it will only flow through the extracellular water and cannot go through cell walls.

25.3 Types of Body Composition Analyzers

We can apply two criteria of classification, which are interrelated: first, according to analyzers which operate at one or more frequencies and, second, according to the number of electrodes which are placed on the individual. The analyzers can be single frequency, for example when these use a single-frequency range (50 kHz). These were breakthrough devices but have the disadvantage that they are incapable of measuring intracellular water. However, analyzers that work with various frequencies (e.g., 50, 100, and 200 kHz) can measure the water both inside and outside cells.

Depending on the number of electrodes that are placed on the individual, analyzers can be bipolar (two electrodes), tetrapolar (four electrodes), and octopolar (eight electrodes). In the bipolar case,

there are two possibilities: one where both electrodes are placed on the so-called upper body and the device is held with both hands, and the other where electrodes are placed on the lower body, that is, on the feet (these are called scale type).

With tetrapolar analyzers, it is necessary to control electrode location and follow certain instructions (Lukaski et al. 1985; Callejo 2007). Thus, all electrodes should be placed on the right side, and of the two that are receptors, one is on the wrist (halfway between the ulnar and radial epiphysis) and the other is located on the ankle (between the medial and lateral malleolus). Similarly, transmitters are located 4 cm from receptor, in the direction of the phalanges.

The individual must be lying horizontally, with arms and legs open at angles of approximately 10–15°. Other factors, such as room temperature, the individual's hydration status, and the menstrual cycle phase, must also be controlled (Callejo 2007).

Octopolar analyzers use eight electrodes, two of which are placed on each foot and the other two are placed on each hand. This technique (often called segmental) also determines the body composition of each individual segment of the body, namely the trunk, the right arm, the left arm, the right leg, and the left leg.

25.4 BIA Equations

In the literature, multiple regression equations have been reported that vary depending on the characteristics of the population analyzed for age, sex, ethnicity, body mass index, etc., and the analyzer used. In these equations, *TBW* and *FFM* were calculated from the value of *Z* or *R* (*Rc* is usually ignored), although most use the resistance. Tables 25.1 and 25.2 show some of the equations recommended by Houtkooper et al. (1996) and Ellis (2000) to calculate, respectively, the TBW and the FFM. The devices used to develop these equations are tetrapolar (except in the work of Boulier et al. 1990, where bipolar device was used) and single frequency at 50 kHz. Also, many formulations have used the so-called impedance index (height^2/resistance (Ht^2/R)) discussed earlier. Table 25.3 contains some formulas recommended by Bray et al. (2001), especially for children.

From *TBW*, *FFM* is calculated using the Siri (1961) equation:

$$\text{TBW} = \text{FFM} \times 0.73$$

25.5 Statistical Methods to Establish the Agreement Between BIA and Anthropometry

Anthropometry and bioimpedance are analytical methods that are based on different fundamentals. Various methods, devices, and BIA equations have been explained previously. It is therefore necessary to ascertain whether the results obtained by using different techniques and devices can be equated.

Table 25.4 Direct measures and composition estimators obtained by anthropometry, bipolar BIA, and tetrapolar BIA in a sample of Spanish youngsters (Marrodán et al. 2007)

	Males			Females		
Variables	Mean	SD	Máx.–Mín.	Mean	SD	Máx.–Mín.
Age (years)	21.48	3.11	31–18	20.59	2.48	32–17
Weight (kg)	76.58	11.98	105.5–51.1	58.10	8.33	92.4–42.0

Fat Free Mass O (kg)	62.69	5.98	74.54–50.43	42.36	6.18	70.96–31.92
Fat Free Mass B (kg)	56.21	5.27	65.76–41.95	42.87	4.16	57.29–33.52

A Anthropometry; *H* Holtain; *O* Omron; *B* Scale

It is necessary to apply appropriate statistical tests to make this comparison. One of these is based on the intraclass correlation coefficient (*ICC*), calculated as follows:

$$\mathrm{ICC} = \left(\mathrm{SD}_{\mathrm{A}}^2 + \mathrm{SD}_{\mathrm{B}}^2 - \mathrm{SD}_{\mathrm{AB}}^2\right) / \left(\mathrm{SD}_{\mathrm{A}}^2 + \mathrm{SD}_{\mathrm{B}}^2 + \mathrm{X}_{\mathrm{AB}}^2 - \left(\mathrm{SD}_{\mathrm{AB}}^2 / n\right)\right)$$

In the above expression, SD_A, SD_B, and SD_{AB} are the standard deviations of the methods A (anthropometry), B (BIA), and the difference between both methods, respectively; X_{AB} is the mean of the differences between both methods and n the number of individuals. This coefficient has values between 0 and 1. It is considered that ICC higher than 0.75 indicates a close agreement between the two methods being compared, values between 0.4 and 0.75 indicate that the agreement is fair to good, and those less than 0.4 indicate the absence of concordance. Another method is the graphical model of Bland and Altman (1986) employed to visualize changes in the differences between the values obtained by anthropometry and BIA (*Y* axis), depending on the mean value obtained by applying both methods (*X* axis).

As an example, Table 25.4 shows the results of a comparative study in which the authors (Marrodán et al. 2007) analyzed, in 106 young adults, body composition by anthropometry and BIA. The equations used were those given by Durnin and Womersely (1974) for density and by Siri (1961) for fat percentage. Three BIA techniques were used: bipolar electrodes to the hands (OMRON BF-306 analyzer), bipolar electrodes to the feet (LAICA EP1340 analyzer), and tetrapolar BIA (Holtain BC analyzer).

In the male series, a greater fat percentage is obtained with all BIA analyzers than with anthropometry. The OMRON bipolar device and the tetrapolar device show very similar results. In the female series, the lowest mean value for fat percentage is obtained with tetrapolar BIA. Both bipolar devices show similar adiposity results and only slightly higher than those obtained by anthropometry.

Table 25.5 Intraclass correlation coefficient (ICC) for the percentage of fat obtained by anthropometry and the three techniques BIA (bipolar OMRON, bipolar scale LAIKA, and tetrapolar BODYSTAT)

	CCI males	CCI females
Anthropometry – Holtain	0.59	0.41
Anthropometry – Omron	0.73	0.54
Anthropometry – Scale	0.33	0.69

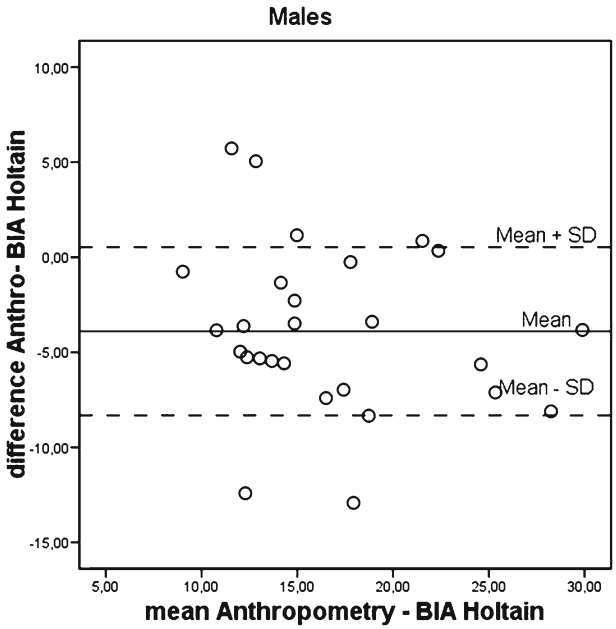

Fig. 25.2 Differences between anthropometry and BIA (Holtain) in males

Table 25.5 shows the intraclass correlation coefficients. The agreement between anthropometry and tetrapolar BIA was better in males. Comparing anthropometry and bipolar BIA, the correlation is higher with the hand analyzer OMRON in males, and with the scale type analyzer (LAIKA) in females. How can we explain these results? Bipolar monitors, also called regional monitors, produce results that depend on fat distribution on the subject analyzed. This means that these results vary, depending on whether the fat is situated on the upper or lower body. In contrast, the tetrapolar analyzer simultaneously evaluated both segments, producing values independent of the preferential location of fatty deposits. To clarify this, it must be borne in mind that, with age, men and women accumulate fat differently. Therefore, scales that take information from the electrodes placed on the feet better reflect the accumulation of fat in the legs, thighs, and buttocks of the female sex. The conclusion is a better match between the fat percentage obtained by BIA scales and the anthropometry in females. However, in males, where fat is deposited preferentially in the region of the thorax and abdomen, the results of fat percentage measured with the OMRON hand analyzer show better agreement compared to the anthropometric method.

The scatter plots resulting from using the Bland and Altman method show different trends according to sex and the BIA technique used. Figures 25.2–25.7 show that the general trend in differences between anthropometry and BIA is always negative for the male series. This means that the

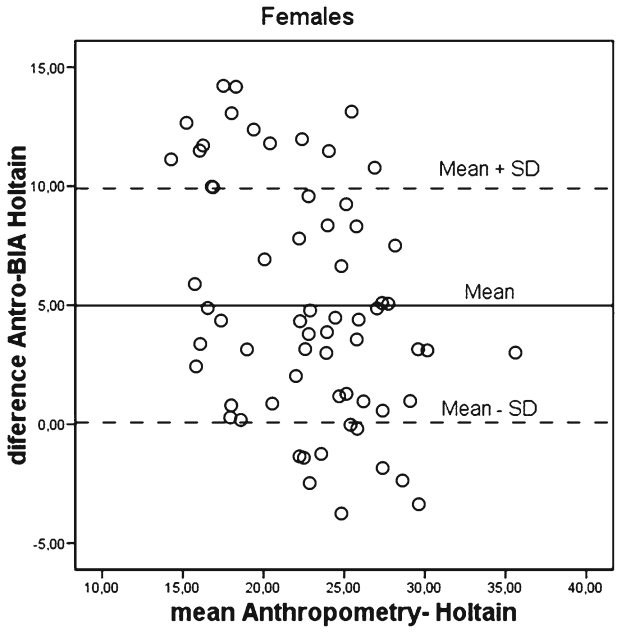

Fig. 25.3 Differences between anthropometry and BIA (Holtain) in females

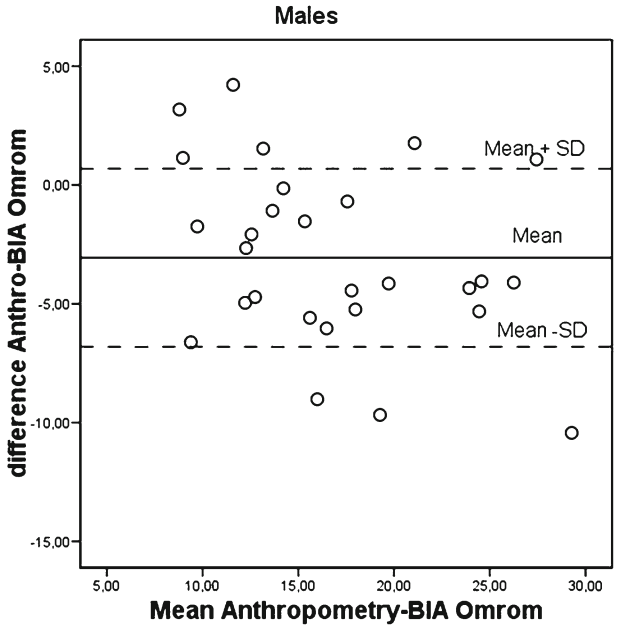

Fig. 25.4 Differences between anthropometry and BIA (OMRON) in males

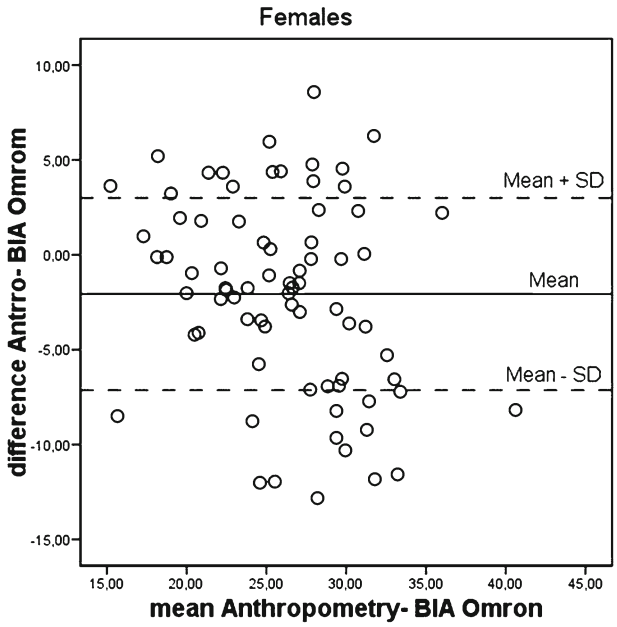

Fig. 25.5 Differences between anthropometry and BIA (OMRON) in females

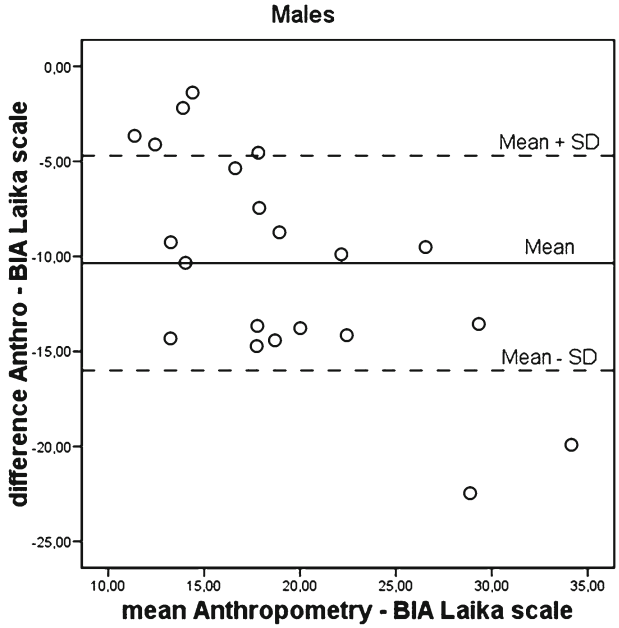

Fig. 25.6 Differences between anthropometry and BIA (LAIKA scale) in males

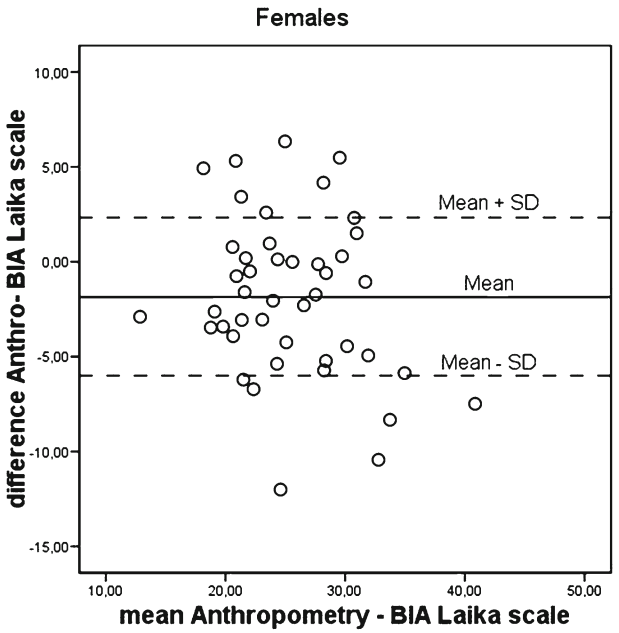

Fig. 25.7 Differences between anthropometry and BIA (LAIKA scale) in females

relative adiposity value is always higher in men when measured by a BIA technique. In the female series, the difference between anthropometry and tetrapolar BIA is usually positive. With bipolar analyzers, differences are close to zero, and take negative values only for higher fat percentages. This means that the tetrapolar analyzer usually offers lower fat percentage results than those obtained through anthropometry. With respect to bipolar devices, both offer adiposity values very similar to those calculated by the Siri equation (1961).

As a second example, results obtained by authors on analyzing body composition by anthropometry and tetrapolar BIA in 86 schoolchildren of both sexes are provided. The anthropometric equations used were those given by Durnin and Womersely (1974) for body density and by Siri (1961) for fat percentage. Tetrapolar BIA was applied using a Bodystat 1500 analyzer. This device directly provides the fat percentage value. It also provides the impedance value in ohms at a fixed frequency of 50 kHz, and this allows another estimate of fat percentage to be made by applying an equation. For this case, the Deurenberg et al. (1991) formula for fat free mass (FFM) was applied:

$$\mathrm{FFM} = 0.438 \times 10,000 \times \mathrm{H}^2 / \mathrm{I} + 7.04 \times \mathrm{E} + 0.308 \times \mathrm{W} + 1.6 \times \mathrm{S} - 8.5$$

H = height (m), W = weight (kg), I = impedance (ohms), S = sex (value 1 for males and 2 for females).

From this value, and knowing the total weight, fat mass (*FM*) was obtained.

Table 25.6 shows the results: first, with the Siri anthropometric equation (1961); second, with the BIA analyzer directly; and third, applying the BIA equation of Deurenberg et al. (1991) to the impedance value in ohms. Compared with anthropometry, BIA overestimated fat in the male series and slightly underestimated it in the female series. The values of ICC show that, between anthropometry and direct BIA, the correlation is very low in male series and is acceptable in female series. When using the Deurenberg et al. (1991) equation, the correlation increases: it is acceptable for the female series and good for the male series (Table 25.7).

Table 25.6 Body fat percentage obtained by different techniques in a sample of 86 Spanish children

	% BF males		% BF females	
Method	Mean	SD	Mean	SD
Anthropometry Siri (1961) equation	17.31	5.84	24.45	5.53
Direct-BIA	19.66	5.75	23.74	5.65
BIA Deuremberg et al. (1991) equation	24.14	9.28	22.11	7.13

Table 25.7 Agreement between anthropometry (Siri 1961) and BIA techniques in a sample of 86 Spanish children

	ICC males	ICC females
Siri-Direct-BIA	0.30	0.43
Siri-BIA Deuremberg et al. (1991) equation	0.73	0.50

The results obtained by the authors in the two cases described suggest that BIA underestimates body fat in relation to anthropometry in females, and overestimates it in males, both children and adults. The results alsoshow that there is better agreement between anthropometry and bipolar BIA with electrodes placed on the hand in males. In contrast, anthropometry correlates more consistently with the bipolar BIA technique with electrodes placed on the feet in females. Finally, agreement between methods decreases as the degree of adiposity of individuals increases.

Lukaski and Siders (2003) and Sun et al. (2005) report an overestimation of the body fat percentage obtained from tetrapolar BIA regarding anthropometry in both sexes. They also note, as does this study, that differences between methods are accentuated in cases of high fat percentage. According to experts such as Fors et al. (2002), the BIA method would have no validity in obese children with high fat rates. Rowe et al. (2006) also find that the correlation between anthropometry and whole-body bioelectrical impedance in children and adolescents decreases with increasing adiposity. However, Goldfield et al. (2006) arrive at opposite results, noting that the scale BIA or foot-to-foot method is appropriate for estimating body composition in obese adults and children, due to its great concordance with the DEXA (dual-energy X-ray absorptiometry) technique. Casanova et al. (2004), obtaining a high ICC between anthropometry and tetrapolar BIA between 6- and 14-year olds (ICC > 0.75) believe that BIA is an excellent diagnostic method. Rodríguez et al. (2008) also consider that tetrapolar BIA is an appropriate method to analyze body composition in children of normal weight and aged between 4 and 6 years. Although the results discussed are partly contradictory, almost all studies show that, despite the higher or lower correlation obtained, the BIA method is not interchangeable with DEXA and anthropometry takenas the benchmark method.

There are not many publications that compare different types of bioimpedance analyzers under the same measurement conditions. Nuñez et al. (1997) and Jart et al. (2000) contrasted the scale type analyzer with the four-electrode BIA technique and obtained different results, depending on the individual age range. Lukaski and Siders (2003) observed that bipolar type BIA analyzers usually underestimate the fat percentage compared to the DEXA technique taken as the gold standard. As in the present study, the correlation between the reference method (anthropometry and DEXA) and the scale is greater for females and, in contrast, there is a greater interrelation between the fat percentage results obtained by the OMRON hand analyzer in males. Other comparative research, such as Dittmar (2003), found significant individual differences in estimating relative adiposity measured by any kind of bipolar monitor (e.g., OMRON BF-302 and scale Tanita BF-538 y 101-A RLJ) and detected a remarkable influence of factors, such as age or gender.

25.6 Applications to Other Areas of Health and Disease

Today, body composition assessment is useful in the clinical, epidemiological, and sports domains. It is essential in the diagnosis and control of obesity and malnutrition. Its use is highly desirable in diseases that seriously affect the nutritional status, such as cancer and AIDS, among others. The analysis of body composition is also useful in situations that alter the balance of body fluids, such as in patients undergoing dialysis, have severe burns, etc. In addition, body composition is a fundamental tool in athlete selection, training monitoring, and exercise planning.

Anthropometry should be applied by trained and experienced personnel. In particular, the measurement of subcutaneous adipose skinfolds is relatively difficult for untrained professionals. Compared to anthropometry, BIA appears to be a simpler and faster method. However, it also has disadvantages. Not all BIA models incorporate in their software prediction formulas applicable in different population groups: children, adults, seniors, athletes, etc. On the other hand, only multiple-frequency analyzers can differentiate intracellular and extracellular water. Also, there are no reference values for all BIA analyzers. Given the above, researchers and health professionals should choose the BIA device that best fits their needs.

25.7 Conclusions

The main aim of this chapter was to compare multiple measurement techniques, devices, or equations to obtain body composition estimators, in a given sample. Several conclusions emerge from the results obtained in the two examples discussed together with the contributions from the literature.

BIA methods are acceptable enough to use in epidemiological studies of nutritional assessment. However, it is necessary to take several considerations into account. Bipolar monitors, also called regional monitors, produce results that depend on fat distribution in the individual. This means that the results vary, depending on fat location in the upper or lower segment of the body. In contrast, with a tetrapolar analyzer, both segments are evaluated simultaneously and this device offers values independent of the localization of fat deposits. The final result is a better match between fat percentage obtained by the scale type BIA analyzer and anthropometry in females and between the hand type BIA analyzer and anthropometry in males. Tetrapolar devices are more accurate in the pediatric age group.

The discrepancy of results at individual, ontogenetic, and gender levels, particularly with bipolar monitors, implies limitations for use in clinical diagnosis, as there are no appropriate standards for each population, gender, and age. It would therefore be highly desirable to develop standards that could be provided to professionals as a reliable benchmark when using any of the devices.

Summary Points

- The methods of bioelectrical impedance analysis (BIA) are increasingly used to estimate body composition. Nowadays, both BIA and anthropometry are used for this purpose. It is necessary, however, to know whether the results obtained by the two techniques are comparable.
- The basis of BIA is the least resistance to the passage of an electric current (low-intensity, low or medium frequency) of the fat-free mass (FFM) compared with adipose tissue or fat mass (FM).
- Single-bioimpedance analysis (S-BIA) devices have only one frequency (usually 50 kHz) for the induction of current. These analyzers allow us to distinguish fat mass from fat-free mass.

Multiple-biompedance analysis (M-BIA) devices use a broad spectrum of frequencies (1–1,500 kHz) and also enable us to differentiate the volumes of intra-and extracellular water.

- Numerous specific BIA equations for age, gender, population, and type of device have been published. Most of these formulas calculate total body weight (TBW) or fat-free mass (FFM) from the impedance index (HT^2/R).
- Intraclass correlation coefficient (ICC) and the graphic method of Bland and Altman are appropriate statistical tests for estimating the agreement between BIA and anthropometry. Also, these tests are useful for comparing results obtained by different types of BIA analyzers.
- BIA methods are useful for assessing body composition in both healthy subjects and patients. In some cases, M-BIA also measured the kinetics of body fluids. Therefore, BIA methods are a good tool in the medical field (clinical and epidemiological) and for monitoring sport.
- S-BIA devices are valid for population studies in adulthood. To study children and adolescents, it is necessary to use M-BIA. For clinical use, M-BIA devices (with four or eight electrodes) are recommended.

Key Concepts

- Anthropometric methods for the analysis of body composition are primarily based on the measurement of subcutaneous fat skinfolds. Bioimpedance analysis (BIA) is based on the resistance of body components to an electric current. Impedance is low in lean tissues, which are mainly composed of intracellular fluids and electrolytes. Impedance is high in fat tissue and is proportional to total body water. Anthropometry cannot assess the changes in hydration levels that the BIA methodology can detect.
- Anthropometry and BIA are two techniques that are used in the assessment of nutritional status. The results obtained by either procedure are comparable only if there is a significant degree of concordance between them. Appropriate statistical tests for this purpose are the intraclass correlation coefficient (ICC) and the Bland–Altman graphic method. A high ICC (>0.75) does not mean that the two methods are interchangeable.
- In adult females, relative adiposity measured by anthropometry shows better agreement with body fat percent assessed by single bipolar BIA (S-BIA) foot-to-foot. In adult males, relative adiposity measured by anthropometry shows better agreement with body fat percent assessed by single bipolar BIA (S-BIA) hand-to-hand. The results obtained by multiple BIA of four or eight electrodes (M-BIA) are independent of adiposity distribution of fat and fit better with anthropometry in both genders. In children, only M-BIAsare appropriate for assessing body composition.
- In BIA, low frequencies cannot pass through cell membranes and detect only extracellular water. High frequencies cross cell membranes and detect extracellular and intracellular water. S-BIA devices work at 50 kHz, but M-BIA operates at various frequency ranges: 5–200 kHz. These latest devices are best for clinical use in monitoring diseases that alter body hydration.

Chapter 26
Fetal Head Circumference as an Anthropometric Index

Emmanuel Stephen Mador, Josiah Turi Mutihir, and John Oluwole Ogunranti

Abstract The present chapter focuses attention on head circumference measurement – an anthropometric parameter – in growing fetuses using ultrasound machine. This is to provide information and glimpse into the nature of the growth velocity during fetal development and to suggest the need for its further studies in the future. Head circumference has been implicated in various conditions and is related to brain size, brain development, intelligence, maternal nutrition, ethnic group and race. It is also of interest in certain clinical conditions such as macrocephaly or indeed microcephaly. More importantly it is a clinical anthropological parameter, by which we determine variations from one location to another or one race or ethnic group to another. In the emerging field of sonographic or ultrasonic embryology, it is a vital tool in the diagnosis of congenital anomalies. When compared with rates in other studies we see differences, which can be explained on the basis of nature and nurture. Needless to say that head circumference follows a bell shaped pattern of growth known for neural tissues and correlates very well with fetal brain growth pattern. But its significance in early maturation of the brain, and its higher values for African babies when compared to other races necessitates the need for further understanding of racial or genetic factors that determine its growth and ipso facto, its relationship to intelligence. This review provides extensive data for head circumference of 13,740 African (Nigerian) fetuses and suggests that early maturation of head circumference in African children vis-a-vis European, is a genetic rather than nutritional factor. Postnatal development however is probably dependent on nutrition and environment rather than genes.

Abbreviations

AC	Abdominal circumference
BPD	Biparietal diameter
cm	Centimeter(s)
CRL	Crown-rump length
FL	Femur length
GSD	Gestational sac diameter
HC	Head circumference
IUGR	Intrauterine growth retardation
mm	Millimeter(s)

n	Sample size
OFD	Occipitofrontal diameter
SD	Standard deviation
SEM	Standard error of mean
TORCH	Acronym for toxoplasmosis, rubella, cytomegalovirus and herpes infection

26.1 Introduction

One of the most important measurements in the evaluation of fetuses is the circumference of the head because this parameter is related to intracranial volume and it permits an estimation of the rate of brain growth. Head circumference (HC) became a useful tool for researchers/anthropometrists in determining the characteristics of human intelligence since Galton (1988) and more so in recent times. In addition, just like growth charts used to monitor the adequacy of nutrition, it will become the anthropometric parameter of the future to determine the adequacy of the development of the brain and ipso facto, intelligence. Head circumference measurement in pregnancy using ultrasound has always been recognized as an established method of assessing fetal growth (Hadlock et al. 1982), dating pregnancies (Callahan et al. 2003), and in the detecting fetal abnormalities (Baker 2001; Woo 2006). It is one of the multiple fetal anthropometric parameters used in obstetrics and sonographic embryology. In this chapter, evidence for the utility of HC as an anthropological parameter (anthropometry), which has variational attributes between geographically separate communities and must require the procurement of normal average values for each community, is presented in an anthropological manner. Furthermore, the HC of contemporary growing fetuses in Nigeria is examined as a prelude to prescribing normal values of HC for the present generation of Nigerian (African) fetuses. Comparisons using HC values obtained in other parts of the world, as reported by previous investigators.

26.2 Head Circumference as an Anthropological Parameter

Physical (biological) anthropology has been the major natural scientific backbone of medical clinical anthropology, and it derives its inspiration from the sciences of Darwinism, Mendelian genetics, embryology, and anatomy. Physical anthropology has been applied differently in different populations. Biological anthropology has changed from the primitive man's basic knowledge to a variety of formidable data about man and his physical characteristics in various societies and places. Anthropometry is a major branch of biological anthropology, and HC is considered a basic feature of anthropometry, which is dependent on both environmental and genetic influences (of a polygenic inheritance nature rather than a simple Mendelian), as all other anthropometric parameters known to man. Head circumference was utilized earlier to denote proper development of the fetus. It remains one of the most important anthropometric parameters of biological anthropology. In estimating fetal weight during intrauterine life, HC is used in conjunction with other fetal parameters, such as biparietal diameter (BPD), abdominal circumference (AC), and femur length (FL). Since Morley (1977) said, "weight charts…form the most convenient estimate of a fetus/child's nutrition and health…" it follows that Morley's approach forms a basis for implicating anthropometry in modern medical practice. It proves that physical anthropological characteristics such as HC can be highly valuable as health indicants or concomitants (Morley et al. 1968). Morley's approach to the study and utility of

weight in clinical practice (Morley 2001) has been examined and found to be a pioneering effort in clinical anthropology (Ogunranti 1987; Nwokoro et al. 2006). This science can be recognized as an applied branch of medical anthropology that has direct relationship with the clinical situation for diagnosis and treatment of patients.

With this definition of clinical anthropology, we just have to associate the clinical utility of HC and its anthropological attribute in order to understand the value of HC as a clinical anthropological parameter. Although the erstwhile approach to clinical anthropology is highly culturally oriented (Kleinman 1980; Ogunranti 1995; Rush 1996), we have formulated a revised form of clinical anthropology, which includes biological data as it affects the developing world (Ogunranti 1986; Rush 1996; Loustaunan and Sobo 1997; Martínez-Hernáez 2008). In view of this factor, one can relate Morley's approach to obtaining weight for clinical utility as a pathbreaking effort in clinical anthropology in general, and our endeavor in procuring normal values for HC in the growing fetus as another effort in clinical anthropology. Ogunranti (1994), taking the cue from Morley in the 1980s, suggested the need for a biologically oriented clinical anthropology, and provided considerable anthropometric data of Nigerians, which proved useful for them in the 1980s and 1990s (Ogunranti 1995).

26.3 Concept of Clinical Anthropology and Head Circumference

Clinical anthropology began as a discipline that recognized the input of medical anthropology in modern health care (Kleinman 1980; Rush 1996). Kleinman, in a series of writings, advanced arguments for the use of medical anthropological information in treatment and diagnosis of diseases in the Western setting. He described this as clinically applied medical anthropology. Medical anthropology, on the other hand, is a discipline that recognizes variation in human adaptive arrangements in relation to medicine and medical systems, and human confrontation with disease and illness (Landy 1977). It therefore recognizes variation in medical systems and medicine in different cultures (Janzen 2002; Martínez-Hernáez 2008). It is strongly linked to cultural modes of diagnosis and treatment of diseases. When such information related to cultural beliefs and attitudes toward sickness and the state of being unwell is applied to the treatment of a patient from a similar environment under the Western system, the technique islabeled as clinical anthropology (Ember 2004).

Our own extension of clinical anthropology has included biological anthropology, as variations do exist for data from culture to culture and community to community. Thus, if the HC of a fetus from Jos in North Central Nigeria is lower than the normal average value of the same for his age obtained at Edinburgh, we can look at the normal values of the Jos's fetuses in order to determine whether such a fetus is abnormal or not. This is the central thesis of biologically derived clinical anthropology, and the thrust of the present concept on anthropometry (Ogunranti 1995; Boixareu 2008).

26.4 Head Circumference as a Growth Parameter

Growth, which is a combination of multiplicative, auxetic, and accretionary parameters, measures the total increase in size of the whole organism. The phenomenon is studied by a growth chart in fetuses or in growing children. The most commonly used parameter to measure growth in the fetus includes BPD, HC, AC, and FL. The first idea about growth chart came from a child research project, which was instituted in New Castle, England. Tanner et al. (1966) prepared cross-sectional standards for weight (attained at each age in English boys and girls), which are widely used as standards today and as comparison figures all over the world. In the USA, extensive studies on height and weight were

conducted on children by Simmons (1944). This was followed by a larger survey, of white and black children, from 1970 to 1976 (Hamil et al. 1976). In Nigeria, the first longitudinal growth study was conducted in Imesi-Ile, Western Nigeria in 1959. Cunningham (1969) compared the growth charts derived from weight studies as compiled by Morley in 1959 for Imesi-Ile and a neighboring village of Oke-Imesi. Collis et al. (1962) obtained figures for 200 children of ages 1–8 years living around Ilesha in western Nigeria, and compared these with figures obtained in Pankshin, the Plateau State of Northern Nigeria. A recent study of Nwokoro et al. (2006) uses a modern approach as well as longitudinal study in western Nigeria.

Fetal growth is defined as the time-dependent changes in body dimensions that occur during the pregnancy. The growth rate of various parameters is rapid especially in the 1st and 2nd trimesters; the parameters change significantly with the advancement of pregnancy, and must be evaluated against the normal value at that age. Fetal anthropometry can be carried out by cross-sectional or longitudinal studies. For a cross-sectional study, fetuses are examined only once during the gestation period. This type of study can be performed over a small period of time, and the data are easier to collect and analyze statistically. A longitudinal study, on the other hand, is one in which a small number of fetuses are investigated serially, at least thrice during the course of pregnancy. This study necessitates that the same fetuses be scanned during the whole gestation, which increases the time needed for data collection considerably, and calls for high motivation on the part of both the mother and the investigator. The growth pattern in HC is the so-called neural growth that follows the pattern of brain growth. It is bell shaped as opposed to reproductive organ growth, which is sigmoid in shape.

26.5 Ultrasonic Embryology 1: Head Circumference as a Parameter of Dating Pregnancy

Ultrasonic embryology is an emerging field which studies the fetus to provide descriptive embryological data and the prediction or diagnosis of congenital anomalies by the application of ultrasound technology. Head circumference is a very useful parameter in ultrasonic embryology as it can be used to predict congenital anomalies as well as embryological dating and clinical staging/dating of pregnancy.

Multiple fetal anthropometric parameters are available to predict the gestational age. These include measurement of gestational sac, crown–rump length (CRL), fetal BPD, HC, occipitofrontal diameter (OFD), AC, and FL.

26.5.1 Frequently Used Parameters

Gestational Sac Diameter (GSD): The gestational or pregnancy sac is usually visible on ultrasound scan at about 5 weeks after the last missed period. The sac may be circular, oval, or even elliptical in shape, with an echogenic margin. An embryonic pole can usually be seen after 6 weeks, and the cardiac flicker is picked up with a real-time scanner (Palmer 1995). GSD has been reported as the first ultrasonic parameter to be used for confirmation of pregnancy.

Crown–rump Length (CRL): Crown–rump length is one of the most reliable ultrasonic anthropometric parameters, and is used in the first trimester. By 7 weeks, the embryo is clearly seen in the gestational sac, and its CRL can be measured in long axis. By this time, the yolk sac can be seen in relation to the

ventral surface of the embryo. The presence of the yolk sac is deemed to be an encouraging sign of fetal well-being, and it remains visible until about 10 weeks of gestation (Hadlock et al. 1992).

The CRL is utilized for estimation of gestational age up to the 11th week, with accuracy in 95% of cases within 2.7–4.7 days. After that, the curvature of the fetus affects the reliability of measurement; therefore, from the 12th week onward, the BPD is considered to be more accurate.

Biparietal Diameter (BPD): This parameter is used in the second trimester, from the 12th week onwards. It measures the maximum distance between the two parietal bones taken from the leading edge of the skull to the leading edge, that is, outer to inner (Hadlock et al. (1982). It can also be measured from outer to outer table of the skull. This axial plane passes through the widest portion of skull where the continuous midline echo of falx cerebri is broken by the cavum septum pellucidum with both the thalami enclosing the slit-like opening of the 3rd ventricle of the brain. Studies report that the growth of the BPD in the mid trimester is linear and rapid, and biological variation at each week of gestation is small. The measurement of BPD from 14 to 26 weeks predicts the correct duration of gestation to the extent of ±9 days in 95% of cases; however, the measurement of the parameter in second trimester (16–20 weeks) routine scan is performed in all good antenatal care centers.

At times, when the fetal head is short and wide (brachycephaly), or long and flattened (dolicephaly), the assessment of age from BPD may be under- or overestimated. Therefore, if the shape of the head appears brachycephalic or dolicephalic, the cephalic index should be calculated. If this is found to be beyond the normal range, the HC should be used to estimate age.

Head Circumference (HC): This parameter is used in the third trimester along with other parameters such as FL. It is measured at the same level at which the BPD is taken, using the ellipsoid mode of the machine, and adjusting the elliptical calipers to the outer margin of the skull table. The accuracy of this parameter is ±2–3 weeks, with 95% confidence interval.

Abdominal Circumference (AC): This ultrasonic fetal anthropometric parameter is less commonly used for the assessment of gestational age. It is, however, more frequently used for monitoring fetal growth, especially in the third trimester, and for estimating fetal weight. The AC is taken at a level where the umbilical vein enters the left branch of portal vein; alternatively, a scan at a slightly lower level, showing a short segment of the umbilical vein, may be taken. The outline of the abdomen should be as circular as possible. Until the 36th week of pregnancy, the HC is larger than the AC; the HC: AC ratio is therefore more than 1; but, after 36 weeks, the AC catches up with the HC, and then continues to grow at a faster rate, so that the ratio of HC to AC near term becomes less than 1 (Chang et al. 2003).

Femur Length (FL): Femur length is a very useful anthropometric parameter used in the second and third trimesters of pregnancy. It grows linearly throughout, and is best measured after 14 weeks of gestation. The diaphysis is measured from the greater trochanter above, to the lateral condyle below. The outer border of femur is straight and the inner border is curved normally. The accuracy of gestational age calculation by FL is within 6–7 days of menstrual age at 95% confidence level. These four parameters are most frequently used for the estimation of gestational age, and sometimes considered as the "gold standard," and they collectively assess the gestational age to the highest degree of accuracy.

26.5.2 Less Frequently Used Parameters

Parameters, less frequently used in the discipline of fetal anthropometry, include fetal transverse thoracic diameter, thoracic circumference, and measurement of long bones, orbit and lens dimensions, and fetal binocular distance. The thoracic diameter and circumference is specially used in assessment of fetal weight.

Fetal orbit, lens dimensions, and fetal binocular distance are used to predict gestational age. The variability (±2 SD) associated with predicting menstrual age using binocular distance is ±14 days between 14 and 27 weeks, and ± 24 days between 29 and 40 weeks, respectively (Tongsong et al. 1992).

Fetal long bones are also used for the assessment of gestational age, but are more frequently in use for detecting divergence from normalcy, for example, in suspected cases of skeletal dysplasias. Bones used for the estimation of gestational age include fetal humerus, radius, ulna, femur, tibia, and fibula (Chitty and Altman 2002). The correct evaluation of gestational age is possible every 2 weeks by assessing all these bones except femur, where evaluation is possible every week before 28 weeks and every 2 weeks after 28 weeks. These biometric parameters are rarely used, as some of these are technically difficult to measure. The size of the cerebellum and transverse cerebellar diameter is considered as a useful anthropometric parameter in estimating gestational age in the second trimester. Fetal clavicular measurement is used in evaluating gestational age and estimating fetal weight. Studies suggest that the gestational age in weeks is approximately equal to the length of the clavicle expressed in millimeters. Interclavicular distance in cases of breech presentation has an added benefit in assessing the capacity of pelvis of the mother for subsequent delivery.

Fetal liver and kidney, at times, are measured for fetal anthropometry (Konge et al. 2002)**.** Parameters such as fetal scapula, sacral length, fractional spine length, foot length, fetal ear length, and the fetal nasal bones are used for dating the fetus periodically. Fetal nasal bones are used, in addition, to detect cases of trisomy 21.

26.6 Ultrasonic Embryology 2: Head Circumference as an Established Method of Detecting Fetal Abnormalities

Limitation of growth potential in the fetus, called intrauterine growth retardation (IUGR), can be either symmetrical or asymmetrical (Table 26.1). Symmetrical growth retardation implies a fetus whose entire body is proportionally small, whereas asymmetrical growth retardation implies a fetus that is undernourished and directs most of its energy to maintaining growth of vital organs, such as the brain and heart, at the expense of the liver, the muscle, and the fat. A high fetal brain-to-liver ratio manifests asymmetrical growth retardation and whereas these organs cannot be directly measured, ultrasound circumference measurement of the fetal skull and the fetal abdomen at the level of the liver can be performed, and would appear to be a logical alternative. Ratios of fetal anthropometric parameters can be useful in screening for growth retardation (Deter et al. 1987), especially when it is asymmetrical. Ratios not involving head measurements tend to be relatively constant after 20 weeks of gestation, hence, can be useful in evaluating fetuses where the dates are uncertain. The ratios of body parameters commonly used for assessing fetal development include BPD to OFD ratio, HC to AC ratio, BPD to FL ratio, thoracic circumference to AC ratio, FL to HC ratio,

Table 26.1 Key features of intrauterine growth retardation (IUGR)

1. Limitation of growth potential in the fetus is called IUGR
2. IUGR can either be symmetrical or asymmetrical
3. Symmetrical IUGR implies a fetus whose entire body is proportionally small
4. Asymmetrical IUGR implies a fetus that is undernourished and is directing most of its energy to maintaining growth of vital organs, such as the brain and heart, at the expense of the liver, muscle, and fat
5. Ratios of parameters can be useful in screening for growth retardation, especially when it is asymmetrical

This table lists the key facts of IUGR, its classifications, and diagnosis

and FL to AC ratio. These ratios can be used in the diagnosis of congenital anomalies, such as Down syndrome, dwarfism, microcephaly, achondroplasia, arthrogryposis multiplex congenital, and congenital amputee.

26.6.1 Biparietal Diameter to Occipitofrontal Diameter Ratio (Cephalic Index)

Cephalic index is the ratio of the BPD of the skull to the OFD and can detect asymmetry in the skull during development (Abuhamad 1996).

The normal range is 74–83%; <74.9% indicates a dolichocephalic skull; from 75% to 79.9% a mesocephalic skull; and from 80% to 84.9% a brachycephalic.

26.6.2 Head Circumference to Abdominal Circumference Ratio

The HC to AC ratio is useful in detecting asymmetrical growth retardation (Chitkara et al. 2000). It varies over the gestational period. When measured by ultrasound, it can differentiate between symmetrical and asymmetrical fetal growth restriction. In symmetrical fetal growth that tends to occur after 28 weeks of gestation, the head to abdomen ratio is normal, but absolute values of AC and HC are low. Common causes of symmetrical growth in the human fetus include early intrauterine infections, such as rubella, toxoplasmosis, or cytomegalovirus, maternal anemia, malnutrition, or chronic blood pressure.

Asymmetrical fetal growth is one that occurs before 28 weeks of gestation. In this case, the head grows normally (and ipso facto the HC remains normal), but the body fails to catch up. Asymmetrical growth is common in congenital anomalies and TORCH infections.

26.6.3 Head Circumference and Nutrition

It is well established that the state of the maternal nutrition influences the nutrition and subsequent growth and development of the child (Kankeow 2007). If the need arises, the fetus is, to a certain extent, provided for at the expense of the mother. For example, when the maternal intake of iron, calcium, or phosphorous is inadequate, the fetus draws on her stores for its requirements. A severe reduction in protein intake, as during starvation, will lead to a lower-than-average weight, length, and HC in the newborn (Callahan et al. 2003). When starvation is sufficiently severe, it may result in sterility of the potential mother, but abortion and malformation do not appear to increase. Infants born to mothers on a good diet during pregnancy usually have, in general, superior health and vigor during early infancy, in comparison to infants of mothers on poor diets.

Although HC can be used to determine the adequacy of nutrition in the fetus and beyond, abdominal length and FLs are better indicators of fetal weight and nutrition than other parameters, to include HC. Whatever be the case, HC can also adjudge the level of fetal nutrition, and can be used in conditions or areas in which IUGR due to starvation or inadequate diet or indeed obesity are a problem. Such conditions have been implicated in studies on kwashiorkor and marasmus, and it has been

shown that post-marasmic children tend to have lower values of HC. This does not seem to affect children with kwashiorkor (Branko 2001) as discussed below.

26.7 Application to Other Areas of Health and Disease

26.7.1 Head Circumference and Microcephaly (Table 26.2)

Microcephaly is a neurological development disorder in which the HC is less than the 3rd centile for a person's age and sex. It may be caused by congenital anomaly, which appears at birth, or may develop postnatally. Microcephalin genes have been implicated in this anomaly. Those born with microcephaly have their HC either normal or reduced in size. They have been found to be of subnormal intelligence.

26.7.2 Head Circumference and Macrocephaly (Table 26.3)

Macrocephaly can be diagnosed if the HC is greater than the 97th centile. It therefore goes without saying that reference values and the use of such values to indicate micro- or macrocephaly would vary from one community to another (Mortimer et al. 2003).

The following conditions can be diagnosed from macrocephaly: autism, neurofibrosis type 1, tuberous sclerosis, Sotos syndrome, Fragile X syndrome, leukodystrophies, Weaver syndrome, Bulldog syndrome, Noonan syndrome, Costello syndrome, Canayan disease, glutaric aciduria type 1, cardiofaciocutaneous syndrome, megalencephalic leukoencephalopathy with subcortical cysts, and D-2 hydroxyglutaric aciduria.

Table 26.2 Key features of microcephaly

1. Microcephaly means a small brain enclosed within a small skull
2. Microcephaly may be caused by maternal heroin addiction or by rubella virus infection
3. Microcephaly is not a structural abnormality, but a severe slowing of the growth rate of the fetal head
4. Microcephaly diagnosis is usually made after 20 weeks of gestation
5. Many microcephalics die shortly after birth and individuals who survive are not only severely mentally retarded but are also dwarfed

This table lists the key features of the condition called microcephaly, which is related to HC measurement and can be diagnosed by it

Table 26.3 Key features of macrocephaly

1. Macrocephaly means a huge brain enclosed within a gigantic skull
2. Macrocephaly is not a structural abnormality but an acceleration of the growth rate of the fetal head
3. Macrocephaly diagnosis is usually made after 20 weeks of gestation
4. Macrocephalics have large head above the 97th centile for sex and age
5. It may be caused by enlargement of cranium or brain
6. When it affects the soft tissue, it may be caused by either abnormal proliferation of brain tissue or accumulation of abnormal metabolic materials

This table lists the key features of the condition called macrocephaly, which is related to HC measurement and can be diagnosed by it

26.7.3 Head Circumference and Growth Chart

Growth charts have been used extensively in the past to determine how normal the growth of a child or a fetus is (Morley 2001; WHO Child Gold Standard 2006). This is also possible using the HC, although weight and height had been used more than HC in community surveys. Growth charts are useful in making a pre-diagnosis of such conditions as Down's syndrome and Turner's syndrome, as the two conditions provide charts that deviate significantly from the norm.

26.7.4 Head Circumference and Intelligence

Variations in head size and brain volume are genetic and, since Galton, it has been customary to associate size of the head (and ipso facto size of brain), as measured by HC, with intelligence. Even the genes responsible for brain size (which is directly related to HC, cranial capacity, OFD, etc.) have been identified even though they vary from one continent to another, and require to be mapped. A 40% correlation between head size and intelligence quotient (IQ) has been found using MRI (magnetic resonance imaging) studies. Brain size, as determined by small size, is said to correlate positively with memory retention in old age and the onset of dementia. It has also been shown that HC is strongly correlated with brain volume, which presumably determines intelligence. Racial studies have shown a relationship between brain size and adult intelligence, but we do not have enough data to determine the situation before birth, which is different from that after birth (Mortimer et al. 2003). This study provides authoritative data on HC in African children with a population size of over 13,740 fetuses.

26.7.5 Miscellaneous Head Circumference Data

Abnormal HC have been implicated in such conditions as benzodiazepine ingestion in utero with its associated microcephaly and low intelligence, pachygyria and all its subdivisions, such as lissencephaly (smooth brain), polymicrogyria, and craniosynosotosis. Also, certain genes are implied in the development of autism and low HC (Gallagher et al. 2004).

A program called DENVER II has been designed to assist in ascertaining health status from such anthropometric parameters as height and weight, and also HC (Frankenburg et al. 1992).

26.7.6 Practical Methods and Technique

There are multiple fetal anthropometric charts for the prediction of gestational age from a given parameter, but no chart exists for the prediction of other fetal parameters using HC measurement.

26.8 Nigerian Head Circumference Studies

A total of 13,740 growing fetuses were studied in Jos, the capital of Plateau State. Plateau State derives its name from the geographical landscape that predominates in this part of the country. It has a population of 3,178,712 (2006 census). The state lies between latitude 7 and 11° north of the

Table 26.4 Mean fetal HC values (in mm) in a Nigerian population

GA (weeks, days)	Number of fetuses (*n*)	Mean HC	SD	SEM
12 to 12 + 6	49	80.9	10.5	1.5
13 to 13 + 6	384	94.1	9.6	0.5
14 to 14 + 6	371	108.6	11.8	0.6
15 to 15 + 6	351	122.5	13.8	0.7
16 to 16 + 6	505	133.0	9.7	0.4
17 to 17 + 6	427	146.1	10.9	0.5
18 to 18 + 6	446	162.1	23.5	1.1
19 to 19 + 6	282	169.4	15.2	0.9
20 to 20 + 6	553	180.7	12.7	0.5
21 to 21 + 6	400	193.0	11.7	0.6
22 to 22 + 6	398	201.9	11.3	0.6

This table gives the mean values of fetal HC measurements for each gestational age in weeks from 12 to 42 weeks' gestation together with their corresponding SDs and standard errors of mean

GA gestational age, *HC* head circumference, *SD* standard deviation, *SEM* standard error of mean, *mm* millimeter

Equator and longitude 7° east. Although located in the tropical zone, the climate of Plateau state is the nearest equivalent of a temperate climate in Europe and USA. The state has over 50 ethnic groups, each with a proud cultural heritage, with no single group large enough to claim majority. Nature has endowed this State with scenic beauty, coupled with an invigorating climate. People from all over the country like staying in Jos; that is why the State has been rightly described as a miniature Nigeria because it contains within itself almost, if not all, the various ethnic groups of Nigeria. The study population consisted of all women with uncomplicated pregnancy, who presented for routine ultrasound at the Centre for Reproductive Health Research, Jos, between December 1997 and April 2002. Every fetus was measured and included only once, so that a pure cross-sectional set of data was constructed. Table 26.4 shows the frequency distribution of fetuses scanned by gestational age, mean HC, standard deviation (SD), and the standard error of the mean (SEM) of HC measurements,

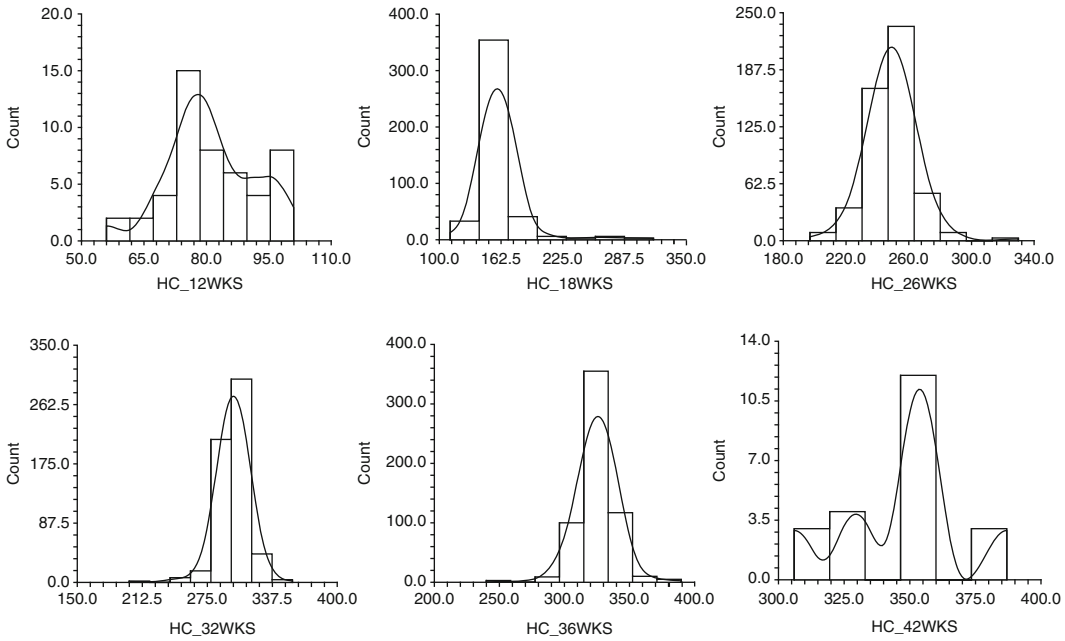

Fig. 26.1 Histograms of HC data at 12, 18, 24, 30, 36, and 42 weeks of gestation. This histograms show the distribution of the HC measurements at 12, 18, 26, 32, 36, and 42 weeks. At 12 and 42 weeks, the distribution is multimodal, whereas 18, 26, 32, and 36 weeks shows symmetrical distribution

carried out on the studied population. From this table, it can be seen that 75% of the fetuses scanned were above 21 weeks of gestation. At each gestational week, over 30 fetuses were examined, with the exception of week 42, where only 22 fetuses were examined. The test for normality is shown in Fig. 26.1 (histogram of HC data) and Fig. 26.2, which shows probability plot for 12, 18, 24, 30, 36, and 42 weeks. Martinez-Iglemicz's goodness of fit test carried out on the fetal HC measurements accepted normality of the data distribution. The geometric means of all sets of measurements are less than their arithmetic means, but greater than their harmonic means, indicating that all the values of fetal HC measurements were not identical. Also, Fig. 26.3 shows skewness of the HC data; Fig 26.4, kurtosis; Fig. 26.5, coefficient of dispersion of all individual observations plotted against gestational age. From these graphs, it can be seen that during the second trimester, the HC measurements were positively skewed, whereas during the third trimester, the measurements were negatively skewed, with wide variation at week 18. Also, the coefficient of dispersion is very high initially, but tapers down as it reaches higher gestational values (Fig. 26.5).

Figure 26.6 shows the scattergram of individual values obtained with the sample size of 13,740. It shows a few outliers, which are more around the latter part of the second trimester and the early part of the third trimester. In Fig. 26.7, mean HC is plotted against gestational age, with error bars showing SD. Mathematical modeling of data demonstrated that the best-fitted regression model (Fig. 26.8) to describe the relationships between HC and gestational age was the third order polynomial regression equation: $y = -0.0029x^3 + 0.0518x^2 + 13.136x - 78.198$, where y is the HC in millimeters, and x is the gestational age in weeks. Figure 26.9 shows mean values of HC in months plotted against gestational age. Values are in Table 26.5. There is a positive polynomial correlation between gestational age (in months) and HC (in millimeters), with a correlation coefficient of $R^2 = 0.9991$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the second order polynomial

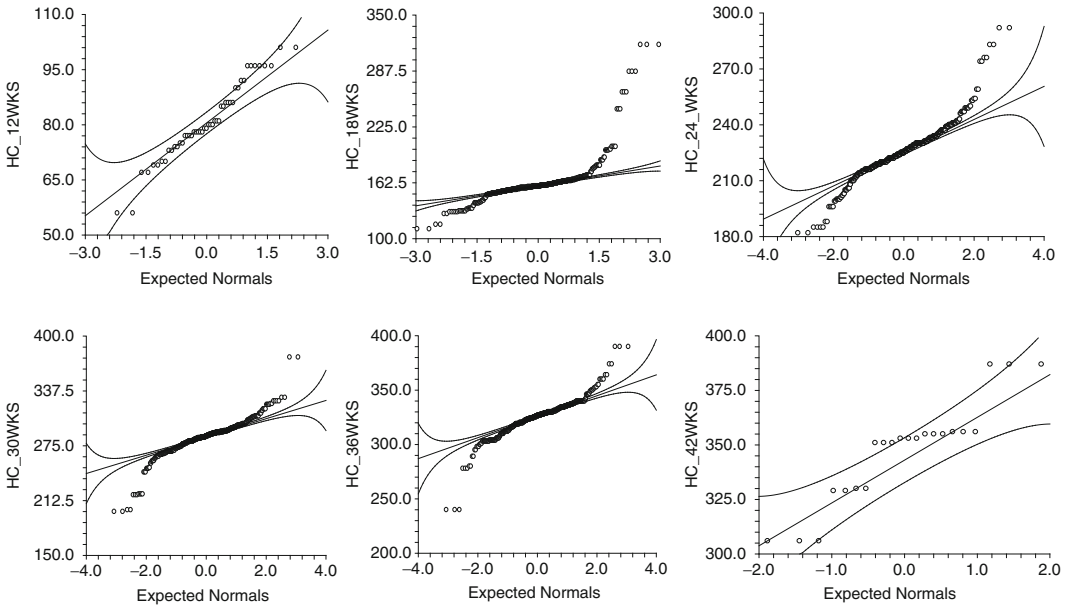

Fig. 26.2 Probability plot of HC data at 12, 18, 24, 30, 36, and 42 weeks of gestation. This probability plots gives a visual impression of whether the normality assumption is valid. They let one determine if the assumption is invalidated by one or two outliers (which could be removed), or if the data follow a completely different distribution

regression equation $y = -3.3238x^2 + 85.755x - 177.78$, where y is the HC in millimeters and x is the gestational age in months. Figure 26.10 shows the histogram of monthly data of HC whose values are also shown in Table 26.5. Figure 26.11 shows the histogram with population sizes for each of the 2nd and 3rd trimesters; see the data in Table 26.6.

26.8.1 Practical Methods and Technique

There are multiple fetal anthropometric charts for the prediction of gestational age using a given parameter, but no chart exists for the prediction of other fetal parameters using HC measurement. When fetal anthropometric parameters, such as BPD, OFD, AC, FL and weight, are plotted against HC, certain hidden relationships can be forced out. For example, Fig. 26.12 shows the relationship of HC with BPD. From the graph, it can be seen that there is a positive linear correlation between BPD and HC, with a correlation coefficient of $R^2 = 0.9997$ ($p < 0.0001$), in Nigerian fetuses. The relationship is best described by the linear regression equation $y = 0.2792x - 0.8656$, where y is the BPD in millimeters and x is the HC in millimeters. Figure 26.13 shows the relationship of HC with OFD, which depicts the regression equation of $y = 0.347 + 0.0528$; $R^2 = 1$; $p < 0.0001$. Figure 26.14 shows the relationship between cephalic index and HC. The relationship is best described by the fourth order polynomial regression equation $y = 1E\text{-}08x^4 + 1E\text{-}05x^3 - 0.0036x^2 + 0.5497x + 49.656$, where y is the cephalic index and x is the HC in millimeters; $R^2 = 0.7451$; $p < 0.0001$.

Other relationships can be calculated outside the skull. Figure 26.15 shows relationship between HC and AC. From the graph, it can be seen that there is a positive linear correlation between AC and

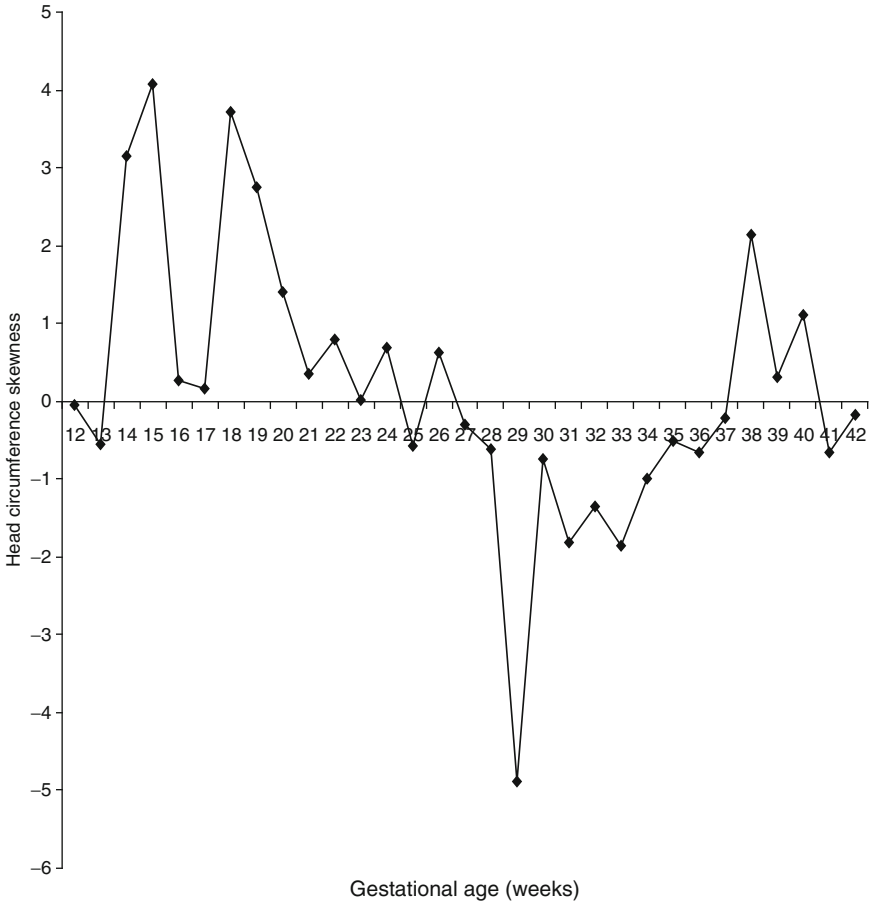

Fig. 26.3 Head circumference data of 13,740 fetuses subjected to skewness analysis at different gestational age ranging from 12 to 42 weeks. The figure shows that the distribution of HC measurements has a longer "tail" to the right of the central maximum than to the left or is skewed to the right from 13 to 24 weeks. From 25 to 37 weeks, the distribution has a longer "tail" to the left of the central maximum than to the right or is skewed to the left. By the time pregnancy reaches term, the distribution becomes skewed to the right before skewing again to the left, as from 41 weeks

HC, with a correlation coefficient of $R^2 = 0.994$ ($p < 0.0001$), in Nigerian fetuses. The relationship is best described by the linear regression equation $y = 1.0644x - 29.032$ where y is the AC in millimeters and x is the HC in millimeters.

Figure 26.16 shows the relationship between FL and HC. There is a positive power correlation between FL and HC, with a correlation coefficient of $R^2 = 0.9962$ ($p < 0.0001$), in Nigerian fetuses. The relationship is best described by the power regression equation $y = 0.046x^{1.2897}$, where y is the AC in millimeters and x is the HC in millimeters. Figure 26.17 shows the relationship between fetal weight, which is strongly correlated with fetal nutrition, and HC. The relationship is best described by the exponential regression equation $y = 57.144e^{0.012x}$, where y is the fetal weight in grams and x is the HC in millimeters.

When the relationship between HC and symphysio-fundal height was determined, it was found that there is a positive polynomial correlation between symphysio-fundal height and HC, with a correlation coefficient of $R^2 = 0.9954$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best

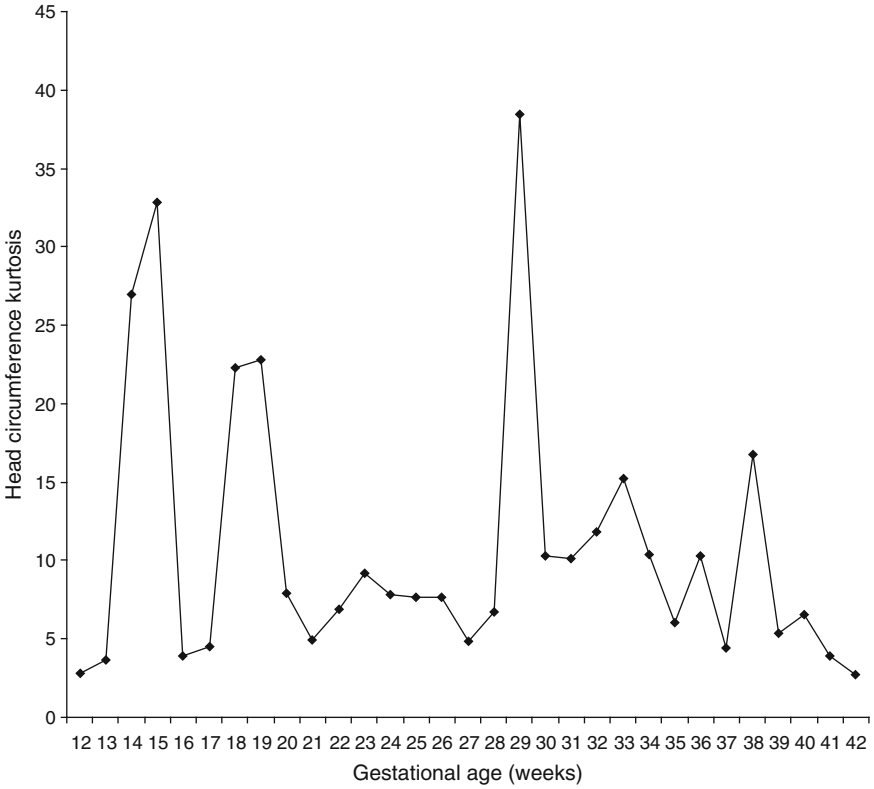

Fig. 26.4 Head circumference data of 13,740 fetuses subjected to kurtosis analysis at different gestational age ranging from 12 to 42 weeks. The figure shows that the kurtosis of HC measurement is leptokurtic at 14, 15, 18, 19, 29, 33, and 38 weeks of gestation, whereas, at 12, 13, 16,17, 20, 21, 22, 23, 24, 25, 26, 27, 28, 20, 31, 32,34, 35, 36, 39, 40, 41, and 42 weeks of gestation, the kurtosis is mesokurtic

described by the sixth order polynomial regression equation $y = –2E\text{-}05x^6 + 0.0037x^5 – 0.2533x^4 + 9.0473x^3 – 177.54x^2 + 1823.4x – 7544.3$, where y is the HC in millimeters and x is the symphysio-fundal height in millimeters; see Fig. 26.18.

Centile values for 3rd, 5th, 50th, 90th 95th, and 97th are plotted in Fig. 26.19. Table 26.6 shows obtained 3rd, 5th, 10th, 50th, 90th, 95th, and 97th centiles of HC at each week of gestation. In Fig. 26.20, they are smoothened into a growth chart, which can be utilized to determine growth and of course brain size development, strongly related to intelligence and wellness, using HC. Table 26.7 shows HC z-scores.

Figure 26.21 shows comparison graph between African (Nigerian) children and European children in the Kurmanavicius et al. (1999) study for 3rd, 5th, 50th, 90th, 95th, and 97th centiles. It is obvious from the comparison graph of Fig. 26.21 that African children maintain a lead over Europeans ones during the development of the skull and HC. When comparison graphs are broken into months (Figs. 26.22–26.28), it is clear that the European children catch up initially at 6 months but still decline till birth.

Figure 26.29 shows the growth rate of the measured fetal HC with a quadratic polynomial mathematical model predictive formula $y = 0.0008x^2 – 0.0095x + 2.1811$ ($R^2 = 0.721$; $p < 0.0001$), where y is the fetal HC growth rate in millimeters and x is the gestational age in weeks. It is clear from this graph that growth rate is much higher in the early stages of development than in the late stages that precede term.

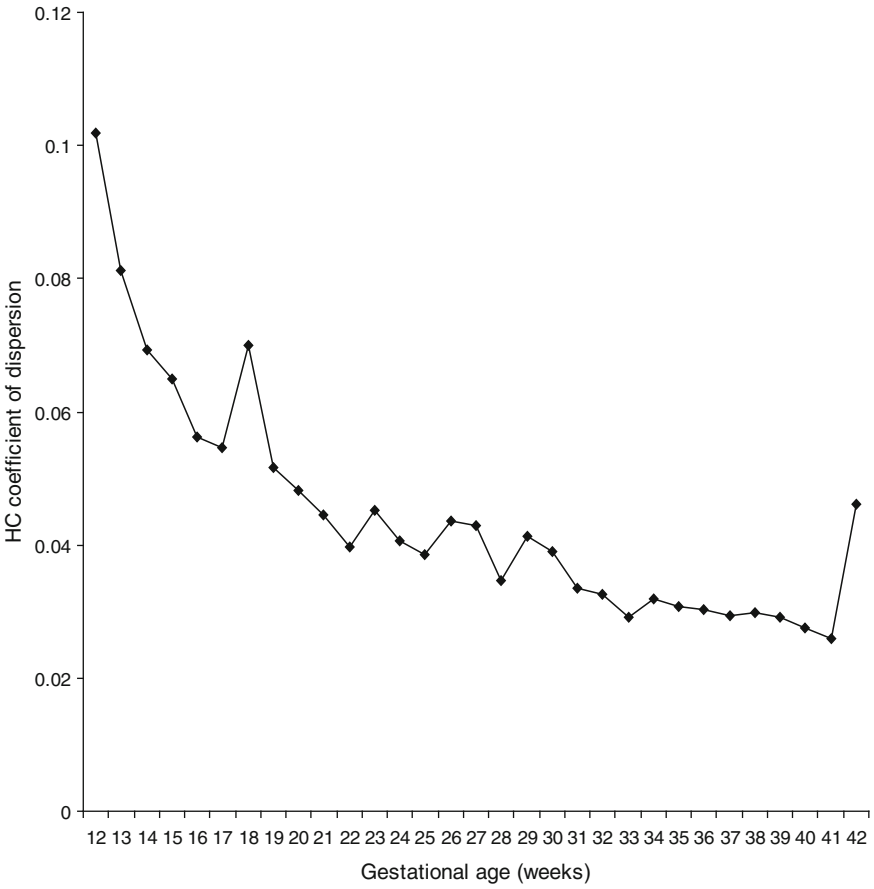

Fig. 26.5 Head circumference coefficient of dispersion in 13,740 fetuses of gestational ages between 12 and 42 weeks. Coefficient of dispersion of HC data of 13,740 fetuses at different gestational age shows a decrease in value as gestational age advances except at 18, 23, 25, 26, 29, 30, and 42 weeks where it peaks. *HC*: head circumference

Ultrasonic fetal anthropometry (Table 26.9) is of great interest in obstetric practice and early pregnancy science. It is helpful in the estimation of gestational age, especially in women who do not remember the dates of their last menstrual period, or whose fundal height on abdominal examination does not correspond to dates. The practice of assessing gestational age in early gestation is valuable in detection of growth aberration in later stages of pregnancy. In addition, fetal anthropometry distinguishes the normal from abnormal fetal structures. Ratios of these measurements calculated for each environment will assist in no small measure in diagnosing certain congenital anomalies, such as Down syndrome, congenital amputee, arthrogryposis multiplex congenita, achondroplasia, gastroschisis, exomphalos, anencephaly, and hydrocephalus. Naeye, as far back as 1973, wrote: "At present there seems to be no completely valid method available to determine normal fetal growth using measurements from neonates because there is no assurance that prematurely born neonates are normally grown." Naeye (1973) went on to say: "Ultrasound and other modalities may eventually solve this problem by providing accurate, sequential in utero measurements of normal fetuses." Regarding fetal length and body weight, was there, for example, a period of peak length velocity and peak weight velocity comparable to the adolescent velocity peaks of height and weight? Tanner (see Morley 2001) had suggested that fetal peak growth velocity in length occurs

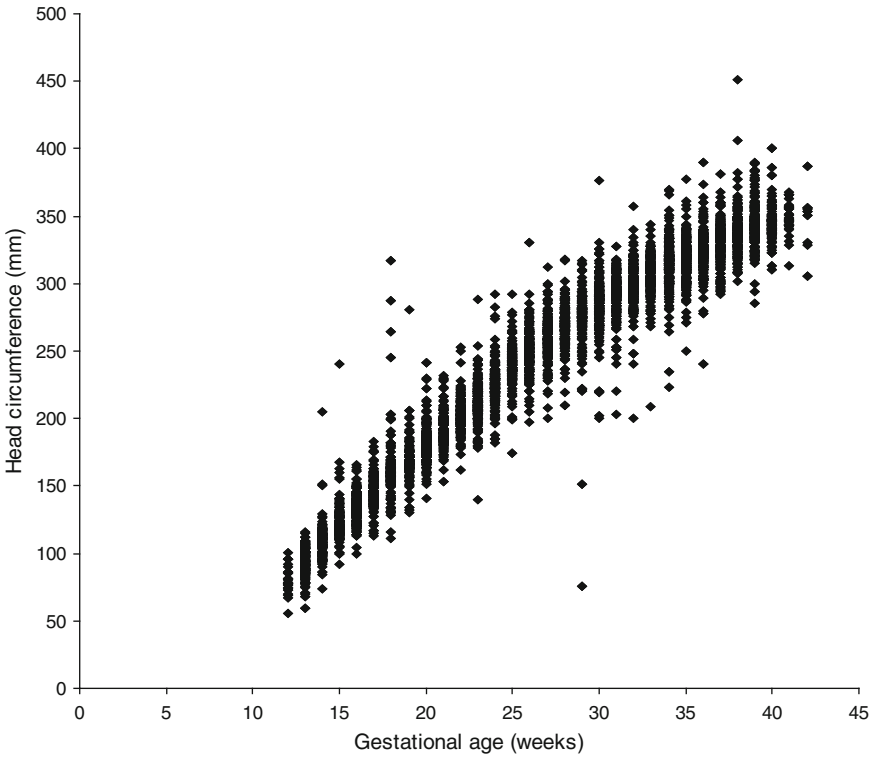

Fig. 26.6 Scattergram of 13,740 fetal head circumference (HC) measurements from 12 to 42 weeks of gestation. The scattergram in figure shows that there are very few bad data points or outliers in the HC measurements of 13,740 fetuses. The outliers are more from 26 to 42 weeks of gestation. This shows the pattern of growth recognized for neural tissue, which suggests growth of brain

around 20 weeks' gestation and in weight a good deal later – around 30 weeks' gestation. Prenatal measurement of fetal parameters, and estimated size and weights vary among different populations, depending upon their racial, demographic characteristics and nutrition. It is therefore important that fetal anthropometry be performed for local population, and local charts of normal anthropometry be constructed and followed for these populations and ethnic groups.

The standard of fetal ultrasound anthropometry was started after Willocks published, probably the first paper on fetal ultrasound cephalometry in 1964. Later, in 1968, fetal cephalometry was included in routine fetal anthropometric scans. Many reference charts and tables have been published since then. However, a number of these were produced using old ultrasound equipment with low spatial resolution in different ultrasound velocities compared with today's modern real-time scanners, which have not only led to the development of improved measurement techniques, but also provided us with multiple fetal parameters (Woo 2006). Several of these charts, however, have methodological flaws, falling short of the ideal attributes of gestational age-related reference curve design, namely non-identification of the statistical method of analysis, a supernormal data set, and inadequate account in variability of measurements with gestation, and failure to present scatter diagrams. In the publications of Altman and Chitty (1994), methodological guidelines were created for the construction of fetal biometry charts.

The final goal of fetal anthropometry is to allow the user to predict information concerning a fetus, and to authenticate how closely the fetus conforms to the prediction. While constructing the fetal anthropometry charts, the statistical justification of the sample size is as necessary as the selection of

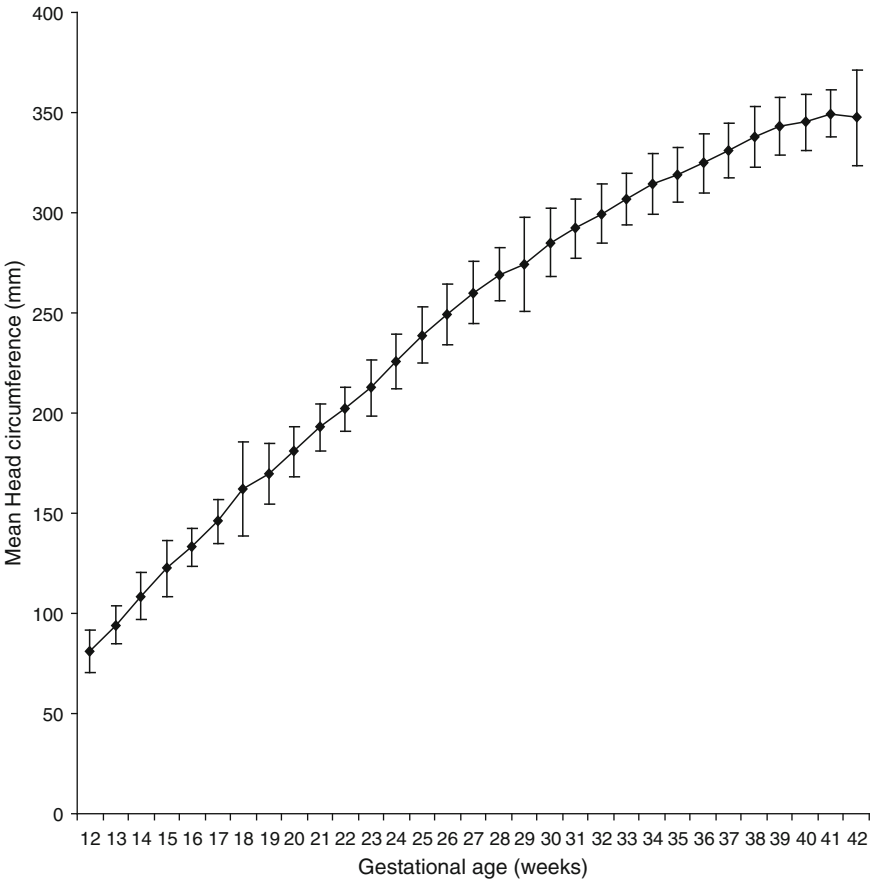

Fig. 26.7 Mean fetal head circumference values in 13,740 fetuses of women at different gestational ages between 12 – 42 weeks. The vertical bars show the values of ± SD. Mean and standard deviation go together like star and satellite. With the mean, we have some idea of the kind of numbers it represents, but the whole story is still a mystery. To clear up the mystery of the hidden numbers that made up a mean, the standard deviation is necessary. For example, the mean ± 1 standard deviation will include about 2 out of 3 numbers in the group while the mean ± 2 standard deviations will include about 95 out of 100 numbers in the group and the mean ± 3 standard deviations will include 997 numbers out of 1,000.

study design type, so that the results may subsequently be generalized to the whole population, or at least to the concerned ethnic group. Mean and SD values of the parameter(s) are computed. The smaller the SD, the less is the variability of the sample around the mean. The SD is also used to describe the statistical limits of "normality." These intervals are called confidence limits. Traditionally, the confidence limits are set at the 5th and 95th centiles. The values of 5th and 95th centiles suggest the lower and the upper limits of normal reference intervals respectively, or normal ranges for the selected parameter. Scattergrams are constructed and regression analysis is done, yielding a specific regression equation that enables one to predict the fetal gestational age, once the specific values of fetal parameter is known.

Fetal anthropometry studies reported from Iran, Oman, Cameron, Bangladesh, Pakistan, and Israel describe the uniqueness and specification of different fetal parameters for their own populations (Stein 1975). Ethnic variations have also been described. Therefore, anthropometric curves for one population may over- or underestimate the fetal age when used for another population with different demographic characteristics. Thus, the construction and use of biometric normograms specific for populations and ethnic groups is always recommended.

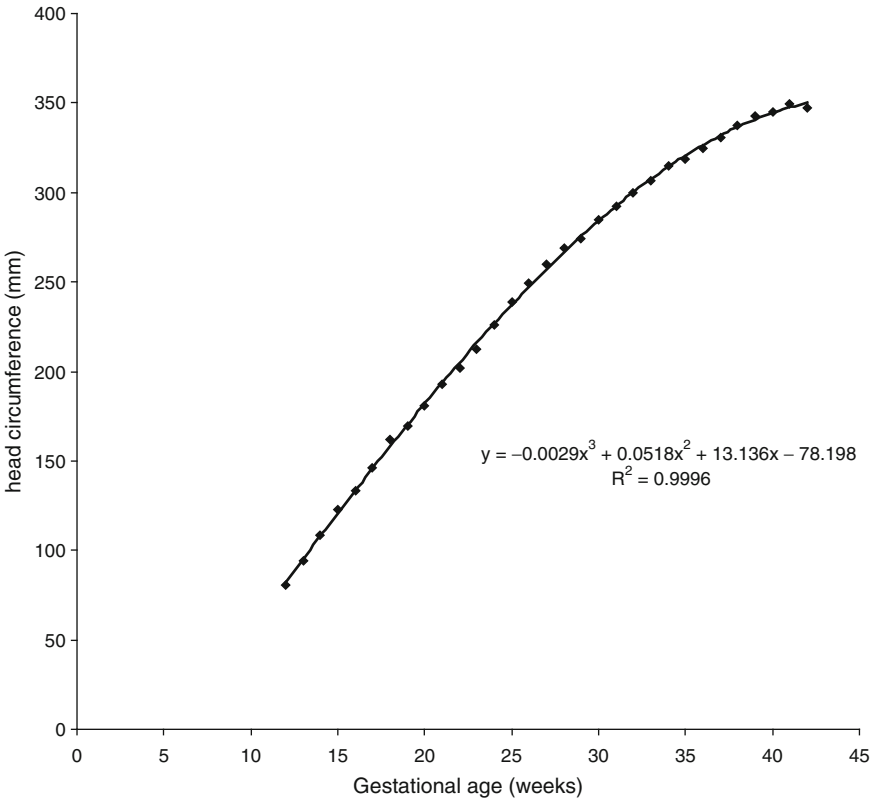

Fig. 26.8 Correlation and regression equation of mean HC values in 13,740 Nigerian fetuses plotted against gestational age in weeks. There is a positive polynomial correlation between gestational age and HC with a correlation coefficient of $R^2 = 0.9996$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the third order polynomial regression equation $y = -0.0029x^3 + 0.0518x^2 + 13.136x - 78.198$, where y is the HC in millimeters and x is the gestational age in weeks

26.9 Conclusion

We have presented mean values ± SD, centile charts, tables, and formulas for fetal HC in Africans derived from a very large sample size (13,740: probably the largest ever recorded) in a cross-sectional study. We have also shown how important these values are in the new and emerging field of ultrasonic embryology and, indeed, clinical anthropology. It is clear when we make comparison with studies in other racial groups such as that of Europeans that the African HC increases faster than that of the European fetus and is bigger than it at birth, on average. We conclude that there is a faster and shorter period of maturation of the skull and the brain, respectively in the African fetus than in the European fetus. We also conclude that modern studies, which implicate HC in intelligence, suggest that the well-known decline in HC in the African vis-a-vis other racial groups occurs after birth and

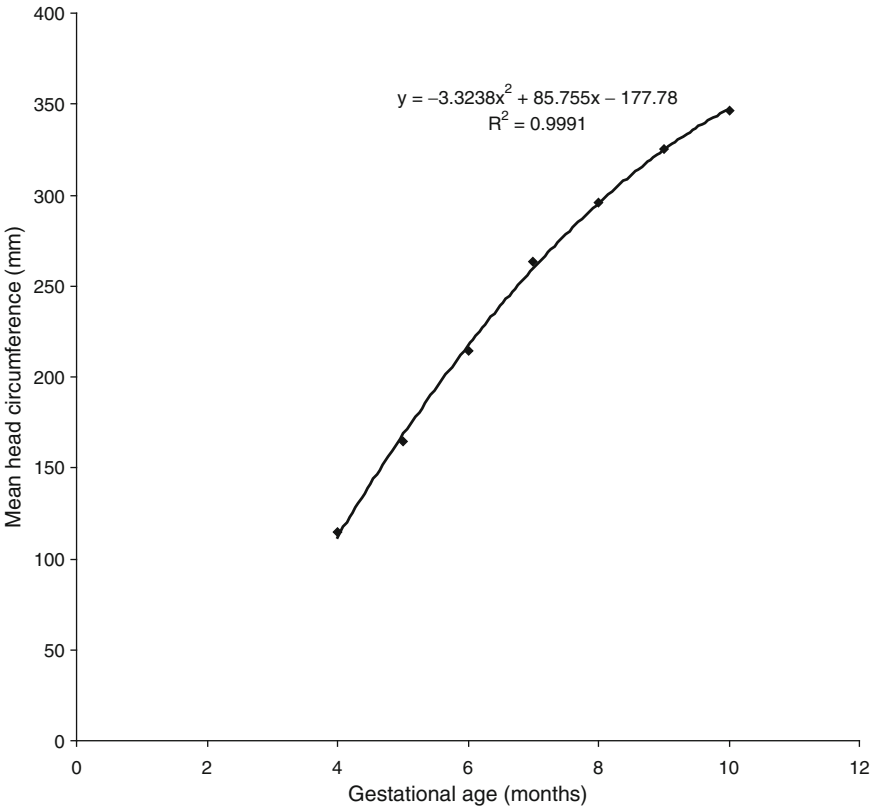

Fig. 26.9 Correlation and regression equation of mean HC values in 13,740 Nigerian fetuses plotted against gestational age in months. There is a positive polynomial correlation between gestational age and HC with a correlation coefficient of $R^2 = 0.9991$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the second order polynomial regression equation $y = -3.3238x^2 + 85.755x - 177.78$, where y is the HC in millimeters and x is the gestational age in months

not before it. We are equally aware that early maturation does not necessarily indicate better intelligence. However, we suggest that postnatal decline in velocity of growth of HC in the African is probably due to low nutrition, and that with improved diet, this seeming difference will be corrected. It is already well documented that postnatal nutrition contributes to the development of intelligence. The significance of nurture rather than nature has placed the African child at a disadvantage not only for HC but also for other well-known anthropometric parameters, such as height and even weight after birth. The future and intelligence of the growing African child is dependent on his nurture more than his nature and this may account for the spuriously low IQ frequently reported by some investigators in Africa. However, we also see that HC is not a good indicator of nutritional status in the fetus, nor is it well correlated with FL, AC, or cephalic index. The prospect for further studies on craniometry and HC measurements, especially in the postnatal human, seems promising, given the intelligence data, as intelligence is increasingly being implicated with these cranial measurements and would ultimately explain them.

Table 26.5 Monthly mean fetal HC values (in mm) in a Nigerian population

GA (months)	Fetuses (*n*)	Mean (mm)	SD	SEM
4	1,660	114.5	16.9	8.4
5	1,708	164.6	14.5	7.2
6	2,184	214.4	18.3	8.1
7	1,975	263.2	10.9	5.5
8	2,247	295.9	9.5	4.7
9	3,095	325.4	9.2	4.1
10	871	346.3	2.9	1.4
Total	13,740			

This table gives the mean values of fetal HC measurements from the 4th month of intrauterine life to the 10th month with their corresponding SD and SEM

SD standard deviation, *SEM* standard error of mean

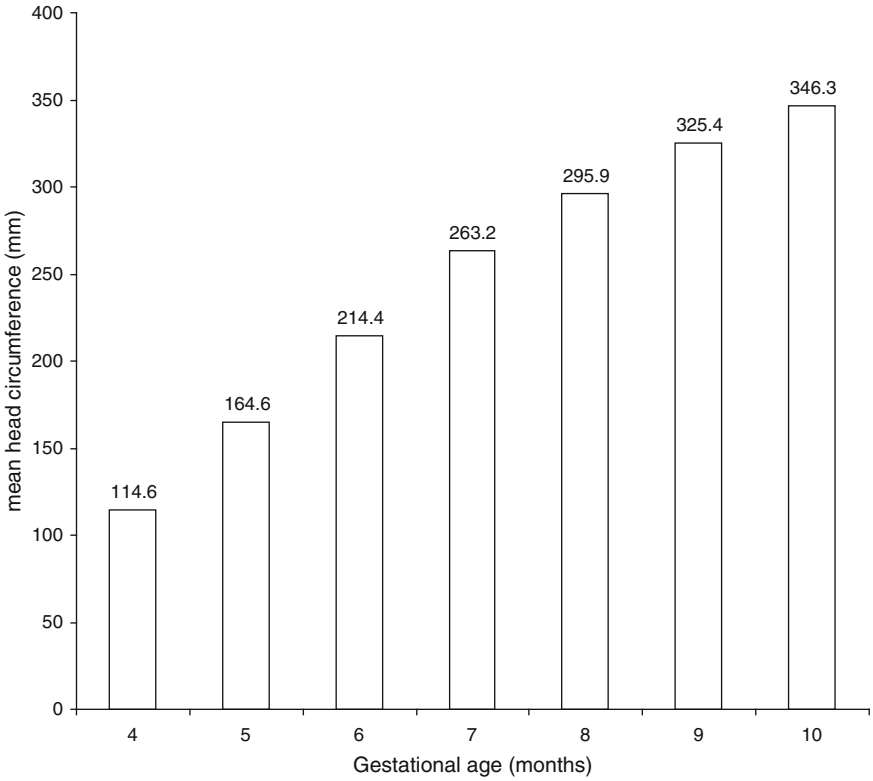

Fig. 26.10 Histogram showing mean HC values in 13,740 HC data of fetuses in women of gestational ages from 4 to 10 months. Histogram shows a steady rise of mean values from 4 to 10 months of gestation. Values shown are HC mean values (see Table 26.5)

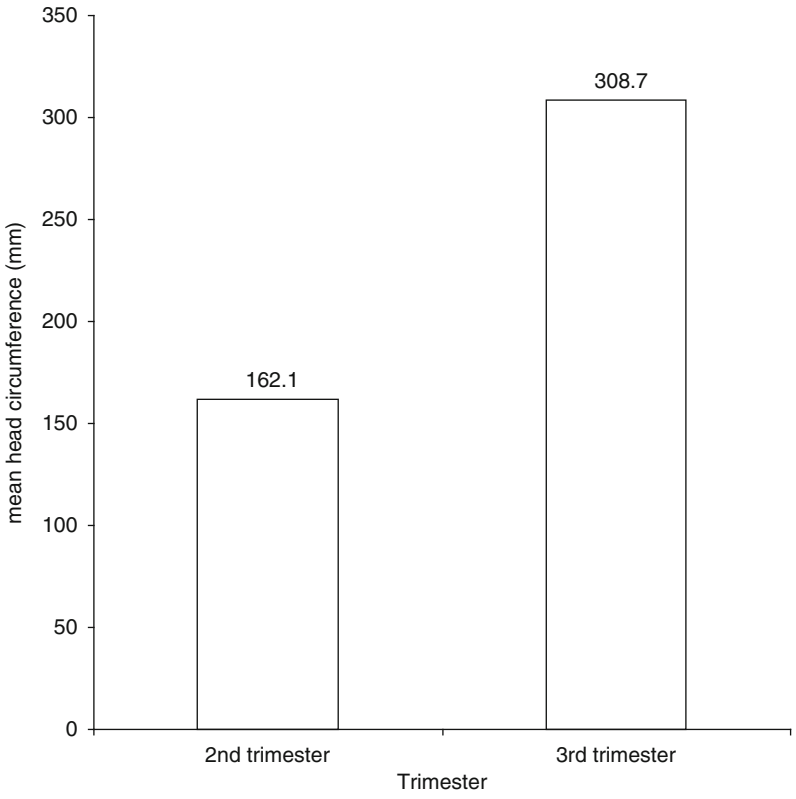

Fig. 26.11 Histogram showing mean HC values in 13,740 HC data of fetuses in women of gestational ages from 4 to 10 months divided into two trimesters. Mean HC show statistically significant higher value for third trimester (SD 32.6) when compared to second trimester (SD 49.7; $p < 0.001$). Values shown are HC mean values. SD: standard deviation (see Table 26.6)

Table 26.6 Mean values of fetal HC by Trimester

Trimester	Fetuses (*n*)	Mean	SD	SEM	Minimum	Maximum	Range
2nd	5,552	162.1	49.7	13.3	80.9	238.7	157.8
3rd	8,188	308.7	32.6	7.9	249.3	349.6	100.3
Total	13,740						

This table gives mean values of HC for 2nd and 3rd trimesters with their corresponding SDs, SEM, and range for each trimester

SD standard deviation, *SEM* standard error of mean

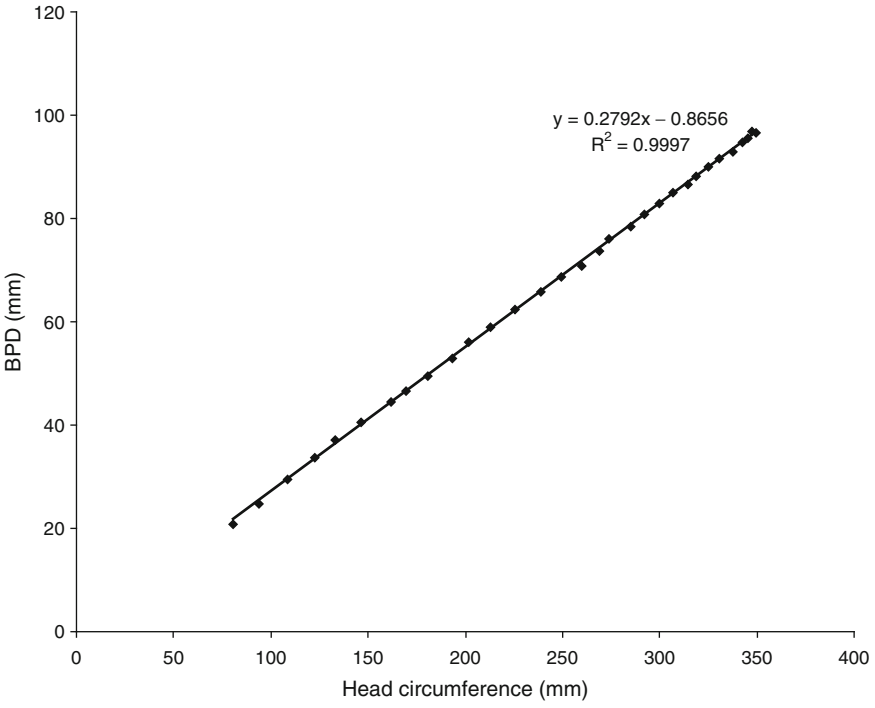

Fig. 26.12 Correlation and regression equation of mean biparietal diameter (BPD) HC values in 13,740 Nigerian fetuses plotted against HC. There is a positive linear correlation between BPD and HC with a correlation coefficient of $R^2 = 0.9997$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the linear regression equation $y = 0.2792x - 0.8656$, where y is the BPD in millimeters and x is the HC in millimeters. BPD: Biparietal diameter

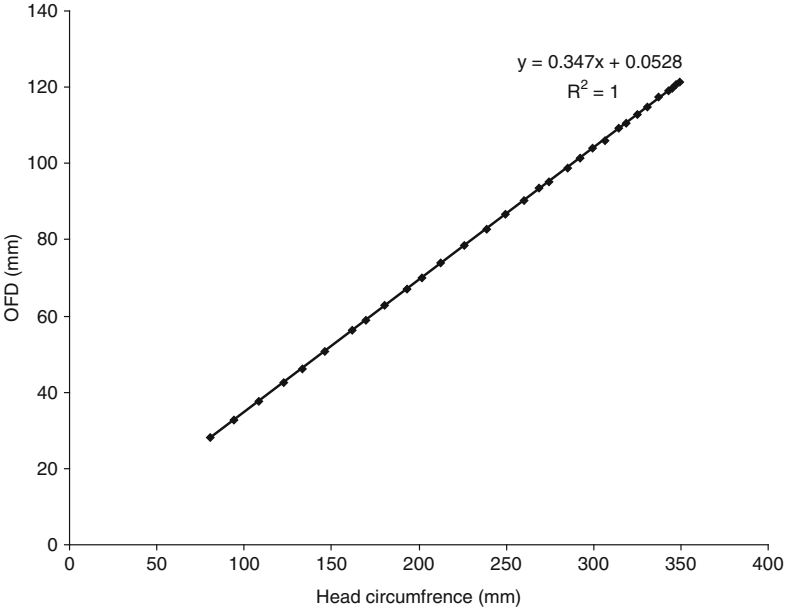

Fig. 26.13 Correlation and regression equation of mean occipitofrontal diameter (OFD)HC values in 13,740 Nigerian fetuses plotted against HC. There is a positive linear correlation between OFD and HC with a correlation coefficient of $R^2 = 1$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the linear regression equation $y = 0.347 + 0.0528$, where y is the OFD in millimeters and x is the HC in millimeters. OFD: occipitofrontal diameter

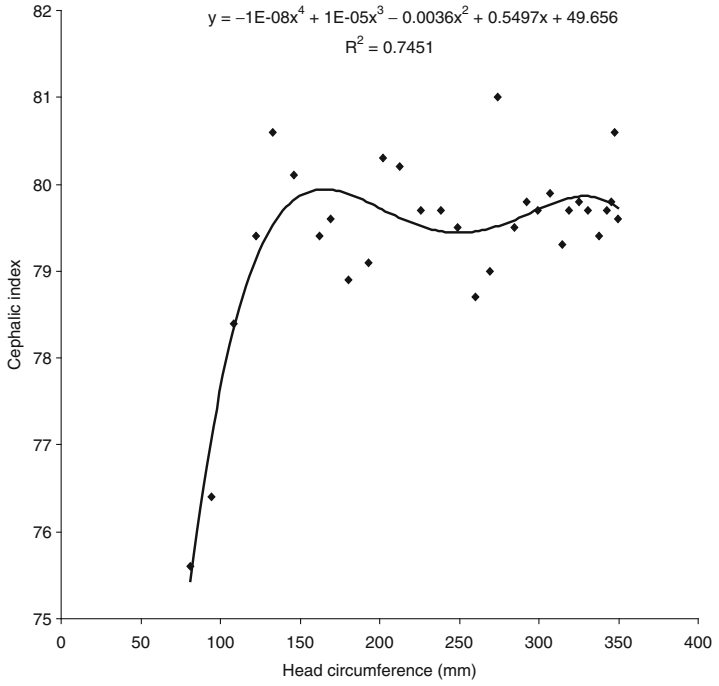

Fig. 26.14 Correlation and regression equation of mean cephalic index HC values in 13,740 Nigerian fetuses plotted against HC. There is a positive polynomial correlation between cephalic index and HC with a correlation coefficient of $R^2 = 0.7451$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the fourth order polynomial regression equation $y = 1E\text{-}08x^4 + 1E\text{-}05x^3 - 0.0036x^2 + 0.5497x + 49.656$, where y is the cephalic index and x is the HC in millimeters

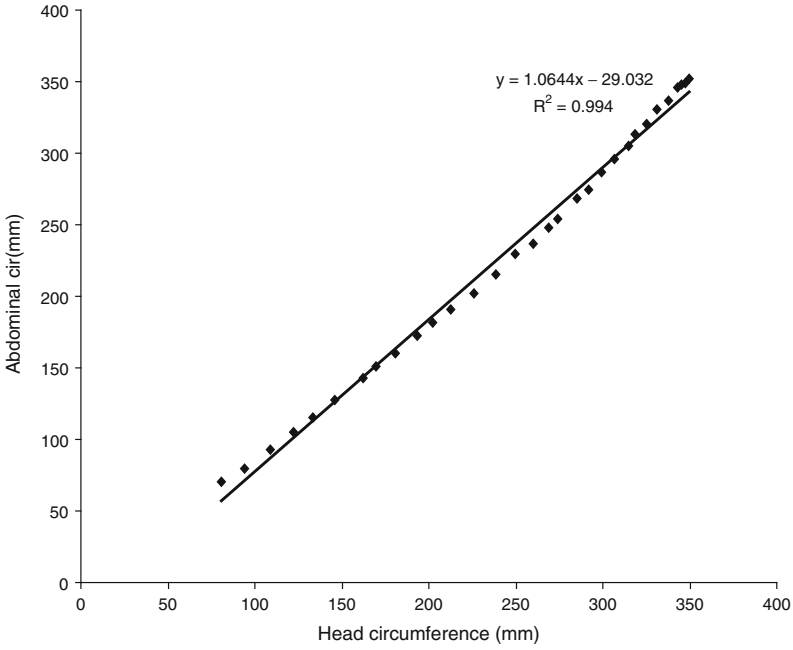

Fig. 26.15 Correlation and regression equation of mean AC HC values in 13,740 Nigerian fetuses plotted against HC. There is a positive linear correlation between AC and HC with a correlation coefficient of $R^2 = 0.994$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the linear regression equation $y = 1.0644x - 29.032$, where y is the AC in millimeters and x is the HC in millimeters

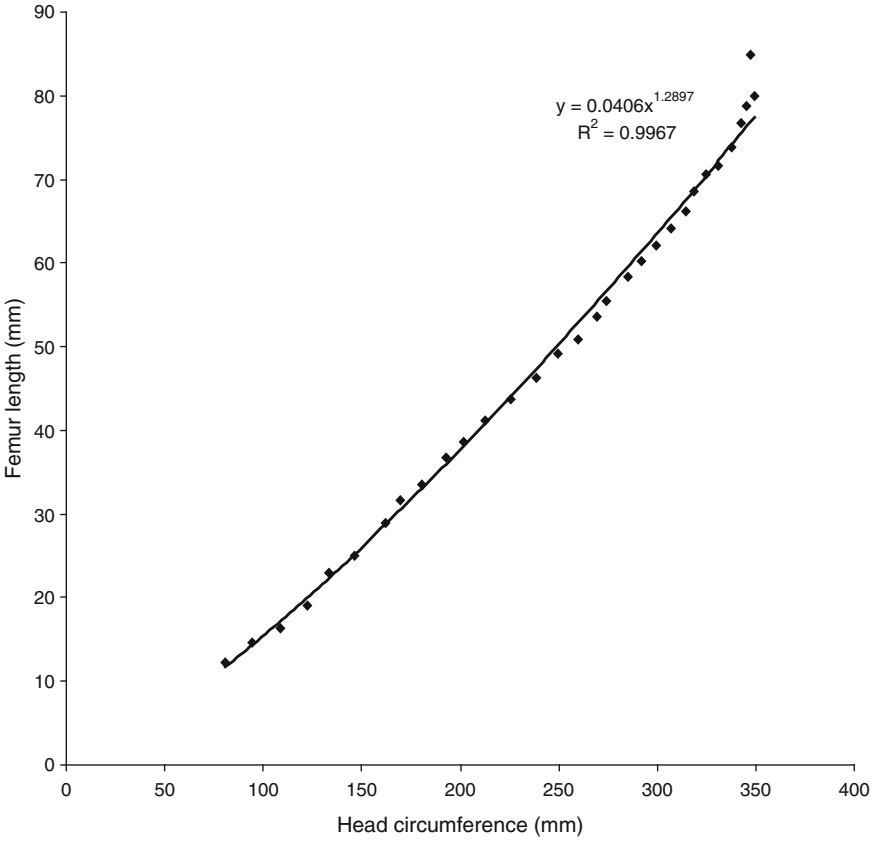

Fig. 26.16 Correlation and regression equation of mean against femur length (FL) HC values in 13,740 Nigerian fetuses plotted against HC. There is a positive power correlation between FL and HC with a correlation coefficient of $R^2 = 0.9962$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the power regression equation $y = 0.046x^{1.2897}$, where y is the AC in millimeters and x is the HC in millimeters

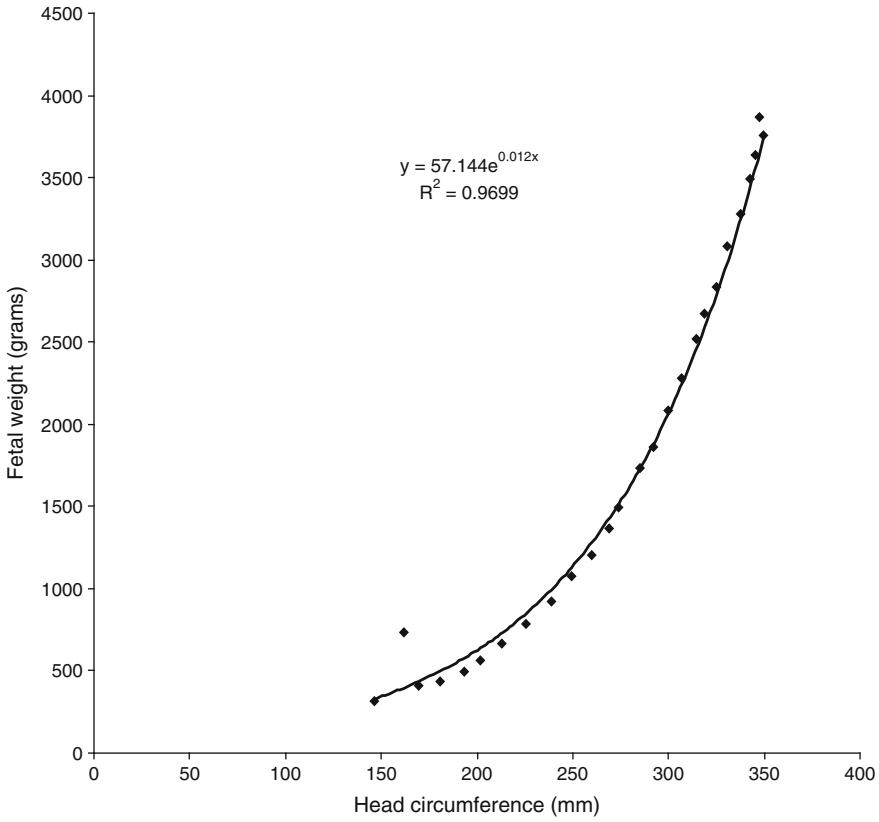

Fig. 26.17 Correlation and regression equation of mean fetal weight HC values in 13,740 Nigerian fetuses plotted against HC. There is a positive exponential correlation between fetal weight and HC with a correlation coefficient of $R^2 = 0.9699$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the exponential regression equation $y = 57.144e^{0.012x}$, where y is the fetal weight in grams and x is the HC in millimeters

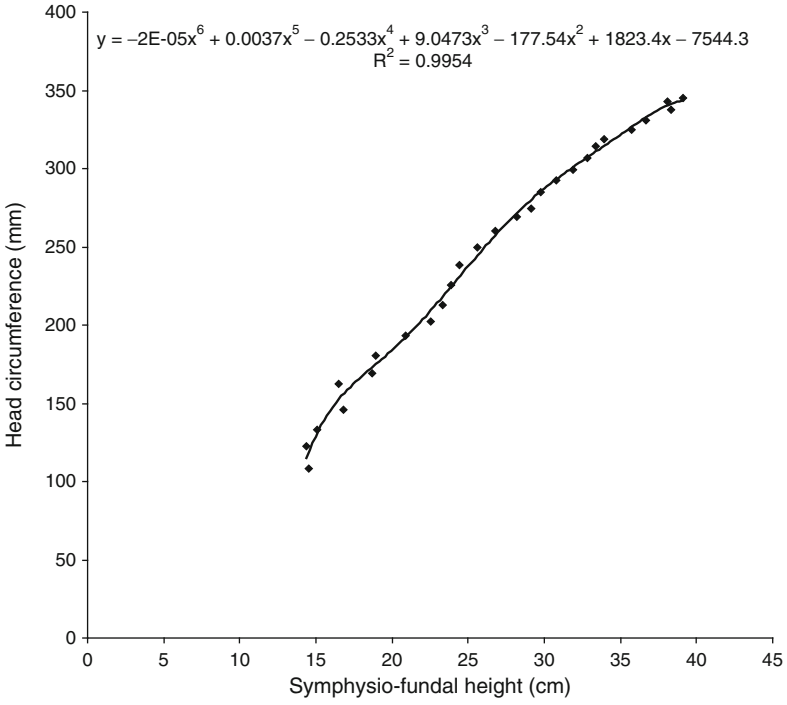

Fig. 26.18 Correlation and regression equation of mean HC values in 13,740 Nigerian fetuses plotted against symphysio-fundal height. There is a positive polynomial correlation between symphysio-fundal height and HC with a correlation coefficient of $R^2 = 0.9954$ ($p < 0.0001$) in Nigerian fetuses. The relationship is best described by the sixth order polynomial regression equation $y = –2E\text{-}05x^6 + 0.0037x^5 – 0.2533x^4 + 9.0473x^3 – 177.54x^2 + 1823.4x – 7544.3$, where y is the HC in millimeters and x is the symphysio-fundal height in millimeters

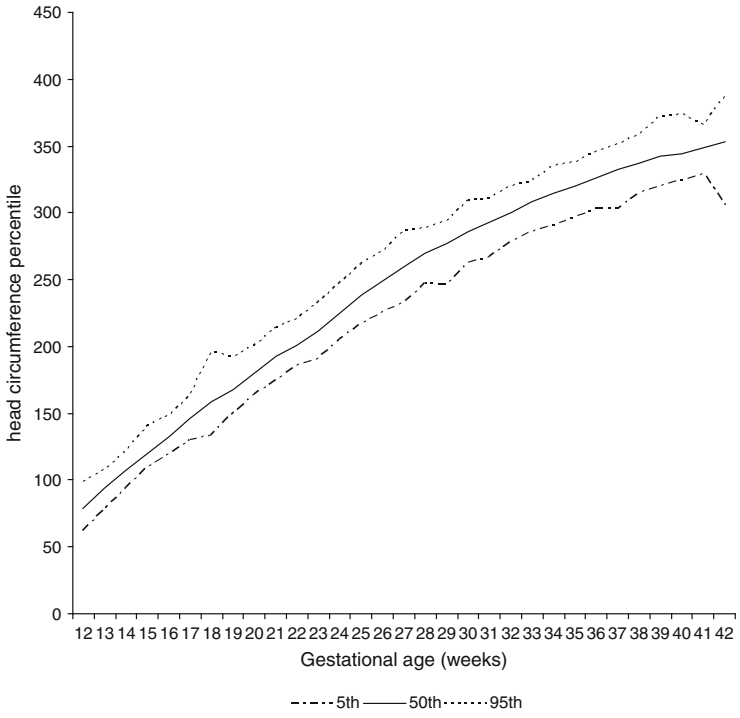

Fig. 26.19 Fifth, 50th, and 97th centiles for HC in 13,740 fetuses at different gestational ages from 12 to 42 weeks. Centile values plotted against gestational age from 12 to 42 weeks. The 5th, 50th, and 95th centiles showing a bell-shaped curve similar to that of the mean curve in Fig. 26.8

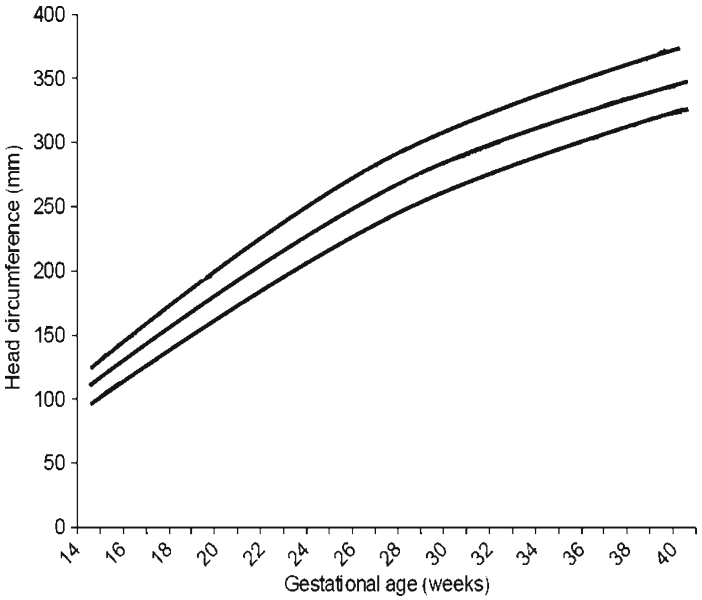

Fig. 26.20 Curves created from 3rd, 50th, and 97th fetal HC centiles. Chart using HC derived from data from 3rd, 50th, and 97th centiles. The curves can be used to monitor growth in a developing fetus to determine its growth velocity and pattern and can be used like other growth charts in this environment

Table 26.7 Centiles of fetal HC measurements

	Head circumference centiles (mm)						
Gestational age	3rd	5th	10th	50th	90th	95th	97th
12 to 12 + 6	56.0	61.5	69.0	79.0	96.0	98.5	101.0
13 to 13 + 6	75.0	78.0	82.0	94.0	106.0	108.0	109.0

26 to 26 + 6	220.0	226.0	232.2	249.0	265.0	272.0	279.0
27 to 27 + 6	230.0	232.7	240.3	260.0	278.0	287.0	292.0
28 to 28 + 6	243.0	247.0	255.0	270.0	284.0	289.0	292.0
29 to 29 + 6	229.2	246.3	260.0	277.0	290.0	294.0	302.0
30 to 30 + 6	250.0	262.3	269.0	286.0	300.0	309.0	315.4
31 to 31 + 6	253.0	267.0	276.0	293.0	309.0	311.0	314.3
32 to 32 + 6	274.1	279.2	284.4	300.0	316.0	320.0	322.0
33 to 33 + 6	280.0	286.0	293.0	308.0	321.0	324.0	328.0
34 to 34 + 6	286.0	290.5	300.0	315.0	330.5	335.0	340.0
35 to 35 + 6	291.2	297.0	301.0	320.0	333.0	338.0	340.8
36 to 36 + 6	301.0	303.0	306.0	326.0	339.0	346.0	351.0
37 to 37 + 6	300.0	302.7	312.3	333.0	344.7	351.0	358.0
38 to 38 + 6	310.9	315.0	320.0	337.0	352.0	359.0	364.0
39 to 39 + 6	318.0	320.3	326.2	342.0	359.0	372.0	378.0
40 to 40 + 6	323.0	324.3	330.0	344.0	360.0	373.5	382.5
41 to 41 + 6	316.0	329.0	335.0	348.5	366.0	366.0	367.6
42 to 42 + 6	306.0	306.0	306.0	353.0	387.0	387.0	387.0

This table gives the 3rd, 5th, 10th, 50th, 90th, 95th, and 97th centile values for fetal HC measured at different gestational age ranging from 12 to 42 weeks. For example, it can be seen from the table that the 10th percentile of HC at 18 to 18 + 6 weeks' gestation is 146 mm. This means that 10% of the fetuses at 18 to 18 + 6 weeks had a mean HC less than 146 mm, whereas 90% had a mean HC greater than 146 mm. Similarly, the 97th percentile with respect to HC at 39 to 39 + 6 weeks is 378 millimeters. Hence 97% of fetuses at 39 to 39 + 6 weeks had a mean HC less than 378 millimeters, whereas 3% had a mean HC greater than 378 mm

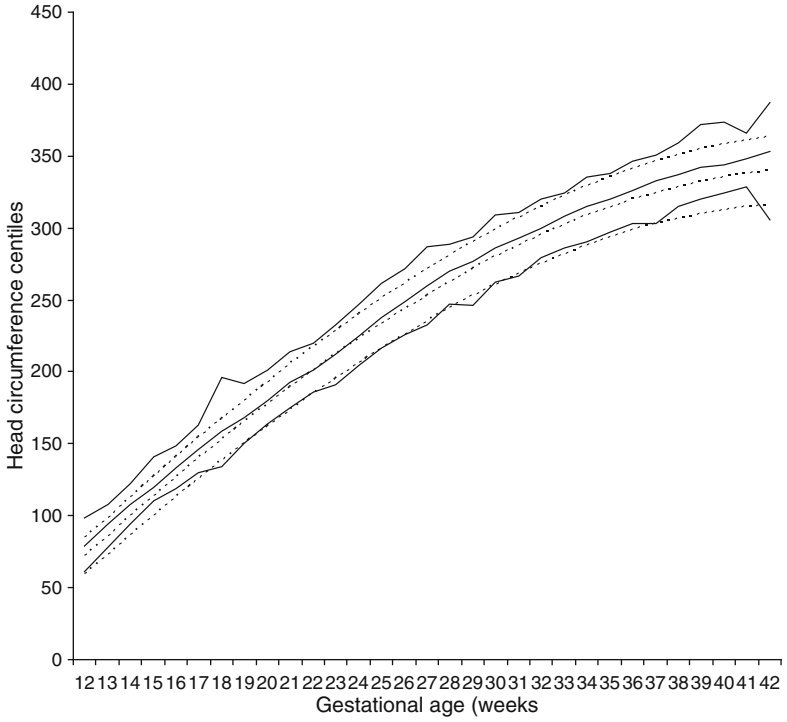

Fig. 26.21 Comparison between centile values of HC in African and European fetuses from 12 to 42 weeks of gestation. Comparison of African (Nigerian) HC 5th, 50th, and 95th centiles values in our study from 12 to 42 weeks of gestation (*solid lines*) with those of European fetuses – Kurmanavicius et al. (1999) (*dashed line*). The trend in the African shows consistently higher values when compared with the European values and more so in later years at the third trimester

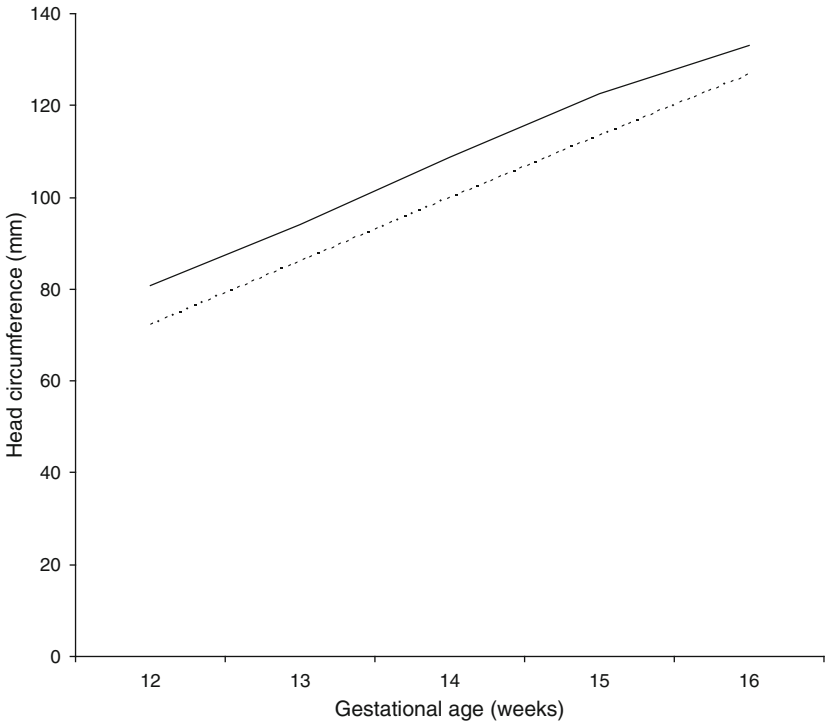

Fig. 26.22 Comparison between centile values of HC in African and European fetuses at 4 months (12–16 weeks) of gestation. Comparison of African (Nigerian) HC centile values in our study at 4 months (12–16 weeks of gestation) (*solid lines*) with those of European fetuses – Kurmanavicius et al. (1999) (*dashed line*). Values are consistently lower in Europeans than in African fetuses

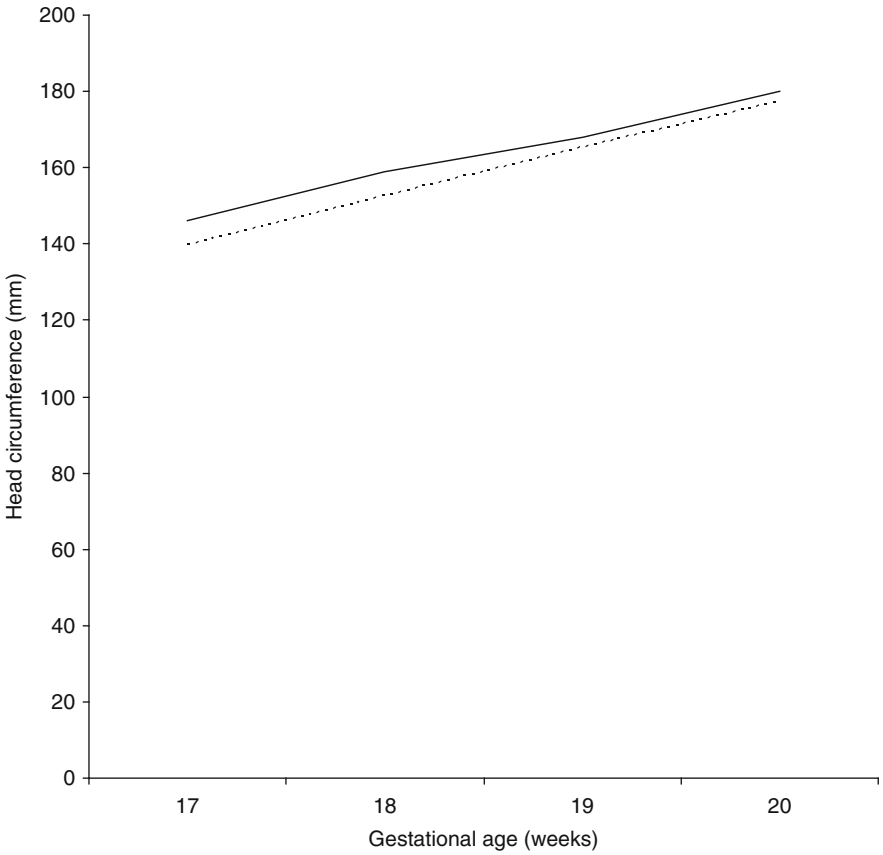

Fig. 26.23 Comparison between centile values of HC in African and European fetuses at 5 months (17–20 weeks) of gestation. Comparison of African (Nigerian) HC centile values in our study at 5 months (*solid lines*) with those of European fetuses – Kurmanavicius et al. (1999) (*dashed lines*). At 5 months, there is little difference in the values of European and African fetuses

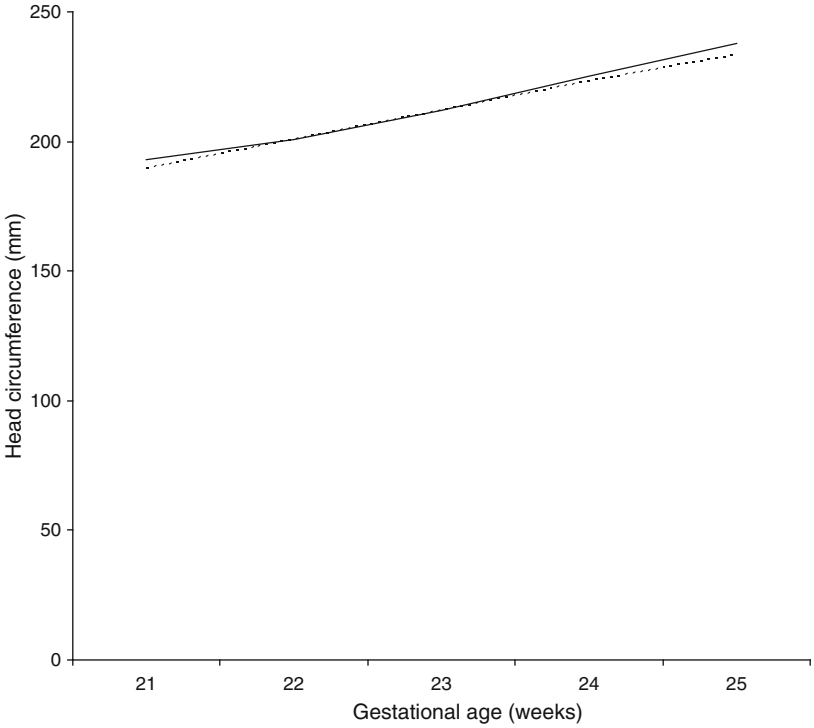

Fig. 26.24 Comparison between centile values of HC in African and European fetuses at 6 months (21–25 weeks) of gestation. Comparison of African (Nigerian) HC centile values in our study at 6 months (*solid lines*) with those of European – Kurmanavicius et al. (1999) (*dashed lines*). At 6 months, there is no difference at all in the values of European and African fetuses

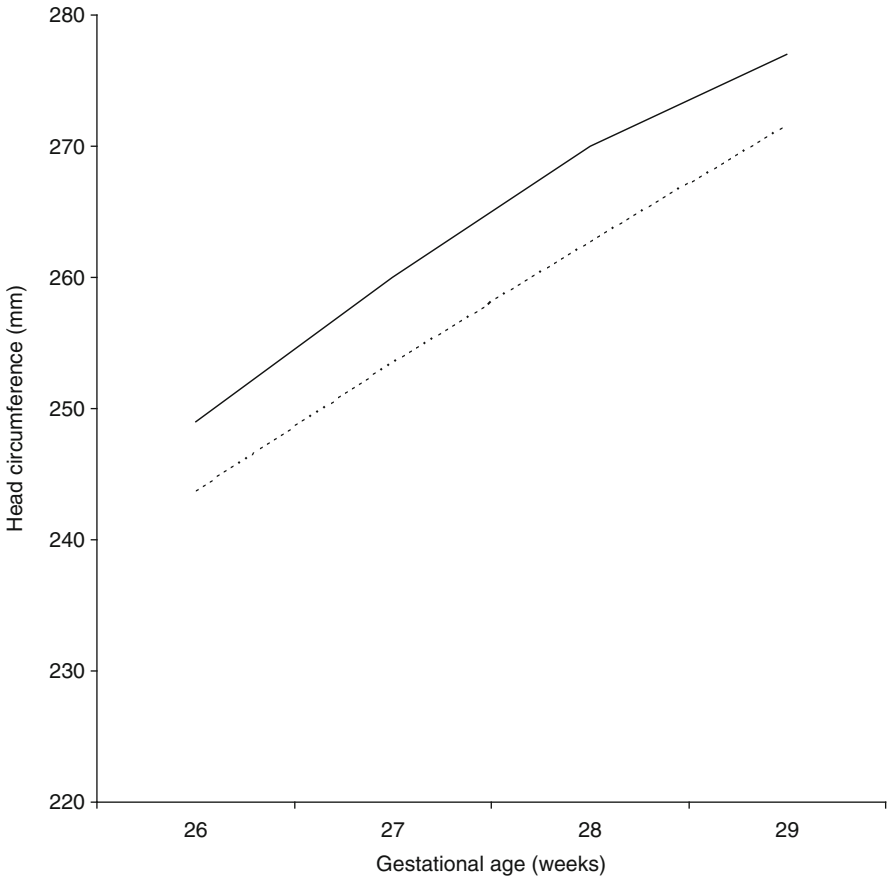

Fig. 26.25 Comparison between centile values of HC in African and European fetuses at 7 months (26–29 weeks) of gestation. Comparison of African (Nigerian) HC centile values in our study at 7 months (*solid lines*) with those of European fetuses – Kurmanavicius et al. (1999) (*dashed lines*). At 7 months, there is difference in the values of European and African fetuses

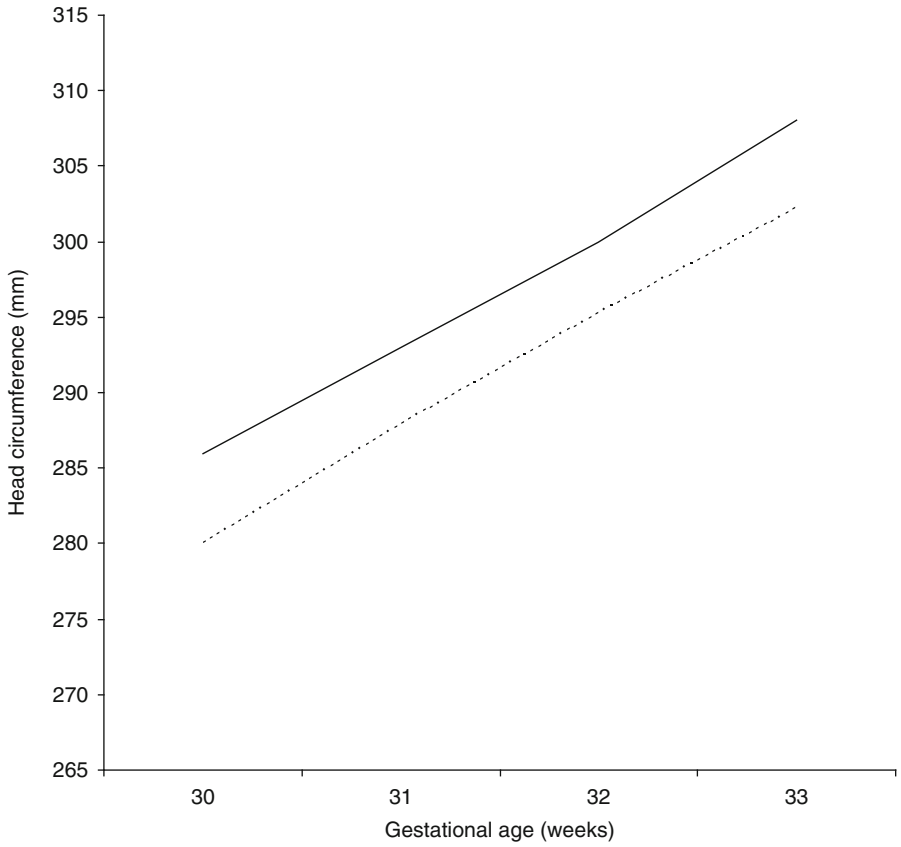

Fig. 26.26 Comparison between centile values of HC in African and European fetuses at 8 months (30–33 weeks) of gestation. Comparison of African (Nigerian) HC centile values in our study at 8 months (*solid lines*) with those of European fetuses – Kurmanavicius et al. (1999) (*dashed lines*). At 8 months, there is difference in the values of European and African fetuses

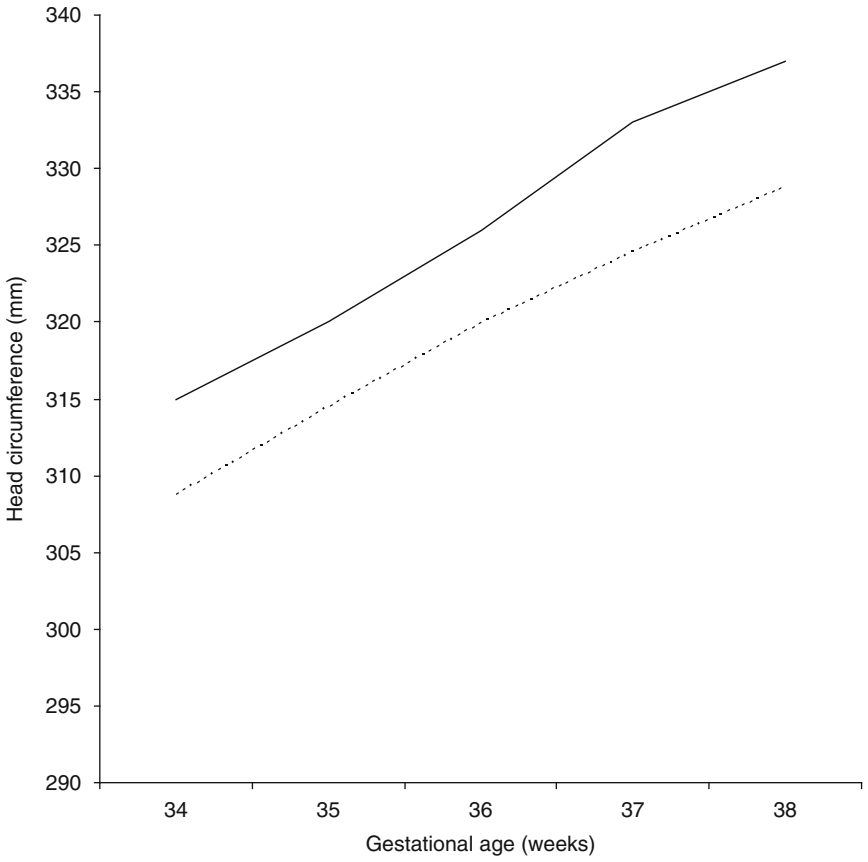

Fig. 26.27 Comparison between centile values of HC in African and European fetuses at 9 months (34–38 weeks) of gestation. Comparison of African (Nigerian) HC centile values in our study at 9 months (*solid lines*) with those of European fetuses – Kurmanavicius et al. (1999) (*dashed lines*). At 9 months, there is difference in the values of European and African fetuses, with African values being consistently higher than European ones

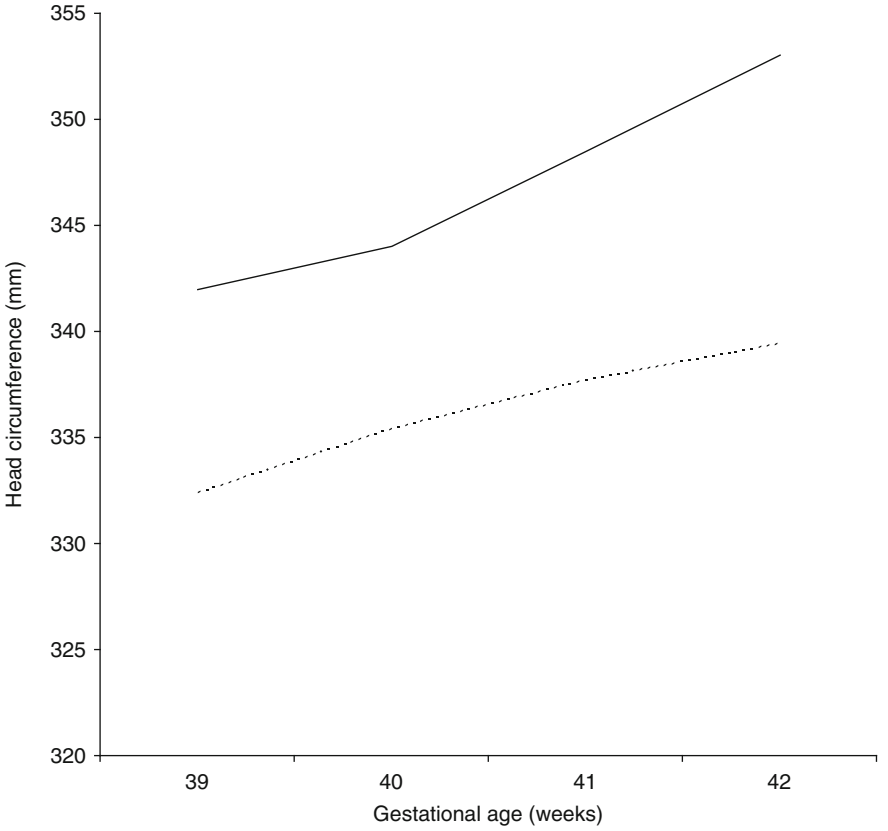

Fig. 26.28 Comparison between centile values of HC in African and European fetuses at 10 months (39–42 weeks) of gestation. Comparison of African (Nigerian) HC centile values in our study at 10 months (*solid lines*) with those of European fetuses – Kurmanavicius et al. (1999) (*dashed lines*). At 10 months, there is considerable difference in the values of European and African fetuses, with African values being consistently higher than European ones. The African values are highest over European ones at this month. It is obvious that, before birth, the African child is far more mature in HC than his European counterpart

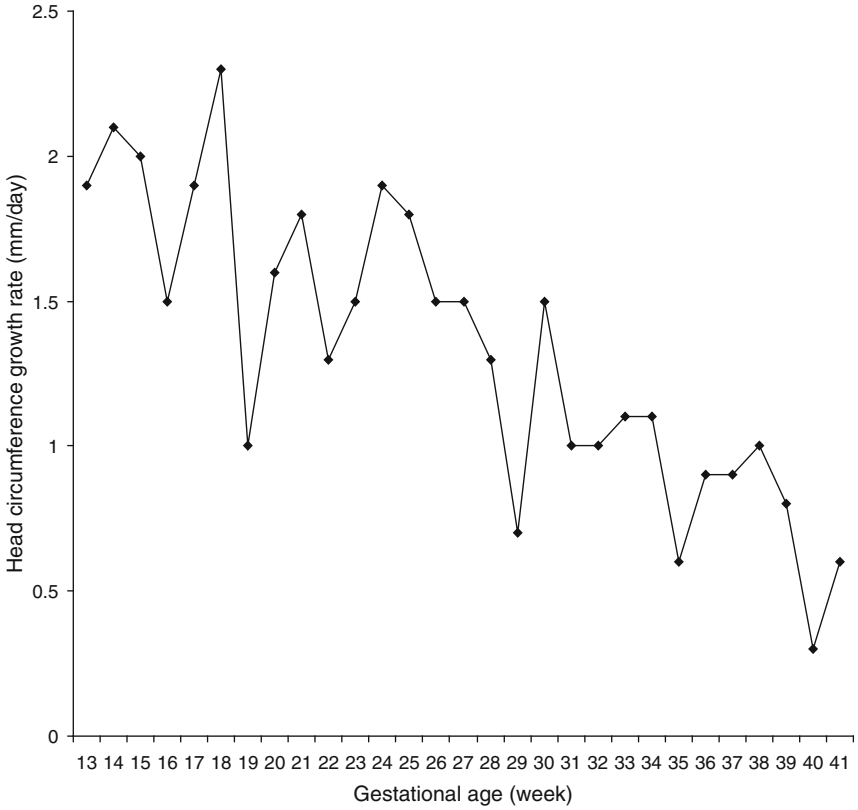

Fig. 26.29 Growth velocity pattern of head circumference in 13,740 Nigerian fetuses.Head circumference growth rate when compared to gestational age. It seems to fall from 12 weeks down to 41 weeks. Its pattern is similar to that of coefficient of dispersion of head circumference values in Figure 26.5

Table 26.8 Standard score (z-score) of HC measurements in 13,740 Nigerian fetuses ranging from 12 to 42 weeks of gestation

Gestational age	Fetuses (n)	Mean z-score
12 to 12 + 6	49	–2.14E-03
13 to 13 + 6	384	–1.46E-03
14 to 14 + 6	371	3.29E-03
15 to 15 + 6	351	–1.75E-03
16 to 16 + 6	505	–3.67E-03
17 to 17 + 6	427	1.35E-03
18 to 18 + 6	446	1.85E-03
19 to 19 + 6	282	–2.29E-03
20 to 20 + 6	553	–1.42E-05
21 to 21 + 6	400	–2.14E-04
22 to 22 + 6	398	–1.16E-03
23 to 23 + 6	478	8.13E-04

(continued)

Table 26.8 (continued)

Gestational age	Fetuses (*n*)	Mean *z*-score
24 to 24 + 6	520	2.31E-03
25 to 25 + 6	388	–2.50E-03
26 to 26 + 6	511	–3.48E-03
27 to 27 + 6	432	1.50E-04
28 to 28 + 6	548	2.63E-03
29 to 29 + 6	484	1.08E-03
30 to 30 + 6	625	2.87E-03
31 to 31 + 6	523	–4.62E-04
32 to 32 + 6	583	1.81E-03
33 to 33 + 6	516	–2.61E-03
34 to 34 + 6	744	–2.90E-03
35 to 35 + 6	739	–1.72E-03
36 to 36 + 6	599	1.58E-03
37 to 37 + 6	532	–1.89E-03
38 to 38 + 6	481	5.51E-05
39 to 39 + 6	525	–2.58E-03
40 to 40 + 6	252	4.50E-04
41 to 41 + 6	72	–3.77E-03
42 to 42 + 6	22	–1.56E-03
Total	**13,740**	

The *z*-score enables us to study head measurements in each gestational age and see how they compare on the same standard; taking into account the mean and SD of each gestational age. For example, HC measurements at 12 weeks are –0.002 SDs from the mean, whereas measurements at 14 weeks are 0.003 SDs from the mean. Again, from the above z-score table, it can be seen that the HC measurements at 20 and 38 weeks are 0.000 deviations from the mean

Table 26.9 Key facts of ultrasonic fetal anthropometry

1. Ultrasonic fetal anthropometry is a technique in sonographic embryology, which measures fetal parts
2. It uses focused, high-frequency sound waves to generate fetal images.
3. It is not invasive
4. Sound is the orderly transmission of mechanical vibrations through a medium
5. The number of these vibrations per second is the frequency (measured in hertz)
6. Audible sounds are in the range of 20–20 kHz
7. "Sound" above 20 kHz is described as ultrasound
8. Ultrasound allows detailed examination of fetal anatomy
9. It is safe for the patient, the fetus, and the sonologist
10. Ultrasonic fetal anthropometry is now the gold standard for assessing fetal growth
11. It involves measurement of BPD, HC, OFD, AC, FL, and fetal weight

This table lists the key facts of ultrasonic fetal anthropometry, the parameters measured using it, its safety, uses, and application in modern embryology

Summary Points

- This chapter provides extensive data for HC of 13,740 African (Nigerian) fetuses and suggests the early maturation of HC in African children vis-a-vis European children is a genetic rather than nutritional factor.
- Head circumference has been implicated in various conditions and is related to brain size, brain development, intelligence, maternal nutrition, ethnic group, and race.

- Head circumference is related to intracranial volume and permits an estimation of the rate of brain growth.
- Head circumference became a useful tool in determining the characteristics of human intelligence since Galton.
- Head circumference is a very useful tool in ultrasonic or sonographic embryology, as it can be used to predict congenital anomalies as well as embryological dating and clinical staging/dating of pregnancy.
- Limitation of growth potential in the fetus, called IUGR, can be either symmetrical or asymmetrical.
- Symmetrical growth retardation implies a fetus whose entire body is proportionally small.
- Asymmetrical growth retardation implies a fetus that is undernourished and is directing most of its energy to maintaining growth of vital organs, such as the brain and heart, at the expense of the liver, muscle, and fat.
- It is well established that the state of maternal nutrition influences the nutrition and subsequent growth and development of the child.
- Microcephaly is that neurological development disorder in which the HC is less than the 3rd centile for a person's age and sex.
- There is a positive polynomial correlation between gestational age (in months) and HC (in millimeters), with a correlation coefficient of $R^2 = 0.9991$ ($p < 0.0001$) in Nigerian fetuses.
- The relationship is best described by the second order polynomial regression equation $y = -3.3238x^2 + 85.755x - 177.78$, where y is the HC in millimeters and x is the gestational age in months.
- The African fetus' HC increases faster than that of the European fetus and is bigger than it at birth, on average.
- The interplay of nurture rather than nature has placed the African in a disadvantaged position not only for HC but also in other well-known anthropometric parameters, such as height and even weight after birth.
- The future and intelligence of the growing African is dependent on his nurture more than his nature and this may account for the spuriously low IQ frequently reported by some investigators in Africa.

Chapter 27
Anthropometry of the Intracranial Volume

Bunyamin Sahin

Abstract Intracranial volume (ICV) is an important data to evaluate the premorbid brain size in pathological conditions. It is also one of the most important characters for determining the racial difference. Several methods have been proposed for the assessment of ICV. Some of them are used only for the macerated skulls and most of them are suitable both for the dry skulls and living subjects. The packing/filling method is the most accurate in vitro method for the measurement of ICV. The others are the craniometry and cephalometry methods predicting the ICV using the measures of length, width and height of the skull directly over the bony structure or lateral and antero-posterior roentgenograms. Finally, the stereological methods are the recently proposed techniques that provide unbiased estimation of the ICV. The requirement for the application of this method is an entire set of two-dimensional slices through the object, provided they are parallel, separated by a known distance, and begin randomly within the object, criteria that are met by standard magnetic resonance and computed tomography imaging techniques. In the presented section we discussed the methods for the assessment of ICV. The filling method seams to be the most accurate for the assessment of cranial capacity. However, it must be used on macerated skulls. Even though the craniometry and cephalometry are quick and easy to apply, the obtained values may not be accurate. The stereological techniques require much more time than the others. However, the obtained values are unbiased and the method could be applied for living subjects.

Abbreviations

CE	Coefficient of error
CI	Cephalic index
CT	Computed tomography
ICV	Intracranial volume
MR	Magnetic resonance

27.1 Introduction

There is a close relation between the size of the head and the brain. Brain growth drives skull growth during childhood (Sgouros et al. 1999; Knutson et al. 2001). The intracranial volume (ICV) increases with age from birth throughout childhood. Maximum growth is achieved in the first 5 years (Piatt and Arguelles 1990–1991; Sgouros et al. 1999). At the age of 16–20 years, ICV reaches its final size and it is thought that ICV does not change its size thereafter (Knutson et al. 2001; Wolf et al. 2003). At about 20 years of age, the volume of the brain starts decreasing, whereas it is presumed that ICV remains constant (Rushton and Ankney 1995; Wolf et al. 2003). Experience has suggested that ICV remains stable even after brain atrophy. Thus, ICV is generally considered to be a more accurate indicator of mature brain volume than head size (Wolf et al. 2003). By combining measures of brain volume and ICV, investigators can infer how much reduction in volume has occurred since brain volume was at a maximum (Jenkins et al. 2000; Knutson et al. 2001). Alternatively, ICV measurements may provide reliable indications of the premorbid brain size in neurodegenerative diseases (Jenkins et al. 2000). For this reason, many studies focus on the assessment of ICV.

Several methods have been proposed for the assessment of ICV of macerated skulls. The packing/filling technique is the most accurate in vitro method for measuring ICV. Other methods such as the linear measurement of skulls and cephalometry are used to predict ICV using the measures of length, width, and height of the skull directly over the bony structure, or lateral and anteroposterior roentgenograms (Manjunath 2002a).

Finally, the recently proposed techniques include the stereological methods that provide unbiased estimation of ICV. The requirement for the application of this method is an entire set of two-dimensional slices through the object, provided they are parallel, separated by a known distance, and begin randomly within the object, criteria that are met by standard magnetic resonance (MR) imaging and computed tomography (CT) techniques (Acer et al. 2007; Sahin et al. 2007, 2008).

27.2 Application to Other Areas of Health and Diseases

The human brain varies widely in size (Knutson et al. 2001). There are several factors that contribute to this variation. Factors related to brain growth, such as gender and physical size, are thought to influence the maximal size of an individual's brain (Raz et al. 1998; Sgouros et al. 1999). Large variability in brain size related to age, sex, and body size makes it difficult to compare solely the brain volume among individuals. To calibrate these variations, the volume fraction between the brain and the intracranial cavity should be evaluated (Whitwell et al. 2001, Mazonakis et al. 2004b). Hence, ICV provides a more stable and accurate normalization factor for estimating volumetric changes at the onset of a disease (Eritaia et al. 2000).

Cranial capacity constitutes one of the most important characteristics for determining racial differences (Hwang et al. 1995; Manjunath 2002a, b). For this reason, the assessment of the accurate volume of the intracranial cavity is very useful for anthropometric studies.

27.3 Intracranial Volume Assessment Techniques

27.3.1 Filling Method

The ICV of the skull can be determined by filling skulls with water and subsequently measuring the quantity of water using a cylindrical measuring glass. For this purpose, ordinary balloons may be

introduced into the cranial cavity via the foramen magnum and filled with water under the pressure. After the filling process, water is poured into a measuring cylinder, and this volume is taken as a measure of the total ICV.

This method is one of the most satisfactory methods of measuring ICV of a dry skull. Acer et al. (2006) tested the accuracy of the method by measuring the cranial capacity ten times of the same cranium; the difference between all measurements varied between 5 and 10 cm^3.

However, the balloons which are lowered into the cranial cavity may burst when they touch the sharp bony structures in the skull base. The problem can be solved by using thicker balloons. Additionally, the procedure of filling the cranium with liquid may be controlled by using an apparatus that measures the pressure within the cranial cavity. This may make it possible to judge the course of filling and the point of termination (Manjunath 2002a).

27.3.2 Packing Method

Packing the skull with a flowing material and measuring its amount is another common method for the assessment of ICV. The filling materials may be small-sized lead shots, sand, seeds, grain, millet, lentil, etc. Before the packing, the holes of the skull should be sealed to protect the leakage of the packing material.

The packing material is poured into the skull through the foramen magnum by means of a funnel. After the introduction of half the material, some of the filling material is shaken front down to ensure the filling of the anterior cranial fossa. As further lead, they are poured and packed by fingers to fill the intracranial cavity entirely. The skull is turned upside down, the packing material is poured into a measuring cylinder, and the amount of the packing material is recorded as the total ICV (MacKinnon 1955).

27.3.3 Craniometry

Craniometry is the technique of measuring the bones of the skull. In this technique, linear distance is measured between a variety of defined cranial and mandibular landmarks (Standring 2005). Some special gadgets (e.g., caliper, head spanner, and measuring tapes) are used for the measurements (Fig. 27.1).

Generally, a measured distance is divided by another distance. Finally, some key indices, which are expressed as percentages, are obtained. The most frequently used index (the breadth/length index) is called the cranial index or cephalic index (CI) in living subjects. It was widely used by anthropologists in the early twentieth century to categorize human populations. Today, the index is only used to describe individuals' appearances and to estimate the age of fetuses for legal and obstetrical purposes. A skull with a CI below 75% is classified as dolichocephalic (long headed). If the CI ranges between 75% and 79.9%, it is classified as mesocephalic (moderate headed). Skulls with a CI greater than 80% are classified as brachycephalic (broad headed) (Standring 2005; http://en.wikipedia.org).

Several formulas have also been calculated to estimate cranial capacity from linear measurements of the length, breadth, and height of the cranium (in centimeters). The standard linear measurements for the craniometry are follows:

1. Maximum head length: The distance between the glabella and inion (*L*).
2. Maximum head breadth: The distance between the parietal eminences (*W*).
3. Auricular height: The distance between the external acoustic meatus and the highest point of the vertex (*H*).

Fig. 27.1 A head spanner and its usage for the measurement of the length and the breadth of a skull

The data obtained from the linear measures are treated with regression formulas proposed by many authors (MacKinnon et al. 1956; Manjunath 2002a; Williams et al. 1989). It should be reminded that all the proposed formulas are the driven from a collection of skulls with known volumes and measured distances. Therefore, the proposed formulas may be different between the races. Moreover, the formulas may change depending on the researches. For this reason, such formulas involve some inaccuracy. The most recently used formula for the prediction of ICV is given by Williams et al. (1989).

$$\text{Males}: \quad 0.337 \times L \times W \times H + 406.01\ \text{cm}^3 \tag{27.1}$$

$$\text{Females}: \quad 0.400 \times L \times W \times H + 206.60\ \text{cm}^3 \tag{27.2}$$

The craniometry measurements are repeated at least three times and the average is considered for the calculation. It is recommended that the same performer should be employed for a particular study.

27.3.4 Cephalometry

Cephalometry is the measurement of the linear distance between certain landmarks of skull from roentgenograms. It is another common method predicting ICV using measurements of length, width, and height of the skull directly over the bony structure on lateral and anteroposterior roentgenograms (Manjunath 2002a).

Cephalometric measurements can be done on any standard lateral and anteroposterior roentgenograms of the skulls. An iron bar with a known length must be placed next to the skull to set the magnification rate of the measurements on the roentgenograms. Nowadays, the digital roentgen machines provide a scale indicating the reduction or magnification rate of the images. Therefore, an iron bar may not be required in practice. The distance between certain landmarks is measured and recorded in centimeters. For this purpose, internal length (*L*), internal height (*Hi*), diameter from

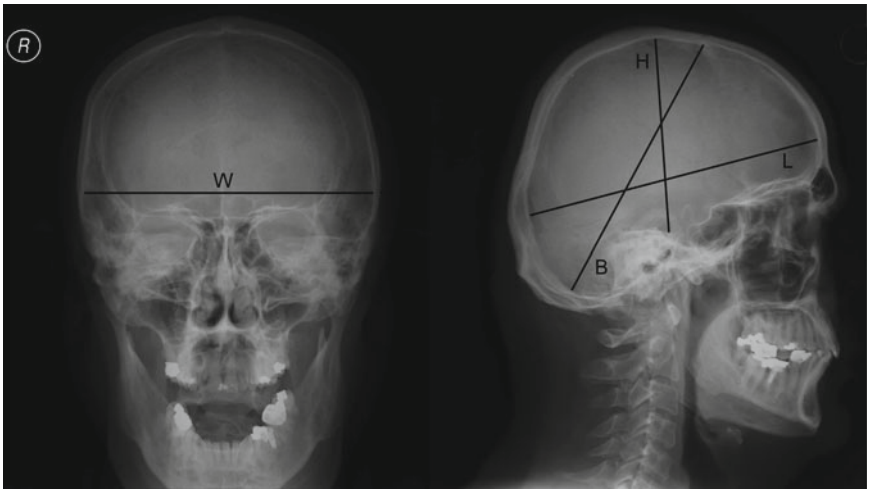

Fig. 27.2 Two standard anteroposterior and lateral cephalograms. Internal length (*L*), internal height (*H*), diameter from bregma to posterior cranial fossa (*B*), and width (*W*)

bregma to the posterior cranial fossa (*B*), and width (*W*) of the skulls on roentgenograms are measured (Fig. 27.2).The obtained data are used for the prediction of ICV by means of a regression formula.

ICV can be calculated using the formula proposed by Bergerhoff, as interpreted below (Sahin et al. 2007).

$$V = \left(\frac{L}{2}\right) \times \left(Hi + \frac{B}{4}\right) \times \left(\frac{W}{2}\right) \times 0.51 \times 8\ \text{cm}^3 \tag{27.3}$$

Published studies use different formulas for the estimation of ICV on roentgenograms, the most commonly used being the ellipsoid formula and MacKinnon's formula or its variations (Sgouros et al. 1999). MacKinnon (1955) was the first to demonstrate a method to estimate the cranial capacity using the cranial length measured on lateral roentgenograms. MacKinnon and his colleagues (1956) in their further studies derived a reliable method for estimating cranial capacity from roentgenograms. The internal lengths, heights, and some other data were measured and a prediction formula was proposed. This formula had been advanced and a new prediction formula based on the resemblance of the cranial cavity to an ellipsoid had been proposed.

A comparative and gold standard study carried out by Sahin et al. (2007) revealed that the volume prediction results obtained by anthropometry and cephalometry were statistically significantly different from the actual volume of skulls obtained by the water-filling method. However, the results of these two methods correlated well with the actual volume of skulls.

In addition to MacKinnon's formula and its variations, several formulas have also been constructed to indicate cranial capacity from length, width, and height of the cranium. However, such volume determinations may be considered to be inaccurate due to their dependence on linear measurements and due to the limited cephalometric landmark validity characterizing the skull radiographs. Various corrections do not entirely remove this inaccuracy (Williams et al. 1989; Sgouros et al. 1999; Mazonakis et al. 2004b).

This problem may be solved by proposing new formulas for different societies or nations. No one can, however, give the assurance that the normalized results are accurate, as the cephalometry method

obtains data from two-dimensional linear measurements. Since the third dimension is absent, these methods always fail to provide accurate information about the third-dimensional value, volume (Sahin et al. 2007).

27.3.5 Cavalieri Principle

Unbiased estimation of organs or structures can be done using the Cavalieri principle of stereological approaches (Cruz-Orive 1997; Roberts et al. 2000). The requirement for applying this method is an entire set of two-dimensional slices through the object, provided they are parallel, separated by a known distance, and begin randomly within the object – criteria that are met by standard sectional radiological imaging techniques. The section thickness of the images is multiplied by the cut surface area of the sections, and the total volume of the interested object is estimated. The cut surface areas of the sections can be estimated using planimetry and point-counting approaches, two methods for estimating volume based on the Cavalieri principle (Sahin and Ergur 2006).

Sectional imaging modalities have provided an opportunity for volumetric quantification of the intracranial cavity. Both CT and MR imaging may produce reliable measurements of ICV. Magnetic resonance imaging offers optimal soft-tissue contrast resolution and multiplanar capability without the use of ionizing radiation. However, CT imaging is still a powerful modality for central nervous system imaging and for subsequent routine ICV measurements because of the reduced scanning duration, its availability, and the detailed depiction of bony structures (Laughlin and Montanera 1998; Sugouros et al. 1999; Mazonakis et al. 2004b).

27.3.5.1 Point-Counting Method

The point-counting method consists of overlying each selected section with a randomly positioned, regular grid of test points. A test point is a plus-shaped line (+) and it is counted if a previously assigned corner of the intersection of the cross lines hit the object. After each superimposition, the number of test points hitting the structure of interest on the sections is counted (Fig. 27.3). Finally, the volume of the structure is estimated by multiplying section thickness, total number of points, and the area represented per point in the grid (Sahin and Ergur 2006). The unbiased estimator is written as follows:

$$V = t \times \frac{a}{p} \times \sum P \text{ cm}^3 \tag{27.4}$$

where t is the section thickness of consecutive sections, ΣP denotes the point counts and (a/p) represents the area associated with each test point, corrected for any change of scale in the images, as it is printed on the hardcopy films (Sahin et al. 2003b).

In the sectional radiological studies, the examined structures are reduced in size. Therefore, it is crucial to know the actual representative area for the points. The magnification or reduction correction may sometimes be tedious. Using the following formula for the scale correction of radiological images will solve the problem:

$$V = t \times \left(\frac{\text{SU} \times d}{\text{SL}} \right)^2 \times \sum P \tag{27.5}$$

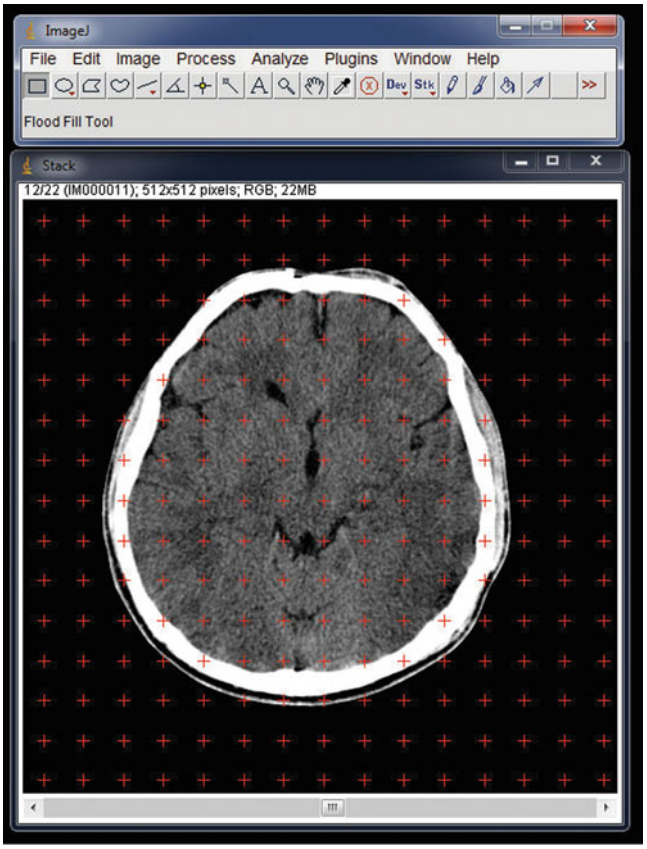

Fig. 27.3 A computed tomography (CT) scan in axial section. A transparent square-grid test system is superimposed randomly covering the entire image frame to estimate the section cut surface area

where t is the section thickness of consecutive sections, SU is the scale unit of the printed film, d is the distance between the test points of the grid, SL is the measured length of the scale printed on the film, and ΣP is the total number of points hitting the sectioned cut surface areas of intracranial space (Sahin and Ergur 2006).

27.3.5.2 Planimetry Method

Planimetry, which involves manually tracing the boundaries of objects of interest on images of sections, is the most commonly used technique. The sum of the measured areas of sections obtained by planimetry is multiplied by the section thickness, and the volume of the structure is estimated (Sahin and Ergur 2006).

The cross-sectional surface area of intracranial space can be measured by the planimetry method using free software. DicomWorks and ImageJ are found on the Internet for free. The latter is distributed by the National Institutes of Health, USA. The final release of the ImageJ has good tools for the estimation of surface area of the structures of interest.

Before the estimation, the scale of the image should be set in the software being used. Following the setting of the image size, the inner boundaries of the skull should be manually traced on each section using the mouse. If the region of interest is distinguished from the surrounding structures

Fig. 27.4 A CT scan in axial section. Inner boundaries of the skulls are manually traced on images to calculate the section cut surface area in the planimetry method

clearly, threshold processing of the program can be done. In this case, clicking on the surface of interest is enough to delineate its boundaries. Then, the software automatically calculates the number of pixels enclosed by the traced skull contours in each section and provides the cross-sectional area of the skull on a slice-by-slice basis (Fig. 27.4). The sum of the areas multiplied by the section thickness provides ICV. The planimetric volume estimation formula can be written as follows:

$$V = t \times \sum A \tag{27.6}$$

where t is the section thickness of consecutive sections and ΣA is the total sectional area of the consecutive sections (Sahin et al. 2003a).

27.4 Planimetry Versus Point Counting and Some Other Details on the Cavalieri Principle

The stereological approach allows the researcher to make appropriate changes on their sampling or estimating procedures. Therefore, the presented method provides a coefficient of error (CE) of estimation for each volume assessment. This way, a researcher can see the potential variability in any given volume measurement. When the CE is high, it can generate obvious problems in accuracy and

hence interpretation. These problems may arise if too few slices or too few points are used for volume estimation. The observer is eligible to change the spacing of points in the grid or the number of slices available in any CT study to obtain a reasonable CE value. It is also important to note that an appropriate grid size and the number of slices required for volume estimation of an object are crucial at the beginning; there is no need to calculate the CE value for repeated sessions (Sahin et al. 2003a). A CE value lower than 5% is in the acceptable range (Gundersen and Jensen 1987).

In the point-counting method, the CE of estimates can be evaluated by means of these consecutive two formulas.

$$\text{Noise} = 0.0724 \times \left(\frac{b}{\sqrt{a}} \right) \times \sqrt{n \times \sum P} \tag{27.7}$$

Noise gives information about the complexity of the examined cut surface area of the specimen. Calculation of the CE using these equations requires knowledge of the value of a dimensionless shape of coefficient $(b / \sqrt{a})$, which is equivalent to the mean boundary length of the profiles divided by the square root of their mean area, and which is a measure of the average shape of the profiles through the structure of interest on the sections. It can be determined using the diagram proposed by Gundersen and Jensen (1987). Five may be a good value for the estimation of ICV; *0.0724* is a constant; n is the total number sections, and ΣP is the total number of points hitting the sectioned cut surface areas of intracranial space.

The final step of the CE estimation is as follows:

$$\text{CE} = \left(\sum_{i=1}^{m} P_i \right)^{-1} \times \left[\text{Noise} + \left(\frac{1}{12} \times \left(\left(3 \times \sum_{i=1}^{m} P_i^2 - \text{Noise} \right) - \left(4 \times \sum_{i=1}^{m-1} P_i \times P_{i+1} \right) + \left(\sum_{i=1}^{m-2} P_i \times P_{i+2} \right) \right) \right) \right]^{1/2} \tag{27.8}$$

where, $i = 1, 2, \ldots, m$ is the number of sections, P is the number of point hitting the sectioned surface areas, Noise is the value obtained earlier, and the others are constants (Gundersen and Jensen 1987; Sahin et al. 2003b).

In the planimetry method, the CE of estimates may be obtained using the following formula:

$$\text{CE} = \left(\sum_{i=1}^{n} A_i \right)^{-1} \times \left[\frac{1}{12} \left(3 \sum_{i=1}^{n} A_i^2 - 4 \sum_{i=1}^{n-1} A_i A_{i+1} + \sum_{i=1}^{n-2} A_i A_{i+2} \right) \right]^{1/2} \tag{27.9}$$

where, $i = 1, 2, \ldots, m$ is the number of sections, A is the measured area of the sections using planimetry, and the others are constants. This formula allows the researcher to evaluate the area changes and the measured cut surface areas in the consecutive section series (Mazonakis et al. 2002; Sahin et al. 2008).

The stereological technique may be optimized by systematically sampling CT sections and by determining an optimum distance between test points of the grid. The counting of approximately 115 points on six to eight systematically sampled CT sections enables the determination of ICV with a CE below 5% in less than 3 min.

The combination of the optimized stereological technique with CT scanning gives the possibility of obtaining acceptable ICV estimations with minimal effort (Mazonakis et al. 2004b). Eritaia et al. (2000) reported that there is a positive relationship between the number of slices used to estimate ICV and the accuracy of that measurement. As the number of slices sampled decreased, ICV between

the estimated ICV and the actual ICV also decreased. In addition, the variance of the estimated ICVs increased. They also reported that ICV can be confidently traced using a 1/10 section sampling strategy, which should result in significant timesaving. This sampling strategy produced 5–10% difference between the estimated volumes. However, it reduced the time required for ICV measurement from 120 to 10 min with minimal loss of accuracy or reliability (Eritaia et al. 2000). Decreasing the number of examined slices by using systematic random sampling will decrease the required time period for the point-counting and delineation process.

Calculation of ICV, CE of estimates, and other related data may be obtained as a spreadsheet using Microsoft Excel for the point-counting and planimetry methods.

Good agreement is reported between results obtained with the point-counting and planimetry techniques, the former being 50% faster. As the point-counting method can be applied to any sets of printed CT images, this approach allows one to perform retrospective and prospective studies, without engaging the CT machines and their PC accessories. Moreover, the procedure of manually tracing boundaries of the intracranial cavity in all CT sections using planimetry is tedious and requires experience (Mazonakis et al. 2002; Sahin and Ergur 2006).

Intracranial volume measurements using CT scans have already been reported in the literature (Abbott et al. 2000; Wolf et al. 2003; Mazonakis et al. 2004b). Most of these attempts to determine ICV were carried out using the technique of manual planimetry (Lyden et al. 1994; Abbott et al. 2000; Mazonakis et al. 2004b). The studies reported that operator intervention was necessary to manually trace the intracranial cavity borders on CT sections. However, manual delineation of the intracranial cavity boundaries is a tedious and labor-intensive process. Point-counting estimations are based on the process of point counting and not on the user's skill in delineating the boundaries of the structure of interest (Mazonakis et al. 2004b). Most of the studies adopting the point-counting technique for organ volume estimations have mentioned that this volumetric approach is superior to the technique of planimetry (Mazonakis et al. 2002, 2004a).

Sahin et al. (2007) used point-counting and planimetry techniques to estimate ICV in a series of CT sections. The results obtained with these two methods were compared with each other and also with the results of other methods. Finally, the results of stereological estimates were compared with the actual volume of skulls to check the accuracy. Their findings revealed that there was no difference between the results of the point-counting and planimetry methods. The results of both stereological methods were, however, statistically significantly different from the actual volume of the skulls. Correlation analysis revealed that the results of point counting and planimetry not only correlated well with each other but also with the actual volume of the skulls. The systematic deviation from the actual volume for the point-counting and planimetry methods resulted in underestimation (Sahin et al. 2007).

Their results showed that increasing the CT section thickness can lead to a growing discrepancy between ICV measurements and the actual volume. This is mainly attributed to the influence of section thickness on the partial volume artifacts presenting on cross-sectional images. It is well known that partial voluming arises when a voxel contains different types of tissues. As a result, the reconstructed intensity ascribed to this voxel in the displayed CT image represents an intermediate value that does not correspond to any real tissue. The partial volume effect is more pronounced in thick sections and can considerably influence the accuracy of the obtained volume measurements (Nawaratne et al. 1997). To minimize this effect, the operator should select CT sections of sufficiently small thickness, thus securing constant attenuation characteristics across the imaging plane.

The problem of underestimation of the stereological methods probably originates from the effect of section thickness on the printed two-dimensional images (Sahin et al. 2008). There are restricted studies evaluating the effects of section thickness on the estimated volume of structures using CT and MR images (Emirzeoglu et al. 2005; Sahin and Ergur 2006). Sahin et al. (2008) evaluated the effect of

section thickness on the estimated ICV in CT imaging. Decreasing the slice thickness to less than 10 mm may decrease the under-projection effect of sectioned structures, which may result in a smaller degree of underestimation (Emirzeoglu et al. 2005; Sahin and Ergur 2006). They scanned the skulls with 2, 3, 5, 7, and 10 mm thicknesses. The volume of the cranial cavity was systematically overestimated in 2 mm-thick scanned sections compared with the actual value of ICV. A mean overestimation of up to 2.0% was found ($p < 0.05$). For section thicknesses of 3, 5, 7, and 10 mm, however, a systematic volume underestimation was observed ($p < 0.05$). The mean underestimation compared to the actual volume of the dry skulls was 2.2–8.5% and 2.6–7.0%, respectively. Ideally, CT scanning with 2.5 mm-thick slices will lead to an ICV estimation that does not deviate from the actual volume. Their study provides a simple mathematical formula that allows the user to calculate the deviation of the estimated ICV from the real volume, if the scanning thickness is different from the ideal (Sahin et al. 2008).

During the windowing of frames, different levels of settings to obtain best view are chosen. Windowing adjustments are related to the nature of scanned structure and the imaging technique. Moreover, Diederichs et al. (1996) showed that a proper windowing must be chosen to obtain maximum intensity projections. In living subjects, the skull is filled with brain, meninges, and cerebrospinal fluid. During the scanning, these structures absorb or reflect X-ray waves to different degrees. For these reasons, windowing parameters must be standardized in the comparative studies.

Summary Points

- The ICV gives information about how much reduction in volume has occurred since brain volume was at its peak. It provides a more stable and accurate normalization factor for estimating volumetric changes at the onset of a disease. It is one of the most important characteristics for determining racial difference.
- Several methods have been proposed for the assessment of ICV. The packing/filling method is the most accurate in vitro method for the measurement of ICV; the others are the craniometry and cephalometry methods. Finally, the stereological methods are the recently proposed techniques that provide unbiased estimation of ICV.
- In the water-filling method, ordinary balloons are inserted into the cranial cavity via the foramen magnum and filled with water under pressure. This method is one of the most satisfactory methods of measuring ICV of a dry skull, and is easy and simple. However, the balloon may burst when it touches the sharp bony structures in the skull base.
- In the packing method, the packing material is poured into the skull through the foramen magnum. As a second step, it is poured into a measuring cylinder and the amount of the packing material is recorded as the total ICV.
- In the craniometry method, the length, width, and height of the skull are measured and the obtained values are treated with the prediction formulas. The formulas may change depending on the race and researches. For this reason, such formulas involve some inaccuracy. Additionally, the same performer should be employed to avoid inter-observer variation.
- The breadth/length index is called the CI. It is only used to describe individuals' appearances and for estimating the age of fetuses for legal and obstetrical purposes. CI below 75% is a long head; that ranging between 75% and 79.9% is a moderate head; and that greater than 80% is a broad head.
- The first formula for the cephalometry was proposed by MacKinnon and his colleagues. For cephalometry, internal length, internal height, diameter from bregma to the posterior cranial fossa, and width of the skulls on roentgenograms are measured. The obtained data are treated with the several regression formulas for the estimation of ICV.

- In the Cavalieri principle, sectional radiological images are used for the estimation of volume. The cut surface areas of the sections are multiplied by the section thickness and the volume is estimated. Point counting and the planimetry are two methods for estimating the cut surface area of the sections.
- In the point-counting method, the volume of the structure is estimated by multiplying section thickness, total number of points, and the area represented per point in the grid.
- The point-counting method is practical and rapid. It does not require sophisticated gadgets. It is timesaving and ideal both for retrospective and prospective examinations.
- Planimetry involves manually tracing the boundaries of objects of interest on images of sections. The sum of the measured areas of sections obtained by planimetry is multiplied by the section thickness and the volume of the structure is estimated.
- Some of the following factors should be considered for the estimation of ICV using CT sections: increasing the CT section thickness can lead to decrease in ICV measurements; ideal section thickness is 2 or 3 mm – if the section thickness is different, some of the correction formulas can be used; standard and optimum windowing should be chosen.

Chapter 28
Anthropometry and Numerical Simulations of a Child Head Model

Sébastien Roth, Jean-Sébastien Raul, and Rémy Willinger

Abstract During growth, a child's head undergoes different modifications in morphology and structure. This chapter presents an anthropometric study in terms of dimension compared to a mathematical method called "the scaling method" consisting of reducing the adult head model with a scaling coefficient to obtain a child head. A detailed sizes and shape analysis of brain contour in sagittal and frontal plans is proposed, for child head versus a scaled adult head. The superimposition of these contours allowed pointing to main differences. Numerical simulations performed with detailed child head model of Strasbourg University, and a scaled adult head finite element model, showed that reducing an adult finite element model to obtain a child head by scaling method does not seem to be realistic. Then, the anthropometry of child head is a fundamental aspect and the creation of specific finite element models of child head are necessary to investigate child injury mechanisms at a numerical level.

MOC	Month-Old Child
CSF	Cerebrospinal Fluid

28.1 Introduction

According to epidemiological studies reported in several countries, traumatic brain injury (TBI) is a major cause of death and disability among the young paediatric population. The most frequent causes of TBI are vehicle traffic accidents, falls and mishandling (Viano et al. 1997). Determination of reliable injury criteria and tolerance limits is essential for understanding injury occurrence mechanisms and for development of protective devices. Investigations of these injuries use comprehension of dynamic behaviour of brain tissues. One of the ways to investigate head trauma is

numerical methods. Indeed, comparing the gravity and type of lesions of the trauma with results of accident simulations can lead to correlate mechanical parameters with specific injuries.

Accident studies in the literature often highlight the gravity and type of lesions of the head/neck system at specific ages, and vary if the accident involves a child or an adult. Indeed, the response of a complex system such as the head is closely linked to the size, the geometry and the constitutive law of the brain and skull.

In order to comprehend head injuries better, many works have experimented using dummies or animals, leading to the definition of injury criterion, such as the HIC (Head Injury Criterion), which is the most commonly used one. However, even if this criterion can evaluate the gravity of a lesion, it cannot make a clear distinction between different injury mechanisms during an impact; this is because it is based on only linear acceleration, and mechanical parameters are not taken into account. Progress in computer science allows development of new methods and new ways in head/neck system studies in order to perform precise finite element (FE) simulations.

Several FE models of the adult head have been developed in the last few decades in order to simulate real-world head trauma with the aim of developing predictive tools for appearance of injuries.

In parallel to adult head studies, the biomechanics for child head injuries become increasingly important. Indeed, accidental free falls or mishandling, such as 'the shaken baby syndrome', are very specific accident cases, very different from adult cases, involve many children and need to be clearly understood. So, it seems very important to study very specific child injury mechanisms.

In this context, it appears very important to investigate the child head at a morphological, anthropometric level, in order to motivate the development of a specific FE model of the child head.

Biomechanical studies investigate the adult head with many criteria and tolerance limits that have been developed using different methods: dummies, finite element analysis, multibody analysis, etc. Some of these methods have been adapted to the child head without considering the consistency of scaling geometry or tolerance limit.

In a first step, a detailed study on child head evolution at a morphological and structural level will be made, with a specific question: 'Can a child head be considered as a scaled adult head?' One of the typical methods, called 'the scaling method', is described in this section and poses questions about its use, its limitations and its guidelines.

According to specific guidelines, specific FE models can be developed by taking into account the main features of the child head, according to the age (fontanels, sutures, diploe, etc.). These realistic models in terms of geometry need accurate material laws to be implemented in an FE code, in order to be a 'biofidelic' model, which can be used for accident reconstructions which are specific to child trauma.

28.2 Child Head Morphology and FE Analysis

28.2.1 Anatomical and Morphological Features of Child Head

We focus first on the morphology of paediatric head as a function of age, and its evolution during growth. At birth, the neurocranium (occipital, sphénoïdal, temporal, parietal and frontal bones) appear to be large relative to the size of the face, as it can be seen in Fig. 28.1. The size of the neurocranium represents approximately 25% of its future size, whereas the face represents only 10–15%. By the end of the second year, the neurocranium has reached approximately 75% of its future size. Growth of the neurocranium is directly related to genetic factors and expansion of the brain: at birth,

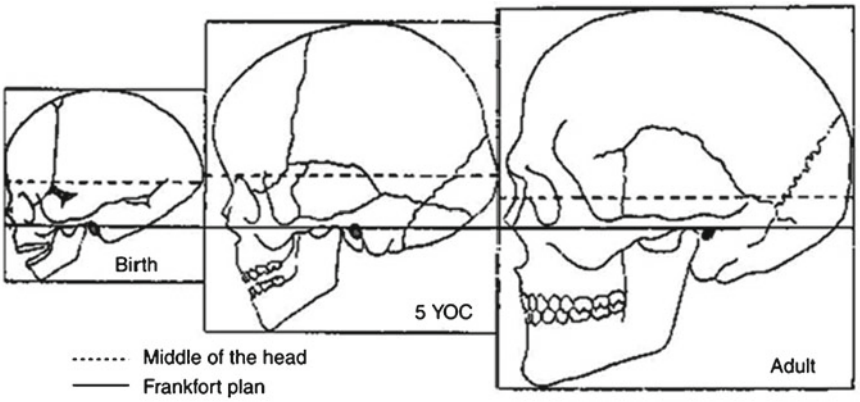

Fig. 28.1 Development of the skull and the face during the growth according to Izard (1950). The three heads are aligned along the Frankfort plane. One can notice the difference in growth of the neurocranium with respect to the face

the weight of the brain is approximately 370 g, reaching up to 1,300 g at the age of 6 years and up to 1,400 g at the age of 19 years.

During the first and early second years, growth of the vault is mainly obtained by ossification at apposed margins of bones, accompanied by some accretion and absorption of bone at surfaces.

Anteroposterior growth occurs at the coronal, sphénotemporal and lambdoid sutures.

Growth in height occurs at the frontozygomatic and squamosal sutures, pterion and asterion.

Growth in breadth occurs at the sagittal, sphenofrontal, sphenotemporal and occipitomastoid sutures and petro-occipital cartilaginous joints. The growth of the face is closely linked to muscular function. The teeth, the tongue and the masticatory muscles are in great part responsible for the growth of the face.

The three heads are aligned with the Frankfort plan in Fig. 28.1. One can notice the difference of growth of the neurocranium with respect to the face (Izard et al. 1950).

The sutures are relatively wide at birth, with large gaps where two or more sutures meet. These areas are called fontanels.

At birth, ossification is incomplete and some bone parts are still separated by fibrous tissue or cartilage.

The main sutures of the newborn are the sagittal suture (between the two parietal bones), coronal suture (between frontal and parietal bones), lambdoid suture (between parietal and occipital bone) and the two parietotemporal sutures (between temporal and parietal bones), as illustrated in Fig. 28.2.

The fibrous membrane, forming the cranial vault before ossification, is not ossified at the angle of the parietal bones, leaving six fontanels, including two median (anterior and posterior) and two lateral pairs (sphenoidal and mastoid).

The fontanels close earlier than the sutures. The first to be closed is the posterior fontanels at the age of 3 months. The sphenoidal fontanel and the mastoid fontanel close, respectively, at 5 and 18 months, whereas the anterior fontanel closes between the age of 24 and 36 months (Fig. 28.3).

After this qualitative analysis of structural aspects, a description of global skull geometry follows. The growth of the skull is closely linked to the growth of the brain. To illustrate the growth of the skull, contours of the brain in a sagittal plan, for different ages, are superimposed. Figure 28.4 illustrates the evolution of the morphology of the brain, which does not grow linearly with age.

As a consequence of brain growth, skull structures do not grow linearly either. Several works concerning size evolution or morphology, such as Dekaban (1977), Roche (1953), Lang and Bruckner (1981), and Lang (1983), have been reported. The authors reported measures of length characteristics during growth, as illustrated in Figs. 28.5–28.7.

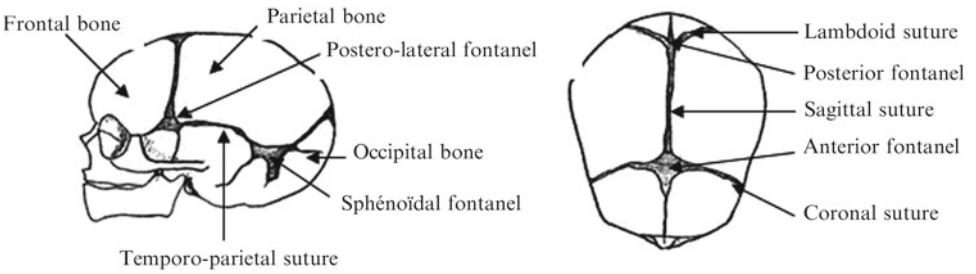

Fig. 28.2 Illustration of infant skull, cranial bone, sutures and fontanels

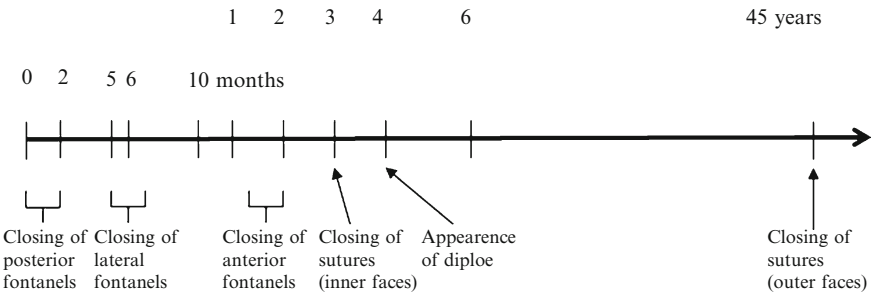

Fig. 28.3 Evolution of sutures and fontanels

Fig. 28.4 Brain morphology as a function of age in the sagittal plan

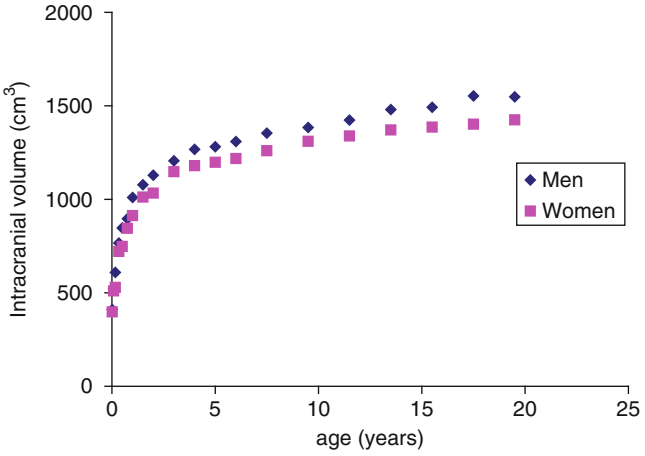

Fig. 28.7 Mean volume of the skull for men (*blue*) and for women (*pink*) according to Dekaban (1977)

Finally, several data on skull dimension of the child head have been collected, and give a first idea of the morphological evolution of the head during growth. These studies can lead (in the next chapter) to an evaluation of the validity of the scaling method, which is often used as an alternative because of the lack of paediatric data by reducing adult anatomy with a scaling coefficient. Indeed, scaling factors are applied to adult morphology in order to obtain child morphology. Are anatomical data reported in the literature coherent with data obtained with the scaling method?

The next paragraph explains child head growth at a morphological and anatomical level pointing out important aspects allowing giving recommendations and guidelines when using the scaling method.

28.3 The Scaling Method: Use, Limitations and Guideline

28.3.1 Definition

The finite element method (FEM) is typically used in biomechanics to understand the dynamic behaviour of a body part, especially of the head, for which a number of FE models have been developed in the last decades. Several anatomists have studied the evolution of skull dimension for males and females since birth. These studies gather a lot of information concerning skull diameters, volumes and characteristic dimensions (Roche 1953; Dekaban 1977), as described in the first paragraph. Based on characteristic dimensions, Mertz (1984) and Irwin and Mertz (1997) developed a method to obtain the child head geometry from the adult one. Because of the lack of studies concerning children, this scaling method seems to be an interesting way to study injury mechanisms for children. A series of coefficient are available in order to reduce mass and dimension of the adult head to obtain child head as reported in Table 28.1.

In parallel to these dimensional parameters, and as very few material constitutive laws are available, the scaling method has been extended to obtain material properties of tissues in children. This theory is based on existing elastic modulus of the skull found by Mc Pherson (1981) in newborn and 6-year-old children and by Hubbard (1971) in adults. A cubic spline was created to fit all the data, suggesting an extrapolation of the bone elastic modulus as a function of age. More recently, authors have studied material properties of children and have established the Young modulus of the skull as a function of age (Margulies and Thibault 2000; Jans et al. 1998). Figure 28.8 shows data obtained by the scaling method superimposed with recent experimentations.

It can be observed in this figure that new experimental data correlate well with those obtained with the scaling method at around 1 year of age. For further ages, more research is clearly needed. Concerning dimensions (length, width and height), is this method reliable in every case?

28.3.2 Comparison Between Anatomical Data and the Scaling Method

Based on experimental data in the literature (contributed by different anatomists named in the first paragraph), a comparison between anatomical data and those obtained with the scaling method is performed, as illustrated in Fig. 28.9.

Table 28.1 Scaling coefficients developed by Mertz (1984) and Irwin (1997)

		6 month old	12 month old	18 month old	3 year old	6 year old	10 year old
Head	$\lambda_x = \lambda_y = \lambda_z$	0.775	0.817	0.844	0.876	0.914	0.931

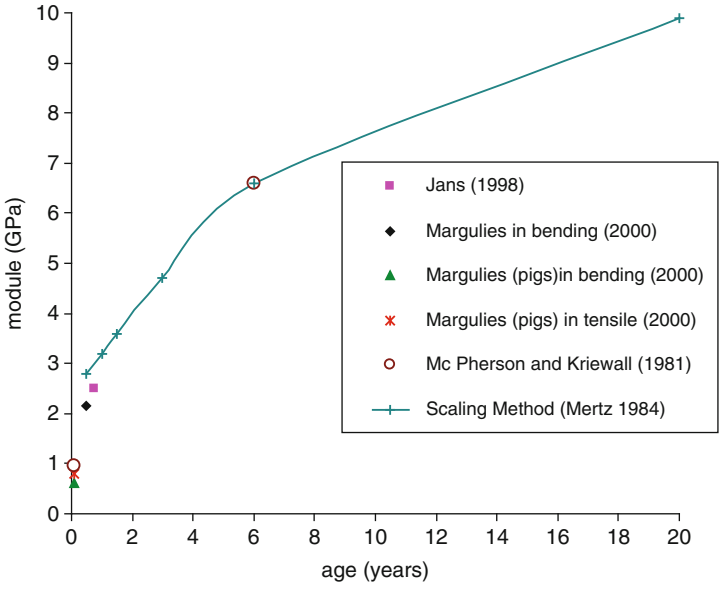

Fig. 28.8 Quasi-static Young modulus of the skull as a function of age: Experimental data and scaling method

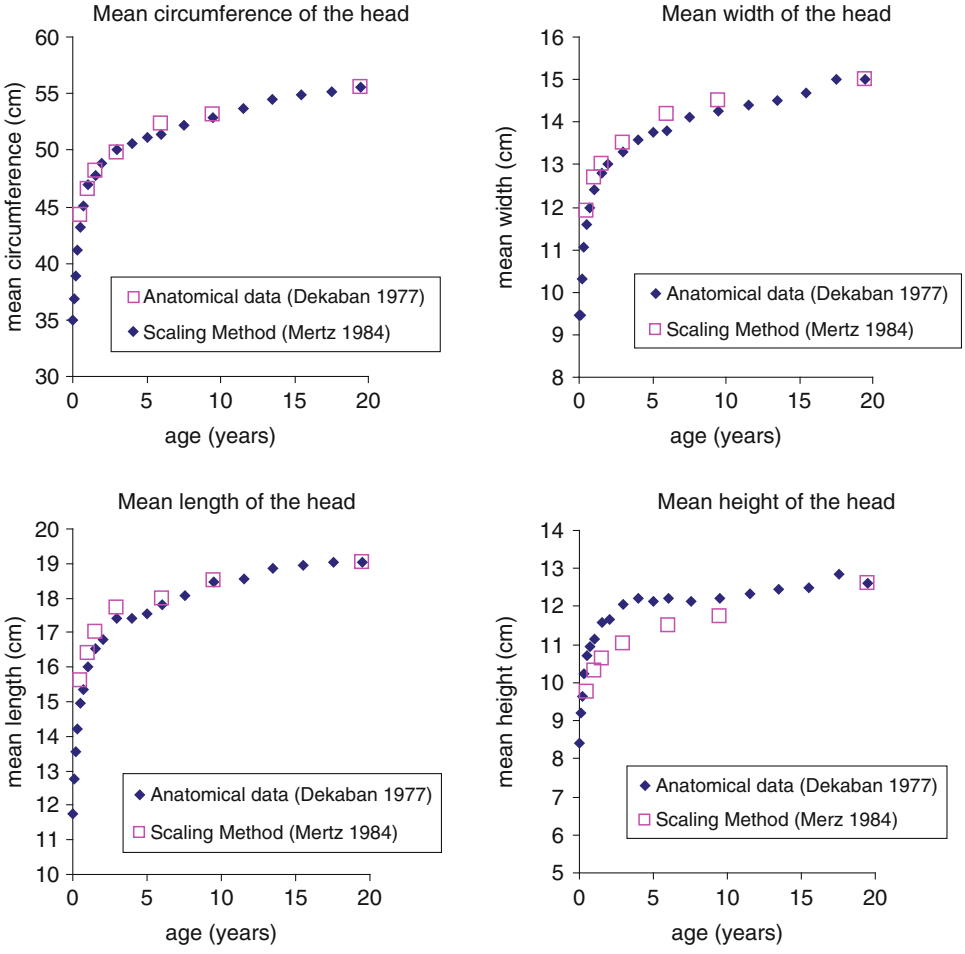

Fig. 28.9 Superimposition of the evolution of the skull circumference, width, length and height as a function of age: anthropometric study and scaling method

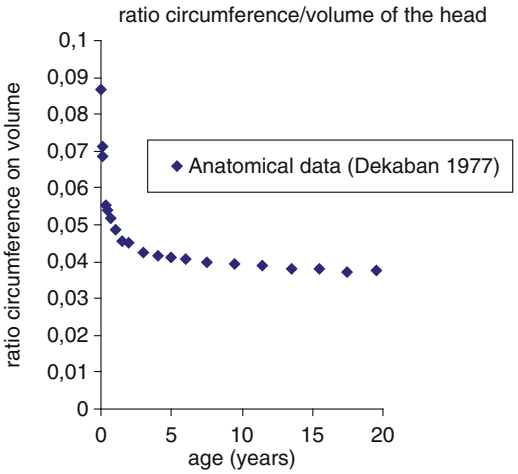

Fig.28.10 Ratio circumference of the head over volume of the head

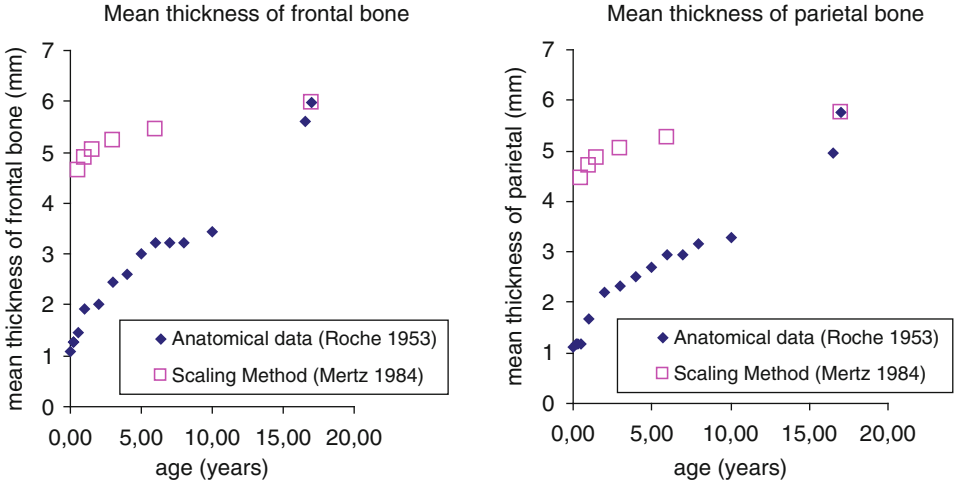

Fig. 28.11 Evolution of skull thickness as a function of age from anatomical study (Roche 1953) and Scaling Method

As far as skull height parameter is concerned, anatomical studies show rapid evolution from birth to 6 years, and stabilisation of the rope of the curve after 6 years of age. This phenomenon is not reproduced by the scaling method.

Figure 28.10 gives a shape parameter as it illustrates the evolution of the ratio of the circumference to head volume. A stabilisation of the curve after an age of 6 years can be observed illustrating that the child's head has a similar shape as an adult head after 6 years of age.

In addition to skull global geometry, skull thickness in frontal and parietal areas has also been reported in previous studies. Figure 28.11 reports data coming from anatomical data and from the scaling method. It can be observed that the thickness, both for parietal and frontal areas, is quite different between the anatomical studies and curves obtained with the scaling method.

In reality, bone thickness changes much more than the scaling method reports.

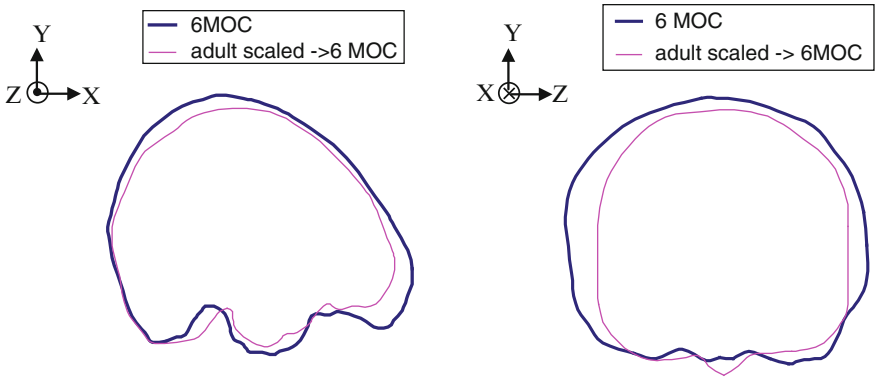

Fig. 28.12 Superimposition of brain's CT scan of a 6 MOC and a scaled brain's CT scan of an adult (sagittal and coronal plan)

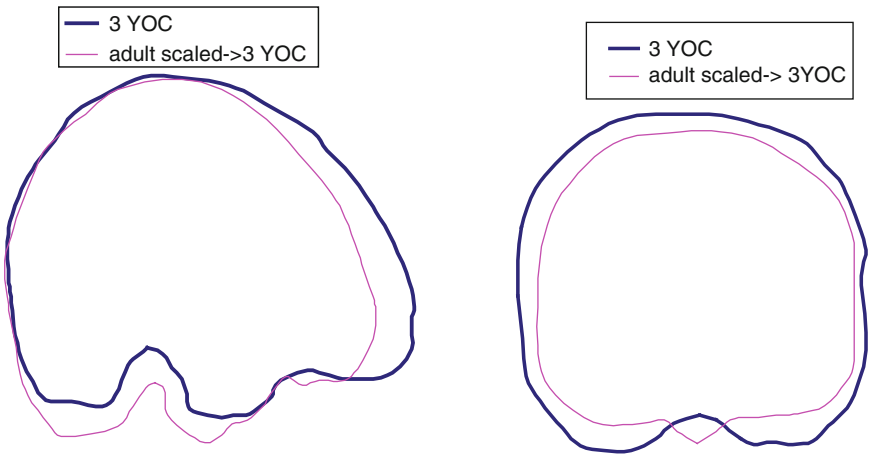

Fig. 28.13 Superimposition of brain's CT scan of a 3 YOC and a scaled brain's CT scan of an adult (sagittal and coronal plan)

Thus, evolution of dimensional parameters illustrated in Figs. 28.9–28.11 shows several limits, which seem to be important in morphological analysis. Indeed, as far as dimensional parameters are concerned, the age of 6 years seems to be a limit. After this critical age, a homothetic evolution until adulthood is observed. For a morphological analysis, we can conclude that the scaling method cannot be applied before 6 years of age because of too large a discrepancy between skull height and thickness.

As far as thickness is concerned, anatomical data show another limit. A large variation can be observed until 10 years of age, and a linear evolution of these parameters after this age until adulthood.

After this analysis of specific skull dimensions, global skull geometry is further investigated by superimposing CT scan slices of the brain obtained in a sagittal and coronal plan for an adult, a 3-year-old and a 6-month-old child.

Therefore, contours of the adult brain obtained from Fig. 28.4 are scaled down according to the Mertz method with appropriate coefficients, respectively, 0.775 and 0.876 for the 6-year-old and the 3-year-old child and superimposed with the scanned child geometry in Figs. 28.12 and 28.13.

Table 28.2 Structural aspect for the application of the scaling method

Structural aspect			
Age	Presence of fontanels	Presence of sutures	Presence of trabecular bone
Newborn	Yes	Yes	No
6 months	Yes	Yes	No
1 year	Yes	Yes	No
3 years	No	Yes	No
6 years	No	No	Yes
10 years	No	No	Yes
Adult	No	No	Yes

Table 28.3 Application field of the Scaling Method

Application Field of the Scaling Method				
	Global Geometry Level			Structural level
Age	D_x	D_y	D_z	■ Thickness of the skull ■ Fontanels and Sutures ■ Trabecular Bone
Newborn	No	No	No	No
6 months	No	No	No	No
1 year	No	No	No	No
3 years	No	No	No	No
6 years	Yes	Yes	Yes	No
10 years	Yes	Yes	Yes	Yes
Adult	/	/	/	/

It can be observed in these figures that the scaling coefficients applied to the geometry lead to a child geometry, which is quite far from the real geometry obtained by CT scans. Indeed, for the 6 MOC, differences between the real geometry and the scaled one in terms of area reach 11% and 17% in the sagittal and the coronal plan, respectively. For the 3 YOC, differences between the real geometry and the scaled one in terms of area reach 4% and 18% in the sagittal and the coronal plan, respectively.

Then, accurate child geometry is needed to obtain a realistic geometry of a 6-month-old or a 3-year-old child head model. Studying child brain injuries with physical or numerical models should be based on the creation of realistic and biofidelic models.

Based on evolution of dimensions, studies of morphology, limitations and guidelines for the use of the scaling method are summarised in Tables 28.2 and 28.3. In these tables, 'yes' in the application field of the scaling method means that the method can be applied.

28.3.3 Conclusion

Scaling methods are often used to obtain the geometry of a child head. They are frequently used for dummies, which use scaling factors to reduce an adult physical or numerical model to the appropriate size. Concerning this method, the present study has shown that skull length and width found by anatomical studies and with the scaling method seem to be in accordance; but, for the skull height,

discrepancies appear. Concerning the circumference/volume ratio, a stabilisation of the curve after the age of 6 years is observed, giving a limit of validity of the scaling method at this age. Concerning the skull thickness, anatomical studies and the scaling method allow observing that the thickness for parietal and frontal bones is drastically lower in anatomical studies compared to the scaling method. From a geometrical point of view, comparison between real head and scaled head has shown significant difference in terms of size and shape, especially at the base of the brain. Finally, from a detailed structural point of view, the child head changes widely during growth, with appearance of trabecular bone, and closing of sutures and fontanels. These important structural aspects are obviously not taken into account with the scaling approach.

28.4 Practical Methods and Techniques: Finite Element Modelling

28.4.1 FEM: A Way to Study Injury Mechanisms

Computer models are increasingly used in biomechanics as an alternative to complicated, practically unfeasible or unethical (human or animal) experiments. FEM is a mathematical method for solving complex physical problems; it is commonly used to investigate injury mechanisms. The finite element modelling technique offers the advantage of being able to model structures with complex shapes and complex mechanical behaviour, leading to the investigation of local behaviour such as local stresses or strains.

For a biomechanical application, such as child head injuries, this method can be very interesting and efficient for modelling injury mechanisms and developing injury criteria.

This method has been widely used for adult head biomechanics, and is beginning to be used for investigating child head injury criteria.

28.4.2 Adult FEMs

Finite element modelling is a widely used tool for investigating the dynamic response of the head under external loading. Presently, about a dozen three-dimensional FEMs of the adult head have been developed that include implementation of constitutive relationships of head components. Among these models, some have been used to simulate real-world accidents and to develop injury criteria based on mechanical parameters. Figure 28.14 and Table 28.4 illustrate these models, with the corresponding threshold for injury appearance.

28.4.3 Child Head FEM

Thus, finite element analysis of adult head has been investigated extensively. However, injury biomechanics applied to the paediatric population is still an emerging field, and only a few FEMs of child head are available in the literature. Only a brief description of models developed in the literature is provided in the present chapter.

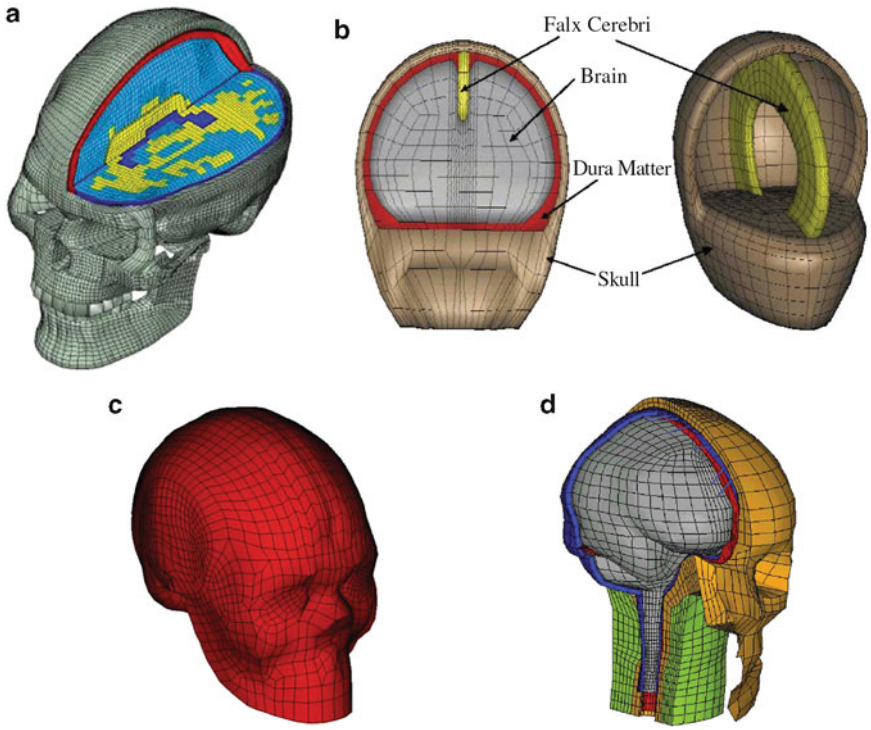

Fig. 28.14 Finite element models that predict injuries' appearances. Wayne State University (**a**) (Zhang et al. 2001), SIMon model (**b**) (Takhounts and Eppinger 2003), Strasbourg ULP98 model (**c**) (Kang et al. 1997) and KTH model (**d**) (Kleiven 2007)

Table 28.4 Adult FE model based Injury mechanisms and injury criteria

FE models	Diffuse Axonal Injuries	Contusion	SDH	Skull fracture
SIMon	CSDM[a] 55%	DDM[a] 7.2%	RMDM[a] 1

[a]Cumulative strain damage measure (CSDM) is associated with the cumulative volume of brain tissue experiencing tensile strains over a predefined critical level. Dilatation damage measure (DDM) is proposed for the evaluation of brain injury that occurs as a result of dilatational stress states. Relative motion damage measure (RMDM) is related to brain motion relative to the interior surface of the cranium

28.4.3.1 Mc Pherson et al

Mc Pherson and Kriewall (1980) developed numerical models to investigate the effects of intra-uterine pressure on parietal bones during labour. This model focusses on skull deformation.

28.4.3.2 Prange et al

Prange et al. (1999) analysed the influence of the size, shape and the mechanical properties of the brain by modelling a coronal slice of a 1-month-old child head.

28.4.3.3 Margulies and Thibault

Margulies and Thibault (2000) developed a hemispheric model and studied the influence of mechanical properties and the structure of the head.

28.4.3.4 Lapeer and Prager

Lapeer and Prager (2001) developed a simplified numerical model of parietal bones to investigate the deformation of foetal skull subjected to uterine pressure during labour.

28.4.3.5 DeSantis Klinich et al

An FEM model of a 6-month-old child has been developed by DeSantis Klinich et al. (2002). They analysed the intracerebral response during simulation of real accidents.

28.4.3.6 Mizuno

Mizuno et al. (2004) developed an FEM of a 3-year-old child, by scaling down the THUMBS model AM50 of TOYOTA, according to the scaling method, using an appropriate coefficient. The material properties of the skull were also scaled down with coefficients of 0.8 and 1.6 for stress and strain, respectively.

28.4.3.7 Guan et al

Guan et al. (2006) developed a finite element model for a 6-month-old child using different types of mesh element to investigate the convergence of the models during a numerical simulation.

28.4.3.8 Coats et al

Coats et al. developed an FEM of the head for a 1.5-month-old infant to reproduce experiments on paediatric bone fracture. The authors compared results of the numerical simulations to experimental tests for different impacted surfaces, in terms of the fracture line. Replication of a number of falls helped find the tolerance limit for skull fracture for the newborn infant head.

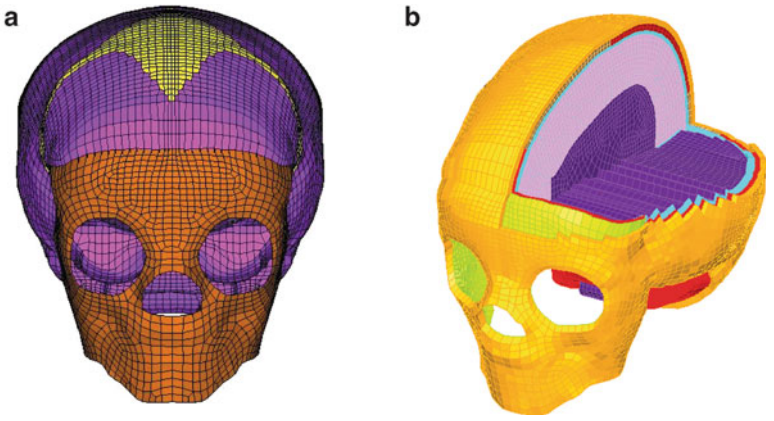

Fig. 28.15 UDS' FE model of a 6-month-old child (2007)

Table 28.5 Material properties for the 6 MOC UDS' model

	Young modulus (MPa)	Poisson ratio	Density (kg/m^3)

Scalp	16.7	0.42	1,200
Skull	2,500	0.22	2,150
Sutures and Fontanels	1,500	0.22	2,150
Brain	$G(t) = G_\infty + (G_0 - G_\infty).e^{-\beta.t}$		
	$G_0 = 5.99 \times 10^{-3}$ MPa $G_\infty = 2.32 \times 10^{-3}$ MPa		
	$\beta = 0.09248$ s^{-1}		
	with a bulk modulus $K = 2{,}110$ MPa		

28.4.3.9 UDS Models

Several models have been developed at Strasbourg University.

A 6-month-old child head model is illustrated in Fig. 28.15, whose material properties are summarised in Table 28.5, and a 3-year-old-child head model is illustrated in Fig. 28.16, with material properties summarised in Table 28.6. The use of these models is described in Section 4 (Roth et al. 2007; Roth et al. 2008).

28.4.3.10 Anthropometric Point of View

The developed finite element models are based on CT scans of children and infants. They closely follow the anthropometry of the head at a specific age. As it was explained in the previous chapter, the child head undergoes modifications during growth. That's the reason why it is necessary to develop a model that reflects the accurate geometry of the head at a specific age. We will discuss in the next chapter the influence of this anthropometry at a numerical level by comparing a real geometry of the head to a head that has been scaled according to the scaling method.

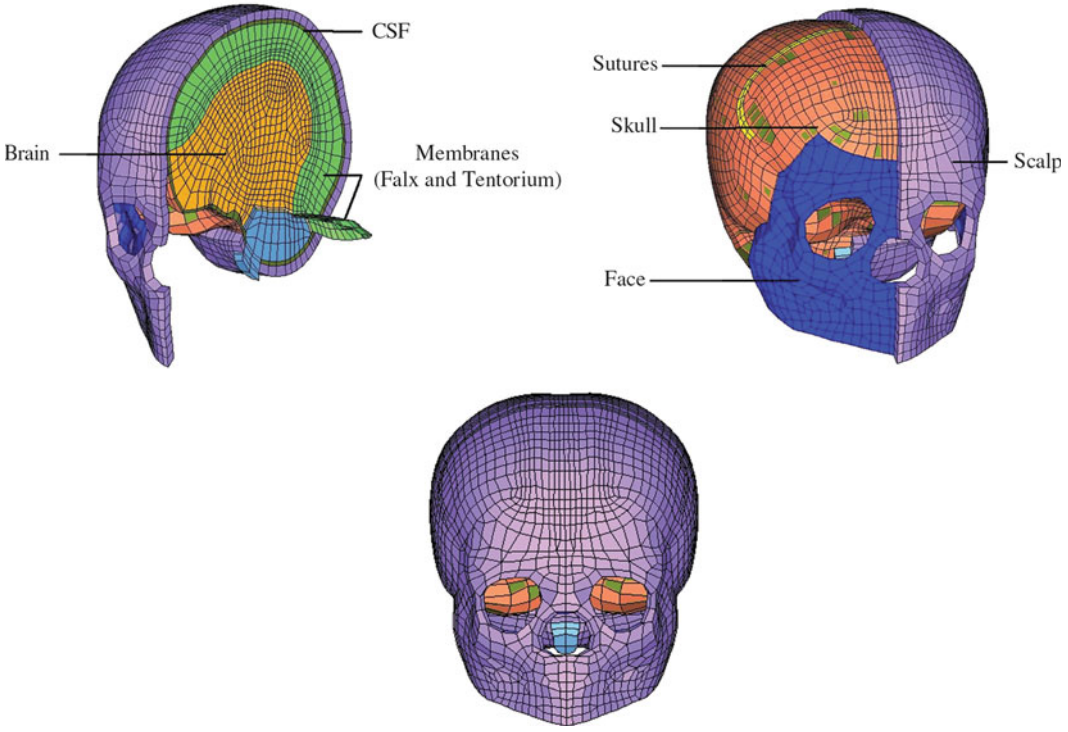

Fig. 28.16 UDS' FE model of a 3-year-old child (2009)

Table 28.6 Material laws used in the 3 YOC head model

	Young modulus (MPa)	Poisson ratio	Density (kg/m^3)
Membranes	31.5	0.45	1,140
Cerebrospinal fluid	0.012	0.49	1,040
Scalp	16.7	0.42	1,200
Skull	4,700	0.22	2,150
Sutures and Fontanels	1,500	0.22	2,150
Brain	• Viscoelastic law 1-mode relaxation (Shuck 1972)		

However, when looking at the evolution of some specific characteristic of the head during growth, especially the circumference/volume ratio, it appears that relative child skull geometrical parameters do not vary after the age of 6 years Even if a 6-year-old child head is slightly smaller than an adult head, its shape is similar to the adult one, as illustrated in Fig. 28.17.

Thus, the creation of a new finite element model of the head of a child older than 6 years does not seem to be useful, as the geometry is very similar in terms of shape to the adult head. In the contrast to younger children, using the scaling method to create a new model (older than 6 years) can be justified. For example, the creation of a 6-year-old finite element model of the head can be developed by

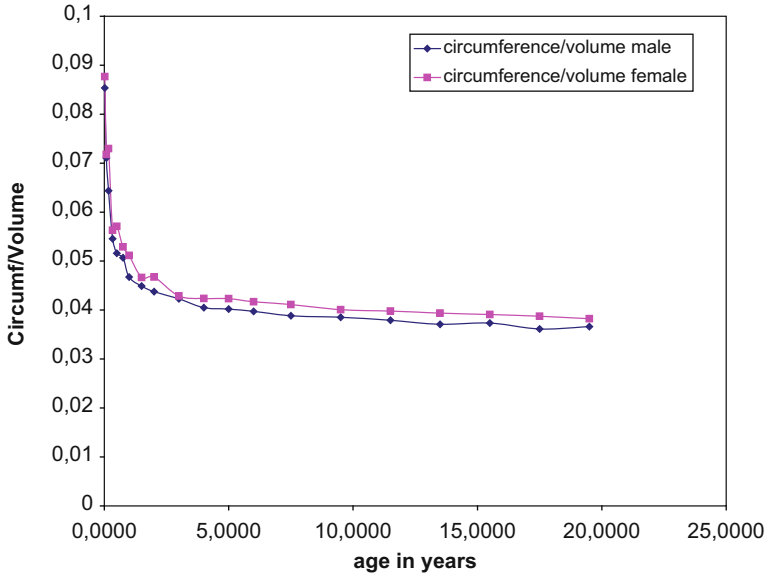

Fig. 28.17 Evolution of the ratio 'circumference/volume' during growth

scaling an adult FE model with the appropriate scaling coefficient ($\lambda_x = \lambda_y = \lambda_z = 0.914$, as suggested by Irwin and Mertz 1997).

28.4.3.11 Limitations of Child Head FE Model Development

The step after finite element development is the comparison of the response of the model to experimental data, as it was performed on adults' heads. However, due to ethical issues, very few data are available in the literature. The only data available are those from Prange et al. (2004) on newborns, which concern skull experimentations. However, it seems difficult to use Prange's experimentations on newborns to validate head measurements of older children.

The response of child brain tissues have not been published yet. Thus, for instance, the child head models cannot be validated, and their biofidelity in terms of mechanical response cannot be checked. However, it seems essential to study the child head at a mechanical level. Investigations on child injury mechanisms should not be avoided because of the lack of experimental data on the child head, as a large number of accident cases or mishandling involves children, infants or newborns.

28.4.4 Conclusion

Finally, this review on head biomechanics shows that the adult head has been widely studied at a numerical level with the development of biofidelic finite element models of the adult head. The responses of these models under dynamic loadings have been compared to experimental data in order to ensure their biofidelity. However, the state of the art concerning the child head is quite dif-

ferent. Indeed, due to ethical reasons, studies on the child head are more difficult. Therefore, the use of the finite element model seems to be an interesting way to study child injury mechanisms.

We will explain in the next paragraph the use of the finite element models developed by Strasbourg University in order to point out the importance of anthropometry (size, shape and morphology).

28.5 Numerical Response of Child Head FEM: Importance of the Anthropometry

28.5.1 The 3 YOC Head Model Versus the Scaled Adult Model

In order to investigate the influence of the geometry of the head on its mechanical response under impact, the new detailed 3 YOC finite element head model is compared to a previously developed

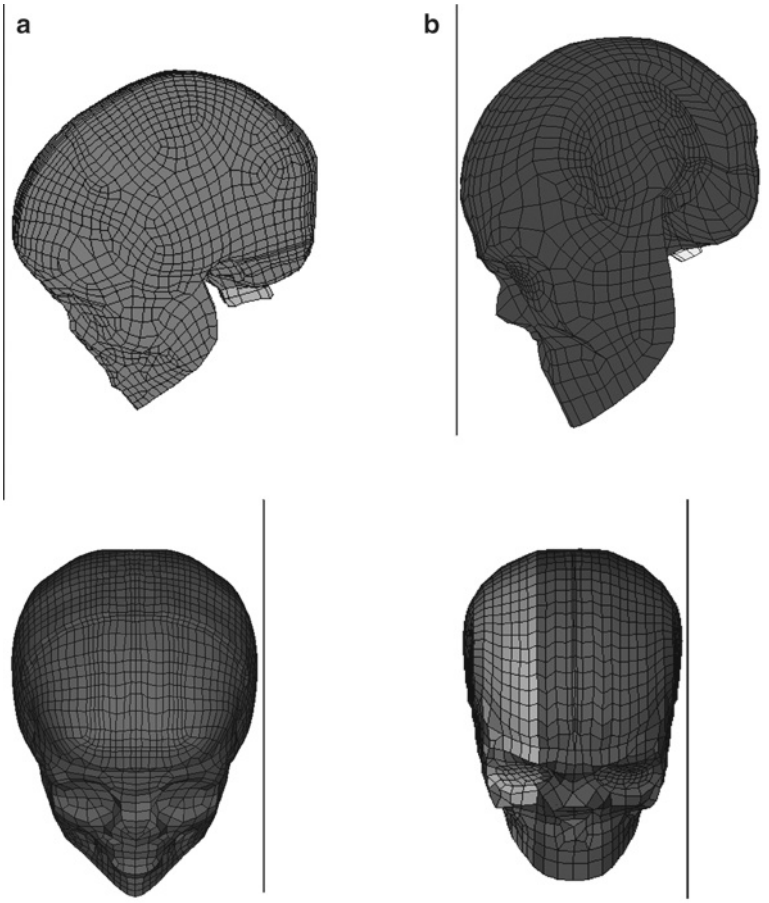

Fig. 28.18 Sagittal view of the detailed 3 YOC model (**a**) and the 3 YOC scaled-down adult head model (**b**) under frontal and lateral impact

Table 28.7 Inertia of both models, the real geometry and the scaled one

	Inertia of the real 3 YOC model (kg.m²)	Inertia of the 3 YOC Scaled down adult model (kg.m²)
I_{XX}	8.4×10^{-3}	1.3×10^{-2}
I_{YY}	7.1×10^{-3}	1.1×10^{-2}
I_{ZZ}	7.4×10^{-3}	9.8×10^{-3}

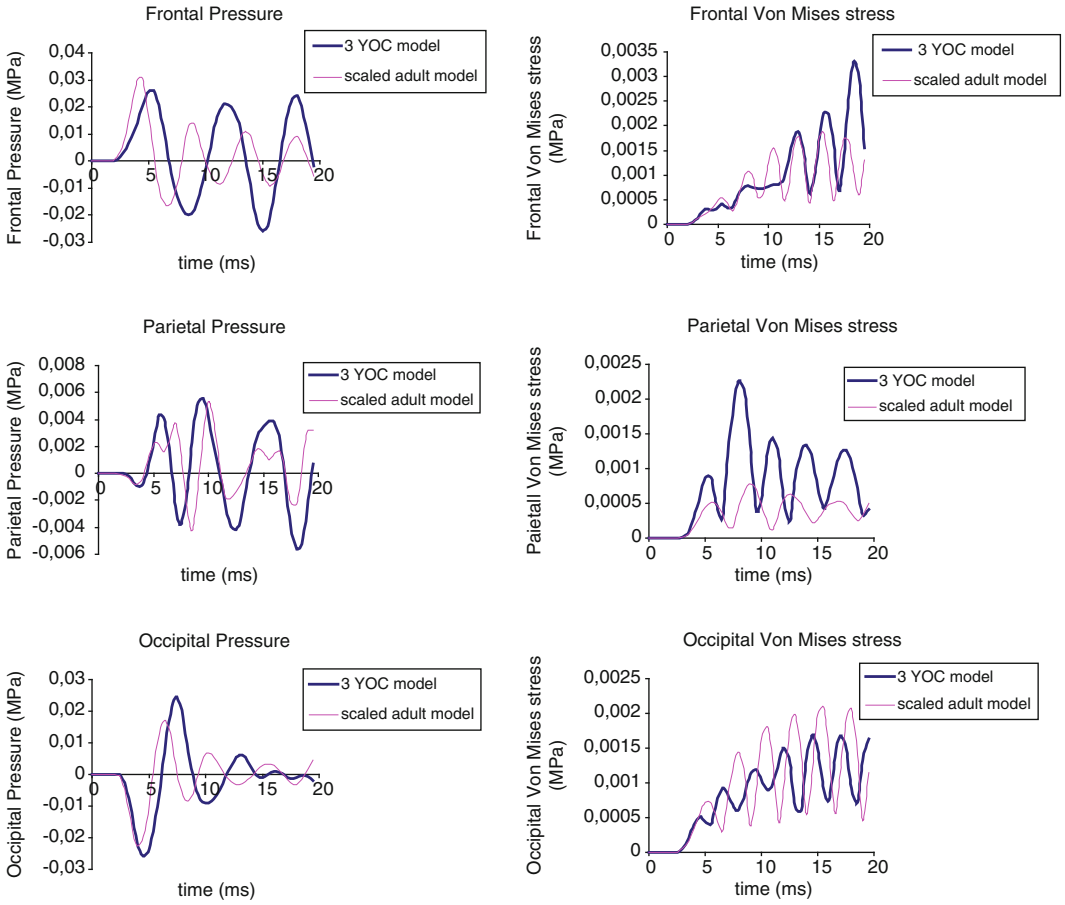

Fig. 28.19 Pressure and Von Mises stress computed with both model in different areas of the brain for a frontal impact

adult head finite element model (Kang and Willinger, 1997), which was scaled down with a 0.876 factor, according to Mertz (1984). The adult head model simulates closely the main feature of the adult head. A sagittal view of both models is displayed in Fig. 28.18.

The 3 YOC finite element model has a total mass of 2.9 kg, whereas the scaled adult head model has a total mass of 3.2 kg. Inertias of both models are listed in Table 28.7, and point out very significant differences (up to 35%). In order to analyse the influence of a child's head geometry, the response of the detailed model versus the scaled down adult head model in terms of intracranial field parameters are compared under similar impact conditions. Two impact cases were therefore simulated: a frontal one and a lateral one, both against a rigid wall at an initial velocity of 1 m/s in order to remain below the risk of skull rupture risk.

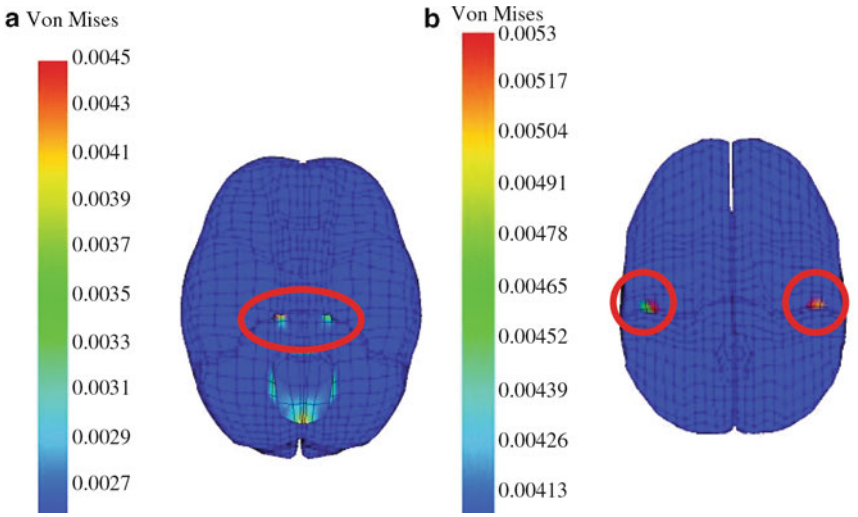

Fig. 28.20 Localisation of maximum Von Mises stress for the 3 YOC model (**a**) and the scaled adult model (**b**) at 13 ms under a frontal impact

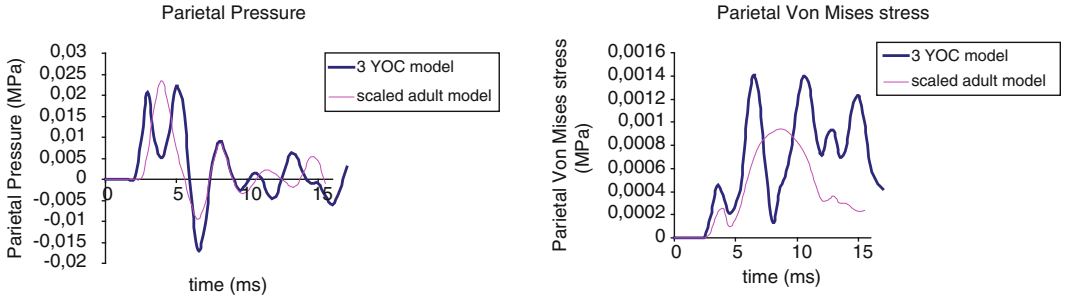

Fig. 28.21 Maximum Von Mises and pressure in the parietal area for a lateral impact

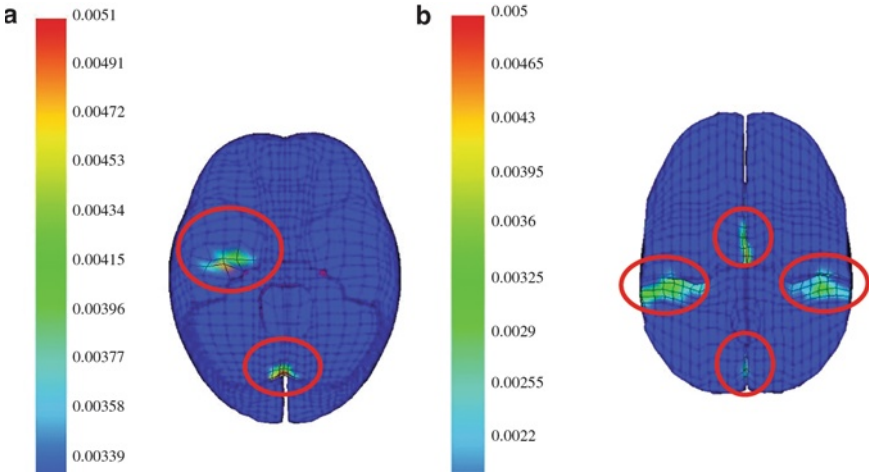

Fig. 28.22 Localisation of maximum Von Mises stress for the real 3 YOC model (**a**) and the scaled adult model (**b**) for a lateral impact

The face and the skull have the same constitutive law, as only the inertial effect of the face was considered for the present model. Facial impacts were not investigated.

With the above geometrical and mechanical properties, the responses of the detailed child head model versus the scaled-down adult head model were compared in terms of intracranial field parameters under similar impact conditions.

Models response in terms of intracerebral pressure and Von Mises stress are reported in Figs. 28.19–28.22 for both child head models successively under frontal and lateral impact. In terms of pressure, the maximum pressure seems to be equivalent for the two models. The 15% pressure difference is probably due to the slight mass difference between the two models. It can be observed in Fig. 28.19 that the shearing stress in the frontal area reaches 2.8 kPa with the real geometry, whereas it reaches 1.7 kPa with the scaled head model. In the parietal area, an important difference is observed, varying from 0.7 kPa for the scaled adult head to 2.3 kPa for the real geometry. This difference is less important in the occipital area. Furthermore, the localisation of maximum shearing stress is quite different for the two models, as illustrated in Fig. 28.20. Here, one can clearly see the influence of the geometry, in the light of the maximum stress localisation. For the scaled model, the maximum stress is located symmetrically at the posterolateral part of the inferior area of the temporal lobes, whereas it is located in the posteromedial part of the inferior area of the temporal lobes for the detailed 3 YOC head model. A similar investigation was performed under lateral impact, as illustrated in Fig. 28.18. Regarding pressure, the maximum in the impact area is of the same order of magnitude for both models and is, therefore, not reported. The responses obtained with the model based on the real geometry in terms of Von Mises stress are underestimated, compared to the scaled-down adult model (0.9 kPa against 1.4 kPa). Results are reported in Figs. 28.30 and 28.31, again in terms of pressure and shearing time histories, and shearing stress field for both models.

As for the frontal impact, the lateral impact leads to maximum stress in the temporal lobe for both models. Difference in terms of Von Mises stress and pressure can be observed between the two simulations (Fig. 28.21). In the new 3YOC model, an area of high stress is located opposite the impact side, at the inferior part of the temporal lobe. For the scaled adult model, areas of high stress are located in the middle of the brain and on the lateral part of the cerebellum, as illustrated in Fig. 28.22. For the 3 YOC brain, Fig. 28.22 shows that the brainstem is part of the maximum stress area, but this phenomenon is supposed to be an artefact due to the boundary condition at the brainstem level. Further investigations of this area would need a coupling of a neck model to the head model.

28.5.2 The 6 MOC Head Model Versus the Scaled Adult Model

In order to investigate the influence of the geometry of the head on the mechanical response, the UDS 6 MOC finite element model was compared with a previously developed adult head finite element model, which was scaled down with a scaling factor of 0.775. The new finite element model has a total mass of 2.2 kg, whereas the scaled adult head model has a total mass of 2.1 kg. The inertia of both models is listed in Table 28.8, and points out very significant difference on the *X*-axis (up to 19%). On the *Y*- and *Z*-axes, inertia is equivalent.

In order to analyse the influence of a child's head geometry, the detailed model versus the scaled-down adult head model responses in term of intracranial field parameters were compared under similar impact conditions. Three impacts were simulated: a frontal, a lateral, and an occipital impact against a rigid wall with an initial velocity of 1 m/s, as illustrated in Fig. 28.23.

Table 28.8 Inertia of both models, the detailed geometry and the scaled one

	Inertia of the detailed 6 MOC model (kg m²)	Inertia of the 6 MOC Scaled-down adult model (kg m²)
IXX	3.9×10^{-3}	4.8×10^{-3}
IYY	5.1×10^{-3}	5.5×10^{-3}
IZZ	4.6×10^{-3}	4.6×10^{-3}

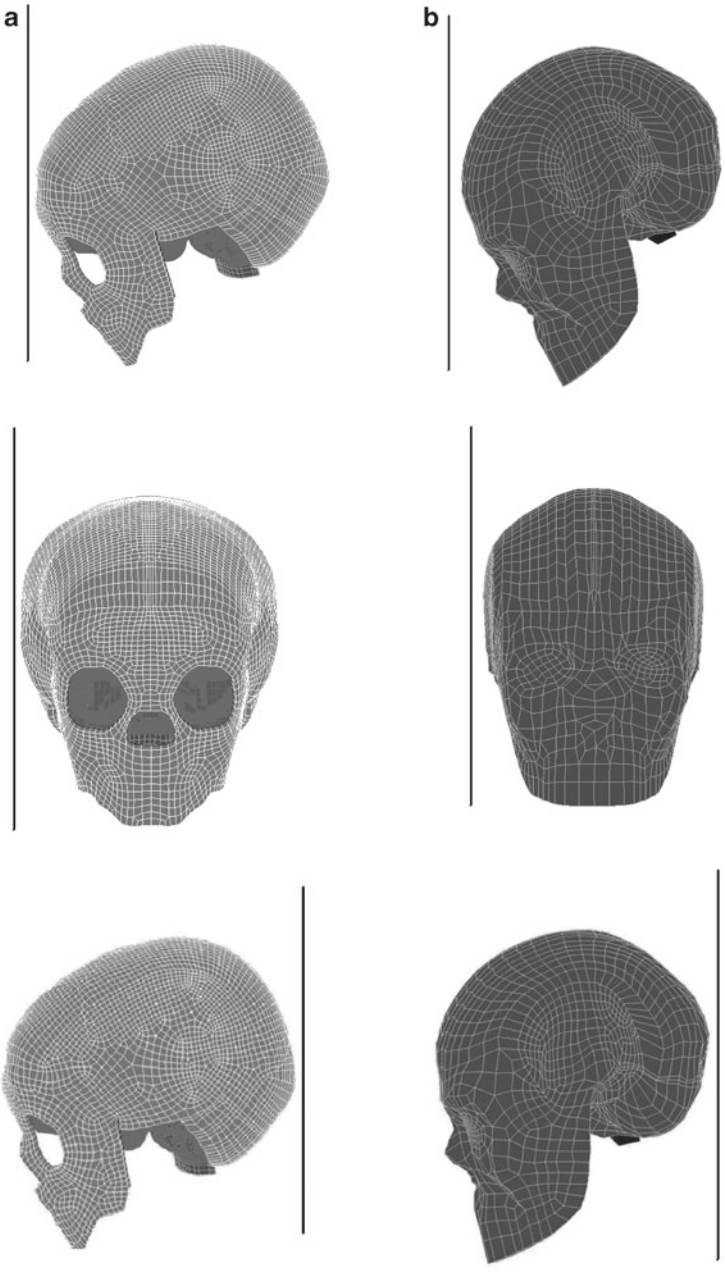

Fig. 28.23 View of the detailed 6 MOC model (**a**) and the 6 MOC scaled-down adult head model (**b**) under frontal, lateral impact and occipital impact

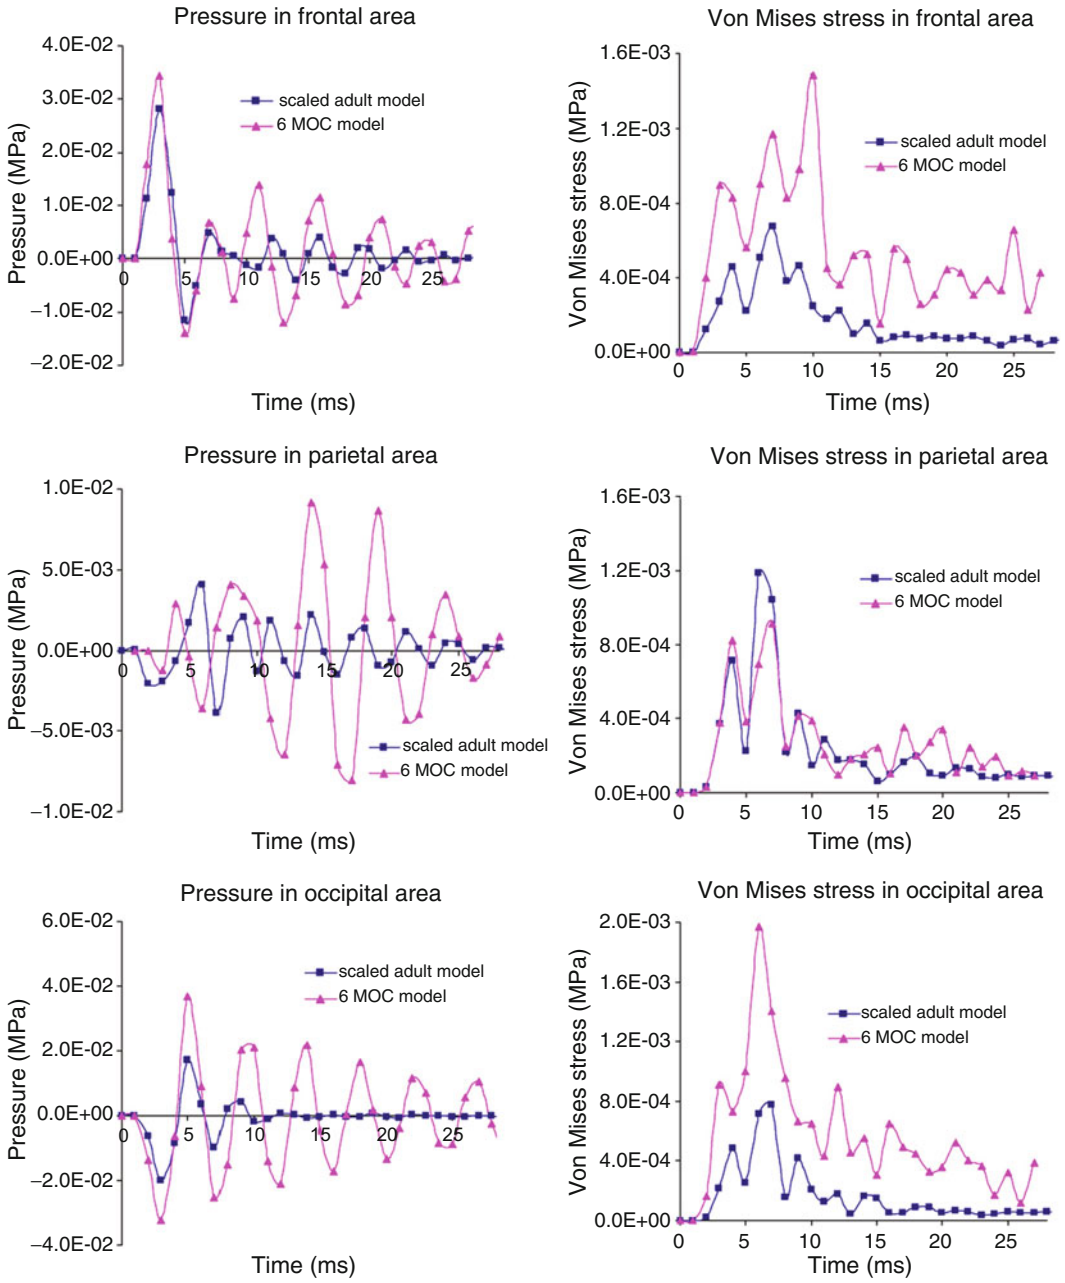

Fig. 28.24 Pressure and Von Mises stress computed with both model in different areas of the brain for a frontal impact

28.5.2.1 Frontal Impact

For frontal impact, the peak pressure in the frontal area for the new 6-month-old model and scaled adult model was 35 and 29 kPa, respectively (Fig. 28.24). In the occipital area, the difference of pressure was more important, and pressure reached 19 and 38 kPa for the 6-month-old model and for the scaled model, respectively. In the parietal area, pressure was 4 and 10 kPa for the 6-month-

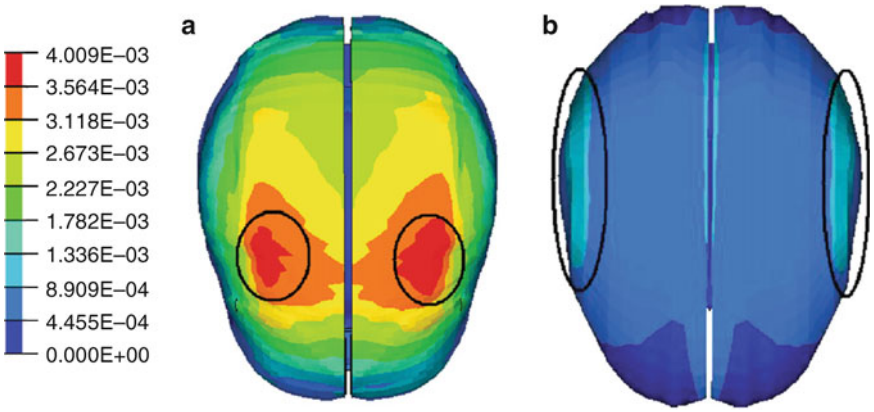

Fig. 28.25 Localisation of maximum Von Mises stress (MPa) in the brain for the 6 MOC model (**a**) and the scaled adult model (**b**) under a frontal impact

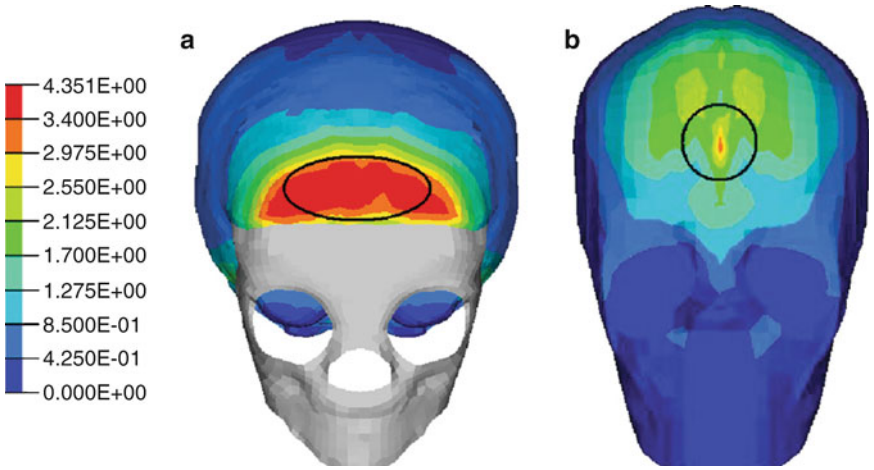

Fig. 28.26 Localisation of maximum Von Mises stress (MPa) in the skull for the 6 MOC model (**a**) and the scaled adult model (**b**) under a frontal impact

old model and the scaled model, respectively. It can be observed in Fig. 28.25 that the shearing stress in frontal area reached 1.6 kPa with the new detailed model, whereas it reached 0.65 kPa with the scaled head model. In the parietal area, Von Mises stress was 1.2 kPa for the scaled adult model and 0.95 kPa for the new detailed model. Also, a large difference of Von Mises stress was observed in the occipital area, being 0.8 for the 6-month-old model and 2 kPa for the scaled adult model. Furthermore, the localisation of maximum shearing stress was quite different for the two models, as illustrated in Fig. 28.25.

When comparing stresses in the skull, the maximum value was located at the impact area, but the distribution was quite different for both models, as illustrated in Fig. 28.26. Furthermore, maximum Von Mises stress was 3.7 and 4.4 MPa for the scaled adult model and the real model, respectively.

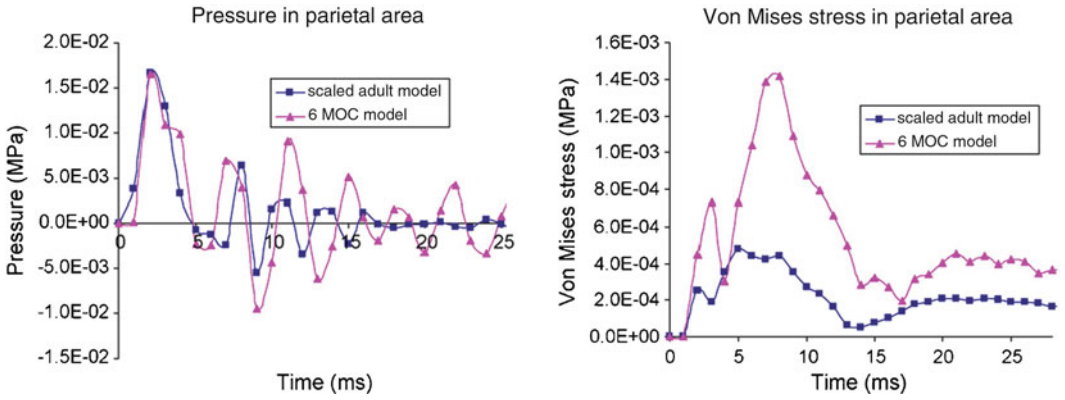

Fig. 28.27 Maximum Von Mises and pressure in parietal area for a lateral impact

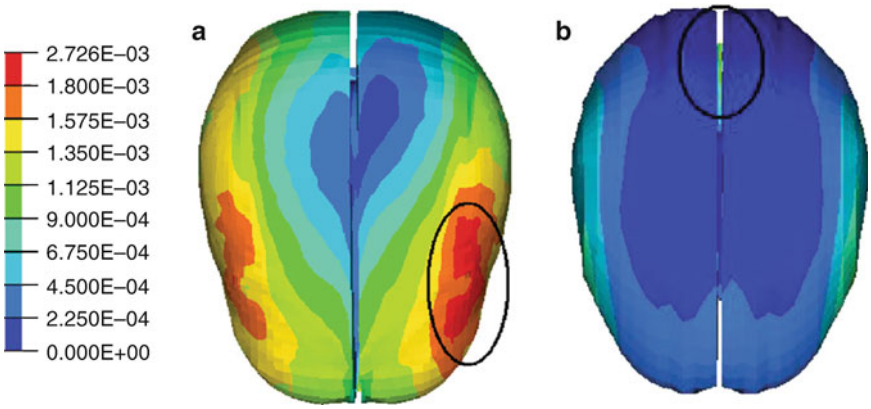

Fig. 28.28 Localisation of maximum Von Mises stress (MPa) in the brain for the 6 MOC model (**a**) and the scaled adult model (**b**) for a lateral impact

28.5.2.2 Lateral Impact

For the lateral impact, the maximum pressure in the impact area was of the same order of magnitude for both models. The response in term of Von Mises stress was 0.4 kPa with the scaled model and 1.4 kPa with the new detailed model, leading to an underestimation of 30% with the scaled model. Results are reported in Figs. 28.27 and 28.28 in terms of pressure, shearing time history and shearing stress field for both models. Similar to the frontal impact, the lateral impact led to different localisation of maximum shearing stress for the two models.

When comparing stresses in the skull, conclusions are the same as for frontal impact, as illustrated in Fig. 28.29. Maximum Von Mises stress was 3.9 and 9.4 MPa for the scaled adult model and the detailed 6-month-old model, respectively.

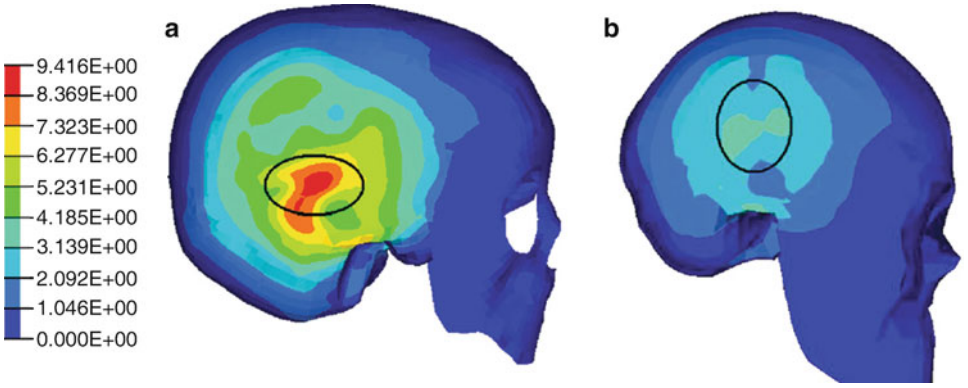

Fig. 28.29 Localisation of maximum Von Mises stress (MPa) in the skull for the 6 MOC model (**a**) and the scaled adult model (**b**) for a lateral impact

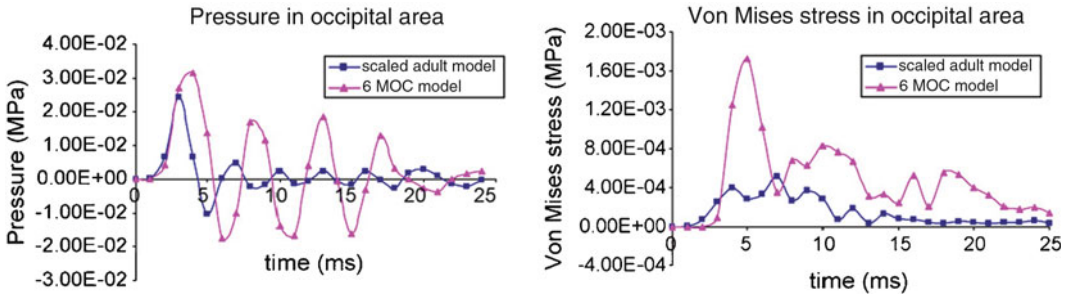

Fig. 28.30 Maximum Von Mises and pressure in the occipital area for an occipital impact

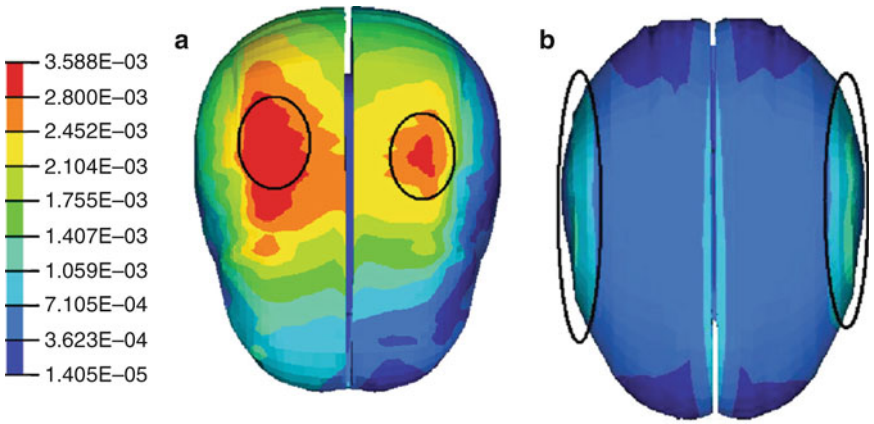

Fig. 28.31 Localisation of maximum Von Mises stress (MPa) in the brain for the 6 MOC model (**a**) and the scaled adult model (**b**) for an occipital impact

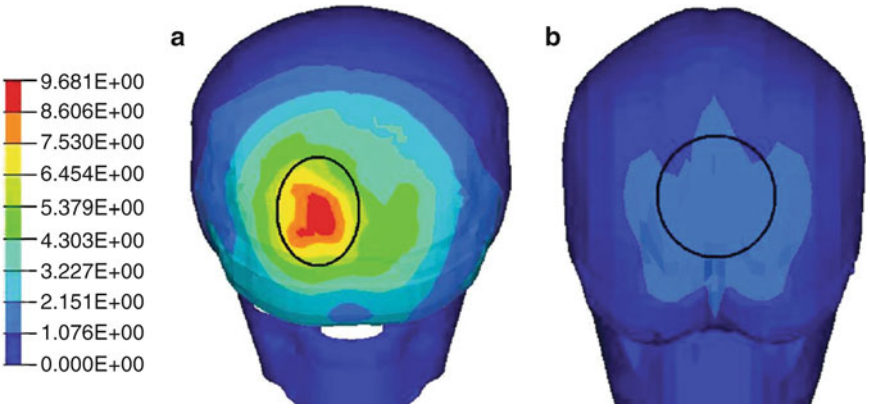

Fig. 28.32 Localisation of maximum Von Mises stress (MPa) in the skull for the 6 MOC model (**a**) and the scaled adult model (**b**) for an occipital impact

28.5.2.3 Occipital Impact

For the occipital impact, Fig. 28.30 shows Von Mises stress time history in the brain in occipital area, at 0.5 kPa for the scaled adult model and 1.8 kPa for the real geometry. Maximum stress was located at the same area as for frontal impact, as illustrated in Fig. 28.31. Stresses in the skull were located in the same area but were 2.3 and 9.7 MPa for the scaled model and the detailed model, respectively, as illustrated in Fig. 28.32.

Finally, morphological, structural and numerical analysis show the importance of the geometry: in order to analyse child head injuries, the creation of biofidelic models of the head appears to be necessary.

28.5.3 Conclusion

Finite element analysis, using realistic geometry, confirms the importance of morphology. Indeed, responses in terms of mechanical parameters are quite different because of the head shape. Furthermore, localisations of maximum stress did not appear in the same area of the brain for the realistic child head compared to the scaled adult head, showing again the importance of an accurate size and shape when performing finite element analysis. The UDS' finite element models (6 MOC and 3 YOC) have shown first interesting results in real-world head trauma reconstruction, and appear to be an interesting tool to study child injury mechanisms.

28.6 Child Anthropometry: Conclusion, Limitations and Prospects

After an anatomical, morphological and structural study, it appears that the child head cannot be considered as a scaled adult head, and that the scaling method commonly used in child head biomechanics has several limitations. The investigation of the child head goes through a precise study of the geometry of the head and specific attention to mechanical properties. Comparison between brain shape at a specific age (Figs. 28.4, 28.12, 28.13) pointed out significant differences in terms of anthropometry. These differences are also identified at a numerical level, which lead to the conclu-

sion that a finite element analysis of the child head can only be performed with a biofidelic model (with respect to size and shape) in terms of geometry. Differences in terms of mechanical parameters illustrate this important point.

Based on these conclusions and motivated by the need for brain trauma investigations among the paediatric population, finite element models of the child head begin to interest the biomechanics community. Indeed, more and more studies examine the child head in terms of numerical analysis. As an example, UDS' finite element models of the child head have been used to simulate complex head trauma configurations, as in the shaken baby syndrome.

Although this chapter summarises new findings in child biomechanics, they are only the first step in the comprehension of child head trauma. Indeed, development of child FEM needs realistic constitutive laws, which are rare in the literature. Even if some mathematical theory (scaling method) allows going further with material properties, experimentations on biological tissues are necessary. More studies are needed in order to improve the biofidelity of constitutive laws to be implemented in FE models. Another important limitation is the lack of experimental data for model validations. Indeed, ethical reasons prevent experiments on child tissues, and one cannot ensure the realistic response of a numerical model (as performed on adult FE models).

Finally, FE analysis is commonly used for real accident reconstruction in order to analyse mechanisms leading to neurological injuries or skull fractures of the adult head (Deck et al. 2008) and also for the paediatric population.

The development of realistic models needs the implementation of a correct constitutive law and also a correct geometry, based on anatomical evolution of the head and of the brain. Anthropometry is essential and infant and child heads (younger than 6 year-old) should not be considered as scaled adult heads. Sections of this chapter dealing with brain and skull evolution and numerical simulations have demonstrated this fundamental aspect.

Key Features of Finite Element Model

Finite element analysis is a numerical mathematical method, which consists of discretization of a continuous space and equations into finite subspace, in order to analyze structures at a local level (stress and strain). Both mesh and material properties are used in a Finite Element Code, to simulate a loading case. This powerful method is more and more used in several fields of mechanical engineering, such as crash field, and civil engineering. In the field of biomechanics, finite element method is used to simulate human body and biological structures in order to investigate their responses under loading case (static, dynamic, impact, etc.).

Summary Points

- During growth, a child's head undergoes different modifications in terms of morphology and structure. Great differences exist between adult and child head in terms of shape, size, and global morphology.
- A comparison between head shape for an adult and a child shows that child head (until the age of 6) cannot be considered as a scaled adult head.
- At a numerical level, a finite element analysis need precise geometry of child head in order to investigate head trauma, and scaling down an adult FE model of the head to obtain a child head is not recommended.
- A detailed geometry of the head is needed in order to investigate head trauma in paediatric population.

Chapter 29
The Farkas System of Craniofacial Anthropometry: Methodology and Normative Databases

Curtis K. Deutsch, Alison R. Shell, Roberta W. Francis, and Barbara Dixon Bird

Abstract LG Farkas created the first comprehensive craniofacial surface anthropometric atlas *Anthropometry of the Head and Face in Medicine* in 1981, and he has continued to develop new measurements and normative data through revision and updates of the atlas and published datasets. Trained in both plastic surgery and medical anthropology, Dr. Farkas created a meticulous measurement system that is based on the identification of anthropometric landmarks. Over the last 25 years he provided extensive hands-on training for clinicians and scientists in North America and around the world. This attention to detail is essential, since these procedures are painstaking and careful instruction is required.

The Farkas system of craniofacial anthropometry has found increasing application in medical and clinical genetics and in plastic and oral/maxillofacial surgery. Quantitative measurements have rendered the diagnosis of dysmorphic features both objective and reliable, a boon to geneticists and surgeons alike. Also, surgical planning has benefited from these metrics which are useful in the assessment of post-operative success. Both of these developments have been facilitated by the publication of the Farkas methods and norms, which continue to be expanded and updated. This craniofacial surface measurement system has become a popular standard reference, providing the most extensive normative database extant for North America.

29.1 Introduction

This chapter provides an overview of Professor Farkas' system of craniofacial anthropometry, and the normative databases created from this methodology. Farkas' work on basic and clinical research, spanning a half century, generated the most comprehensive craniofacial measurement procedures to date. These methods have provided a framework for physical anthropology research, and have found application in a variety of disciplines such as medicine, including plastic surgery, oral/maxillofacial surgery, and medical and clinical genetics.

Farkas' craniofacial measurement system, as an alternative to subjective visual inspection (Holmes et al, 1987), is very much in the spirit of Lord Kelvin's call for quantification (Deutsch and Mulliken 2001): "I often say that when you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind; it may be the beginning of knowledge, but you have scarcely in your thoughts advanced to the state of Science, whatever the matter may be" (Thomson 1883). Though there had been earlier efforts to develop limited numbers of craniofacial anthropometric measurements (notably the pioneering efforts of Feingold and Bossert 1974), Farkas introduced remarkable complexity and breadth in formulating his methods and creating his normative databases.

LG Farkas provided these means of quantification by formalizing objective, reliable means of measuring craniofacial size and shape. He adapted classical measurement techniques and created novel anthropometric procedures to produce comprehensive anthropometric atlases of the human head and face. Below, we outline his methods, the compilation of his normative databases, and their use in a variety of disciplines. Finally, we describe how his direct measurement methods are now being extended to state-of-the-art digital morphometry.

29.2 The Farkas Atlases

The first atlas of measurements, *Anthropometry of the Head and Face in Medicine*, was published in 1981, with a revised atlas appearing in 1994. These surface measures were made with an array of direct anthropometric devices, many of them adaptations of classical instruments, such as sliding and spreading calipers, angle meters, and protractors. Additionally, he designed many instruments, tailor-made for specific classes of measurement (Farkas 1981), for example, a large double-sliding caliper with levels for projective measurements extending from the cranial vertex.

The 1994 atlas is a compendium of projective linear measurements, arcs, angles of inclination, and deviations, each connecting anthropometric landmarks that can be reliably identified (Fig. 29.1 and Table 29.1). This network of landmarks extends across single midline structures and paired measurements. Lateral asymmetries of these paired measurements are also enumerated as normative data. Additionally, in 1986, Farkas and Munro published norms for within-subject ratios of individual measurements in *Anthropometric Facial Proportions in Medicine*.

The most extensive norms in the Farkas atlases are for anthropometric measurements within the Caucasian North American population. Whereas the original 1981 atlas focused on Caucasian norms, the Farkas (1994) edition was expanded to include a broader age range of subjects, as well as samples of Chinese and African–American individuals. In this second edition, the norms included data for 2,326 Caucasian North American individuals, ranging in age from 1 year to adulthood. This edition of the atlas, *Anthropometry of the Head and Face*, has been called "a quantitative foundation… for the human head and face and their features…of obvious value to plastic surgeons, but also for

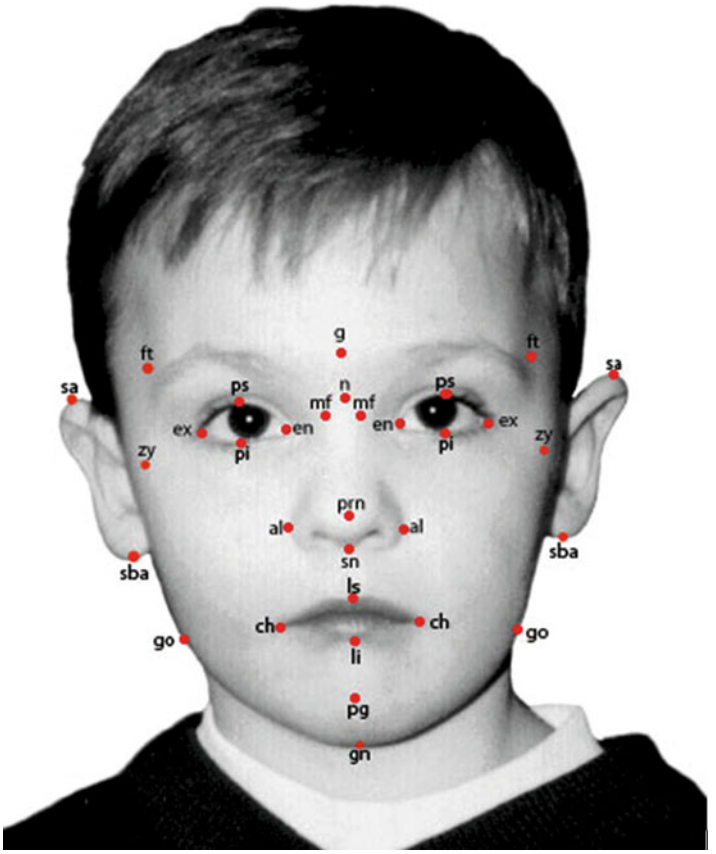

Fig. 29.1 Anthropometric landmarks (selected). See Table 29.1 for landmark abbreviation key

clinicians and researchers in other areas as well as others with a professional interest in dimensions of the head and face" (*Book News* Reference and Technical Reviews 1994).

The North American Caucasian norms include 132 craniofacial anthropometric measurements (70 single and 62 paired). Of these, 103 measurements are linear and 29 angular: 15 cranial (Table 29.2), 31 facial (Table 29.3), 21 orbital (Table 29.4), 28 nasal (Table 29.5), 18 labial (Table 29.6), and 19 auricular (Table 29.7).

In recent years, Farkas and his colleagues began collecting norms for additional ethnic groups, in conjunction with an international consortium of investigators. Their initial efforts are published in Farkas et al. (2005). Further efforts are underway to collect new normative databases outside of North America, for example in southern China (Jayaratne et al., in preparation).

29.3 Practical Methods and Techniques: Training and Reliability

These painstaking anthropometric measurement techniques require extensive training in order to be performed reliably (Farkas and Deutsch 1996). Autodidacts, who have learned merely from written methods, often find, after training, that many of their original measurements have substantial errors.

Table 29.1 Definitions of anthropometric landmarks (see Fig. 29.1)

Landmark	Name	Definition
g	*Glabella*	The most convex sagittal midline point between the eyebrows
ft	*Frontotemporale*	The point of concavity on each side of the forehead above the supraorbital rim, lateral to the elevation of the linea temporalis
zy	*Zygion*	The most lateral extents of the zygomatic arches
go	*Gonion*	The inferior aspect of the mandible at its most acute point (the mandibular angle)
sl	*Sublabiale*	The most inferior sagittal sagittal midline point of the lower cutaneous lower lip, at the labiomental sulcus
pg	*Pogonion*	The most protrusive anterior sagittal midline point of the chin
gn	G*nathion*	The lowest median landmark on the inferior aspect of the mandible
en	*Endocanthion*	The most medial point of the palpebral fissure, at the inner commissure of the eye
ex	*Exocanthion*	The most lateral point of the palpebral fissure, at the outer commissure of the eye
ps	*Palpebrale superius*	The most superior aspect of the palpebral fissure at the sagittal midline of the free margin of each upper eyelid
pi	*Palpebrale inferius*	The most inferior aspect of the palpebral fissure at the sagittal midline of the free margin of each lower eyelid
n	*Nasion*	The sagittal midline point of the nasal root at the nasofrontal suture
mf	*Maxillofrontale*	Lateral extents of the base of the nasal root at the junctures of the maxillofrontal and nasofrontal sutures
al	*Alare*	The most lateral extents of the alar contours
prn	*Pronasale*	The most protrusive point of the nasal tip (apex nasi), identified in lateral view
sn	*Subnasale*	The midpoint of the point of inflection of the columellar base at the juncture of its lower border with the surface of the philtrum
ls	*Labiale superius*	The sagittal midline point of the upper lip (at the upper vermilion line)
li	*Labiale inferius*	The sagittal midline point of the lower lip (at the lower vermilion line)
ch	*Cheilion*	The most lateral points at the labial commissure
sa	*Superaurale*	The most superior point of the helix of the auricle
sba	*Subaurale*	The most inferior point of the lobule of the auricle

The Standard deviations (SDs) for many population measurements are small, and minor measurement inaccuracies can translate into large errors in standardized scores. Take, for example, variability seen in measurements of the width of the head (the linear distance between the eurions, the most lateral extents of the cranium). For school-aged children of both genders, SDs for head width range between 4.2 and 6.3 mm. During our studies at the Craniofacial Centre of Children's Hospital Boston, we have trained many surgeons to perform Farkas-based measurement protocols. For those surgeons who already had some familiarity with the Farkas atlas (but not hands-on training), we conducted a pre-test to document their measurements before giving instruction, and then went on to provide formal training. After the surgeons had been trained, they repeated these measurements on the same subjects seen earlier. A comparison of the pre- and post-tests revealed that their measurements of head width in particular were frequently off by several millimeters; thus, it was not unusual for the

standardized (z-) score to be in error for this measurement by a full SD or more. In contrast, after training, the surgeons and other extensively trained examiners typically have achieved test–retest and interrater reliability coefficients >0.90. More recently, these have been extended to include digital measurements using the Farkas system (see below; e.g., Aldridge et al. 2005; Baca et al. 1994; Weinberg et al. 2006; Wong et al. 2008).

Dr Farkas and his trainees have extended instruction to a network of investigators and clinicians. There is also a video introduction to the anthropometric landmarking system (Deutsch et al. 1995), with a discussion of direct measurements and 3D surface imaging. However, it provides only a brief initiation, and does not provide requisite training for the Farkas methods. Also, a complementary description of anthropometric procedures has been published by Kolar and Salter (1997).

A new edition of the Farkas methods and norms is under preparation (see later). It is worth noting that subsets of Farkas' normative data have been reproduced as nomographs in handbook form by Hall et al. (e.g., 2003), but these do not include the measurement means and SDs needed to compute *z*-scores, conditioned on age, gender, and ethnicity, that are found in the Farkas atlases.

29.4 Digital Imaging Techniques

As the means of 3D digital surface acquisition have become available (e.g., laser scanning and stereophotogrammetry), there has been increasing interest in the clinical and research community for image analytic techniques.

One clear advantage of using surface images is that they provide a resolute data set for storage, thus allowing subsequent morphometry. This provides an opportunity to the clinician and investigator for ad libidum post-acquisition measurement.

Another advantage of using digital surface scans is that they permit image acquisition of young children and developmentally disabled individuals, who sometimes cannot sit still for long for a direct anthropometric examination. Some of the 3D imaging devices that became commercially available in the 1990s could capture an image in a matter of seconds, but – rapid as this was – this period was long enough to introduce motion artifact. Fortunately, later advances in alternative imaging techniques (e.g., 3D stereophotogrammetry) permitted image capture in less than 2 ms. With this rapid acquisition, image distortion was no longer a problem (see discussion by Wong et al. 2008).

Morphometry can be performed directly on the 3D image. The point cloud generated by the imaging system is plotted in space, and *x*, *y*, *z* coordinates are computed for the scanned surface. 3D stereophotogrammetry measurements are resolute and reliable (Aldridge et al. 2005; Baca et al. 1994; Weinberg et al. 2006; Wong et al. 2008; Tan et al. in preparation). In order to utilize the Farkas direct anthropometric norms, it is important to provide validation of direct against digital measurement. Indeed, in a study of the metric qualities of the 3dMD sterophotogrammetry imaging device (Wong et al. 2008), the majority of measurements via direct anthropometry and image analysis by trained raters were highly correlated.

29.5 Digital Normative Database

Efforts are now underway to make available the Farkas norms in electronic format to the clinical and research community. These norms have recently been structured within a digital database, *FaceValue*, created with the support of the US National Institute of Dental and Craniofacial Research. This will provide the clinical and research community streamlined access to the norms, and the opportunity to readily compute standardized scores conditioned on demographics. The objective is to make the Farkas norms more user-friendly by creating a computer-based interactive craniofacial measurement database for them. The software is designed to (1) facilitate ready access to look-up tables conditioned on patient demographics, using a menu-driven, landmark-based interface; (2) permit computation of standardized measures for patients, including user-created functions; (3) generate reports for anthropometric protocols, conditioned on professional specialization; and (4) export derived scores to databases for documentation and statistical analysis.

29.6 Application to Plastic Surgery and Oral/Maxillofacial Surgery

In addition to being a medical anthropologist and dysmorphologist, Dr Farkas was a plastic surgeon. His anthropometric methods were designed to accommodate the craniofacial surgeon in pre-surgical planning and post-surgical evaluation. As Dr Paul Tessier wrote, it is first necessary to determine for the patient "what is 'ortho' and what is 'dys'" (foreword to Farkas and Munro 1986). The Farkas system permits the surgeon to establish concretely the degree and type of abnormality using his toolbox of measurements. We discuss further the quantitative assessment of dysmorphology in the context of medical and clinical genetics (see below).

Anthropometric work-ups have proven helpful in planning surgical procedures and evaluating outcomes for a number of conditions, including cleft lip–cleft palate and craniosynostoses (Farkas et al. 1993; Farkas and Forrest 2006; Mulliken et al. 2001; Oh et al. 2008). For example, in unilateral coronal synostosis (UCS), Burvin et al. (1999) employed anthropometric analysis to compare the outcome of two contrasting surgical techniques (homeotopic vs. heterotopic positioning of frontal elements) in the correction of dysmorphology. Further, Oh et al. (2008) used the Farkas procedures to study the long-term outcome of UCS patients who had fronto-orbital advancement in infancy. They determined that, even with surgical intervention, these patients displayed residual, consistent middle and lower facial asymmetry.

The Farkas quantitative measures provides the metrics for designing the type and degree of planned surgical alterations, and it can be useful to combine these measures with complementary imaging techniques. For example, instantiation of craniofacial surface images and their landmarks to radiographic, CT-, and MRI-based images will delineate the relationship between the facial surface and the underlying tissue. This multimodal approach can be useful in designing surgical interventions, as seen in an example drawn from a clinical work-up by Altobelli and his collaborators at the Surgical Planning Laboratory at Brigham & Women's Hospital (Boston, MA, USA). They merged a craniofacial surface image (acquired by a Cyberware laser scanner) with both 3D CT and MRI data for a case study of a patient with Crouzon syndrome. This autosomal dominant genetic condition, a form of craniofacial dysostosis, is characterized in part by orbital hypertelorism (an abnormally large distance between the eyes). A 3D digital template was then constructed and used to estimate the optimal parameters for repositioning the patient's orbits more medially (Altobelli 1994).

The response of soft tissues to the changes in the underlying bony architecture is still not well understood. As Altobelli points out, surgical design is best conceived from the "outside in," that is, first determine the ideal position of the craniofacial surface, then move the bones to accomplish the desired result. This approach is superior to the "inside out" model of repositioning and augmenting the bones, in the hopes that the surface response will be acceptable.

29.7 Application to Developmental Biology

Quantitative measures of dysmorphology can also be used to examine early developmental factors. It is possible to study anomaly combinations chosen to indicate specific developmental classes of dysmorphogenesis (Farkas and Deutsch 1996). These include the chronological origin of dysmorphogenesis, the mechanism of alteration, and embryonic primordia (Anlagen) from which dysmorphic features arise. By the 19th day of embryonic development, the germ layers and their subdivisions have formed into recognizable, discrete masses, and craniofacial differentiation first appears within these Anlagen. The brain and face derive in part from the same primordia, and embryologic "fate-mapping" studies describe how Anlagen correspond to specific derivatives in both craniofacial

and brain regions (Couly and LeDouarin 1987). Therefore, a gene or untoward environmental effect that produces brain maldevelopment can also affect the features of the head and face. Indeed, distinctive patterns of dysmorphology are often seen in genetic conditions and teratogenic syndromes. Quantitative tests of these brain–face relationships are made possible by anthropometric methods; one example is the correlation of craniofacial asymmetry, defined by Farkas' measurements, and brain midline maldevelopment predicted by fate maps (Deutsch et al. 2000).

29.8 Application to Medical and Clinical Genetics

The Farkas methods have also been used by geneticists in the diagnosis of craniofacial dysmorphology. With the aid of the Farkas atlases and normative databases, it has been possible to create a protocol permitting objective, reliable assessment of dysmorphic features (Deutsch and Farkas 1994; Farkas and Deutsch 1996). Here, craniofacial anomalies can be measured as standardized (e.g., *z*-) scores, conditioned on demographics. Importantly, they are quantified on a graded continuum that spans from normalcy to minor anomalies to major dysmorphic features.

A common challenge to the geneticist is the problem of heterogeneity with respect to both etiology and phenotype, and this holds true for many complex disease states (Thornton-Wells et al. 2004). This problem is particularly challenging in the field of neuropsychiatric disorders, for example, autistic disorders, which have a statistical overrepresentation of craniofacial anomalies. In addition to the large number of identified medical conditions found to be associated with one of these disorders, there may be numerous currently unidentified syndromes. Here, two approaches utilizing quantitative dysmorphology phenotypes can be used to come to grips with heterogeneity. Collections of anomalies across patients can be cluster-analyzed to determine whether they cohere. Alternatively, patients can be cluster-analyzed by anomalies to determine whether subgroups of individuals emerge as a function of anomaly combinations. The provision of continuously distributed measurements, for example, *z*-scores derived from the Farkas norms, rather than simple dichotomous variables, is likely to boost statistical power to detect existing associations.

Another anthropometric approach used in clinical genetics research is to describe dysmorphology associated with specific conditions. Farkas system measurements have been used to study several craniofacial disorders, including Apert (Farkas et al. 1985), Crouzon (Kolar et al. 1988), Down (Deutsch and Mulliken 2001), and Treacher-Collins (Farkas et al. 1989) syndromes. It is noteworthy that application of these methods to the study of these syndromes not only validated prevailing clinical opinion on the occurrence of specific anomalies, but also identified dysmorphic features that had gone hitherto unidentified. More recently, quantitative dysmorphology methods have been used to characterize specific genetic microdeletions and microduplications, including the recurrent copy number variant 16p11.2 (McCarthy et al. 2009). The Farkas methods revealed that the microdeletion and microduplication of this chromosomal region had contrasting effects on patients' head size, with the former associated with markedly larger head circumference than the latter.

29.9 Applications to Other Areas of Health

There is also potential for broad use in biometrics and bioinformatics. This has not yet been fully realized, perhaps because an electronic version of the Farkas databases has not been widely available. The distribution of the normative data in a digital format will hopefully make the databases more tractable to IT-based analysis.

Anthropometric methods have also been applied to a variety of other fields, including industrial fabrication. They have been used in the molding of helmets and goggles on a "tailor-made" basis that conform to the individual.

Further, the Farkas methods have also been used as a tool in forensics. One example is the application of facial morphology measures on a developmental continuum to "age" photographs. That is, a photograph of a child can be measured and morphed using existing norms to estimate facial appearance with advancing age. Farkas was an early adopter of aging algorithms that have aided search efforts for missing children (Farkas 1994).

Summary Points

- The Farkas anthropometric methodology permits objective, reliable quantification of craniofacial morphology.
- The anthropometric examination is painstaking and requires training.
- The Farkas normative databases allow computation of standardized (*z*-) scores, based on age, gender-, and ethnicity-specific characteristics.
- These methods permit quantitative assessment of dysmorphology on a continuum, and are commonly used for individual case studies, delineation of patterns of anomalies in heterogeneous patient groups, and in the description of distinctive facial appearance in identified craniofacial syndromes.
- The Farkas methodology is also a useful adjunct in craniofacial surgical planning and assessment.
- These procedures also are useful in population-based physical anthropology research, forensics, and biometrics.
- Advances in 3D craniofacial surface imaging are permitting rapid image capture, which can then be analyzed using Farkas system-based computer-aided morphometry.

Key Facts

Table 29.8 Key facts

• The Farkas craniofacial anthropometrics system delineates methods for landmark-based craniofacial anthropometry. These techniques provide objective, reliable quantification of craniofacial morphometry. Extensive normative databases allow computation of standardized (*z*-) scores, based on age-, gender-, and ethnicity-specific characteristics
• These methods permit quantitative assessment of dysmorphology on a continuum, for individual patients and groups, that are of utility in medical and clinical genetics. Further, they are helpful in plastic and oral/maxillofacial surgical planning and assessment. The methods and norms also find application population-based physical anthropology research, forensics, and biometrics
• 3D craniofacial surface images are increasingly used in computer-aided morphometry. Further, plans are underway for a release of the normative database in digital format, permitting flexible computation of mathematical functions

Acknowledgments It is with sadness that we report that Leslie G Farkas MD CSc Dsc FRCS passed away on 16 October 2008. He lived to the age of 93 years, and had continued working well into 2007. We owe a debt of gratitude to Dr Farkas for having the vision, energy, and dedication to create his measurement system and to apply it to numerous areas of clinical practice and research. He was truly the father of modern craniofacial anthropometry (Naini 2009), who served as a generous mentor to generations of students and colleagues.

Additionally, we would like to thank Marko Katic and Tanya Hreczko for their consultation.

Chapter 30
Anthropometry of Soft Facial Tissues

John S. Bamforth

Abstract The head is the most visible part of the human anatomy and is the way that people recognize each other visually. It is the site of food intake; all the major sensory organs associated with food detection and procurement are located in the head (vision, smell and hearing), together with all the structures to protect these vital organs. The muscles associated with food capture and chewing are also those associated with defense and are powerful. They have prominent insertions into the jaw and broad areas of origin on the cranium.

Less powerful striated muscle take origin at the cranium or jaw and are inserted into the fascia of the skin. These muscles originally served as muscles protecting vital organs and orifices but have, with time, come to function more as muscles of facial expression and phonation, with very precise movements that convey the state of mind of the individual quickly.

The various components of the soft tissue of the face are usually considered separately (muscle, connective tissue and adipose tissue), although they function as one coordinated system. For example, the connective tissue network, which contains elastic fibers, permits rapid deformation and relaxation of the face by the muscles of facial expression and phonation.

This chapter will reflect upon the embryological and fetal development of the components of the soft tissues of the face; commonly used methods of assessing the soft tissues together with their advantages and disadvantages and variation of the soft tissues with sex, age, ponderosity and race. Finally, some practical uses of this information will be examined.

30.1 Introduction

The skull is the scaffold forming the foundation of the face, and determines to a large extent, the size and shape of a face and the individual components. The soft tissues cloak the skull and give the face recognizable form. Genetic influences determine the basic shape and structure of the face; this must include both the bony architecture and the distribution of the soft tissue, although this particular aspect has never been studied. The state of nutrition, sex, and racial group are other potential modifiers of facial soft tissue. External influences (trauma and disease) will also modify the appearance, together with surgical and dental manipulation.

Estimating the mass and distribution of the soft tissues of the face is not an easy task. Some areas of the face are very mobile and elastic; others are relatively fixed and vary little with facial movement.

Each method of measurement has its own strength and weakness; these must be considered when interpreting facial tissue depth measurements. Different investigators also have different levels of expertise and, therefore, different error rates.

30.2 Derivation of the Soft Tissues of the Face

The soft tissues of the face, in common with all other facial connective tissues including bone, are derived embryologically from the cephalic neural crest and the core mesoderm. This is distinct from other parts of the body, where all connective tissue is derived from the lateral plate mesoderm.

The initial embryological event requires setting up an axis in the cranial region, defining anterior and posterior, right and left, and rostral and caudal. This occurs under the influence of the homeobox genes, particularly the Hox series, which pattern the rhombomeres. With the development of the neural tube and the formation of the neural crest tissues, there is a coordinated migration of tissues to the branchial arches, where they will differentiate and further migrate to the facial primordia, and thence into the definitive fetal face. The process involves cell migration and programmed cell death, most of which is locally determined and coordinated after the cells have migrated into the branchial arches. Cell death occurs around the developing orifices and the points of fusion of facial primordia (particularly in the formation of the midface, the nose, and the upper lip and the palate). This whole process is under genetic control, and events take place over precise time periods (usually hours, but sometimes minutes) following gestation. The fate of cells migrating into branchial arches is not decided until after the migration, and is controlled to a large extent by local endoderm, ectoderm, neural crest and paraxial mesoderm interactions. The major genes involved in this process are the bone morphogenetic proteins, fibroblast growth factor supergene family, and hedgehog (see Chai and Maxson 2006 for a review).

As these events are sequential, development of both the brain and the face is interconnected. Basic malformations of the brain are therefore frequently accompanied by particular facial abnormalities.

30.3 Components of the Facial Soft Tissues

The soft tissues of the face are bounded on the outermost surfaces by the skin. The inner surface is the skull or cartilage. The skin comprises epidermis and dermis. These structures are thin and relatively constant in thickness in the face. Beneath the skin are muscle, adipose tissue, and connective tissue. The striated muscle in the face is grouped into discrete groups of fibers around the natural orifices in the head, and provides a sphincter-like action around these orifices. Adipose tissue is

universally dispersed within the subcutaneous layer in small quantities and between the muscle fibers. It is also aggregated in discrete subcutaneous fat pads over the front and side of the face. The deep fat pads (parapharyngeal and buccal fat pads) are pads that are placed between the masticatory muscles and within the pharynx, and facilitate muscle movement in swallowing.

These components will be considered individually. Although nerves, blood vessels, and lymphatics have a very important functional role in facial movement and nutrition, they are a minor component of the overall soft tissue, and will not be considered further here.

30.3.1 Facial Muscle

The face has a large number of muscles. Those that influence the appearance of the face may be divided into those that are concerned with mastication, those concerned with sphincter function (around the eyes and mouth), and muscles whose function has been modified through evolution to become more connected with facial expression and phonation.

Muscles of mastication have their origin at the skull, particularly the temporal region, and are inserted into the jaw. These are relatively large and powerful muscles; hence, both origin and insertion of the muscle are a bony structure. Humans do not typically use biting as a method of defense, and our food tends to be cooked, and is softer; therefore, human muscles of mastication are not as big as those in our closest primate relatives, and the points of attachments to the skull and jaw are not so marked.

Sphincteric muscles have their origin on the skull, and are inserted into aponeuroses that blend with the skin. These are concentrated around the natural orifices and perform sphincter functions, for example, aiding in closure of the eyes, retaining food in the mouth, aiding in suckling and feeding, and dilating or contracting the nostrils. Many of these muscles have become primary muscles of facial expression and speech, and control of these muscles is very precise.

Normal facial muscle function depends intimately on the normal function of other components of the soft tissue. For example, the muscles of mastication and of the pharynx will not function normally without the buccal and parapharyngeal fat pads that provide a virtual gel pad buffer. Similarly, the muscles of facial expression and those assisting in speech will not function normally without the reticular facial ligament system, which permits the face to quickly relax to a neutral position once a facial expression or spoken word has been communicated.

In standard anatomy textbooks, the facial muscles are shown as single discrete muscles implying a discrete but coordinated function. More recent work has suggested that the muscles are functionally connected to each other and to their points of insertion, so that they act in a more coordinate fashion than previously thought (Breitsprecher et al. 1999). In particular, all the muscles of facial expression situated around the upper lip, philtrum, and the nose essentially connect the chondral growth center of the nose (the septal cartilage) with the frontal and zygomaticomaxillary suture systems of the face. This coordinate action results in symmetrical forces being applied to these facial sutures, which in turn are intimately connected with development of the bony midface. The skull sutures in a fetus and young child are relatively parallel to each other and filled with osteoid, not the rigid interdigitating structures they become in later life. Therefore, relatively little force applied to the facial bones at this age can have a large influence on growth and symmetry of the skull. Where the muscle action is asymmetrical in utero (as in cleft palate), marked facial asymmetry of both soft and hard facial tissues will result. When muscle action is weaker than normal, or the connective tissue attachments are more lax, this often results in a characteristic, recognizable change in facial morphology.

Total muscle mass varies between individuals, but sexual dimorphism is not marked. The muscles are also in constant use and change with age appear not to be marked.

Fig. 30.1 Location of the subcutaneous fat pads of the face. An artist's rendition of the subcutaneous compartments of the face

30.3.2 Facial Ligaments

The face has a rich network of skin ligaments. The ligaments run from the periosteal surface to the fascia of the dermal layer. They are reticular in formation, often branching with adipose tissue interspaced between the lattices (for a review, see Nash et al. 2004). Ligaments are subject to changes with age and with exposure to sun, giving rise to a wrinkled appearance (Braverman 1986). The facial ligament system not only performs natural tissue boundaries (which are important in limiting diseases, such as infection and tumor), but also provides an elasticity to the face that permits muscles of facial expression and phonation to act quickly and sequentially.

30.3.3 Adipose Tissue

There are three main places where fat cells accumulate: diffusely in the dermis, in discrete symmetrical pads below the dermis at the front and side of the face, and deeply between muscles of mastication and the pharyngeal muscles.

Immediately below the surface of the skin in most parts of the face, there is a layer of adipose tissue that mingles with the subcutaneous capillary network, dermal papillae, and eccrine ducts.

The discrete accumulations of adipose tissue at the front and sides of the face are situated in multiple independent anatomical compartments (Rohrich et al., 2007). These fat compartments may broadly be divided into a nasolabial compartment, three cheek fat compartments, three orbital compartments, a forehead compartment, a temporal compartment, and a jowl compartment (Fig. 30.1).

The boundaries appear to form natural planes through which blood vessels and nerves run to serve both the fat compartment and the skin overlying it. The compartmentalization of the superficial fat layers has important implications for the face in terms of changes with aging and disease (Donofrio 2000), as no one compartment responds exactly the same way to a stimulus as another compartment. For example, the upper malar compartment in older people increases in size relative to the middle and inferior compartments in older people (Gosain et al. 2005), whereas the temporal compartment decreases in size with age (Stephan and Devine 2009). These changes alter the shape of face from the round, cherubic face associated with childhood to the more angular face associated with older age.

In addition to these superficial layers, there are deeper layers of facial fat, notably the buccal and parapharyngeal fat pads and the sub- and retro-orbicularis layers of fat.

The deeper fat pads (buccal and parapharyngeal) are metabolically inert fat pads that assist the function of masticatory and pharyngeal muscles by providing a gel-pad buffering separation between the muscles (Kahn et al. 2000). They have few mitochondria and show little change in size with state of nutrition (although they do atrophy in some disease states, notably facial hemiatrophy and AIDS).

30.4 Practical Methods and Techniques of Measuring Facial Soft-Tissue Depth

The next section will discuss: the soft-tissue landmarks; the most common methods that have been used to assess soft-tissue depths; and the accuracy of commonly used methods.

30.4.1 Soft-Tissue Landmarks

Facial soft tissue is surveyed by measuring the depth of the soft tissue, which overlies the conventional facial landmarks. Both landmarks and soft-tissue measurements can be reliably reproduced, both within and between observers (Farkas 1994). Facial landmarks are conventionally located and marked with the head in the Frankfort horizontal position. Measurement of tissue depths is also ideally measured with the head in this position in order to standardize the effect of gravity on the soft tissues. Tissue depth is the smallest measured distance between the epidermis of the skin and the nearest hard tissue element (usually the bone of the skull), generally measured at right angles to the hard surface.

The tissue depth at specific landmarks is denoted by a superscript dash placed above the accepted notation describing a landmark. Thus, tissue depth at the pogonion landmark is referred to as pg-pg′, sometimes abbreviated to pg′. No commonly used method of measuring tissue depth is routinely able to distinguish between the soft-tissue components (muscle, connective tissue, and adipose tissue), although special techniques may do so (Gosain et al. 2005).

Many of the facial landmarks are defined by palpation; thus, many of the bony landmarks used to locate the discrete facial points are close to the surface of the skin and, therefore, are likely to have less soft tissue between the skin surface and the bone than in non-landmark areas of the face. Therefore, fixed errors (e.g., instrument error) will tend to be relatively larger when the measurement is small. Measurements over non-bony landmarks rely on midpoint or chord constructions, and may be more difficult to reproduce. Tissue depths give little information about shape or architecture (e.g., of the superficial facial fat pads).

Table 30.1 Key features of anthropometry of soft facial tissues

1. Facial tissue depth is conventionally measured as the shortest distance between uncompressed skin and underlying cranial bone, measured in the Frankfort horizontal position
2. Methods used to measure tissue depth routinely include needle puncture, plain film radiography, computerized tomography, magnetic resonance imaging, and ultrasound. The technical error of measurement of any method is approximately 10%
3. The ponderosity of adult subjects has a greater influence on facial tissue depths than sex or race
4. Soft tissue comprises muscle, connective tissue, and adipose tissue, together with blood vessels, lymphatic vessels, and nerves. The tissues function as a coordinate system and their movement influences the growth of the bony cranium
5. Changes in shape and architecture of facial soft tissues are poorly represented by the traditional facial tissue depth measurements

This table lists the key features of facial soft tissue and measurement of these tissues

Despite this, measuring tissue depths over landmarks is useful, and nearly all the work published on soft-tissue depths of the face is based on such assessments. These studies have formed the basis for comparison of faces in medical, surgical, anthropological, and forensic literature.

30.5 Commonly Used Methods to Assess Tissue Depth

The commonly used methods of assessing tissue depth are needle puncture, plain radiography, computerized tomography (CT), magnetic resonance imaging (MRI), and ultrasound. All these methods have advantages and disadvantages (Table 30.2). All methods have a systematic bias; some methods give higher tissue depth values at some landmarks than given by other methods (Table 30.3; Stephan and Simpson 2008). Note that for methods that involve CT and MRI, different protocols have been used for scanning. For CT, this markedly affects tissue depth estimates even when the operator and the machine are constant (Kim et al. 2005). Although no similar data exists for MRI, it is likely that the same will apply. There is a need to standardize protocols when using these methods.

30.6 Precision and Accuracy of Commonly Used Methods

Little attention has been given to precision and accuracy of soft-tissue measurement of the face, until recently. Studies on accuracy (the relationship between the surface landmark placed on the skin and the bony landmark underneath it) are not easy to do, and there is limited data. Some of the newer techniques that permit a three dimensional reconstruction (e.g., CT and MRI), are able to examine this relationship to some extent, and the relationship appears accurate (Tilotta et al. 2009), but data are scare. There is more information concerning precision (relationship of two or more measurements of the same parameter taken at different times). Anthropologists routinely use the technical error of measurement (TEM) and its derivative, the coefficient of reliability (R), to estimate the precision of measurement. TEM is expressed in the unit of measurement; for most landmarks, it is estimated at 5–10% of the measured value. For a scientific measurement, this is just acceptable, but relatively imprecise. This lack of precision is remarkably similar, no matter what technique is being used to estimate soft-tissue depth (Domaracki and Stephan 2006; Smith and Throckmorton 2004; Van derPluym et al. 2007). Lack of precision of measurement complicates the comparisons between

Table 30.2 Comparison of advantages and disadvantages of the commonly used methods of measuring soft-tissue depth

Method of measurement	Advantage	Disadvantage
Needle puncture	Low cost	Invasive
	Operating characteristics well defined	Most information from cadavers, soft tissue may not accurately reflect living tissue
	Measurements can be made in Frankfort plane	Compression of soft tissues inevitable during measurement
Plain film radiography	Standard cephalograms widely used in dentistry and medicine	Exposure to ionizing radiation, patient selection may bias results
	Films generally taken in Frankfort plane	Only of use where surface landmark and bony landmark are parallel to the film plate
	Relatively inexpensive	Metallic implants (braces and fillings) may interfere with measurements
	No compression of tissue whilst taking measurement	
Computerized tomography	Widely used in medicine and dentistry	Expensive
	Images are digital and easy to manipulate (e.g., absorption characteristics of soft and hard tissue relatively easy to distinguish)	Requires exposure to ionizing radiation, patient selection may introduce bias
	Accuracy of surface landmark placement relative to bony landmark can be verified	Patient motion artifact (voluntary or involuntary) may interfere with measurements
	Paired landmarks easily measured	Radio opaque objects (e.g., fillings, braces) may distort images and measurements
		Images are not in Frankfort plane, gravity effects on soft tissue are possible
Magnetic resonance imaging	No exposure to ionizing radiation, ethically acceptable to image subjects for tissue depth estimation	Very expensive
	Can be repeated on same subjects to obtain longitudinal data	Images generally not acquired in Frankfort plane
	No soft-tissue compression during measurement	Requires exposure to high-intensity magnetic field, subjects with metallic exposure not eligible
	Images are digital and easy to manipulate (e.g., absorption characteristics of soft and hard tissue relatively easy to distinguish)	Subject motion artifact distorts images
	Accuracy of surface landmark placement relative to bony landmark can be verified	
	Paired landmarks easily measured	
Ultrasound	No exposure to ionizing radiation can be used repeatedly in the same subject	Probe must touch skin surface, tissue compression possible with inexperience operator
	Portable, can be used in the field	Operating characteristics of portable equipment differs according to manufacturer and must be defined before use
	Measurements made in Frankfort plane	

Table 30.3 Systematic bias of soft-tissue measurement according to method of measurement

Measurement technique	Landmarks at which tissue depths are consistently higher than with other techniques	Landmarks at which tissue depths are consistently lower than with other techniques	Measurement technique that most closely correlates
Needle puncture	–	–	–
Plain radiology	All midline landmarks	Lateral landmarks: gonion and zygion	–
CT scan	All midline landmarks	All midline points	MRI
MRI scan	–	All midline points	CT
Ultrasound	Supra M2, infra M2, gonion, mid infraorbital, anterior masseter border	–	Needle puncture (except for Supra M2)

individuals because relatively small differences will not be detectable. Significant differences between comparison groups reported in literature should be interpreted in light of some measurement of precision, preferably the TEM.

30.7 Normal Values for Tissue Depths

Tables 30.4 and 30.5 give two sets of recently published values for tissue depths. Tables 30.4 and 30.5 have been derived from the data of De Greef et al. (2006). These were measurements derived from a cohort of 967 normal North European Caucasian individuals, using ultrasound. This is the largest sample published by one group to date; the other commonly used databases (Rhine and Moore 1984; Helmer 1984) were based on much smaller sample sizes (73 and 123, respectively). In addition, the data of De Greef et al. are more modern (2006), which is important when considering the steady rise in obesity during the time interval.

Table 30.6 has been adapted from Stephan and Simpson (2008), and is a compilation of data derived from previous publications, weighted in favor of the larger studies. It has not been fractionated by age, sex, or race. When lumping data from diverse sources derived from using different techniques and over a timescale in excess of 100 years, it is very possible that the aggregate measurement error will overshadow small (but real) changes.

Note that the facial landmarks employed by the two studies are somewhat different. Only four landmarks are the same in both tables (nasion, mid-philtrum, zygion, and gonion) and four others are similar, but not identical (mid-mandibular, supra M2, sub (infra) M2, and glabella). For the four landmarks that are comparable, there is good agreement between the tables.

30.8 Soft-Tissue Variation with Sex

Sexual dimorphism in tissue depth has been reported (Manhein et al. 2000; Rhine et al. 1984; De Greef et al. 2006); these differences are small and variable between studies, and remain under investigation. When all data from all sources are pooled, there is very little difference between men and women (Stephan et al. 2005). This is largely corroborated by a single large study between men and women; in general, the variation in tissue depth in men is more than in women, as evidenced by the standard deviation.

Table 30.4 Soft-tissue depth for facial landmarks for women, fractionated for age and basal metabolic index

	Basal metabolic index																											
	<20										20–25										>25							
	Age range										Age range										Age range

Soft-tissue depth from 62 published papers on facial soft-tissue depth. The weighted mean is derived from a subset of studies that reported standard deviations

S is the number of studies used to generate the weighted mean. Negative values for estimated minimum indicate that the distribution of all the values was not normal

There also remains the possibility that the lack of precision of present techniques of soft-tissue measurement will not permit detection of differences between the sexes. For example, differences in the shape of the soft-tissue fat pads of the face will be difficult to detect using conventional techniques.

Data with respect to children and juveniles is lacking at present, so this conclusion cannot be extended to subjects with remaining growth potential.

30.9 Age-Related Changes on Soft Tissues of the Face

Age-related changes may broadly be discussed below as those that occur with growth and those that occur with senescence.

30.9.1 Soft-Tissue Changes with Growth

With growth, there are subtle facial changes that will affect the soft tissues of the face, for example, the increase in size of the nasal cavity and the change in mandibular angle with age as well as the development of the secondary dentition.

There have been a limited number of studies examining changes in soft-tissue depth over designated landmarks with growth (see review by Stephan and Simpson 2008). Pooled data from these studies show steady linear growth in soft tissue at all landmarks. The known exceptions include the nasion (the soft-tissue depth decreases from infancy until the age of 6–8 years, after which it remains relatively constant) and the temporal fat pad (which is relatively larger in sub adults, giving rise to a slight temporal bulge above the zygoma, which becomes less pronounced with age: Stephan and Devine 2009).

30.9.2 Soft-Tissue Changes Due to Senescence

Changes with senescence affect all soft tissues. Changes in the body muscle mass with age do not usually affect the muscles of facial expression (Gosain et al. 2005). However, the temporalis muscle does undergo some atrophy with age (Stephan and Devine 2009), although this decrease in mass is overshadowed by a decrease in the temporal fat pad, which overlies the muscle. Changes in adipose distribution, especially in the facial fat pads, give rise to a general change in facial contours with age (Donofrio 2000). Restoring the volume of these fat pads to the volumes present at a younger age may give an older face a more youthful appearance. Although preliminary, there is evidence that changes in fat pad content with age may not simply be a matter of loss or gain of adipose tissue, but a more complex redistribution of fat, for example, selective hypertrophy of the upper-cheek fat pad (Gosain et al. 2005). These changes are difficult to capture using conventional techniques for measuring soft-tissue depth.

In addition, there is a more general change resulting in loss of elasticity of connective tissue (especially elastin). When acted upon by the facial muscles, the skin will no longer spring back to a resting position, but will tend to sag and develop creases. This effect is compounded by accumulated actinic damage to which the face is prone (Braverman 1986).

30.10 Variation Due to State of Nutrition

The state of nutrition affects the appearance of the face. Selective pathological loss of facial fat, such as noted in HIV-associated lipoatrophy, results in atrophy of the facial fat pads, particularly the temporal and buccal fat pads, giving the face a more aged appearance than normal (Coleman et al. 2009).

Subjectively, it is apparent that fat people have fat faces. Objectively, one recent large study has demonstrated a positive relationship between ponderosity and facial tissue depths (see Tables 30.4 and 30.5). This relationship is particularly pronounced in the cheek and jowl area of the face, which are the sites of the superficial fat pads. The correlation of tissue depths, at landmarks in these regions, with the BMI was greater than with either age or sex, indicating that nutritional status has a relatively large impact on facial soft tissue.

30.11 Racial Variation

Although several studies have reported small but statistically significant differences in soft-tissue depths of the face between races (Aulsebrook et al. 1996), it is difficult to determine whether these are in fact meaningful. First, the definition of race varies between the papers, but usually depends on self-reporting. Second, the differences reported are small compared to the normal within race variation and compared to the error of measurement. Third, deviations between different studies in the same population vary as much as the well-known differences between the group under study and other racial groups.

Also, as noted, such variation as might exist could reside in the superficial fat deposits, for which there is as yet no universally accepted method of assessment.

30.12 Conclusions

30.12.1 Application to Other Areas of Health and Disease

Assessment of the soft tissues of the face have applications in forensic science, cosmetic and orofacial surgery, medical genetics, and other branches of medicine.

In forensic science, study of the soft tissue of the face permits reconstruction of the face for the purpose of identification. This is particularly important for solving homicides, and identifying victims of accidents, terrorist activity, victims of genocide. Once a tentative identification has been made from a skull reconstruction, molecular techniques involving living relatives can be used to assess the likelihood of a positive identification being correct. Forensic techniques have also been used to reconstruct the face of important historical individuals for whom a skull is available.

Knowledge of the soft tissues of the face is important in the practice of cosmetic surgery. Cleft lip and palate is one of the most common birth defects. Good cosmetic correction of this defect depends on a good understanding of the action of the muscles of the face and palate. In particular, because the repairs are done within the first year of life, it is important to try and achieve symmetry of muscle action, so that the action of the muscle on the underlying facial bone results in proper development of the midface and the nasal passages. Reconstruction to a resemblance of the previous appearance after major facial injury requires knowledge of muscle attachments and facial fat distribution.

As the population ages, there has been an increasing demand for cosmetic surgical procedures that can restore a more youthful appearance. The face is a particular challenge, as it is the area most exposed to sun, and therefore accumulates actinic damage. This aspect compounds the natural aging effect of decreased elasticity (due to elastin and collagen degradation), resulting in facial muscles acting on the skin to produce wrinkles. Temporary paralysis of these muscles using botulinum toxin will ameliorate the wrinkles, but the treatment is symptomatic and not permanent. Part of the problem is restoring the youthful contours of the face and this requires knowledge of the superficial fat pads of the face and changes that occur to these fat pads with aging. A study of what happens to the facial muscles with age is still in progress; preliminary evidence suggests that the facial muscles do not, unlike other skeletal muscles, atrophy with age. This is possibly because they are in constant use.

In the field of medical genetics, there are many conditions in which unrelated patients resemble each other so closely that positive identification (of a condition) can be made. This field is called dysmorphology. At present, this is almost entirely a subjective discipline, which depends heavily on memory and experience of the physician. Increasingly, attempts have been made to match faces using quantitative methods. Although the results of these studies are very interesting, the work has not yet produced a clinically useful method of assisting with diagnosis, possibly because we do not yet have sufficient knowledge of what constitutes normal (Hammond et al. 2004).

Finally, there are emerging diseases that will tax our ability to restore faces to normal, notably in patients undergoing treatment for HIV. In this condition, there is a tendency for the face to loose facial fat and become prematurely aged in appearance.

Summary Points

- Facial soft tissues cloak the skull and give the face a recognizable form.
- Measurement of facial soft-tissue depths over facial landmarks assist in reconstruction of faces from skulls, measurements rather less used for cosmetic surgical purposes.
- Different methods of measuring soft-tissue depth give slightly different results, depending on the method itself, the position of the subject when measurements are taken, and whether measurements are made *in vivo* or on cadavers.
- Differences in soft-tissue depth between the sexes, interracially, and with age are relatively insignificant compared to the differences noted with increasing ponderosity.
- Routine soft-tissue depth estimations are not typically fractionated into component tissues, and, in aggregate, give limited information about the shape and architecture of structures, which influence facial appearance, such as, the superficial fat pads.

Chapter 31
Anthropometry of Facial Beauty

Chiarella Sforza, Alberto Laino, Gaia Grandi, Gianluca M. Tartaglia, and Virgilio F. Ferrario

Abstract Esthetic criteria have been defined in almost all cultures, but the actual existence of codified facial characteristics in attractive people is still matter of debate. In our laboratory, we analyzed the three-dimensional facial characteristics of 415 children, adolescents and women considered "attractive," selected either by casting agencies (children and adolescents, 4–17 years of age) or by juries of National beauty competitions (adult men and women, 18–30 years of age). Their facial soft tissues were measured with a non-invasive computerized instrument, and several measurements obtained. Data were compared to those collected in 629 healthy persons of the same sex, age, and ethnicity, selected using criteria of dentofacial normality.

In Caucasian children, facial attractiveness was characterized by an increased development of the facial middle (maxilla) and upper thirds (forehead), with a wider and deeper face, but less vertically developed in the lower third. During adolescence, a female face was considered attractive when it was wider, shorter and less deep, with relatively larger forehead and maxilla, and a reduced mandible relative to the maxilla. Facial attractiveness in adult Caucasian women was characterized by a prominent facial middle third, with full lips; a relatively large face with a reduced mandible and increased forehead; reduced vertical dimensions. Overall, attractive women seemed to maintain several facial characteristics of babyness. In adult Caucasian men and boys in their late adolescence, attractiveness seemed to be positively influenced by facial markers of high testosterone levels, with a more prominent chin. Esthetic guidelines offer information about the preferences of the general public within a given context, and possibly about the desires and requests of the patients. They can be useful tools for those professionals who can improve the facial appearance of their patients, providing indications for the best kind, timing and goals of orthodontic, orthopedic, and surgical treatments. However, esthetic guidelines should always be used within a well-founded knowledge of craniofacial and dental physiology. No procedure should be imposed on each face, or followed blindly. Even the best and most updated esthetic guidelines must remain only a part of the treatment goals.

31.1 Introduction

Investigations into the esthetic implications of dental and orthodontic treatments are becoming increasingly available in the international literature. For instance, a search on PubMed database using the keyword "Esthetic*" returned 17,411 entries for the period 1950–2009; using "Esthetic* and face," a total of 2,896 entries was obtained, and the combination "Esthetics and orthodontics" resulted in 1,787 entries (www.pubmed.gov, accessed on June, 7, 2009). Of these 1,787 entries, 177 had been published in the last 18 months.

Esthetic criteria have been defined in almost all cultures (Ferrario et al. 1995; Peck and Peck 1995; Nguyen and Turley 1998; Auger and Turley 1999; Matoula and Pancherz 2006), but the actual existence of codified facial dimensions, angles, and ratios in attractive people is still a matter of debate. Scientific researches on the quantitative, measurable bases of facial attractiveness are therefore still in progress (Bisson and Grobbelaar 2004; Kiekens et al. 2006; Matoula and Pancherz 2006; Orsini et al. 2006; Sforza et al. 2007, 2008, 2009).

Current theories of evolutionary psychology show that the esthetic appraisal of adult faces depends on various combinations of averageness, symmetry, neoteny (babyness), and youthfulness, and sexual dimorphism: attractive female faces possess several characteristics of babyness, attractive male faces offer a mix of masculinity, health, developmental stability, and social dominance (Fink et al. 2005; Bashour 2006a, b; Naini et al. 2006). From an evolutionary perspective, human facial attractiveness seems to signal mate quality (Lie et al. 2008).

Attractiveness is becoming a matter of concern, even in the case of children and adolescents. Cinema and television, fashion industry, advertising, all use the attractiveness of growing persons. Children and adolescents with a non-attractive face are considered less intelligent, and may be isolated and undervalued than persons with an attractive face, even by their peers (Johnson and Sandy 2003). An attractive face is often considered the key to success, and parents and children seek medical transformation of non-attractive dentofacial characteristics (Griffin and Langlois 2006; Kiekens et al. 2006).

Medical and dental practitioners therefore face an increasing demand for treatments, mostly esthetic requests, and should approach the problem with the most advanced instruments and methods for diagnosis and treatment planning (Van der Geld et al. 2007). The assessment of facial soft tissues should be made by three-dimensional analyses; and several non-invasive techniques allow a detailed reconstruction of facial anatomy (Ferrario et al. 1995, 2003; Sforza et al. 2007, 2008, 2009). Additionally, the practitioners should know those quantifiable, objective facial characteristics that are currently considered by the public as "attractive" (Ferrario et al. 1995; Nguyen and Turley 1998; Auger and Turley 1999; Fink et al. 2005; Griffin and Langlois 2006; Matoula and Pancherz 2006; Orsini et al. 2006; Sforza et al. 2007, 2008, 2009).

Notwithstanding general biological and psychological criteria for facial attractiveness, several studies demonstrated that secular trends, and even cultural background, can influence the perception of beauty, at least for adult subjects (Nguyen and Turley 1998; Auger and Turley 1999; Bashour 2006a). In our society, the perception of attractiveness is deeply influenced by media. Television, cinema, advertisements, and fashion industry; all enter our life projecting facial characteristics that

are implied to portray perceptions of beauty, health, and fitness, mixed with feelings of social achievement, intelligence, richness, and happiness: a beautiful face becomes the key to success (Johnson and Sandy 2003; Griffin and Langlois 2006; Orsini et al. 2006).

31.2 Quantitative Analysis of Facial Attractiveness

In our laboratory, we analyzed the three-dimensional facial characteristics of children, adolescents, and women, considered "attractive." Their facial soft tissues were measured with a non-invasive computerized instrument, and several measurements were obtained. Data were compared to those collected in healthy persons of the same sex, age, and ethnicity, selected using criteria of dentofacial normality. The possible presence of measurable esthetic characteristics was assessed. If esthetically pleasing faces possess codified facial dimensions, angles, and ratios, these measurements could be used by orthodontists and maxillofacial surgeons as a reference for dentofacial modifications.

31.2.1 Selection of Attractive Persons

Attractive children and adolescents were independently selected by a commercial casting agency located in northern Italy. The agency was asked to provide data for white Caucasian children and adolescents of both sexes with an attractive face (Sforza et al. 2007, 2008). These children normally act in cinema and television, and are used for advertising and in the fashion industry; overall, their faces could be considered "positive," "acceptable," and "trendy" by the general public (Orsini et al. 2006).

Attractive adult women and men were measured during several national beauty competitions that took place between 2006 and 2008. They were those admitted to the semifinal and final stages of the competitions, and were measured just before the semifinal stage of the relevant competition (Sforza et al. 2009).

31.2.2 Analyzed Subjects

A total of 1,029 white Caucasian, Northern Italian persons aged 4–30 years were analyzed.

As many as 614 were reference subjects; all were healthy, and had normal dentofacial dimensions and proportions; no subjects with a previous history of craniofacial surgery, trauma, or with congenital anomalies were included.

A total of 415 were attractive subjects, selected either by casting agencies (children and adolescents, 4–17 years of age) or by juries of national beauty competitions (adult men and women, 18–30 years of age). Parts of the data collected in the attractive persons were previously published (Sforza et al. 2007, 2008, 2009).

All the analyzed persons, and the parents/legal guardians of those underage, gave their informed consent to the experiment. All procedures were non-invasive, did not cause damages, risks, or discomfort to the subjects, and were preventively approved by the local ethic committee (Table 31.1).

Table 31.1 Analyzed subjects

	Sex	Age (years)	Attractive	Reference
Children	Girls	4–5	14	11
	Boys	4–5	8	19
	Girls	6–7	18	45
	Boys	6–7	21	13
	Girls	8–9	14	43
	Boys	8–9	47	55
Adolescents	Girls	10–12	24	39
	Boys	12–14	22	87
	Girls	13–15	23	51
	Boys	15–17	24	54
Adults	Women	18–30	139	71
	Men	18–30	61	126

More than 1,000 subjects were quantitatively assessed in our laboratory.

31.2.3 Collection of Facial Landmarks

A detailed description of the data collection procedure can be found elsewhere (Ferrario et al. 2003; Sforza et al. 2007, 2008, 2009). In brief, the procedure takes place in two separate steps, and is followed by off-line calculations. At first, for each person, a set of 50 soft-tissue landmarks were located and marked on the cutaneous surface using a black eyeliner (Fig. 31.1). Three-dimensional (x, y, z) coordinates of the facial landmarks were then obtained with a three-dimensional electromagnetic computerized digitizer (3Draw, Polhemus Inc., Colchester, VT). During data collection, the subject sat in a natural head position in a chair with a backrest. Landmark digitization took approximately 1 min. Files of the three-dimensional coordinates were obtained, and original computer programs were used for all the subsequent off-line calculations.

31.2.4 Data Analysis

The x, y, and z coordinates of the landmarks were used to estimate several facial linear distances, angles, areas, and volumes (Ferrario et al. 1995; Sforza et al. 2007, 2008, 2009). Euclidean geometry was used for all calculations; the volumes of facial structures were computed as the sum of several tetrahedra, with the 50 landmarks serving as nodes (vertices of the tetrahedra). In particular, the following were computed:

- Distances (unit, mm): upper facial width (ex-ex); lower facial width (go-go); mouth width (ch-ch); anterior upper facial height (n-sn); anterior lower facial height (sn-pg); posterior facial height (t-go); middle facial depth (sn-t); mandibular corpus length (pg-go); upper lip to E-line distance, ls-(prn-pg); and lower lip to E-line distance, li-(prn-pg);
- Angles (unit, degrees): facial convexity excluding the nose (n-sn-pg); facial convexity including the nose (n-prn-pg); upper face convexity (t-n-t); lower face convexity (t-pg-t); mandibular convexity (go-pg-go); maxillary prominence, soft-tissue analog of skeletal ANB angle (sl-n-sn); facial divergence (t-n)^(go-pg); nasolabial (prn-sn-ls); mentolabial (li-sl-pg); and interlabial (sn-ls^sl-pg);

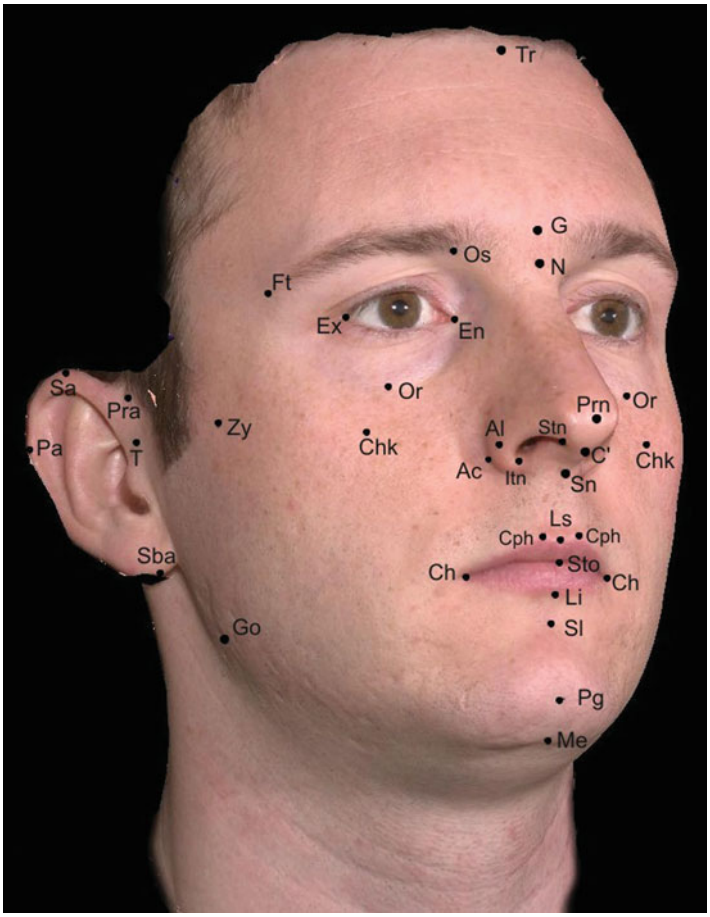

Fig. 31.1 Digitized facial landmarks: *Tr*, trichion; *G*, glabella; *N*, nasion; *Prn*, pronasale; *C'*, columella; *Sn*, subnasale; *Ls*, labiale superius; *Sto*, stomion; *Li*, labiale inferius; *Sl*, sublabiale; *Pg*, pogonion; *Me*, menton; *Ex*, exocanthion; *En*, endocanthion; *Os*, orbitale superius; *Or*, orbitale; *Ft*, frontotemporale; *Zy*, zygion; *Chk*, cheek; *T*, tragion; *Pra*, preaurale; *Sa*, superaurale; *Pa*, posturale; *Sba*, subaurale; *Al*, alare; *Ac*, nasal alar crest; *Itn*, inferior point of the nostril axis; *Stn*, superior point of the nostril axis; *Cph*, crista philtri; *Ch*, cheilion; *Go*, gonion. The 50 soft-tissue facial landmarks used in the analysis are shown

- Volumes (unit: mm^3): total facial volume (volumes of all facial structures from the external cutaneous surface up to a quasi-frontal plane passing through trichion, tragi, and gonia); facial upper-third volume (forehead), measured between the plane passing through the trichion, the frontotemporale landmarks, and the tragi, and a quasi-horizontal plane passing through the tragi and the exocanthia; facial middle-third volume (maxilla), comprised of the plane passing through the tragi and the exocanthia, and a plane connecting the cheilion landmarks and the tragi, approximately corresponding to the maxillary and cheek regions; facial lower-third volume (mandible), comprised of the cheilion–tragi plane and a plane drawn between pogonion and the gonia; and nasal volume;
- Ratios (unit, percentage): middle facial width to facial height (t-t/n-pg); posterior to anterior lower facial height (t-go/sn-pg); forehead to total facial volume; and mandibular to maxillary volume.

31.2.5 Statistical Calculations

"Reference" and "attractive" persons were divided into sex and age groups. For children, the same age groups were used for both sexes: 4–5 years, 6–7 years, and 8–9 years. For adolescents, different age groups were used for the two sexes because of the different timing of pubertal growth spurt (Ferrario et al. 2003). Girls and boys were divided into "young" and "old" adolescents: girls aged 10–12 years and 13–15 years, respectively; and boys aged 12–14 years and 15–17 years, respectively (Sforza et al. 2008).

Adult men and women measured in the different beauty competitions were analyzed together.

For each sex and age group, data were compared to those collected in the relevant reference subjects by computing z-scores. The z-score is a measure of the distance between a subject datum and the reference mean expressed in standard deviation units: z-score = (subject value − mean value of the reference group) divided by the standard deviation of the reference group. Positive z-scores indicate that the measurement is larger in the analyzed subject group than in the reference population; in contrast, negative z-scores indicate a smaller measurement in the subject group than in the reference population; by definition, the reference population has a mean z-score of 0, with a standard deviation of 1.

Descriptive statistics (mean and standard deviation) were computed for each group. Significance of the z-scores was assessed by Student's t tests (if the subject value is equal to the mean value of the reference group, the z-score is zero; the null hypothesis of the test is that the z-scores are null); the significance level was set at 5% ($p < 0.05$).

31.3 Results

On an average, attractive children had significantly larger upper (forehead), middle (maxilla), and total facial volumes than reference subjects (Fig. 31.2, Table 31.2). They also had a larger forehead-to-facial volume ratio, and a smaller mandible-to-maxilla volume ratio. Attractive adolescent girls

Several soft-tissue facial volumes allow one to discriminate between reference population and attractive subjects

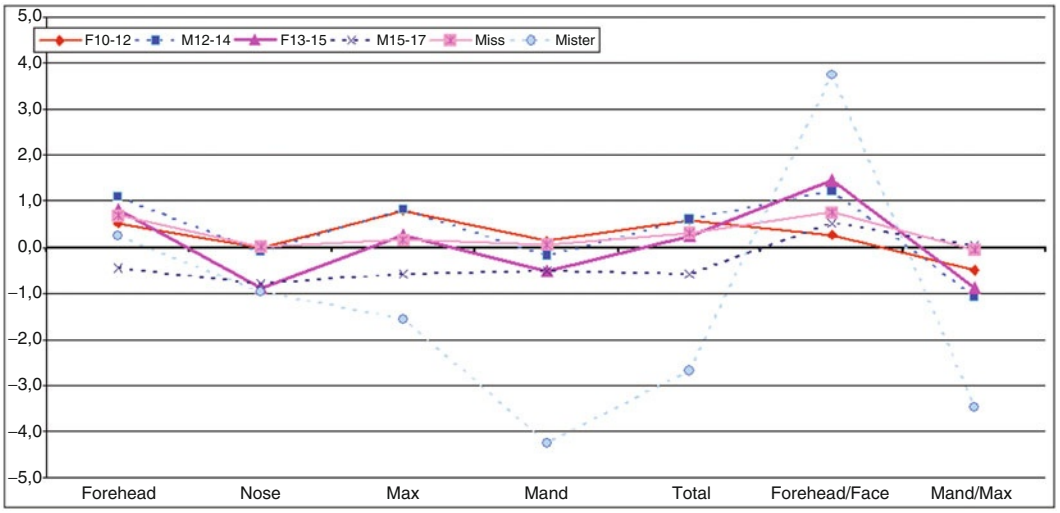

Fig. 31.3 Facial volumes and volume ratios in attractive adolescents and adults (*F* girls; *M* boys; *miss* adult women; *mister* adult men). All values are *z*-scores. In adolescents and young adults, the differences in soft-tissue facial volumes are less evident than in children

and women also had similar characteristics, with larger facial volumes (forehead, maxilla, and total) and forehead-to-facial volume ratios, and smaller mandible-to-maxilla volume ratios, than reference subjects (Fig. 31.3).

In contrast, attractive adolescent boys and men had different patterns: the youngest adolescents (12–14-year old) were similar to children and women, whereas the oldest adolescents (13–15-year old) and the men had smaller faces than reference subjects. In particular, attractive men had

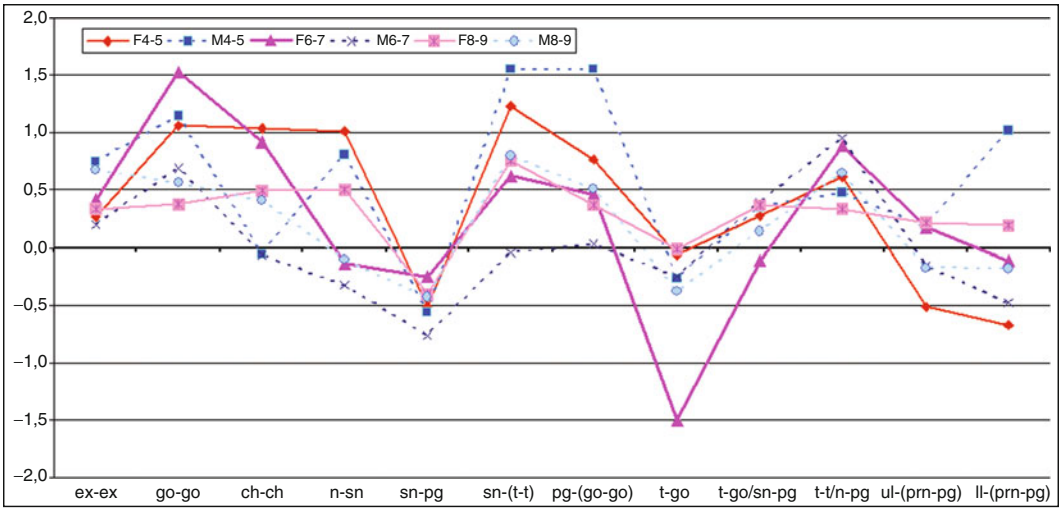

Fig. 31.4 Facial distances and ratios in attractive children (*F* girls; *M* boys). All values are *z*-scores. Several soft-tissue facial distances are different in attractive children as compared to reference subjects

significantly smaller total, maxillary, and mandibular volumes, with an increased forehead-to-facial volume ratio, and a reduced mandible-to-maxilla volume ratio.

In attractive children, horizontal and anteroposterior facial dimensions (upper and lower facial widths, mouth width, middle facial depth, and mandibular corpus length) were larger than in normal subjects (Fig. 31.4, Table 31.3). Vertical distances were either similar in attractive and reference children (lower posterior facial height), or somewhat larger (upper anterior facial height), or somewhat lower (lower anterior facial height). Overall, middle facial width to facial height ratio was larger in attractive children as compared to normal peers. The position of upper and lower lips relative to the esthetic prn-pg line varied in the various age groups.

Attractive adolescent girls, women, and younger adolescent boys had a significantly larger upper facial width than reference subjects (Fig. 31.5). Upper anterior facial height was significantly smaller in attractive adolescent boys, older adolescent girls, and adult persons than in the reference population. Middle facial width to facial height ratio was large in all attractive groups; the differences were significant in the 10–12-year-old girls, and in adult men and women.

When compared to reference women, the upper and lower lips of attractive women were significantly closer to the esthetic prn-pg line. Attractive women also had a significantly large posterior to anterior lower facial height than that of reference women.

In attractive men, mouth width, anteroposterior facial dimensions, posterior facial height, and posterior to anterior lower facial height were significantly larger, whereas lower facial width and upper anterior facial height were significantly smaller than in reference men.

Overall, the analyzed facial angles had a variable pattern in the attractive children (Fig. 31.6, Table 31.4). Among the most constant characteristics were reduced facial divergence and sagittal facial convexity (i.e., a more prominent face in the sagittal plane), a smaller mentolabial angle, and an increased maxillary prominence, than in reference children. Facial convexity in the horizontal plane was reduced in all attractive children except in the 4–5-year-old girls. Additionally, attractive girls had significantly increased nasolabial and interlabial angles than normal girls.

The nasolabial angle was somewhat smaller in attractive adolescents and adults when compared to reference persons (Fig. 31.7). Attractive adolescent girls and the youngest adolescent boys had a larger facial convexity in the horizontal plane than their reference peers.

Attractive men had significantly smaller maxillary prominence and facial divergence than reference men. Overall, their faces were more prominent in the horizontal plane, with a larger mandibular prominence (more prominent chin), but were less prominent in the sagittal plane (increased facial convexity angle n-sn-pg).

31.4 Discussion

In our society, the perception of attractiveness is highly influenced by media: every day television, cinema, advertisements, and the fashion industry give us facial "standards" that should describe persons on the basis of characteristics such as beauty, health, fitness, social achievement, intelligence, richness, and happiness (Sforza et al. 2009). In synthesis, a beautiful face becomes the key to success (Griffin and Langlois 2006).

Therefore, there is an increased esthetic demand for facial cosmetic surgery: patients not only ask to correct major disfigurements, but also to provide modifications of dentofacial physiognomies considered non-attractive. However, orthodontists and maxillofacial and plastic surgeons do not always know which facial characteristics are currently considered "attractive" by the general public (Bashour 2006b; Naini et al. 2006). Indeed, objective, quantitative data on the three-dimensional facial morphology of persons considered "attractive" are still scanty.

In the current investigation, the facial characteristics of a group of attractive children, adolescents, and young adults were examined in three-dimensional space to find some constant pattern of variation from reference persons of the same age, sex, and ethnicity. Considering the components believed to enter into the perception of attractiveness (Bashour 2006a, b; Edler et al. 2006; Naini et al. 2006), the faces of attractive children showed several general characteristics of babyness: a larger forehead, and a smaller mandible with a proportionately larger and more prominent maxilla than reference children. Attractive child faces had larger horizontal and anteroposterior facial dimensions, with a reduced facial convexity in the horizontal plane (flatter faces).

Facial characteristics of babyness were also found in attractive adolescent girls and women, whereas attractive adolescent boys had different patterns: the youngest adolescents (12–14-year old) resembled children and women, whereas the oldest adolescents (13–15-year old) were more similar to adult men. The faces of attractive adult men were characterized by smaller maxillary prominence, facial divergence, and facial convexity in the horizontal plane than those of reference men, with a

more prominent chin, a facial marker of increasing testosterone levels (Fink et al. 2005, 2007; Schaefer et al. 2005; Bashour 2006a, b; Orsini et al. 2006).

In synthesis, attractive younger persons and women shared several facial features resembling neoteny (babyness) and youthfulness, whereas attractive older adolescents and men had faces expressing a clear sexual dimorphism, with more masculine characteristics.

These findings are in good agreement with previous reports performed on either two-dimensional (photographs and radiographs) or three-dimensional (classic and digital anthropometry) records (Farkas 1994; Ferrario et al. 1995; Fink et al. 2005, 2007; Bashour 2006a, b; Isiksal et al. 2006; Naini et al. 2006; Sforza et al. 2007, 2008, 2009).

For instance, previous cephalometric studies found an increased facial convexity in adolescents, considered attractive (Kiekens et al. 2006; Matoula and Pancherz 2006), whereas a relatively more prominent chin was associated with high prenatal testosterone levels, and high circulating testosterone (Fink et al. 2005, 2007; Schaefer et al. 2005). Currently, facial markers of high testosterone levels are believed to signal a good immunocompetence, with a (possible) better genetic background: mating with men with these characteristics may result in a healthier offspring (Fink et al. 2005; Lie et al. 2008).

Previous studies in attractive women found that more prominent lips were associated with an increased esthetic appraisal (Auger and Turley 1999; Farkas 1994; Ferrario et al. 1995; Bisson and Grobbelaar 2004; Matoula and Pancherz 2006; Sforza et al. 2007, 2008, 2009; Van der Geld et al. 2007). Indeed, lips are very rich in estrogen receptors (Caisey et al. 2008), and richer and fuller lips are often associated with a larger female fertility (larger estrogen levels): mating with these women may offer larger probabilities of reproduction (Lie et al. 2008).

In the current investigation, this finding was well replicated for adult women, whereas no constant labial patterns were observed for children and adolescents. Indeed, physiological variations in dental formula (incisor and canine exfoliation and eruption) may explain this finding, at least between 6 and 14 years of age. Nevertheless, the position of maxillary incisors is one of the key factors for a balanced smile, and it should be attentively assessed by the orthodontist (Isiksal et al. 2006).

Children and adolescents were analyzed in a period of rapid somatic growth, when several facial and dental characteristics undergo large modifications, with individually determined growth velocities and growth spurs. This could explain the lack of statistical significance in some of the analyzed facial measurements. Nonetheless, all the measurements were sufficiently homogeneous, and allowed to determine some patterns typical of an attractive face.

According to previous reports, the cultural background of the judge seems to influence esthetic choices in the dentofacial region (Johnson and Sandy 2003; Isiksal et al. 2006; Matoula and Pancherz 2006): dental and surgical professionals are usually more critical in their assessment of facial esthetics than non-professionals (Johnson and Sandy 2003; Isiksal et al. 2006; Orsini et al. 2006). Moreover, esthetics should be evaluated by laymen, those people who actual seek orthodontic or maxillofacial treatment (Kiekens et al. 2006).

Esthetic guidelines could be obtained by measuring persons considered attractive by the general public (cinema and television actors and actresses, and fashion and advertising models) (Peck et al. 1991). Therefore, in the current investigation, attractive people were chosen by professionals from a casting agency, and by judges in beauty competitions, thus avoiding medical and dental practitioners. All judges were unaware that the persons were to be measured in a scientific investigation.

This method of selection has been widely used before for adult subjects: winners in beauty competitions, professional models, and performing actors (Peck et al. 1991; Sforza et al. 2009); television actresses (Ferrario et al. 1995); and photographs of professional models published in fashion

magazines (Nguyen and Turley 1998; Auger and Turley 1999; Bisson and Grobbelaar 2004). Apparently, no previous studies selected children and adolescents with similar procedures, apart from those made in our laboratory (Sforza et al. 2007, 2008).

In conclusion, professionals in the dental and medical fields should be provided with esthetic guidelines referring to subjects of the same age, sex, and ethnic group as their patients; the guidelines should also be updated, considering the evolution of the esthetic canons within a given society (Nguyen and Turley 1998; Auger and Turley 1999; Bashour 2006a, b). These guidelines may offer useful indications for the best kind, timing, and goals of orthodontic treatment, with the best cost/benefit ratio.

Among the limitation of the current study is the analysis of only some of the factors that are currently considered to enter into the appraisal of facial attractiveness (Bashour 2006a, b), and no assessments about symmetry and averageness were made. Theories of perceptual psychology underline the importance of a reduced fluctuating asymmetry for esthetic appraisal: a reduced level of fluctuating asymmetry is usually considered to reflect higher developmental stability, with better body characteristics that may be transmitted to the offspring (Brown et al. 2008). At the same time, literature reports contrasting results on facial symmetry: actual measurements made in attractive men and women do not support a direct link between attractiveness and perfect symmetry (Peck et al. 1991; Ing et al. 2006). A further study may assess symmetry in the current groups of attractive persons, together with a wider set of angles and distances including other facial structures, comprised of eyes and ears.

As to the averageness hypothesis (Bashour 2006a, b), the topic was not assessed in detail in the present study.

A further limitation of the present investigation is the assessment of only attractive persons from Italy. Possibly, a different ethnic/social context may prefer different kinds of attractive faces, even if the good accord between the current findings and previous literature reports makes the selected facial patterns sufficiently reliable for Caucasian persons.

31.5 Conclusions

In conclusion, when compared to the reference, healthy population, attractive persons from Italy had (Table 31.5):

- During childhood: a larger face, with an increased development of the facial middle (maxilla) and upper third (forehead); overall, the face was wider and deeper (dimensions and horizontal convexity), but less vertically developed in the lower third; a more convex profile, with a more prominent maxilla relative to the mandible.
- During adolescence: wider, shorter, and less deep faces with relatively larger upper and middle facial third, and a reduced mandible relative to the maxilla; a reduced nasolabial angle; and in older boys, a more prominent chin.
- During young female adulthood: wider faces with relatively larger upper facial third (forehead); larger facial width relative to facial height; more prominent lips, with a reduced interlabial angle;
- During young male adulthood: smaller faces with a relatively larger forehead; reduced mandibular to maxillary volume ratio; reduced horizontal and vertical dimensions in the facial lower third; increased anteroposterior facial dimensions; reduced facial divergence and maxillary protrusion; increased facial convexity angle in the sagittal plane (flatter face); and reduced facial convexity in the horizontal plane, with a more prominent chin.

The principal quantitative soft-tissue facial differences between reference population and attractive subjects are listed

31.6 Applications to Other Areas of Health and Disease

Facial esthetics is one of the principal concerns of orthodontists and maxillofacial surgeons (Auger and Turley 1999). The creation of a harmonic occlusion, within a well-functioning stomatognathic apparatus, must always consider the effect of teeth position on facial soft tissues. Orthodontists and surgeons should therefore be provided with updated esthetic guidelines (Nguyen and Turley 1998; Auger and Turley 1999; Bashour 2006a, b).

These guidelines should therefore become useful tools for those professionals who can modify (possibly, improve) the facial appearance of their patients (Bashour 2006a, b; Kiekens et al. 2006; Naini et al. 2006), providing indications for the best kind, timing, and goals of orthodontic, orthopedic, and surgical treatments. Additionally, guidelines offer information about the esthetic preferences of the general public within a given context (Bashour 2006b; Naini et al. 2006), and possibly about the desires and requests of the patients. However, esthetic guidelines are tools that should only be used within a well-founded knowledge of craniofacial and dental physiology. No procedure should be imposed on each face, or followed blindly. Even the best and most updated esthetic guidelines must remain only a part of the treatment goals.

At the same time, when restoring harmony and function in the dental arches, the effect of teeth position on facial soft tissues should always be considered within the global framework of facial esthetics (Bashour 2006a, b; Isiksal et al. 2006; Naini et al. 2006).

Summary Points

- Esthetic guidelines offer information about the preferences of the general public within a given context, and possibly about the desires and requests of the patients.
- Esthetic guidelines can be useful tools for those professionals who can improve the facial appearance of their patients, providing indications for the best kind, timing, and goals of orthodontic, orthopedic, and surgical treatments.
- However, esthetic guidelines should always be used within a well-founded knowledge of craniofacial and dental physiology. No procedure should be imposed on each face, or followed blindly. Even the best and most updated esthetic guidelines must remain only a part of the treatment goals.
- In Caucasian children, facial attractiveness is characterized by an increased development of the facial middle (maxilla) and upper thirds (forehead), with a wider and deeper face, but less vertically developed in the lower third.
- During adolescence, a female face is considered attractive when is wider, shorter, and less deep, with relatively larger forehead and maxilla, and a reduced mandible relative to the maxilla.
- Facial attractiveness in adult Caucasian women is characterized by a prominent facial middle third, with full lips; a relatively large face with a reduced mandible and increased forehead; and reduced vertical dimensions. Overall, attractive women seem to maintain several facial characteristics of babyness.
- In adult Caucasian men and boys in their late adolescence, attractiveness seems to be positively influenced by facial markers of high testosterone levels, with a more prominent chin.

Acknowledgments We are deeply indebted to all the staff and students of our laboratory, who helped in data collection and analysis. Dr. Patrizia Frangella organized the data collection in attractive persons. The financial support of the Consiglio Direttivo of the Società Italiana Di Ortodonzia (SIDO) is also gratefully acknowledged.

Chapter 32
Three-Dimensional Facial Morphometry: From Anthropometry to Digital Morphology

Chiarella Sforza, Claudia Dellavia, Marcio De Menezes, Riccardo Rosati, and Virgilio F. Ferrario

Abstract Several basic and clinical disciplines are interested in the quantitative assessment of the dimensions of human facial soft-tissue structures (eyes, nose, mouth and lips, chin, ears), and of their reciprocal spatial positions and relative proportions. Anatomical and anthropometric descriptions, medical evaluations (genetics; maxillo-facial, plastic and esthetic surgery; dentistry), forensic medicine, they all need reference three-dimensional data collected on healthy, normal individuals selected for sex, age, ethnic group, to be compared to those obtained on the single patient. Data collection should be made non-invasively, rapidly, simply, directly on the subjects using low-cost instruments. All data should be digital, thus entering computerized data bases that can be used to visualize and simulate treatment. Currently, in clinical investigations and research classic direct anthropometry is being replaced with various three-dimensional image analyzers. Optical, non-contact digitizers (mainly, laser scanners and stereophotogrammetric devices) perform a fast digitization of the face, providing a detailed analysis of the soft-tissue surface. Contact instruments (electromagnetic and electromechanic digitizers) digitize discrete soft-tissue facial landmarks. Subsequently, landmark coordinates are used into mathematical and geometric models of the face, and angles, distances and ratios similar to those measured in conventional anthropometry can be obtained. Additionally, multivariate methods of analysis, obtained either from geometric morphometry or from other analytical methods, could be used. Overall, computerized instruments seem sufficiently reliable, simple and fast to be used also within clinical contexts, thus providing useful quantitative information to allow a better patient care, without submitting the subjects to potentially harmful procedures.

32.1 Introduction

In man, the head is the most complex structure of the body. It accommodates the central nervous system, the eyes and ear structures, and the first parts of the digestive and respiratory apparatuses. It is characterized by the face. Communication and interaction with the environment, as well as personal identification, all depend on the face (Sforza and Ferrario 2006; DeAngelis et al. 2009).

Anthroposcopy (observation) and anthropometry (measurement) are currently used to analyze facial morphology in several basic and applied fields that cover a wide range of life and medical sciences (Sforza and Ferrario 2006). Both play an important role in the diagnosis of several dysmorphic syndromes, especially for the assessment of borderline patients (Douglas et al. 2003; Hammond et al. 2004; Dellavia et al. 2008; Maal et al. 2008; Fang et al. 2008; Schwenzer-Zimmerer et al. 2008).

Apart from expert observation of facial characteristics, quantitative assessments of the dimensions of facial soft-tissue structures (such as eyes, nose, mouth and lips, chin, and ears), their reciprocal spatial positions and relative proportions are important components in the clinical analysis of patients with facial alterations and deformities, as well as in treatment planning, and in the final evaluation of results (Yamada et al. 2002; Hajeer et al. 2004; Hammond et al. 2004; White et al. 2004; Dellavia et al. 2008; Maal et al. 2008).

Indeed, a global, three-dimensional, quantitative assessment of craniofacial characteristics may help in clinical diagnosis. This analysis should consider both the hard- and the soft-tissue structures. Clinical assessments for surgical (maxillo-facial, plastic, and esthetic) or dental (orthodontics and prostheses) treatments should combine the conventional radiographic analyses of the skeleton with evaluations of the soft-tissue structures, thus providing a complete evaluation of any patient. At all occasions, patient data should be compared to those of healthy subjects of the same age, sex, race, and ethnic group.

Classic direct anthropometry has greatly helped clinicians in the past (Farkas, 1994), but, presently, the advent of digital techniques for the imaging of the facial skeleton should be combined by some new methods for soft-tissue facial imaging and measurement (Table 32.1).

Currently, in clinical investigations and research, classic direct anthropometry is being coupled and even replaced with various three-dimensional image analyzers. These instruments can be divided into two main categories: optical, non-contact digitizers, and contact instruments. In the current chapter, classic anthropometry will be reviewed, and advantages and limitations of the modern facial digitizers will be presented and discussed.

Table 32.1 Key points: conventional anthropometry versus digital instruments

		Digital instruments	
	Conventional anthropometry	Optical	Contact
Cost	Negligible	Expensive (8–10 times higher than contact instruments)	Limited
Patient time	Long	Negligible	Limited
Off-line operator time	Negligible	Long	Negligible
Setting	Everywhere	Often laboratory or clinic only	Easy transport
Information content	Low	High	Medium to low
Adding new measurements, correcting errors	Impossible	Easy	Difficult
Assessment of anatomical landmarks	Direct (inspection/palpation)	Digital (inspection only)	Direct (inspection/palpation)

The main differences between conventional anthropometry and digital instruments are listed

32.2 Direct Facial Anthropometry

Direct anthropometry has been the first method for the in vivo, quantitative, three-dimensional assessment of the human face, and it still continues to be used in several basic and applied fields that cover a wide range of life and medical sciences (Farkas 1994). Conventional, direct anthropometry is currently considered the gold standard for in vivo assessments: it is simple and low cost; it is non-invasive; and it does not require complex instrumentation (Farkas 1994; Zankl et al. 2002).

A further advantage of conventional anthropometry is the existence of normal databases for almost all craniofacial measurements, at least for white Caucasians (Farkas 1994; Zankl et al. 2002), whereas norms for other ethnicities are more scanty (Farkas 1994; Farkas et al. 2005).

At the same time, direct anthropometry is time consuming, it necessitates very well trained and experienced examiners, and it is very demanding for both the clinician and the patient (Douglas et al. 2003; White et al. 2004). Each facial measurement (linear distance or angle) is taken individually, a long procedure prone to error (Aldridge et al. 2005), and no permanent record of the facial arrangement is maintained. Therefore, missing values, miscalculations, or reading errors cannot be corrected once the subject has been released.

Furthermore, direct anthropometry does not provide digital coordinate data that could be used to measure new features, or to extract more complex calculations (surface and volume estimations, analyses of symmetry, and form and shape quantification) (Shaner et al. 2000; Douglas et al. 2003; Ferrario et al. 2003; Hammond et al. 2004; White et al. 2004; Mori et al. 2005; Fang et al. 2008; Schwenzer-Zimmerer et al. 2008).

An ideal method for the quantitative evaluation of the patients should combine:

- Non-invasive, low-cost instruments that could directly be carried off-site to meet the patients
- A fast, simple, data-collection technique that provides three-dimensional digital data and a permanent record of the facial morphology
- Computerized reference databases collected from healthy, normal individuals of same sex, age, and ethnic group as the patients
- The use of computerized techniques for visualization, simulation, and quantitative assessment of the treatment

Most of these requirements are currently met by digital, computerized anthropometry. At the same time, several investigations performed both in vivo and on inanimate models also compare conventional and computerized anthropometric data to assess if they could be, at least in part, exchanged, thus opening new possibilities to basic researchers and clinicians (Sforza and Ferrario 2006). Good results have been obtained for both global facial analyses, and for the assessment of selected parts of the face (e.g., soft-tissue orbital features, facial profile measurements, and mouth and nasal dimensions) (Sforza and Ferrario 2006; Weinberg et al. 2006; Ghoddousi et al. 2007; Wong et al. 2008; Ozsoy et al. 2009; Plooij et al. 2009). Overall, the conventional anthropometric and digital data seem sufficiently interchangeable, at least from a practical, clinical point of view.

32.3 Instruments for Three-Dimensional Digital Morphometry

Two main groups of instruments can currently be used for computerized, soft-tissue three-dimensional facial anthropometry: optical, non-contact instruments (laser scanners, three-dimensional range cameras, optoelectronic instruments, stereophotogrammetry, and Moiré topography) and contact instruments (electromagnetic and electromechanical digitizers and ultrasound probes).

All these instruments are non-invasive, not potentially harmful (apart from some limitations for laser light, but that seem to have been overcome in the last generation of laser scanners), and do not provoke pain or discomfort to the subjects.

Both kinds of instruments have advantages and limitations that should be considered according to the investigated problem and the human resources (Table 32.2).

32.3.1 Optical Instruments

The most used instruments of this category are laser scanners and stereophotogrammetric systems. Laser scanners illuminate the face with a laser light source, and digital cameras capture the reflected light; the depth information is obtained by triangulation geometry (Majid et al. 2005; Hennessy et al. 2006; Schwenzer-Zimmerer et al. 2008). During data acquisition, either the face (with a rotating stool) or the laser light moves to scan the entire surface. In the first scanners, the laser light was not safe for the eyes, but current instruments are stated to be not dangerous. Accuracy and resolution are reported between 0.5 and 1 mm, and approximately 10 s are necessary for a complete scan. Critical parts of the face are the ears, the nostrils, and the chin. Shadows, local facial characteristics (hairs and nevi), and a dark complexion may hamper the digitization (Majid et al. 2005).

Stereophotogrammetry uses a light source (either patterned or conventional) to illuminate the face, and two or more coordinated cameras record images from different points of view (Fig. 32.1) (Majid et al. 2005; Ghoddousi et al. 2007; Sawyer et al. 2009; Wong et al. 2008; Plooij et al. 2009). A previous calibration, made with objects with known geometric characteristics, supplies the mathematical information to obtain a stereoscopic reconstruction of the face (Fig. 32.2). The system can also record facial texture, and combines the three-dimensional information with an accurate reproduction of all facial characteristics (Fig. 32.3). Accuracy and resolution are around 0.5 mm, and 2 ms can be sufficient for a facial scan. Surface artifacts, limited lateral coverage, and shadows effects are limitations that stereophotogrammetry shares with laser scanning, but they seem of relatively less importance.

Figure 32.4 shows an example of facial reconstruction by stereophotogrammetry. The finer the mesh is the better is the reconstruction. Some artifacts (low-resolution scan) can be found under the chin and the ear, and inside the nostrils.

Both these methods supply a wealth of data for each face (typically, laser scanning can describe the face with approximately 80,000 points, Hennessy et al. 2006, whereas stereophotogrammetry can obtain 300,000–450,000 surface points, Weinberg et al. 2004), thus allowing a complete assessment of both qualitative and quantitative features that are permanently recorded into the computer. Also, the time necessary to obtain a complete facial scan is negligible, thus reducing or abolishing motion artifacts, a feature particularly important for the assessment of children and disabled persons. In this aspect, stereophotogrammetry performs better than laser scanning, with appreciably faster scan times.

Both instruments have relatively lengthy post-processing times because the different facial pictures must be mathematically combined to obtain the three-dimensional surface. This time strictly depends on the host computer. Another limitation of these optical methods is the cost of the instrumentation, and, in some instances, the dimensions and need for special settings that cannot be taken away to meet the patients at other locations. Portable stereophotogrammetric instruments and handheld laser scanners have been developed, and used for facial analysis outside laboratory or clinical facilities (Douglas et al. 2003; Schwenzer-Zimmerer et al. 2008). Resolution and accuracy are around 1 mm, and are considered adequate for basic and clinical studies (Hennessy et al. 2006), even if motion artifacts may often limit their use.

Table 32.2 Principal characteristics of currently used computerized, three-dimensional, soft-tissue facial digitizers

	Motion artifacts	Post processing	Landmarks	Information	Critical parts of face	Dimensions	Cost
Optical scanners							
Laser scan	Limited (approx. scan time 2 s)	Lengthy (it depends on the host computer)	Identified only on the digital image; no physical compression	All surface	Imaging hairs impossible; difficult imaging of nostrils, ears, and neck	Transportable	Expensive
Stereo-photogrammetry	Negligible (approx. scan time 10 ms)	Lengthy (it depends on the host computer)	Identified on both the digital image and directly on the skin; no physical compression	All surface and texture	Potential problems with hairs; difficult imaging of ears	Often bulky but transportable	Expensive
Contact instruments							
Electromagnetic digitizer	Present (approx. scan time for 50 landmarks 60 s)	Fast	Directly identified on the skin; possible physical compression	Only selected landmarks	Potential problems with metal and electromagnetic fields (orthodontic brackets)	Movable with ease	Limited
Electromechanic digitizer	Present (approx. scan time for 50 landmarks 60 s)	Fast	Directly identified on the skin; possible physical compression	Only selected landmarks		Movable with ease	Limited

The main differences between the most used digital instruments for facial anthropometry are listed

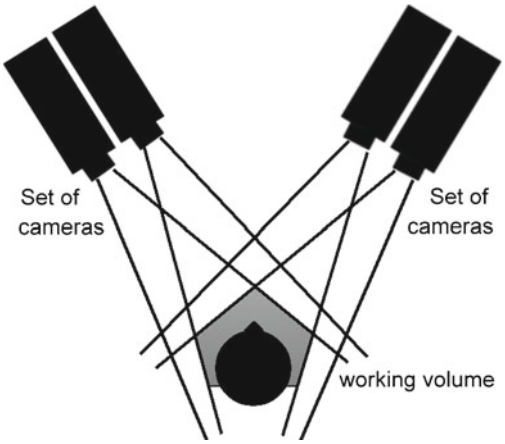

Fig. 32.1 Schematic diagram of a stereophotogrammetric set. The main components of a stereophotogrammetric instrument are shown

Fig. 32.2 Example of facial reconstruction made by stereophotogrammetry. Surface rendering of a three-dimensional facial reconstruction made by stereophotogrammetry

Although the optical instruments supply a detailed recording of the soft-tissue facial characteristics based on a large quantity of soft-tissue points, they do not individualize single anatomical landmarks. Landmarks are recognized on the digital reconstructions of the face, using all computer tools of zoom, rotation, and translation (of the image) (Hammond et al. 2004; White et al. 2004). This procedure can result in some discrepancies between the actual anatomical landmarks and their digital counterparts because some landmarks cannot be obtained by simple inspection, and only facial palpation allows their identification (for instance, gonion). Therefore, a number of standard landmarks (and subsequent measurements) should be excluded from the analysis (Weinberg et al. 2004; White et al. 2004).

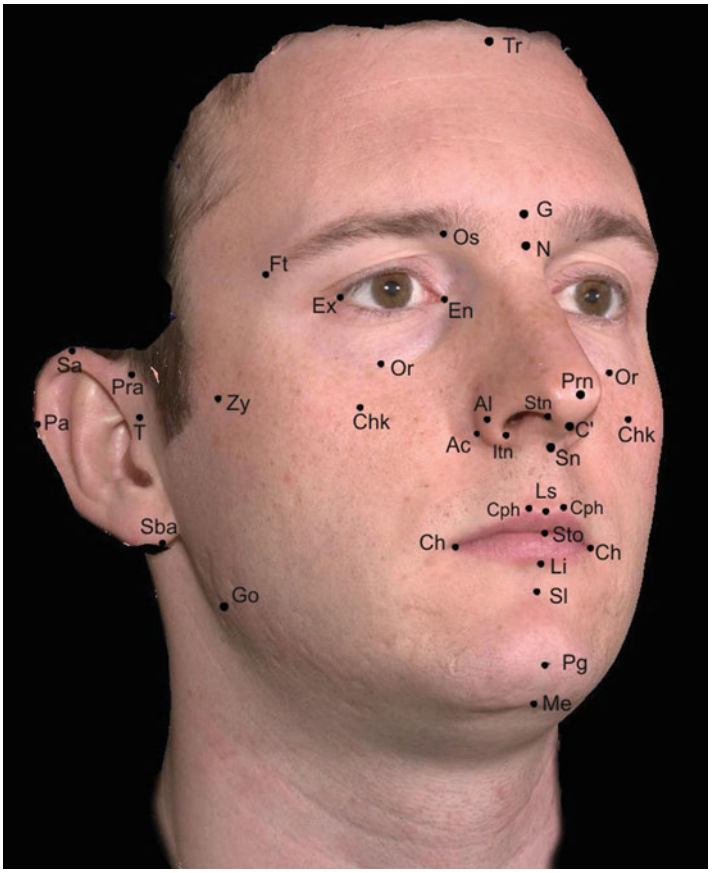

Fig. 32.3 Facial reconstruction made by stereophotogrammetry with the relevant facial texture. A set of soft-tissue facial landmarks is also identified. The final image produced by stereophotogrammetry is shown

Considering that stereophotogrammetry also collects the soft-tissue texture, for this technique some landmarks can be directly labeled on the face before data acquisition (Fig. 32.3) (Weinberg et al. 2004). Unfortunately, the procedure cannot be undertaken with most laser scanning systems because the ink used for the mark is not digitized by the scanner. Previous labeling also improves accuracy in landmark recognition (Weinberg et al. 2004).

The optical instruments need no physical contact with the skin, thus eliminating the risk of cutaneous compression, and of potential injuries during measurements (Douglas et al. 2003; Majid et al. 2005; Sawyer et al. 2009).

32.3.2 Contact Instruments

Ultrasound probes, and electromagnetic and electromechanic digitizers are among the most used contact instruments. They digitize single, selected, facial landmarks, thus reducing the information obtained from each face, but providing the coordinates of facial features that directly correspond to anatomical and anthropometric structures (Ferrario et al. 1998, 2003; Sforza et al. 2007, 2009; Dellavia et al. 2008; Ozsoy et al. 2009).

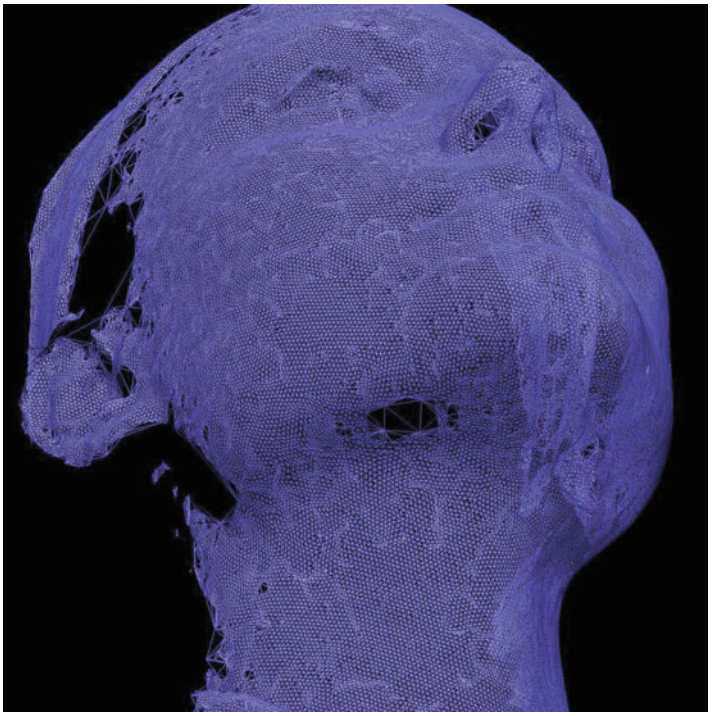

Fig. 32.4 Facial reconstruction made by stereophotogrammetry with mesh rendering. Under the chin, a small-size defect in the mesh reconstruction can be seen

Ultrasound probes use acoustic waves in the megahertz frequency domain, whereas electromagnetic and electromechanic digitizers are based on electromagnetic waves. The instruments have no invasiveness and pose no biological hazard.

For the face, ultrasound images the skeletal surface and its soft-tissue cover (Sforza and Ferrario 2006). While the method is widely used for prenatal, intrauterine imaging and diagnosis, and three-dimensional reconstructions of the fetal face are a current clinical practice, its application for postnatal facial morphometrics is limited. Currently, it is used only for the in vivo measurement of the thickness of facial soft-tissue cover.

Electromagnetic and electromechanic digitizers provide the three-dimensional coordinates of landmarks that are actually touched one by one by the instrument's stylus (Ferrario et al. 1998, 2003; Sforza et al. 2007, 2009; Dellavia et al. 2008; Ozsoy et al. 2009). The field of the electromagnetic digitizer used in our laboratory (3Draw, Polhemus Inc., Colchester, VT) provides a three-dimensional working volume (three spatial coordinates) of approximately $30 \times 30 \times 76$ cm; it has a resolution of 0.005 mm/mm range, and an accuracy of 0.08 mm. The electromechanical digitizer (Microscribe G2, Immersion Corporation, San Jose, CA) is a multi-joint-arm digitizer, with an accuracy of 0.38 mm in a 127-cm workspace. Within each joint, an optical encoder works with a microchip to send the joint angle to a host computer; the three-dimensional coordinates of the stylus are therefore provided.

A set of facial landmarks is previously marked on the face of the subject; landmarks are identified by inspection or palpation (as in conventional anthropometry), and are marked with a small black dot. Subsequently, the subject is positioned within the working volume of the instrument, and asked to stay motionless, while the operator gently touches the facial landmarks one by one using a stylus

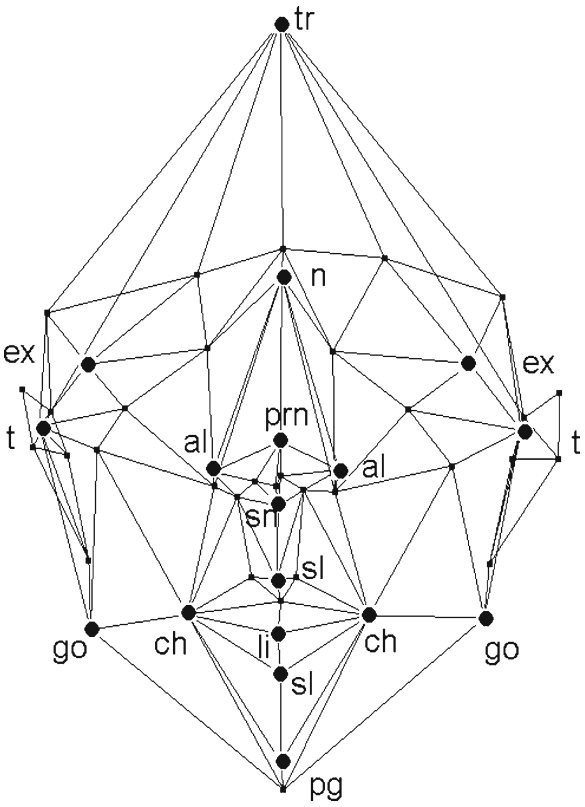

Fig. 32.5 Example of facial reconstruction made by contact instruments. All nodes of the image correspond to facial landmarks and some of them are labeled for clarity (tr, trichion; ex, exocanthion; n, nasion; prn, pronasale; ala, ala nasi; sn, subnasale; ch, cheilion; sl, sublabiale; go, gonion; pg, pogonion). A schematic facial diagram obtained from a 50-landmark digitization

connected to the digitizer. With both instruments, data collection for a set of 50 landmarks needs 50–60 s for each subject (Ferrario et al. 1998), and motion artifacts could occur.

The principal limitations of the instruments are the reduction of information, and the time necessary for data acquisition. The acquisition of only single, selected landmarks impedes the production of lifelike facial models (Fig. 32.5) (Ferrario et al. 1998), and the application of the method as a communication tool is difficult, in particular with the patients (Hajeer et al. 2004). Also, no permanent records of the facial appearance are obtained, and it is not possible to correct the position of a landmark off-line, or to introduce new landmarks.

Data acquisition time is extremely long when compared to that necessary for an optical facial scan (even if it is remarkably short when compared to conventional anthropometry, Farkas 1994; Douglas et al. 2003), and movements of facial muscles (especially around mouth and eyes), as well as global head movements, may occur during digitization.

The calibration of the electromagnetic instrument can be altered by electromagnetic interferences and metal objects. To avoid interferences with the electromagnetic field, data collection should be performed in a controlled environment, with all electromagnetic devices (e.g., computers, video recorder, power supply of the digitizer, and mobile telephones) and metal objects positioned at a minimum of 2 m from the digitizer (Ferrario et al. 1998). Also, the subject should not wear a metallic object on the head (for instance, voluminous earrings), and the operator should not wear a metallic object or a watch on the arm that uses the stylus.

In contrast, the electromechanic instrument does not need any special environment for acquisitions.

Both instruments provide the files of the three-dimensional (x, y, z) coordinates of the facial landmarks, and computer programs devised in the laboratory are used for all the subsequent off-line calculations. Using both digitizers, Ferrario and co-workers (Ferrario et al. 1998, 2003; Sforza et al. 2007, 2009; Dellavia et al. 2008) have analyzed more than 1,000 faces of healthy, normal persons from childhood to old age, together with a 100 faces of disabled or diseased persons; overall, the method seemed sufficiently reliable for anatomical and clinical investigations of selected facial characteristics. Some applications of their method are shown in other chapters of the current book. In their investigations, Ferrario and co-workers (Ferrario et al., 2003; Sforza et al. 2007, 2009; Dellavia et al. 2008) focused on the analysis of facial measurements similar to those obtained by conventional anthropometry (linear distances and angles), as well as on estimates of the volumes and surface areas of selected parts of the face (mouth and lips, nose, eyes, and ears). Additionally, they provided quantitative evaluations of facial symmetry and shape, independently from size (Sforza and Ferrario 2006).

In general, contact instruments are less expensive than optical ones (approximately 8–10 times less), and they can be moved with ease from the laboratory to meet the subjects at alternative locations; additionally, they directly provide the three-dimensional coordinates of the anatomical landmarks of interest, without any additional off-line calculations (Ozsoy et al. 2009).

32.4 From Anatomical Landmarks to Digital Morphology

Landmarks represent the link between conventional and digital anthropometry (Sforza and Ferrario 2006): conventional anthropometry identifies soft-tissue landmarks, and places some instrument (calipers or protractors) over them. Distances are obtained between a pair of landmarks; angles are comprised among three landmarks (Farkas 1994). The entire surface comprised between the landmarks is neglected, apart from observation of specific features (anthroposcopy). Fundamentally, digital anthropometry collects a set of digital landmarks from the soft-tissue surface, and uses their spatial x, y, z coordinates as endpoints for calculations based on Euclidean geometry: linear distances and angles similar to those provided by conventional anthropometry are computed.

Together with these classic measurements, mathematics and geometry allow the assessment of more complex characteristics from the same set of landmarks used by conventional anthropometry: estimations of volumes and surfaces, analyses of symmetry, and detailed assessments of shape independently from size (Ferrario et al. 1998, 2003; Shaner et al. 2000; Douglas et al. 2003; Hajeer et al. 2004; Aldridge et al. 2005; Mori et al. 2005; Sforza et al. 2007, 2009; Dellavia et al. 2008; Fang et al. 2008; Sawyer et al. 2009; Schwenzer-Zimmerer et al. 2008).

Additionally, the enormous amount of data collected by some of the digitizers allows detailed assessments of all inter-landmark surfaces, for instance, with the development of pattern recognition algorithms (Hammond et al. 2004; Hennessy et al. 2006).

In our laboratory, we currently identify 50 soft-tissue landmarks on each face (Ferrario et al. 1998). The landmarks are located on the forehead, eyes, nose, lips and mouth, chin, ears, and lateral facial surface (Table 32.3, Fig. 32.3). Twelve of them are on the midline, whereas 19 are identified on each hemi-half of the face. This set of landmarks was chosen to be used with the contact instruments, and it is a good compromise between a sufficiently detailed individuation of the anatomical characteristics of the face and digitization time. Currently, the use of an optical, stereophotogrammetric instrument allows the selection of an even wider set of landmarks, according to the problem being investigated. Nevertheless, the use of a standard set of landmarks allows the consistent assessment of subjects in both longitudinal and cross-sectional studies.

Table 32.3 Set of 50 facial landmarks currently digitized with contact instruments. The landmarks are shown in Fig. 32.3

			Midline	Paired
Forehead	tr	Trichion	✓	
	g	Glabella	✓

32.5 Applications to Other Areas of Health and Disease

Basic human research has obtained valuable results using three-dimensional anthropometry, and several anatomical studies have quantitatively described normal facial growth, development, and aging, allowing the creation of databases that could be used for the quantitative assessment of patients (Zankl et al. 2002; Douglas et al. 2003; White et al. 2004; Mori et al. 2005; Dellavia et al. 2008; Maal et al. 2008; Sawyer et al. 2009; Sforza et al. 2009).

Clinicians working with the head and face (maxillo-facial, plastic, and esthetic surgeons; and orthodontists and prosthodontists) are those mostly interested in this three-dimensional information (Zankl et al. 2002; Ferrario et al. 2003; Hajeer et al. 2004; Sforza et al. 2007; Dellavia et al. 2008; Maal et al. 2008; Sawyer et al. 2009; Schwenzer-Zimmerer et al. 2008; Ozsoy et al. 2009; Plooij et al. 2009). Indeed, current non-invasive diagnostic methods could reduce the biological burden of repeated examinations for patient assessment, treatment planning, and evaluation of results. This is particularly important for those children whose malformations cannot be corrected in a single episode, but require several surgical, orthopedic, and orthodontic interventions between birth and

adult life (White et al. 2004; Dellavia et al. 2008; Schwenzer-Zimmerer et al. 2008; Plooij et al. 2009). Also, the use of a piece of three-dimensional information that considers both the underlying skeletal structure and the overlying soft-tissue cover is valuable in the global assessment of the patient (Maal et al. 2008; Plooij et al. 2009).

The three-dimensional digitization of craniofacial characteristics is also widely used for the manufacturing of individualized ortheses, prostheses, and safety headgears: the imaged part of the body is used as a CAD (computer-aided design) source, and via CAM (computer aided machinery) technology, the artificial manufact is produced, with a reduction in time, costs, and patient discomfort.

Along with these classical fields, internal medicine that deals with general diseases is currently investigating possible associations between variations in facial morphology and body disorders: the search for low cost, fast, and non-invasive markers of more complex diseases has been particularly important in the metabolic field. Rapid screening, standardization of functional examinations, progression of disease, and quantification of side effects can all benefit from specific markers that can be longitudinally repeated with minimal discomfort to the patient, and a reduced monetary cost. In particular, applications in uremic patients on chronic dialysis, in patients with undiagnosed celiac disease, in obese adolescents, and in HIV-infected patients, have been proposed (Sforza and Ferrario 2006).

Hypotheses about the relationships between facial shape and asymmetry, and aspects of cognition that involve the anterior brain, are currently tested with investigations on three-dimensional facial morphology. Indeed, during early fetal life, there is a strict relationship between face and anterior brain: the localization of facial alterations, together with the known timing of their embryological development, may offer more insights into brain development and its alterations (Shaner et al. 2000; Hennessy et al. 2006; Sforza and Ferrario 2006).

Three-dimensional assessments of facial morphology are also used for low-cost screening of neurodevelopmental alterations such as the fetal alcohol syndrome that involve characteristics facial alterations. Borderline patients or gene carriers could also be screened using quantitative tools assessing selected facial features (Douglas et al. 2003; Fang et al. 2008). The development of cost-effective methods for field screening seems particularly important in low-income countries and areas, where the patients cannot be offered all the opportunities which are available in more developed parts of the world (Douglas et al. 2003).

Together with the direct assessment of the living, digital facial morphology is currently successfully applied into several forensic fields (DeAngelis et al. 2009): for instance, all techniques for facial reconstruction from skeletal remnants need three-dimensional sex-, age-, and ethnic-based normal databases that should be renewed considering the secular trends in body dimensions. Three-dimensional data are also necessary to artificially “age” facial images of kidnapped children, as well as to give an age to victims of pornography and pedopornography.

Forensic, commercial, and security identification of persons is increasingly using virtual images, and three-dimensional digital images should be used instead of conventional anthropometry (DeAngelis et al. 2009) to determine the identity of probands.

Virtual applications are also usefully employed in computerized simulations for the entertainment arena: television, cinema, virtual reality, and computer games all use digital three-dimensional sources obtained non-invasively from both humans and animals.

32.6 Conclusions

In conclusion, digital, computerized, non-invasive instruments for three-dimensional facial anthropometry appear to offer new possibilities for both basic investigators and clinicians. Detailed quantitative (and often also qualitative) information about the facial soft tissues of a given patient may

allow a better and faster diagnosis, especially when the relevant reference values (selected for age, sex, and ethnic origin) are available.

Maxillo-facial, plastic, and esthetic surgery, as well as orthodontics and dental prostheses, may usefully apply this information.

Computerized tools may also permit to simulate treatment, and to provide an approximate idea of the final outcome, thus facilitating the process of informed consent. Longitudinal assessments can offer a quantitative evaluation of the post-treatment results, with concomitant evaluations of the possible relapse.

At the same time, the same clinical reasoning used for conventional anthropometry can be used, via the maintenance of landmark-based measurements.

Summary Points and Practical Methods

- A global, three-dimensional, quantitative assessment of the craniofacial characteristics may help in clinical diagnosis.
- Together with conventional radiographic analyses of the skeleton, the soft-tissue structures should also be analyzed to provide a complete evaluation of any patient, and should be compared to those of healthy subjects of the same age, sex, race, and ethnic group.
- Both contact and optical computerized instruments can be used for the three-dimensional analysis of facial soft tissues.
- Contact instruments allow the assessment of selected facial landmarks with a reduced monetary price.
- Optical instruments allow a detailed record of all facial surfaces, but they are more expensive.
- Three-dimensional virtual facial reconstructions are currently used in several medical, forensic, and industrial fields.

Acknowledgments We are deeply indebted to all the subjects who served as volunteers in our laboratory. The precious work of staff and students, who helped in data collection and analysis, is also gratefully acknowledged.

Chapter 33
The Concept of Anthropometric Facial Asymmetry

Senem Turan Ozdemir

Abstract Facial asymmetry is a common finding in healthy subjects and in esthetically pleasing faces. It is believed that normal craniofacial skeletons have some degree of asymmetry which is compatible with normal dental occlusion, and mild facial asymmetry is often disregarded by clinicians. In parallel with increasing demand for facial aesthetics and recent advances in facial aesthetic surgery, patients have become more sensitive to facial asymmetry which may occur after the operation. In this context, objective evaluation of facial asymmetry by extended facial analysis before and after the operation has gained importance.

Facial asymmetry analysis can be performed as objective and/or subjective. Soft tissues of the face can be evaluated by subjective analysis; however, skeletal asymmetries compensated by the overlying soft tissue may not be recognized most of the time. Objective assessment of the asymmetry degree of both soft and hard tissues of the face before facial operations, aesthetic and orthodontic procedures in particular, will allow a more accurate analysis of the treatment results.

Anthropometric measurement is one of the methods used for the quantitative analysis of facial asymmetry. Although anthropological studies on face have been extensively addressed in the literature, anthropologists have rarely examined facial asymmetry. The concept of facial asymmetry and anthropometric measurement of facial asymmetry will be reviewed in this chapter.

33.1 Introduction

The human face is an organ which is unique to an individual with its dental, skeletal, and soft-tissue structures, and has harmony and balance within itself. Symmetry is one of the fundamental features of these structures. Although symmetry is often considered to be an essential part of beauty and attractiveness, a feature lacking symmetry may also be regarded as beautiful, based on its inherent harmony and balance. Stedman's Medical Dictionary (2006) defines symmetry as the "equality or correspondence in form of parts distributed around a center or axis, at the two extremes or poles, or on two opposite sides of the body." When applied to facial morphology, symmetry and balance refer to the state of facial equilibrium, the correspondence in size, shape, and arrangement of facial features on opposite sides of the median sagittal plane.

It should be kept in mind that the body is not perfectly symmetrical. Interestingly, the human form is, in general, externally symmetrical and internally asymmetrical. The face is asymmetric to the extent that it is acceptable and regarded to be within normal limits. It is this degree of asymmetry that gives the face its natural appearance (Fig. 33.1). This is because a fully symmetric face with perfect mathematical ratios will present as a mechanical image rather than a natural one.

Facial asymmetry can be simply defined as one side being larger than the other (Smith 2000). It can further be classified into normal (minor or mild, i.e., non-pathologic) and abnormal (pathologic). In normal individuals, there are subtle differences between the dimensions of the left and right halves of the face, which alone do not normally result in an esthetically unpleasing appearance (Ferrario et al. 1995, 2001). Asymmetry becomes clinically important when it affects function, esthetics, or social acceptance of an individual. Numerous disorders, such as hemifacial microsomia, unilateral craniosynostoses, temporomandibular joint disorders, cleft lip/palate, and hemifacial athrophy (Parry–Romberg syndrome), have been reported to be associated with facial asymmetry. These conditions often result in pathologic asymmetry (Bishara et al. 1994).

Although many investigators consider asymmetry as a normal facial feature, with the increasing concern about facial appearance, patients now complain of even slight asymmetry. Some patients believe that asymmetry develops or progresses during, or after, plastic or orthodontic treatment. Preoperative and postoperative evaluations of facial asymmetries in plastic and maxillofacial surgeries make it possible to plan the scope and method of surgical operations, and a comparison with the limits of normal facial asymmetry allows evaluating the therapeutic results. In this regard, it is important to know the limits of normal facial asymmetry. Furthermore, Skvalirova (1993) emphasized that calculation of the range of normal asymmetry may have practical implications – for example, accurate definitions of congenital defects such as hemifacial microsomia – although the range of suggested normal asymmetry is arbitrary, and it is open to question how many standard deviations should be used for its determination. Several facial asymmetry studies have been conducted in healthy individuals to quantify the amount of normal variability. Shaner et al. (2000) have pointed out that normal limits of soft-tissue asymmetry in the measurements taken from the upper and middle regions of the face did not exceed 5 mm in males and 6 mm in females, as a general rule. In the same study, it has been suggested that measurements involving the lower regions of the face had a much higher normal variability, with the differences between the two parts being 6 mm or greater. Ferrario et al. (2001) indicated that differences between the most symmetric and asymmetric groups were less than 2.5 mm.

The focus of the majority of facial asymmetry research has been the identification of the facial side of greatest magnitude and the localization of asymmetry. In the literature, there is no consensus regarding the dominant side of face and the localization of asymmetry. Whereas the left side has been found to be more dominant in some studies (Vig and Hewitt 1975; McIntyre and Mossey, 2002; Ercan et al. 2008a), the right side has been found to be more dominant in others (Farkas and Cheung 1981; Ferrario et al. 1994, 1995, 2001; Shaner et al. 2000;). While Farkas and Cheung (1981) have reported that the most asymmetric part of the face (69.2%) was the upper-third portion,

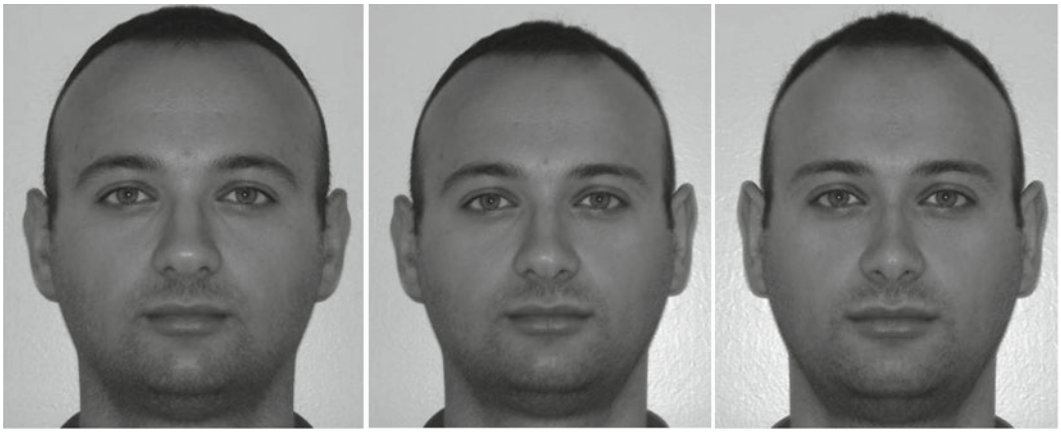

Fig. 33.1 Normal and perfectly symmetrical faces. *Left*: original face. *Middle*: a perfectly symmetrical face made of the left half of the original face. *Right*: a perfectly symmetrical face made of the right half of the original face

Ferrario et al. (1994) have reported that it was the middle and lower thirds. Shaner et al. (2000) have stated that measurements obtained from tragion and gonion had a much greater normal variability. The functional adaptation response to asymmetrical masticatory activity has been suggested as the main cause of asymmetries in the lower part of the face (Vig and Hewitt 1975). Asymmetric position of the right and left tragions as a cause of side differences has previously been mentioned by several authors (Farkas and Cheung 1981; Ferrario et al. 1994, 1995). Features of the central face including the orbits, nose, and orolabial region present much less asymmetry (Farkas 1981).

33.2 Analysis of Facial Asymmetry

Facial asymmetry analysis can be objective and/or subjective. Soft tissues of the face can be evaluated by subjective analysis; however, skeletal asymmetries compensated by the overlying soft tissue may not be recognized most of the time.

Quantitative analysis of facial asymmetry has increasingly become a subject of investigation in recent years. It has been conducted by measurements made to a midfacial symmetry plane, or by comparing paired measurements of bilateral facial features and, thus, local changes in the right and left halves of the face have been obtained. For such examinations, traditional morphometric measurements, such as metric distances, areas, angles, and ratios, have been calculated for the left and right sides (Burke and Healy 1993; Shaner et al. 2000; Ferrario et al. 2001; Baudouin and Tiberghien 2004). However, Ferrario et al. (1995) mentioned that such methods provide information, which only refers to local imbalances, and does not allow full facial analysis, and does not reflect shape differences between the two sides. In recent years, new methods, such as geometric morphometry, have emerged in terms of the quantitative evaluation of facial asymmetry (Ferrario et al. 1995; Ercan et al. 2008a). Different methods used for facial asymmetry analysis and their results have been summarized in Table 33.1.

The following issues are crucial in quantitative facial asymmetry analysis:

- Standardization of the method in use
- Accurate identification of landmarks to be used in the measurements
- Accurate determination of facial midline

Table 33.1 Facial asymmetry

Author	Year	Method	Subjects	Landmarks used	Result
		Direct anthropometry			
Farkas et al.	1981	Direct anthropometry, spreading caliper	308 healthy Canadian Caucasians (154 boys and 154 girls)	Tragion, nasion, exocanthion, gonion, subnasale, cheilion, gnathion	Asymmetry was found to be very common but average differences between right and left measurements were mild (3 mm or 3%) with the *right side* usually the largest. The most common and largest asymmetries were found in the upper third of the face.
Skvarilova et al.	1993	Direct anthropometry, sliding caliper	720 normal (360 boys and 360 girls) subjects aged 6–18 years	Tragion, otobasion superius, nasion, otobasion inferius, subnasale, cheilion, gonion, gnathion, exocanthion	Extend of facial asymmetry is the same in the both sexes and does not change with age. Facial asymmetries have mostly a fluctuating character, usually with slight predominance of the *right side*. The range of normal asymmetry for lateral facial dimensions was determined as 4–5mm.
		Indirect anthropometry			
		Two Dimensional			
Smith et al.	2000	Frontal photographs	90 subjects (45 male and 45 female)		Left hemiface of the males were reliable larger than the right hemiface. In contrast right hemiface of the females were reliable larger than the left hemiface.
Song et al.	2007	Fontal photographs	1,282 volunteers (761 males 521 females) 18–29 years of age	Exocanthion, cheilion, cross point between median line and bilateral exocanthion, cross point between median line and bilateral mouth corners	Right dominant type was observed more frequently than the left dominant type in both genders. Measurement of horizontal angulations of frontal photographs of faces can be used to assess facial asymmetry.
Chatrath et al.	2007	Frontal photographs	300 patients requesting rhinoplasty surgery	Tragus, lateral cantus, medial cantus, lateral alar margin, oral comissure	Objectively 97% of patients had significant degrees of facial asymmetry, with the midline to ala distances showing the most variations and the midline to oral comissures showing the least variations. Subjectively, 38% of results were perceived as asymmetrical.

Haraguchi et al.	2008	Frontal photographs	1,800 Japan subjects (651 males and 1149 females) mean age 15 years 3 months		Of subjects with facial asymmetry, 79.7% had a wider right hemiface, and 79.3% of those with chin deviation had left sided laterality. Laterality in the normal asymmetry of the face, which is consistently found in humans, is likely to be hereditary rather than an acquired trait.
		Others			
		Three Dimensional			
Ferrario et al.	1994	3D Distance From Symmetry (DFS)	80 young healthy white adults (40 female 40 male)	Midline landmarks: nasion, subnasale, pogonion, trichion, pronasale, B' point bilateral landmarks: eye lateral cantus, tragus, gonion, nasale ala, labial comissura	Soft tissue facial asymmetry was evident especially in the middle (tragus) and lower (gonion) thirds of the face. The right side of the face larger than the left side.
Ferrario et al.	2001	3D, Distance From Symmetry (DFS)	314 healthy white subjects (40 male 33 female adolescents), aged 12–15 years; 73 female and 89 male young adults, aged 18–30 years; 41 male and 38 female adults ages 31–56 years	Midline landmarks: nasion, pronasale, subnasale, pogonion, menton paired landmarks: exocanthion, endocanthion, orbitale superius, frontotemporale, zygion, tragion, nasal alar crest, cheilion, gonion	A slight soft tissue asymmetry found in normal subjects, maximum normal asymmetry slightly greater in females. Tragion, gonion and zygion were the most asymmetric landmarks
Ferrario et al.	2003	3D, Distance From Symmetry (DFS)	18 cleft lip and palate white patients (11 male and 7 females aged 19–27 years) and 161 healthy controls (73 female and 89 male)	Midline landmarks: nasion, pronasale, subnasale, pogonion, menton paired landmarks: exocantion, endocanthion, orbitale superius, frontotemporale, zygion, tragion, nasal alar crest, cheilion, gonion	Most patients had a larger left side of the face, female patients had a somewhat larger lateral asymmetry than the male patients, and UCLP patients were more asymmetrical 8CLP
		Stereophotogrammetry			
Shaner et al.	2000	3D Stereophotogrammetry	medically normal (32 normal males age 1.6 years to adulthood and 38 normal females age 1.7 years to adulthood) and syndrome affected individuals	Lateral landmarks: tragion, zygion, gonion, exocanthion, centre of the iris, endocanthion, alare, subalare, cheilion, christa philtri midline landmarks: glabella, sellion, pronasale, subnasale, labiale superius, labiale inferius, sublabiale, pogonion	In the statistically significantly different measurements, those from the right side were dominant, with one exception in each group, except normal males.

(continued)

Table 33.1 (continued)

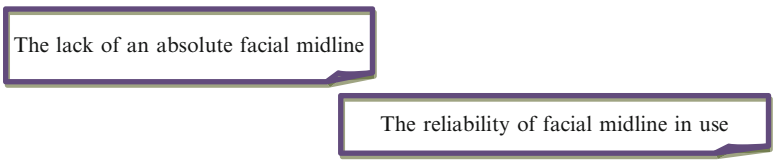
Author	Year	Method	Subjects	Landmarks used	Result
Hajeer et al.	2004	3D Stereophotogrammetry,	44 Patients; 20 ClassIII cases treated by bimaxillary osteotomy; 12 classIII cases treated by maxillary advancement alone, 12 class II cases treated by bimaxilary operations	Endocanthion, exocanthion, nasion, pronasale, alar curvature, subnasale, cheilion, superior label sulcus, stomion superius, stomion inferius, labiale superius, labiale inferius, inferior labial sulcus, pogonion, menton	
		EDMA, Shape analysis			
Ferrario et al.	1995	3D Photogrammetry, EDMA	80 Young Healthy White Caucasian Adults (40 Males, 40 Females 19–32 years old)	Trichion, nasion, pronasale, subnasale, B Point, pogonion, eye lateral canthi, nasal alae, labial comissures, tragic, gonia	Right side dominant
Ercan et al.	2008	2D Photogrammetry, EDMA	321 young adult (171 females and 150 males) 17–23 years of age	Midsagittal landmarks:trichion (tr), supraglabella (sg) nasion (n), pronasale (pr), subnasale(sn), labiale superior (ls), stomion (sto), labiale inferior (li), sublabiale (sl), and gnathion (gn). Bilateral landmarks: trichion; supraglabella; frontotemporale, frontozygomaticus, exocanthion; endocanthion; palpebrale superior; palpebrale inferior, zygion; gonion, nasion; pronasale; columella; subnasale; alare; labiale superior; stomion; labiale inferior; sublabiale; crista philtri;cheilion, pogonion; menton, and superaurale; subaurale.	Asymmetric linear distances between the two sides of face were found more commonly at the middle third of the face (maxillary bone, zygomatic corner and lower orbital border) in both sexes. The left side of the face was most commonly dominant in both sexes

Different methods used for facial asymmetry analysis and their results

Standardized method and subject position allow accurate facial asymmetry analysis. It is important to note that a standard head position is essential for measurement. Natural head position (NHP) is the most appropriate, as it is the most reproducible and provides a natural face orientation for treatment planning (Lane and Harrell 2008).

The accurate identification and reliability of the landmarks are the most important indicators of the accuracy of the facial asymmetry analysis. One way to increase accuracy is to mark the landmarks before measuring them (Kolar and Salter 1997). Many soft-tissue landmarks reflect the underlying bony structure. The bony points must be palpated with a finger to find the soft-tissue equivalent (Kolar and Salter 1997). Some soft-tissue landmarks, such as endocanthion, exocanthion, cheilion, and crista philtre can be clearly identified without palpation or marking. Meticulous identification of soft-tissue landmarks and marking of the landmarks determined by inspection and palpation before the acquisition of photographs will certainly improve the reliability of measurements (Ferrario et al. 1995, 1998). It is important to understand the various sources of error that can affect anthropometric measurements during location of landmarks. Lack of precision results in variability among repeated measurements of the same specimen, and has two components: (1) observer error in locating landmarks and (2) instrument error in identifying landmark coordinates (Kohn and Cheverud 1992; Lele and Richtsmeier 2000). It is crucial to analyze the reliability of the landmarks. To achieve reliability, all landmarks should be marked by the same investigator on all subjects (Ercan et al. 2008b). The reliability of the landmarks is also important while determining the midline. Inaccuracies while determining the landmarks will lead to substantial inaccuracies in measurement, thus reducing the method's reliability.

By definition, symmetry is the "correspondence in size, shape, and relative position of parts on opposite sides of a dividing line or median plane or about a center or axis"(Stedman 2006). This dividing line, which is used to attain symmetry, is known as the midline. It is the fundamental reference for all deviations causing asymmetric facial features. The key to evaluating facial asymmetry is defining the criteria that determine the facial midline (Haraguchi et al. 2008). However, the literature is not clear regarding verifiable guidelines for the determination of midline of the face (Bidra et al. 2009). Based upon convention and dogma, most clinicians choose one specific anatomic landmark and an imaginary line passing through it. Thus, the clinician is left with no predictable guidelines, and must determine the midline based on unverified landmarks (Bidra et al. 2009). Consequently, there are two basic caveats in terms of facial midline.



Facial midline (facial symmetry axis or vertical reference line) has been constructed in several ways. It can be constructed using two main landmarks (Naini et al. 2008). The mid-philtrum of the upper lip (Cupid's bow) will be in the midline of the face. A line joining this point to the mid-glabellar region (glabella), midway between the eyebrows, forms the facial midline (Fig. 33.2). In the symmetrical face, this line will extend to the midpoint of the chin (Naini et al. 2008). In routine medical practice, the facial midline can also be constructed beginning at the central hairline point and crossing the central point of the nasal bridge, the central point of Cupid's bow in the upper lip, and the bottom of the chin (Chatrath et al. 2007). In studies evaluating soft-tissue asymmetry with frontal facial photographs, the facial midline was defined as the perpendicular bisector of the line between the centers of the right and the left pupils (Fig. 33.3) (Haraguchi et al. 2008). First, the distance between the

Fig. 33.2 Facial midline. Facial midline determined using glabella and the mid-philtrum of the upper lip (Cupbid's bow)

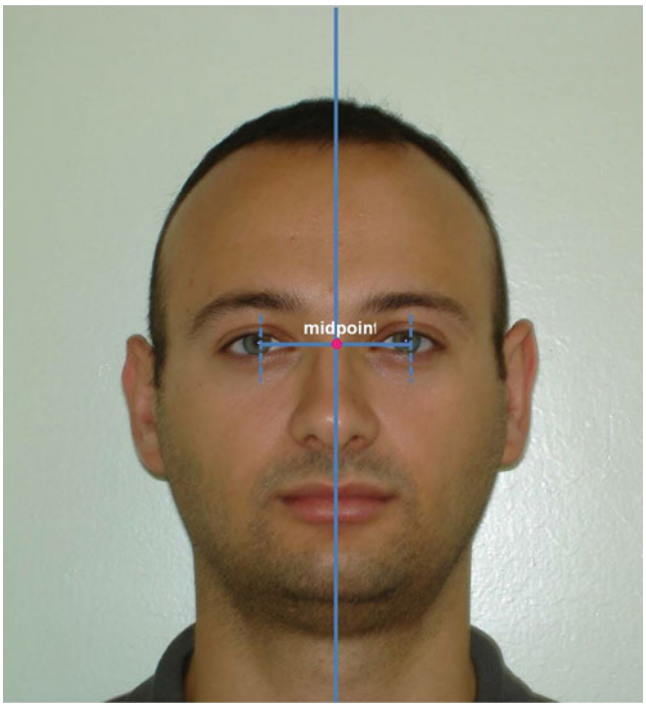


Fig.33. 3 Facial midline. The perpendicular line intersecting the middle point of the horizontal line which connects each pupil centers

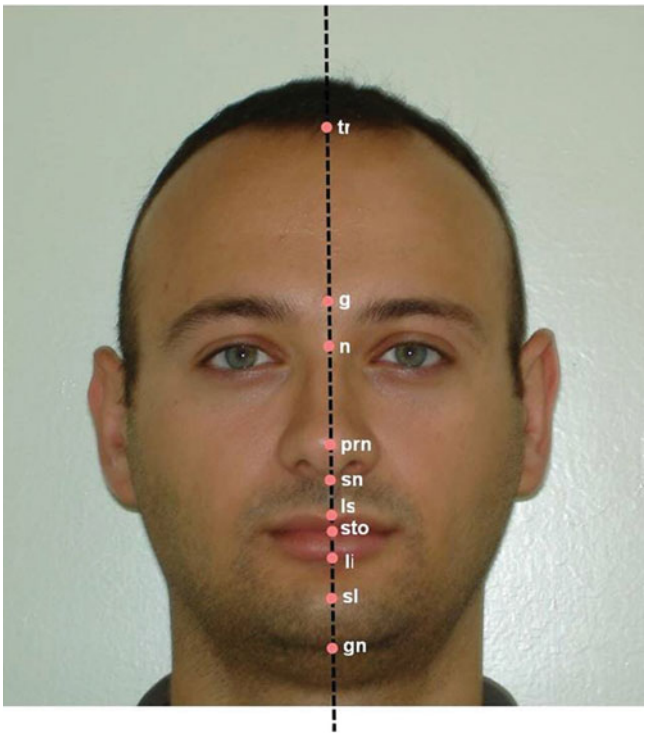

Fig. 33.4 Facial midline. The landmarks located on the midline frequently used to determine the facial midline. Dashed line represents facial midline (facial soft-tissue landmarks: *tr*: trcihion, *g*: glabella, *n*: nasion, *prn*: pronasale, *sn*: subnasale, *ls*: labiale superius, *sto*: stomion, *li*: labiale inferius, *sl*: sublabiale, and *gn*: gnathion)

centers of the two pupils is determined. Then, at the midpoint of this distance, a line perpendicular to the interpupillary line is drawn in order to divide the face into two halves.

In literature, landmarks situated on the midline are also used in order to specify the facial midline (Ferrario et al. 1994, 1995, 2001, 2003; Shaner et al. 2000; Ercan et al. 2008a). The most frequently used midline landmarks for determining the facial midline are trichion, glabella, nasion, pronasale, subnasale, labiale superius, stomion, labiale inferius, sublabiale, and gnathion (Fig. 33.4). However, the midline landmarks do not always refer to facial midline (Ferrario et al. 1994; Bidra et al. 2009). Ferrario et al. (1994) used a 3D coordinate system and found that the axis of symmetry was not located in the midline points. Moreover, the landmarks are frequently located in areas affected by asymmetry, and are thus unsuitable for correctly determining the symmetry axis.

The lack of a method to determine an accurate facial midline, and the question of reliability concerning the determined midline, are two important factors effecting the accuracy of the measurement distances obtained from each hemiface. Hence, further studies are required.

33.3 Anthropometric Facial Asymmetry Analysis

Anthropometric measurement is one of the methods used for the quantitative analysis of facial asymmetry. From the anthropometric point of view, facial asymmetry has been investigated in limited number of studies. Initial studies have been published by Farkas (1981). Anthropometric analysis of facial asymmetry is based on the comparison of homolog measurements that are obtained separately from the right and left hemifaces. These measurements can be performed both by direct and indirect

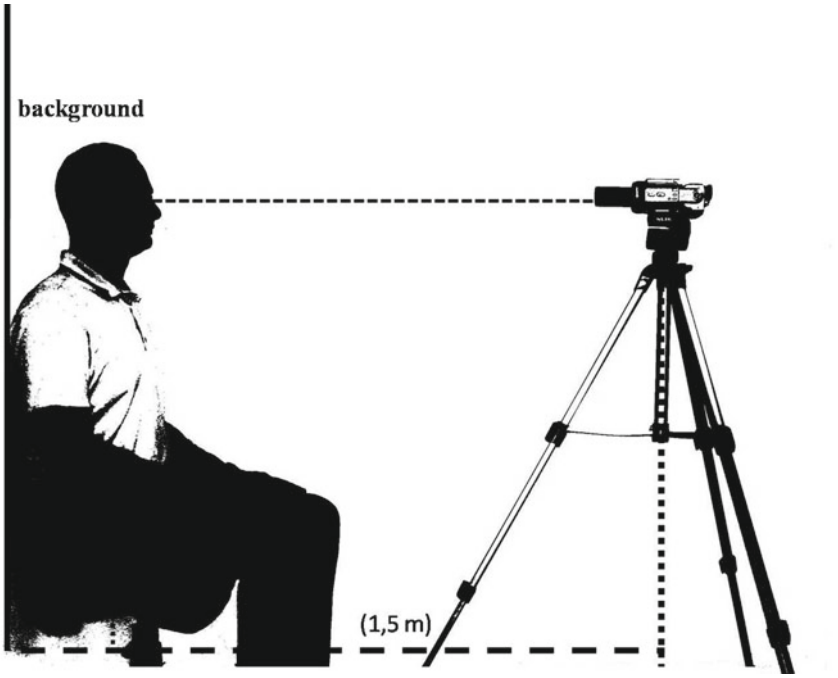

Fig. 33.5 Standardized photographic technique. The figure showing the photographic technique taken in a natural head position, while sitting in a chair within a standard distance (1.5 m is frequently recommended) in a comfortable position with eyes focusing on the lens

methods. Direct measurement is the oldest method used. This method is time-consuming and has several other disadvantages, such as difficulty of patient adaptation (especially in children and infants), problems concerning repeatability of measurements, and archiving of data. Therefore, indirect measurement instruments including photograph, cephalogram, stereophotograph, laser scanning, and computerized tomography have increasingly become popular in recent years. Photogrammetry is a fast and inexpensive method with superior patient compliance. The most important disadvantage of two-dimensional (2D) photogrammetry is its inability to assess facial depth. Three-dimensional (3D) photogrammetry appears to be a more appropriate technique in this respect.

Photogrammetric analysis: In photogrammetry, measurements are taken from standard photographs. The camera position, the distance between the camera and the subjects, and the head position of the subjects should be standardized (Fig. 33.5). The photographs should be obtained in the natural head position, while sitting in a chair within a standard distance (1.5 m is frequently recommended) in a comfortable position, with eyes focusing on the lens. Prior to imaging, careful attention should be paid to ensure that the subjects do not rotate their heads, especially along the vertical axis. In order to take optimal frontal and lateral images, the subjects should not be wearing glasses, their face should not be covered with hair, and their mouth should be closed as in a normal occlusion.

After acquiring the standardized digital images, these images are transferred to the computer and saved in JPEG format. In anthropometric measurements from digital images, tpsDig developed by F. James Rohlf is one of the most frequently used software, both for the marking of the landmarks and for the determination of the distance in pixels. Standard anthropometric landmark labeling on digital facial photograph through tpsDig is shown in Fig. 33.6. The reliability of the landmarks should be analyzed. Intra-observer reliability obtained from two consecutive monthly markings will significantly

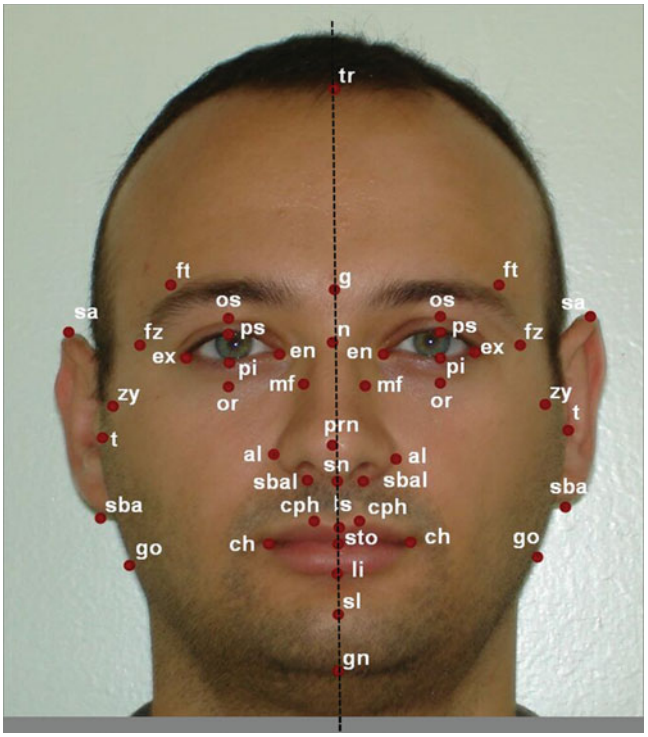

Fig. 33.6 Standardized anthropometric landmarks. *Midline landmarks*: trichion (*tr*), glabella (*g*), nasion (*n*), pronasale (*prn*), subnasale (*sn*), labiale superius (*ls*), stomion (*sto*), labiale inferius (*li*), sublabiale (*sl*), and gnathion(*gn*); *paired landmarks*: frontotemporale (*ft*), frontozygomaticus (*fz*), maxillofrontale (*mf*), endocanthion (*en*), exocanthion (*ex*), palpebrale superius (*ps*), palpebrale inferius (*pi*), orbitale superius (*os*), orbitale inferius (*or*), zygion (*zy*), alare (*al*), subalare (*sbal*), crista philtre (*cph*), cheilion (*ch*), gonion (*go*), supraaurale (*sa*), subaurale (*sba*), and tragion (*t*)

affect the reliability of the results. A ruler is used for the measurement of the distances between the landmarks in digital images, and, later on, the unit distance (1 cm) is calibrated with its equivalent in pixels in order to obtain measurement values separately from the right and left hemifaces.

33.4 Anthropometric Measurements

Several anthropometric measurements have been used by various authors to determine facial asymmetry. The majority of these measurements are from horizontal–linear measurements obtained from the left and right hemiface, and these are mainly defined by Farkas (1981). In the analysis of facial asymmetry, tragion-glabella (supraorbital depth), tragion-nasion (upper face depth), tragion-exocanthion (orbital depth), otobasion superius-nasion, and otobasion superius-exocanthion (temple depth) are located in the upper third; tragion-subnasale (maxillary depth), tragion-cheilion (mid-cheek depth), and otobasion inferius-subnasale (midface depth) are located in the middle third, and otobasion inferius-gnathion (lower face depth) and gnathion-gonion (mandibular body length) are located in the lower third of the face (Fig. 33.7). All paired linear measurements are given with their synonyms in Table 33.2. Of these distances, exocanthion-gonion, exocanthion cheilion, condylion laterale-gonion, and tragion-gonion are relatively perpendicular, the rest are horizontal–oblique. Besides the anthropometric measurements mentioned above, other different anthropometric measurements are noteworthy in the literature (Chatrath et al. 2007). One of the other anthropometric measurements used in facial asymmetry is the distance between the facial midline and homogeneous landmarks located on the left and right hemifaces, according to

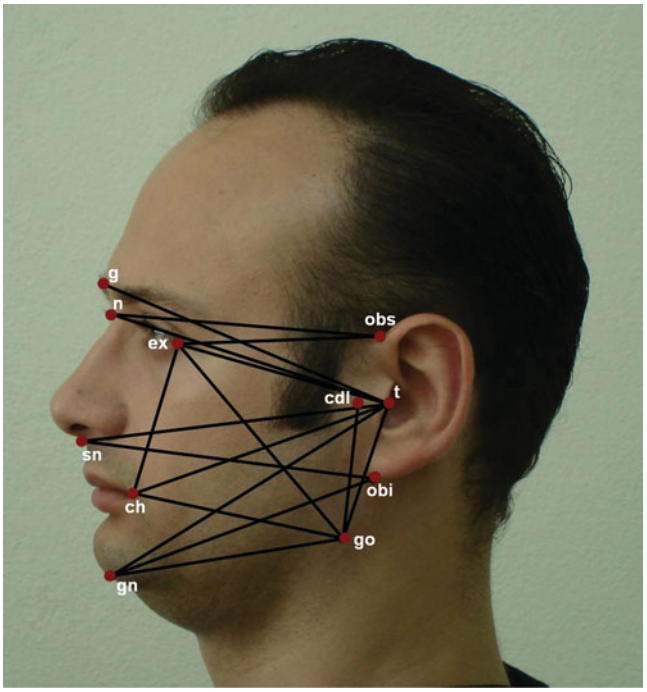

Fig. 33.7 Paired anthropometric measurements for facial asymmetry. Figure showing the left side of the paired measurements (facial soft-tissue landmarks: *g*: glabella, *n*: nasion, *obs*: otobasion superius, *ex*: exocanthion, *cdl*: condylon laterale, *t*: tragion, *sn*: subnasale, *obi*: otobasion inferius, *ch*: cheilion, *go*: gonion, and *gn*: gnathion) anthropometric measurements: t-g, t-n, t-ex, t-sn, t-ch, t-gn, t-go, cdl-go, gn-go, ex-go, ex-ch, obs-n, obs-ex, obs-gn, obi-sn, obi-gn

Table 33.2 Anthropometric measurements

Landmarks	Linear measurements	Synonyms
t-g (r&l)	Supraorbital depth (glabella-tragion)	Supraorbital–aural depth, tragio-glabellar depth
t-n (r&l)	Upper face depth (nasion-tragion)	Tragio-nasal distance, upper-third face depth
t-ex (r&l)	Orbital depth (exocanthion-tragion)	Orbito-tragial depth, upper cheek depth
t-sn (r&l)	Maxillary depth (subnasale-tragion)	Middle- third face depth, tragio-subnasal depth
t-ch (r&l)	Mid-cheek depth (tragion-cheilion)	Labio-aural depth
t-gn (r&l)	Mandibular depth (tragion-gnathion)	Lower-third face depth, gnathion-tragial depth
t-go (r&l)	Tragion-gonion	None
cdl-go (r&l)	Mandibular ramus height (gonion-condylion laterale)	None
gn-go (r&l)	Mandibular body length (gnathion-gonion)	Lower jaw/mandible depth/length
ex-go (r&l)	Lateral facial height (exocanthion-gonion)	Cheek height/orbito-gonial distance/orbito-mandibular
ex-ch (r&l)	Exocanthion-cheilion	None
obs-n (r&l)	Otobasion superius-nasion	None
obs-ex (r&l)	Temple depth (otobasion superius-exocanthion)	None
obs-gn (r&l)	Upper gnathion–aural depth	None
obi-sn (r&l)	Mid-face depth (otobasion inferius-subnasale)	Lower subnasale-aural depth
obi-gn (r&l)	Lower face depth (otobasion inferius-gnathion)	Lower gnathion-aural depth

The table lists and explains the most used facial asymmetry measurements. Paired anthropometric linear measurements obtained from the profile and their synonyms in different sources are given

the midline (Fig. 33.8). Anthropometric measurements obtained from frontal facial images for asymmetry analysis are given in Table 33.3. In addition, surface measurements obtained from each hemiface are also used in the analysis of asymmetry (Farkas 1981). These measurements are given in Table 33.4. Special measurements used in facial asymmetry analysis are summarized in Table 33.5 (Kolar and Salter 1997).

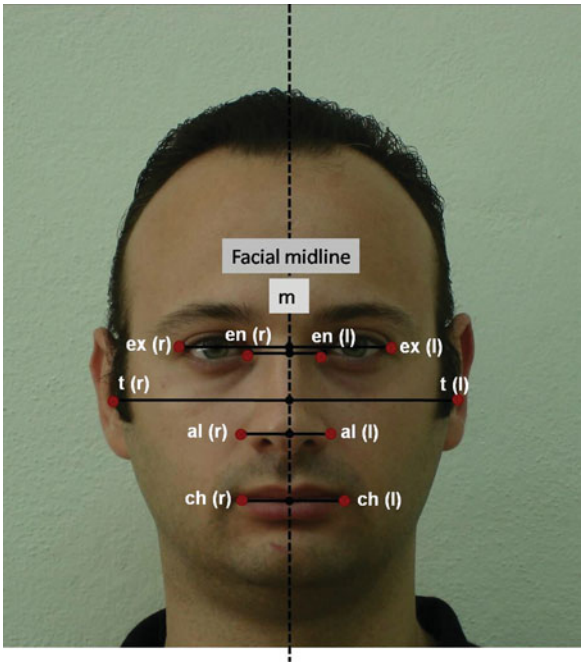

Fig. 33.8 Anthropometric measurements of facial asymmetry. Frontal facial photograph: m: facial midline (illustrated by dashed line) anthropometric facial soft-tissue landmarks for facial measurements: *ex*: exocanthion, *en*: endocanthion, *t*: tragion, *al*: alare, and *ch*: cheilion) Anthropometric measurements: en-m (r&l), ex-m (r&l), t-m (r&l), al-m (r&l), and ch-m (r&l)

Table 33.3 Anthropometric measurements obtained from frontal facial images

Landmarks	Linear measurements
en-m(r&l)	Endocanthion to facial midline
ex-m (r&l)	Exocanthion to facial midline
t-m(r&l)	Tragion to facial midline
al-m(r&l)	Alare to facial midline
ch-m(r&l)	Cheilion to facial midline

Landmarks	Special measurements
n-prn (nasion-pronasale)	Nasal bridge deviation
sn-prn (subnasale-pronasale)	Collumella deviation
ch-ch (cheilion-cheilion)	Labial fissure inclination
en-en (endocanthion), ex-ex (exocanthion), sbal-sbal (subalare), and ch-ch (cheilion)	Vertical landmark dislocation
prn (pronasale), sn (subnasale), and gn (gnathion)	Facial midline deviation

Other special measurements used in the analysis of the facial asymmetry

33.5 Applications to Other Areas of Health and Disease

The symmetric appearance of the face is an indication of health and attractiveness. Even a mild asymmetry can easily be noticed. An esthetic symmetric appearance is one of the main goals of plastic surgeons and orthodontists, within the treatment. Therefore, the evaluation of facial asymmetry is important for esthetic and orthodontic surgery. Another field in which facial asymmetry is taken into consideration is facial growth. Some authors indicated that asymmetric appearance of the face changes with age (Melnick 1992). Melnick showed that the side of mandibular dominance was a function of age: at 6 years, the left side was the largest, whereas, at 16 years, the right side was dominant in boys; the right side was dominant at 12 years in girls (Melnick 1992). It will be important to study asymmetry levels during certain age periods in terms of both acquiring information on the etiology of asymmetry and the planning of the treatment. Yet, there is an asymmetry in craniofacial anomalies accompanied by dysmorphology. Symmetry analysis of the face is helpful in the anthropological evaluation of dysmorphology. Regarding Shaner et al. (2000), considering that the facial asymmetry degree is higher in syndrome-effected individuals than in normal individuals, the obtained results may be helpful to detect the syndrome in some uncertain patients, if such a difference is accurate. Except for the congenital syndromes, other congenital anomalies, such as hemifacial microsomia, plagiocephaly, and cleft lip/palate; developmental anomalies, such as facial hemiathrophy (Parry–Romberg syndrome); and some acquired pathologies, such as condylar trauma and degenerative joint diseases (especially temporomandibular joint), are accompanied by facial asymmetry. The Parry–Romberg syndrome is a good example of a group of diseases accompanied by facial asymmetry. It is an acquired progressive hemifacial atrophy characterized by atrophy of subcutaneous fat and bone structure of unknown pathogenesis. Usually, the left side is affected rather than the right side. It is generally hard to determine a facial midline, according to the deviation in the facial midline structures, due to the loss of soft and bone tissues on one hemiface. It is important to make an objective determination of the facial asymmetry in terms of the accurate evaluation of the response given to the treatment applied in order to correct the asymmetry in this pathology and other similar pathologies.

Summary Points

- Facial asymmetry is a common finding in healthy subjects and in esthetically pleasing faces.
- No consensus exists in the literature regarding the degree, side, and spatial localization of facial asymmetry.
- Standardization of method, accurate identification of landmarks to be used in the measurements, and accurate determination of facial midline are crucial in facial asymmetry analysis.
- Anthropometric analysis of facial asymmetry is based on the comparison of homolog measurements that are obtained separately from the right and left hemifaces.
- Different anthropometric measurements have been used by various authors to determine facial asymmetry.

Key Features

Key features of facial asymmetry.

1. Anthropometric methods as well as other methods are used in the analysis of facial asymmetry.
2. Anthropometric measurements can be obtained by using both 2D and 3D images.
3. The measurements of healthy individuals are important for the normal asymmetry value assessed within the normal limits.
4. Different facial midline and paired landmarks used in the analysis of facial asymmetry and different results have been reported.
5. Studies of asymmetry in healthy individuals are emphasized regarding the issue of which side has dominancy, and it was reported that right side is more dominant.
6. In recent years, analysis of facial asymmetry was carried out by using a new method called EDMA shape analysis method.

Different methods used for facial asymmetry analysis and their results

Chapter 34
Periorbital Anthropometric Measurements

Ümit Beden and Matej Beltram

Abstract Periorbital anthropometric measurements are important in defining cosmetic, pathologic and ethnic variations. In this term, assessment of periorbital landmarks is categorized into three subclasses: periorbital soft tissue, bony orbit, and ocular projection. Measurements of periorbital soft tissue include position of eyelids, height of eyelid skin crease and eyebrows, palpebral slant angle, position of the canthal commissura, epicanthal folds, and horizontal and vertical palpebral apertures. Additionally, margin reflex distances, which reflect eyelid position relative to the eye globe, are included in most cases. Function of the levator palpebralis and its indirect indicator, margin-limbal distance, are other parameters involved in evaluation of periorbital soft tissue. The bony orbit is the socket that encompasses the extra ocular muscles, and the eye with its appendages. Its shape and dimensions are noteworthy in many congenital and traumatic craniofacial malformations. In this respect, interorbital distance, interorbital angles, inter-canthal distances (between both medial and lateral canthi), and interpupillary distance are included during evaluation of the subjects. Ideally, assessment of bony orbit requires imaging techniques. The last parameter of the periorbital anthropometry, the ocular projection, is one of the most widely used parameters in diagnosis of orbital disorders. It reflects the intraorbital volume to content relationship. It is especially significant in orbital tumors and Graves' orbithopathy.

Abbreviations

HPA	Horizontal palpebral aperture
LCT	Lateral canthal tendon
VPA	Vertical palpebral aperture
MLD	Margin – limbal distance
MRD	Margin – reflex distance
MRD-1	Margin – reflex distance of the upper eyelid
MRD-2	Margin – reflex distance of the lower eyelid
IICD	Inner intercanthal distance
OICD	Outer intercanthal distance
IPD	Interpupillary distance

34.1 Introduction

Having both cosmetic and functional relevance, the periorbital area is one of the most important regions in ophthalmic, reconstructive, plastic surgery and anthropometric evaluation. The structures that form the periorbital area, such as bony orbit, eyelids, canthal tendons, and eyebrows, are usually accepted to be the major landmarks in recognition of the sense of beauty and racial decent because interracial variation is usually most prominent in the periorbital area (Kunjur et al. 2006). In terms of periorbital anthropometric measurements, various dimensions are proposed hitherto (Figs. 34.1–34.4, Table 34.1), and, in clinical practice, it is usually not practical to address all these dimensions at once which mostly requires distinct software or photography (Gonzales et al. 2005). Nevertheless, any specialist interested in periorbital anthropometry in health and disease should have a sense of these dimensions and be competent in evaluating periorbital relations.

The structures that form the periorbital region can be subdivided into three groups: periorbital soft tissue, the bony orbit, and the ocular projection. In this chapter, we will give detailed information for evaluation and assessment of these dimensions individually.

34.2 Periorbital Soft Tissue

Eyelids, canthal tendons, and canthal commissura

Eyelids are composed of an anterior and posterior lamella. The anterior lamella is composed of skin and orbicularis oculi muscle. The posterior lamella is composed of a tarsal plate and a smooth muscle of Mullers, lined posteriorly by the mucosal membrane of conjunctiva. The firmness of the eyelids is supplied mainly by the tarsal plates that are anchored to the medial and lateral bony orbit by corresponding canthal tendons (palpebral ligaments). Thus, both tarsal plates and canthal tendons are necessary to maintain the horizontal stability of the eyelids.

Tarsal plates measure 10–12 mm vertically in the upper eyelid, and 3–4 mm in the lower eyelid. At the medial and lateral junctions of upper and lower eyelids, the superior and inferior limbs of canthal tendons join to form a canthal commissura. Thus, each eye has a medial and lateral canthal commissura. The medial and lateral commissura of one eye are aligned vertically with those of the

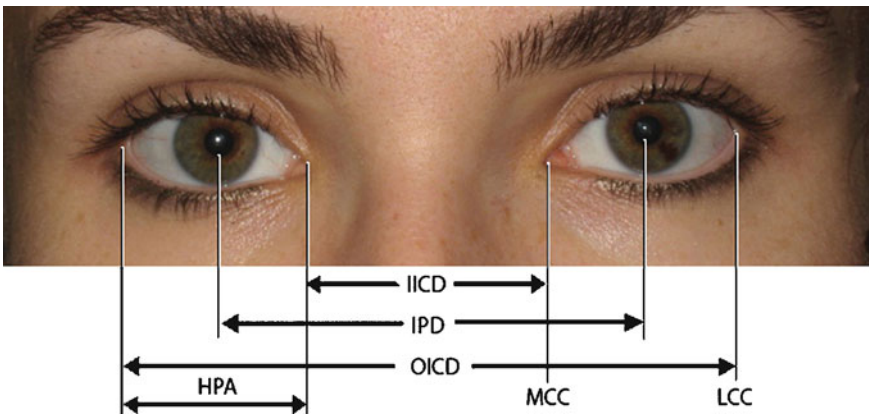

Fig. 34.1 Inner Intercanthal distance *(IICD)*, interpupillary distance *(IPD)*, outer intercanthal distance *(OICD)*, horizontal palpebral aperture *(HPA)*, medial canthal commissura *(MCC)*, and lateral canthal commissura *(LCC)*

Table 34.1 Description of parameters involved in periorbital anthropometric evaluation

Palpebral slant	An imaginary line connecting medial and lateral commissura of the same eye
Palpebral slant angle	The angle between palpebral slant and an imaginary horizontal line
Horizontal palpebral aperture	Distance between medial and lateral canthi
Vertical palpebral aperture	Distance between upper and lower eyelid in gaze of primary position of gaze
Levator function	Upper eyelid margin excursion from upgaze to downgaze
Margin–limbal distance	Distance from lower limbus (6 o'clock position) to the lower margin of the upper eyelid in upgaze
Margin reflex distance	Distance between eyelid margin and central pupillary light reflex
Margin reflex distance – 1	Margin reflex distance of the upper eyelid
Margin reflex distance – 2	Margin reflex distance of the lower eyelid
Upper eyelid crease	Line that is formed by levator aponeurosis insertion to the pretarsal skin, separating the lower pretarsal skin from the higher preseptal skin
Upper eyelid crease height	Distance between lower margin of the upper eyelid and eyelid crease line when it first appears as the patient starts to look up from downgaze
Epicanthus	Presence of a skin fold covering the medial canthus
Epicanthus tarsalis	Epicanthus involving the upper eyelid
Epicanthus palpebralis	Epicanthus involving both eyelids
Epicanthus inversus	Epicanthus involving the lower eyelid
Epicanthus superciliaris	Epicanthus involving the eyebrow
Inner intercanthal distance	Distance between the inner canthi of both eyes
Outer intercanthal distance	Distance between the outer canthi of both eyes
Interpupillary distance	Distance between pupils of the right and left eye
Eyebrow height	Distance between lower borders of the eyebrow and the upper eyelid when the eyes are open
Upper lid skin distance	Distance between lower borders of the eyebrow and the upper eyelid in downgaze
Interorbital distance	Distance between both medial walls of both orbits
Ocular projection	Distance between the corneal apex and the lateral orbital rim on side view

other eye. However, medial and lateral commissura of the same eye are not aligned vertically, as the lateral commissura is located superiorly to the medial commissura. Thus, an imaginary line connecting the medial and lateral commissura of the same eye is usually not horizontal, and is called palpebral slant (Fig. 34.3). The angle between this imaginary line and a horizontal line determines the palpebral slant angle (Fig. 34.3). The palpebral slant is usually directed upward laterally, as the lateral canthi are located about 1.5–2 mm superior to the medial canthi (van den Bosch et al. 1999; Gonzales et al. 2005; Beden et al. 2007). It is slightly higher in females (van den Bosch et al. 1999). This slant is increased in the Mongolian race, and it is called *mongolian slant* when the lateral canthi are located more superiorly. Otherwise (when the lateral canthi are located lower than the medial canthi), the palpebral slant is directed downward, and this configuration is called *antimongolian slant*. The palpebral slant is among the most important and useful entities in the detection of many traumatic and congenital anomalies, such as Down syndrome. It is also one of the most readily perceived characteristics of facial identity as well as racial descent. It is increased in Orientals, and tends to decrease with age. The palpebral slant angles reported in the literature are given in Table 34.2.

The lateral canthal tendon (LCT) has both static and dynamic functions. Among its static functions are: converting the circular contraction of the orbicularis to the horizontal-eyelid-converting vector, and being the insertion point of the Lockwood ligament, the lateral horn of the levator palpebralis muscle, the lateral check ligament of the lateral rectus muscle, and preseptal orbicularis muscles (Bedrossian 2002; McCord et al. 2003; Beden et al. 2007). A dynamic feature of the lateral canthal

White neonates	18.5	

tendon is provided by horizontal movement of the lateral canthus, and supposedly contributes to globe protection, non-verbal communication and preservation of the lateral visual field (Beden et al. 2007). The reported vertical width of the lateral canthal tendon is about 6.6 mm, with a horizontal length of 7.5–10.6 mm (Gioia et al. 1987; Beden et al. 2007). It inserts 1.5 mm posterior to the inner margin of the lateral orbital rim (Gioia et al. 1987; Beden et al. 2007). Involutional descent of the lateral commissura is a well-known feature, which results in palpebral slants directed downward with advancing age (Beden et al. 2007; Odunze et al. 2008).

Horizontal palpebral aperture (HPA) is the distance between the medial and lateral canthal commissura (Fig. 34.1). It tends to increase in the first two decades of life (Fox 1966; Ozturk et al. 2006). It increases by 10% between ages 12 and 25 years, and decreases after 45 years of age (van den Bosch et al. 1999). There are controversial reports about involutional decrease in HPA. Bosch reported that it decreases with age, and this decrease is due to the laxity of the LCT (van den Bosch et al. 1999). In another study, however, involutional decrease in HPA could not be confirmed (Beden et al. 2007). HPA was rather reported to stay constant in spite of increasing LCT/HPA ratio with advancing age (Beden et al. 2007). HPA is 28–30 mm long and the dimensions reported in the literature are given in Table 34.3.

Vertical palpebral aperture (VPA) is the distance between the upper and the lower eyelid in primary position of gaze (Fig. 34.2). The upper eyelid covers 1.5–2 mm of the limbus at 12 o'clock, and the lower lid barely touches the limbus at 6 o'clock. The higher point of the upper eyelid is usually slightly medial to the center of the pupil, and the lower point of the lower eyelid is usually slightly lateral to the center of the pupil. Normal VPA measures 9–11 mm, and is larger in women than in men. Peak values of approximately 8–13 mm were reported for blacks and whites in the Western population (Fox 1966; Ozturk et al. 2006; Beden et al. 2007; Park et al. 2008a). It increases until the second decade, and then remains constant until the fifth decade.

The average VPA distance is 9.6 mm for white adults (9.7 mm in males, 9.9 mm in females) (Ozturk et al. 2006; Beden et al. 2007). Values of 10.3 and 10.4 mm in young adult white males and females were also reported (Bozkir et al. 2003). It is reported to be 7.8–8.2 mm in Korean adult male subjects, and 8.2–8.5 mm in female subjects (Park et al. 2008a). It is 4.87 mm in white newborns (Ozkagnici et al. 2001).

Function of the levator palpebrae muscle is directly reflected to the upper eyelid, and measured as the excursion of the lower margin of the upper eyelid, from downgaze to upgaze. Levator function is essential in determination of surgery type for blepharoptosis repair. While measuring levator function, the physician applies gentle pressure on the eyebrow to prevent transfer of frontalis muscle action to the upper eyelid. Normally, levator function is between 12–18 mm in white adults and 8–13 mm in Asians (Bedrossian 2002; Park et al. 2008a).

Margin–limbal distance (MLD) is another way to predict the levator palpebralis muscle function. It is the distance from lower limbus (6 o'clock position) to the lower margin of the upper eyelid in upgaze. This measurement is not frequently used in routine practice, and normative data have not been established so far. However, when levator resection is planned for treatment of blepharoptosis, MLD of the ptotic eye is subtracted from that of the other (healthy) eye, and this difference is used to determine the amount of levator muscle resection in blepharoptosis surgery.

Margin reflex distance (MRD) is the distance between eyelid margin and central pupillary light reflex in primary position of gaze. MRD-1 is the measurement of the upper eyelid-reflex distance, and MRD-2 is the lower eyelid-reflex distance (Fig. 34.2). Thus, MRD-1 plus MRD-2 is equal to the vertical palpebral aperture size (Fig. 34.2).

MRD-1 is the distance between lower margin of the upper lid and light reflex on the cornea in primary gaze (Fig. 34.2). It is directly related to the resting position of the upper eyelid and palpebral aperture. Normally, the upper eyelid is set 1–2 mm inferior to the superior limbus and the MRD-1 is usually 3.5–4.5 mm (Beden et al. 2007).

MRD-2 is the distance between the upper margin of the lower lid and the light reflex on the cornea in primary gaze (Fig. 34.2). Put another way, it is the difference between vertical palpebral aperture and MRD-1 (Fig. 34.2). Beden reported MRD-2 to be 5.63 mm on average for white adults (Beden et al. 2007).

Upper eyelid crease is the line that is formed by levator aponeurosis insertion to the pretarsal skin (Fig. 34.4). It is the landmark separating lower pretarsal skin from higher preseptal skin. It is also an important landmark because of being the incision site in most upper eyelid or orbital surgeries. It is observed in most Western population, and in 30% and 41% in Asian males and females, respectively (Park et al. 2008a, b).

The distance between lower margin of the upper eyelid and eyelid crease line is the eyelid crease height (Fig. 34.4). It is measured in downgaze so that both the eyelid margin and the eyelid crease are clearly visible. In primary gaze, however, the skin above the eyelid crease

tends to sag downward, rendering visible eyelid crease height smaller. In that case, the distance measured is called pretarsal skin height (Fig. 34.2). Pretarsal skin height is 3.0 mm in females and 2.1 mm in males (van den Bosch et al. 1999). It is 1.7 mm in the fist decade of life in whites, and it increases to 2.3 mm in the third to fourth decade, and gradually decreases thereafter (Cartwright et al. 1994).

Measurement of eyelid crease is usually not consistent because the crease position is subject to change with gaze position, levator tonus, downward sagging of preseptal skin, and by the pressure applied to preseptal skin to observe the eyelid crease line during measurement. It should preferably be measured when it first appears as the patient starts to look up from downgaze (Fig. 34.4). It is 2–4.9 mm in the first decade of life, and it increases to 7.1 mm in adult life (Cartwright et al. 1994; Ozkagnici et al. 2001). Values reported in the literature vary between 5.9 and 11 mm in different studies (Cartwright et al. 1994; Ozturk et al. 2006; Park et al. 2008a). Although mean values of 7–8 mm for Western males, and 7–12 mm for Western females are usually accepted, recent studies have reported the effect of gender to be insignificant on eyelid crease position (Cartwright et al. 1994; Ozturk et al. 2006). When present, it is usually located lower in Asian subjects. Reported values are 6.6 and 6.5 mm in male and female Asian subjects, respectively (Park et al. 2008a).

Epicanthus (epicanthal fold) is the presence of a skin fold covering the medial canthus. It usually appears between the third and the sixth month of gestation in every race, and disappears before birth. It is called epicanthus tarsalis when this extra skin fold is in the upper eyelid, epicanthus superciliaris when it is located higher through the eyebrow, epicanthus inversus when it is in the lower eyelid, and epicanthus palpebralis when it involves both eyelids (Johnson's classification). Although it is said that only the Mongolians retain it after birth, it was detected in 42.2–50% in Koreans (Park et al. 2008a). It is present in more than 90% of both male and female subjects younger than 10 years, and it disappears gradually with age, presenting in only 10% of those in their fifties or older (Park et al. 2008a). Regarding the type of epicanthus, it is epicanthus tarsalis in 50.5%, epicanthus palpebralis in 25.7%, epicanthus superciliaris in 21.4%, and epicanthus inversus in 2.4% (Park et al. 2008a).

Intercanthal and interpupillary distances are distances between inner canthi (inner intercanthal distance – IICD), outer canthi (outer intercanthal distance – OICD), and pupils (interpupillary distance – IPD) (Fig. 34.1). They are important in detection of congenital and traumatic craniofacial anomalies. Although there are controversial reports in the literature about the effect of age and sex on these parameters, IICD and OICD usually stabilize after the first and second decades, respectively (Freihofer 1980; Singh and Banerjee 1983; Fledelius and Stubgaard 1986; Osuobeni and al-Gharni 1994; Ozturk et al. 2006).

Distance between both the medial canthi is called inner canthal distance (IICD) (Fig. 34.1). It should be noted that it is not the distance between both bony orbits, as soft tissue is taken as reference point. This distance is affected by the length of medial canthal ligament, which anchors tarsal plates to medial orbital wall. It is called telecanthus when this distance is increased. Telecanthus is primary when IPD and interorbital distances are normal, and secondary when IPD and interorbital distances are increased (i.e., hypertelorism) (Murphy and Laskin 1990).

Interpupillary distance is the distance between both pupils (IPD) (Fig. 34.1). Practically, it is measured as the distance between light reflexes of both eyes in primary position of gaze. As the light reflex is not a stationary point, this may lead to inaccurate measurements, and one can also measure the same distance as the distance between either the nasal or the temporal limbus of both eyes.

Table 34.4 IICD and IPD reported in the literature

Population	IICD (mm)	IPD (mm)	References
Black males	35.7	66.3	Murphy and Laskin (1990)
Black females	33.1	62.6	
White adults	32.1	60.83	Beden et al. (2007)
White adult males	30.7	60.6	Ozturk et al. (2006)
White adult females	30.2	60.1	
Black males	35.8	68.97	Barretto and Mathog (1999)
Black females	34.18	65.93	
White males	35.53	65.15	
White females	32.95	61.47	
Asian males	35.3–38.8	59.9–69.4	Park et al. (2008a)
Asian females	33.4–38.3	63.2–66.6	
Young adult white males	30.7	63.9	Bozkir et al. (2003)
Young adult white females	30.0	60.8	

According to accumulated data, IICD is 32±3 mm and IPD is 63±3mm (Murphy and Laskin 1990). IICD and IPD values reported in the literature are given in Table 34.4.

The distance between both outer canthi is outer intercanthal distance (OICD) (Fig. 34.1). Practically, it is the sum of HPA on both site and inner intercanthal distance, and it is not as popular as inner intercanthal distance and interpupillary distance in clinical practice. It is reported to be 91.3–95.9 mm in white males, and 90.1–92.0 mm in white females (Bozkir et al. 2003; Ozturk et al. 2006).

Eyebrows (the foundation of human expression) should be included in any periocular assessment because of their effect on eyelid position. While strongly affected by age and sex, eyebrows are usually located on the superior orbital rim in males, and slightly higher in females. The lateral end of the eyebrow is at the same line, with or slightly superior to its medial end, and 10 mm above lateral orbital rim. The brows' higher location and steeper temporal arching in females is proposed to be one of the most important landmarks that lend to esthetics. Although this is a widely accepted aim for upper face rejuvenation surgery, quantitative assessment of eyebrow height and position is not well established in the literature. Reports of eyebrow position are controversial because of racial differences and measurement technique discrepancies. They are usually inaccurate, especially if the patient plucks her eyebrow, has ptosis, and had botulinum toxin injection. Eyebrow position easily changes with gaze position and frontalis muscle contraction. Brow height is measured as the distance between lower borders of eyebrow and upper eyelid when the eyes are open (Fig. 34.2). When this distance is measured as the eyes are closed, or in downgaze, it is called upper lid skin distance (Fig. 34.4).

Cartwright reported eyebrow height to be 5.8–7.1 mm in white adults (Cartwright et al. 1994). Ozturk, however, reported an eyebrow height of 9.7–9.9 mm (Ozturk et al. 2006). According to Park, it is 12.4±2.4 mm in male subjects, and 12.0±1.9 mm in female subjects, in Koreans Park et al. 2008a). It is 7.18 mm in white newborns, and 11.8 and 9.4 mm in white females and males, respectively (van den Bosch et al. 1999; Ozkagnici et al. 2001).

Brow descent is a well-known entity, which is the main reason for most facial rejuvenation surgeries. It is due to progressive laxity of scalp and forehead tissue. Brow descent (ptosis) is defined as presence of brow level below the superior orbital rim. It is usually more pronounced laterally because the medial part of the brow has strong attachments to the orbital rim. Odunze reported that this descent of brow is noticeable in the third decade in whites, which is much earlier than in African Americans (Odunze et al. 2008).

34.3 Bony Orbit

The bony orbit has a pyramidal shape. The orbital rim is rounded and thicker than the orbital walls. It has an incomplete circular shape forming a spiral medially. The ends of the spiral represent the anterior and posterior lacrimal crest, which are the boundaries of the lacrimal fossa.

The distance between both medial orbital walls is the interorbital distance. Hypertelorism is an increase in distance between both bony orbits, and hypotelorism is the opposite. True hyper- and hypotelorism are usually congenital, and they are usually associated with other cranial or midfacial anomalies (Murphy and Laskin 1990). Clinically, measurement of hyper- or hypotelorism is controversial because of soft tissue overlying the bony orbit. IPD is usually used instead of interorbital distance, and is a useful value in evaluation of distance between both orbits. Other techniques that can be used for hyper- or hypotelorism are plain radiography and CT. Radio-opaque markers can also be used to facilitate measurement on X-ray film (Murphy and Laskin 1990).

The medial orbital rim is located 20 mm anterior to the lateral orbital rim. Medial walls of the orbits are 25 mm apart, and parallel to each other. The lateral wall of one orbit is at 45 degrees to the medial wall of the same side, and at right angles to the lateral wall of the opposite side. The volume of the orbit is approximately 30 cm^3, with vertical and horizontal lengths of 30 and 40 mm, respectively. It has a depth of 40–45 mm, and largest coronal dimension of 1 cm posterior to the orbital rim.

34.4 Ocular Projection

Ocular projection is the distance between corneal apex and lateral orbital rim. This distance reflects the relationship between intraorbital volume and content. It is an important clinical entity in orbital diseases, craniofacial anomalies, Graves' ophthalmopathy, and periocular rejuvenation surgeries. It is called exophthalmos when this distance is increased, and enophthalmos when decreased. An exophthalmometer is any device that measures the ocular projection. Although it is possible to measure this distance with a ruler from lateral view, there are other techniques that are used for clinical purposes, such as Hertel's, Krahn, Luedde's, Carl Zeiss, Keeler, and Naugle exophthalmometer, as well as radiographic techniques and computerized tomography (Kim and Choi 2001; Kumari Sodhi et al. 2001; Segni et al. 2002; Vardizer et al. 2005). In spite of being criticized as inaccurate, Hertel's exophthalmometry is still the most frequently used method in proptosis evaluation. Values measured by imaging techniques (such as computerized tomography) are reportedly greater or lesser than those measured by Hertel's exophthalmometer (Kim and Choi 2001; Segni et al. 2002).

It is called comparative exophthalmos when ocular projection is detected to increase over a period of time, relative exophthalmos when more than 2 mm of asymmetry is detected between left and right eyes, and absolute exophthalmos when ocular projection is beyond the established normative upper limit, which is around 21 mm in most studies (Barretto and Mathog 1999). A gradual increase in the first decade of life is reported with values of 9.11 mm in the 3-year-old group, to 11.67 mm in the 10-year-old group (Nucci et al. 1989).

It is relatively easy to establish comparative and relative exophthalmos in clinical practice. Racial anthropometric differences, however, render establishment of absolute exophthalmos much more difficult, as a widely accepted upper limit is impractical. Hence, there are many studies in the literature trying to establish normative data of ocular projection for different populations. Ocular projection values reported in the literature are given in Table 34.5.

Table 34.5 Ocular projection values (Hertel readings) reported in the literature

Population	Hertel (mm)	Lower limit (mm)	Upper limit	Standard deviation	Sample size	References
Adult white male	17.00	11.7	22.3	2.65	65	Barretto and Mathog (1999)
Adult white female	15.98	11.5	20.4	2.22		
Adult black male	18.23	13.7	22.8	2.26	61	
Adult black female	17.27	14.4	20.2	1.44		
Adult white male	16.55	11.31	21.71	2.58	127	Migliori and Gladstone (1984)
Adult white female	15.46	10.74	20.80	2.33	200	
Adult black male	18.56	12.30	24.65	3.08	113	
Adult black female	17.90	12.60	23.04	2.57	241	
Adult white male	16.0	11.4	20.6	2.30	325	de Juan et al. (1980)
Adult white female	14.7	10.9	18.5	1.92		
Adult black male	17.9	13.2	22.6	2.86	402	
Adult black female	17.1	11.7	22.5	2.71		
Adult black males	18.20	12.3	24.14	2.97	309	Dunsky (1992)
Adult black females	17.46	12.2	22.74	2.64		
Adult white males	13.49	5	20	2.49	970	Beden et al. (2008)
Adult white females	13.27	5	21	2.40	1,507	
Adult white males	13.49	8	20	2.60	240	Bilen et al. (2007)

Summary Points

- Periorbital anthropometric measurements are mandatory for cosmetic, pathologic, or ethnic evaluation.
- Periorbital evaluation involves measuring soft tissue, bony orbit, and ocular projection.
- Main landmarks in periocular soft tissue are eyelids with anchoring canthal tendons, eyebrows, and upper eyelid crease.
- Parameters of periorbital soft tissue involves position of eyelids, height of eyelid skin crease and eyebrows, palpebral slant angle, position of the canthal commissura, epicanthal folds, and horizontal and vertical palpebral apertures.
- Bony orbit is the socket that encompasses the extra ocular muscles, and the eye with its appendages.
- Measurements of the bony orbit are important in many congenital and traumatic malformations.
- Measurements of orbital parameters include: interorbital distance, interorbital angles, intercanthal distances (between both medial and lateral canthi), and interpupillary distance.
- Ocular projection reflects intraorbital volume to content relationship.
- It is one of the most significant parameters for orbital tumors and Graves' ophthalmopathy.

Table of key facts of periorbital anthropometry
Periorbital anthropometric measurements are mandatory for cosmetic, pathologic, or ethnic evaluation.
Periorbital evaluation involves measuring bony orbit, soft tissue, and ocular projection.
Main landmarks in periocular soft tissue are eyelids with anchoring canthal tendons, eyebrows, and eyelid crease.
Measurements of the bony orbit are important in many congenital and traumatic malformations.
Ocular projection reflects the relationship between the intraorbital volume and content. It is one of the most significant parameters for orbital tumors and Graves' ophthalmopathy.

Practical Methods and Technique

Palpebral slant angle

Take a picture of the patient's face. Have a hard copy and draw a line passing through medial and lateral canthi of one eye (palpebral slant). Draw another line passing through both medial canthi of both eyes (horizontal line). Measure the angle between two lines at the intersection point in the medial canthus. You can also use a flat computer screen instead of a hard copy of the picture.

Horizontal palpebral aperture

Let the patient look straight ahead. Hold a ruler horizontally in front of his/her eye. Measure the distance between medial and lateral canthi..

Vertical palpebral aperture

Let the patient look straight ahead. Hold a ruler vertically in front of his/her eye. Measure the distance between upper and lower eyelid.

Levator function

Sit at the same level as the examinee. Let the patient look down. Put your thumb on his/her eyebrow to prevent frontalis muscle effect on the eyelid. Ask him/her to look upward. Measure upper eyelid

margin excursion from downgaze to upgaze. Repeat this maneuver a few times and take the average of two to three measurements.

Margin–limbal distance
Sit at the same level with the examinee, and let him/her look upward. Measure the distance from lower limbus (6 o'clock position) to the lower margin of the upper eyelid in upgaze.

Margin reflex distance
Sit at the same level as the examinee, and let him/her look straight toward a penlight. Measure the distance between the upper eyelid margin and the central pupillary light reflex and note it as MRD-1. Then, measure the distance between the lower eyelid margin and the central pupillary light reflex and note it as MRD-2.

Upper eyelid crease
Sit at the same level as the examinee, and let him/her look down. Ask him/her to look up slowly and note the skin crease on the upper eyelid when it first appears as the patient starts to look up from downgaze. Measure the distance between the lower margin of the upper eyelid and eyelid crease line.

Epicanthus
Epicanthus is noted if an extra skin fold covers the medial canthus. It is recorded as epicanthus tarsalis if the skin fold involves the upper eyelid, epicanthus palpebralis if the skin fold involves both eyelids, epicanthus inversus if the skin fold involves the lower eyelid, and epicanthus superciliaris if the skin fold involves the eyebrow.

Inner intercanthal distance
Let the patient look straight ahead. Hold a ruler horizontally in front of his/her eye. Measure the distance between inner canthi of both eyes.

Outer intercanthal distance
Let the patient look straight ahead. Hold a ruler horizontally in front of his/her eye. Measure the distance between outer canthi of both eyes.

Interpupillary distance
Hold a penlight to the patient's face and let him/her look straight ahead. Measure the distance between the pupillary light reflex of the right and left eye or the distance between the temporal limbus of the right eye and the nasal limbus of the left eye.

Eyebrow height
Let the patient look straight ahead. Hold a ruler vertically in front of his/her eye. Measure the distance between the lower borders of the eyebrow and the upper eyelid.

Upper lid skin distance
Let the patient look down. Hold a ruler vertically in front of his/her eye. Measure the distance between the lower borders of the eyebrow and the upper eyelid.

Ocular projection
Take a simple ruler, of transparent plastic preferably. Take your position laterally, at 90° to the examinee and palpate with a finger the lateral part of the orbital rim. Position the ruler horizontally and press it against the examinee's lateral orbital rim, at the height of the center of the eyeball. Read the distance on the ruler from the corneal apex to the lateral orbital rim.

*Measurement of ocular projection with an exophthalmometer is in the domain of a trained ophthalmologist.

Anthropometry of Eyelids

Dae Hwan Park and Chang Hyun Oh

Abstract The normal morphological and functional values of eyelids and orbits are varied according to race, sex, and age. Unfortunately, there is a paucity of information related to these values. The authors quantified and statistically analyzed nine morphologic and functional values in 234 male and 264 female. Among adults, the mean value for the palpebral fissure was 27.0 ± 1.8 mm in males and 26.8 ± 1.7 mm in females in the horizontal dimension and 8.0 ± 1.0 mm in males and 8.2 ± 1.1 mm in females in the vertical dimension. The average slant of the palpebral fissure was 7.9° ± 2.4° in males and 8.8° ± 2.3° in females and the average height of the opened upper eyelid was 12.4 ± 2.4 mm in males and 12.0 ± 1.9 mm in females. The average height of double fold in the closed eye was 6.6 mm in males and 6.5 mm in females, and the average intercanthal distance was 38.4 ± 3.0 mm in males and 38.2 ± 2.8 mm in females. The average interpupillary distance was 64.6 ± 2.9 mm in males and 63.6 ± 2.9 mm in females. The peak level of growth in the vertical dimension of the palpebral fissure was reached between ages 10 and 13 years, that of the intercanthal distance was between ages 14 and 16 years, and that of horizontal dimension of the palpebral fissure was between ages 17 and 19 years.

35.1 Introduction

Eyelids show significant differences in morphology and structure with age and race. In case of unilateral ptosis surgery, the size and shape of the normal eyelid might be used as a guide for operation. However, for bilateral operation, normal anthropometric values become important. Therefore, it can be said that normal values of eyelids by age and sex are most important in blepharoplasty and reconstruction. In this context, the authors were required to measure eight items including the horizontal dimension of the palpebral fissure (HDPfi) the vertical dimension of the palpebral fissure (VDPfi) and the slant of the palpebral fissure, applied to 498 male and female subjects between the age of 6 and 80 years, and to statistically analyze them according to age and sex.

35.2 Methodological Consideration

For measurements, we had the subject sit opposite an examiner at the same eye level and gaze at the center of the examiner's nasal muscle. With the McCoy facial Trisquare and a millimeter-gauged ruler, we measured the horizontal and vertical dimensions of the palpebral fissure, the height of open upper eyelid, the fold type and height, the incidence and type of epicanthus, the intercanthal distance, and the interpupillary distances. For accuracy, we took two measurements at an interval of 5 min, and recorded the mean values. To measure the slant of the palpebral fissure, a 105-mm camera was used at 1-m distance, to photograph both eyes clearly. We developed the photograph and measured it using a graduator.

We statistically analyzed measured results by age and sex. Considering that physical growth peaks during the teen years, we subcategorized it into three groups for statistical analysis, and categorized other age groups by 10-year intervals. For the statistical processing, all measured values are represented by mean ± SD, and the *t*-test was performed for the significance test with a less than 5% of significance level. No correction was made for multiple testing.

We subdivided the upper eyelid into eight items, and analyzed each item according to age and sex. In particular, we performed the *t*-test for two neighboring age groups by item-wise, verified significance, and compared mean values from the point of the completion of growth ($p < 0.05$).

35.3 Horizontal Dimension of the Palpebral Fissure

For the horizontal dimension of the palpebral fissure, Adler reported a mean value of 25 mm (Alder 1975), and Farkas et al. reported a mean value of 31.0 mm, in adults (Farkas et al. 1985). In Asians, Baek et al. reported a mean value of 29.1 mm in adults (Baek et al. 1995). Park et al. reported mean values of 29.7 mm in adult male subjects and 28.4 mm in adult female subjects (Park et al. 1990). Cho et al. reported mean values of 34.2 mm in male subjects and 33.4 mm in female subjects (Cho et al. 1993). This article showed slightly lower values than others, with a mean of 27.0 mm in adult male subjects and a mean of 26.8 mm in adult female subjects; and male subjects showed greater values than female subjects ($p < 0.05$) without significant difference from the other subjects with 27 and 30 mm values (Fig. 35.1). Values reached the peak level of growth at 10–13 years of age, and remained stationary and gradually decreased as subjects approached their fifties ($p < 0.05$).

35.4 Vertical Dimension of the Palpebral Fissure

For the vertical dimension of the palpebral fissure, Moses reported peak values of approximately 8–10 mm (Moses 1987) without a significant difference between blacks and whites. Duke-Elder reported a mean value, in the Western population, of approximately 9–13 mm (Duke-Elder 1916). Jung and Hong reported mean values of 8.2 mm in Korean adult male subjects and 8.5 mm in female subjects (Jung and Hong 1974), and Cho et al. reported values, in Asian male and female subjects, of 8.2 and 8.5 mm, respectively, at 18 years of age (Cho et al. 1993). This article also reported values of 8.0 mm in male subjects and 8.2 mm in female subjects, with no significant difference according to sex (Fig. 35.2). These values are similar to the figures reported by Cho et al. and Moses (Cho et al. 1993; Moses 1987). Noh and Choi reported that the vertical dimension of the

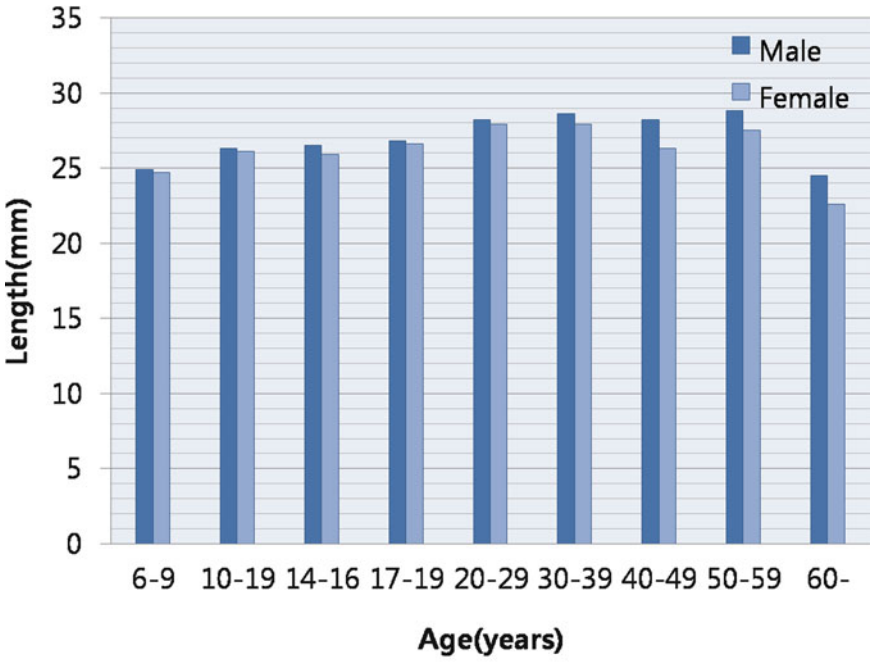

Fig. 35.1 Horizontal dimension of the palpebral fissure. The horizontal dimension of the palpebral fissure was 27.0 ± 1.8 mm in male subjects and 26.8 ± 1.7 mm in female subjects

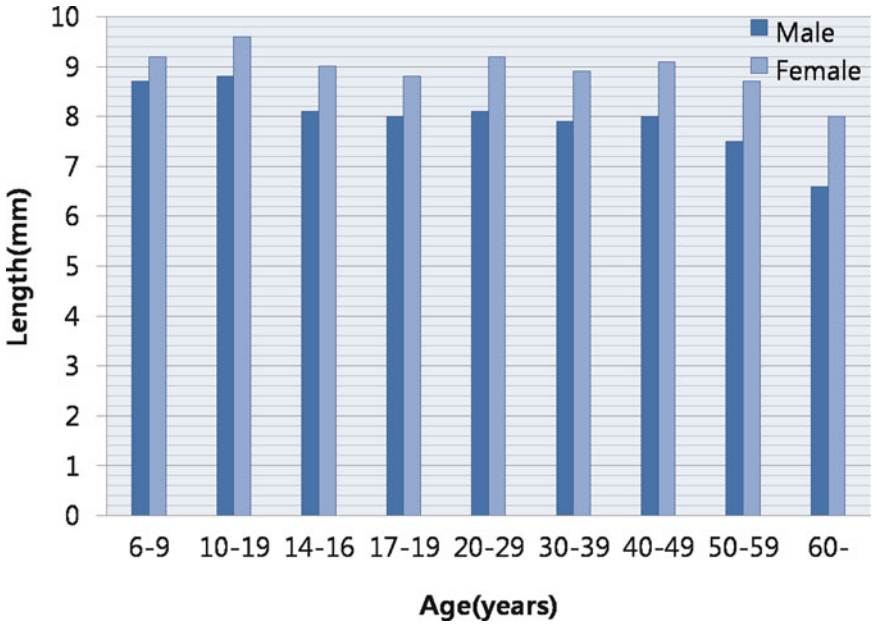

Fig. 35.2 Vertical dimension of the palpebral fissure. The vertical dimension of the palpebral fissure was 8.0 ± 1.0 mm in male subjects and 8.2 ± 1.1 mm in female subjects

palpebral fissure reached the peak value at 10 years, and showed no significant difference according to age subsequently (Noh and Choi 1981). However, this review showed that the vertical dimension of the palpebral fissure reached a specific level between 10 and 13 years of age and decreased gradually as subjects approached their fifties ($p < 0.05$).

35.5 Slant of the Palpebral Fissure

For the slant of palpebral fissure, Park et al. reported a mean value, in male and adult female subjects, of 9.5° and 10.6°, respectively, which appeared greater in male subjects than in female subjects (Park et al. 1990). This article also reported values of 8.4° in male subjects and 8.9° in female subjects, which appeared greater in female subjects than in male subjects ($p < 0.05$). Regarding the esthetic criteria, Adler suggested the same level of medial and lateral canthus at front gaze (Adler 1975). In terms of Western esthetic criteria, the lateral canthus lies slightly higher than the medial canthus, which is slightly low in the upper portion of the palpebral fissure. Park et al. reported that the slant of the palpebral fissure was a value of 8.8° (Park et al. 1990). In this review, which used a 105-mm lens to minimize distortion of photographs and maintained a 1-m distance between the camera and the examinee to prevent distortion; values of 8.4° in male subjects and 8.9° in female subjects were observed, in which female subjects showed a greater decline than male subjects. The slant of the palpebral fissure showed a peak level at 10–13 years of age. As the age increased, it showed a gradual decrease ($p < 0.05$) (Fig. 35.3).

35.6 Double Fold

A double fold is a crease which is generated when the levator palpebrae superioris is attached to pretarsal orbicularis and skin. It is observed in most Western female subjects and approximately 40% of Asian female subjects (Park and Na 1975). This article observed a double fold in 36.1%, slightly less than others. Regarding fold type, a single fold appeared in 68.9% of male subjects and 58.0% of female subjects. A double fold appeared in 30.5% of male subjects and 41.4% of female subjects, and a triple fold appeared in 0.6% of male subjects and 0.6% of female subjects. A single fold appeared more frequently in male subjects than in female subjects and vice versa with the double fold (Fig. 35.4). The size of double fold was 6.6 mm in male subjects and 6.5 mm in female subjects, with no significant difference according to sex.

35.7 Epicanthus

The epicanthus seemed to give an impression of upward slant of the palpebral fissure. It mostly appears between 3 and 6 months' gestation in the fetus in every race, and disappears before birth. However, it is said that only the Mongolians retain it after birth (Gifford 1928). Park et al. reported that the epicanthus was observed in about 45% of Asian male subjects and in approximately 62% of Asian female subjects. The younger the subjects, the higher the incidence with which it showed. The authors observed it in 51.0% of male subjects, in 49.0% of female subjects, and in 42% in total. Classified by

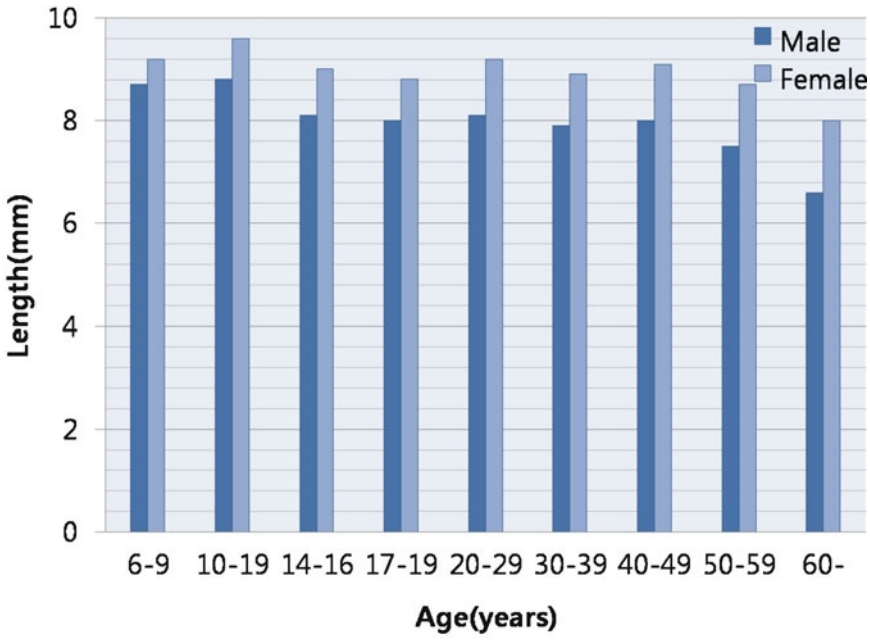

Fig. 35.3 Slant of the palpebral fissure. The slant of the palpebral fissure was 7.9° ± 2.4° in male subjects and 8.8° ± 2.3° in female subjects

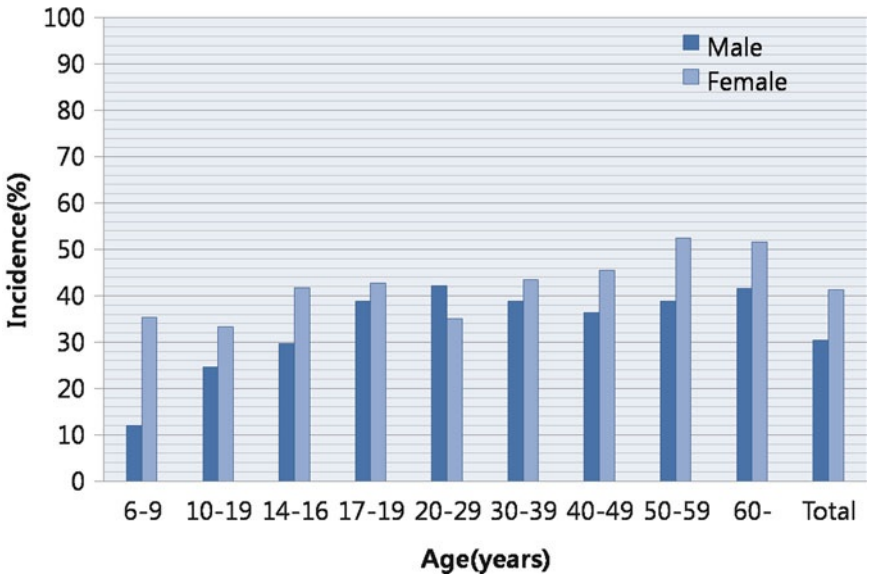

Fig. 35.4 Incidence of double fold. A double fold was found in 36.1%, in total, with a higher incidence in females (41.3%)

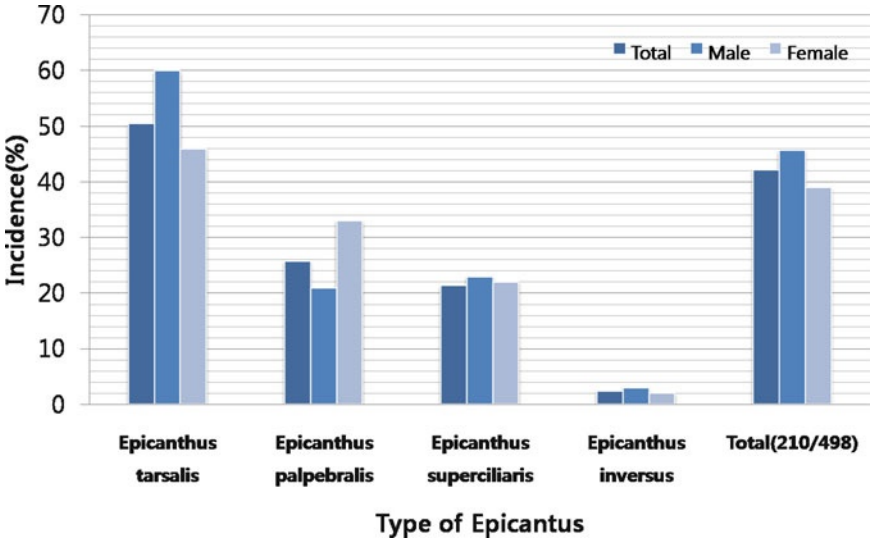

Fig. 35.5 Incidence and type of epicanthus. Epicanthus appeared 42.2% in total, and the most common type was epicanthus tarsalis. The growth pattern can be classified as continuously increasing, decreasing, and stationary after reaching the peak level

age, more than 90% of both male and female subjects younger than 10 years demonstrated it, and as the age increased, it disappeared gradually, and 90% was lost in those in their fifties or older. For the type of epicanthus, epicanthus tarsalis was found most frequently, with 31.3% in male subjects and 46.7% in female subjects, followed by epicanthus palpebralis, epicanthus superciliaris, and epicanthus inversus in descending order of frequency (Fig. 35.5).

35.8 Intercanthal Distance

For intercanthal distance, Kim et al. reported a mean value of 3.6 mm for female subjects between 12 and 26 years of age (Kim et al. 1985). The authors reported a mean value of 37.4 mm in male subjects and 35.9 mm in female subjects aged 21–22 years (Kim et al. 1988). Park et al. reported a mean value of 36.3 mm in male subjects and 33.4 mm in female subjects in their twenties (Park et al. 1989). Hwang et al. reported 34.0 mm for beautiful women in their twenties and 36.7 mm for average looking women (Hwang et al. 1996). Cho et al. reported mean values of 35.3 mm in male subjects and 35.5 mm in female subjects aged 18 years (Cho et al. 1993). Cho et al. reported mean values of 37.2 mm in male subjects and 35.0 mm for female subjects aged 18–27 years (Cho et al. 1989). Further, Park and Na reported that the distance increased rapidly between 1 and 4 years of age, then increased gradually, and reached its almost full-grown value at 10–14 years of age (Park and Na 1975). Park et al. reported that both male and female subjects attained the peak values of, respectively, 36.5 and 37.1 mm, at 15–19 years of age. This review also showed that both male and female subjects reached a specific level at 14–16 years of age and that their level slightly increased after their sixties ($p < 0.05$) (Fig. 35.6). It also displayed mean values of 38.4 mm in adult male subjects and 38.2 mm in adult female subjects without demonstrating statistically significant difference according to sex.

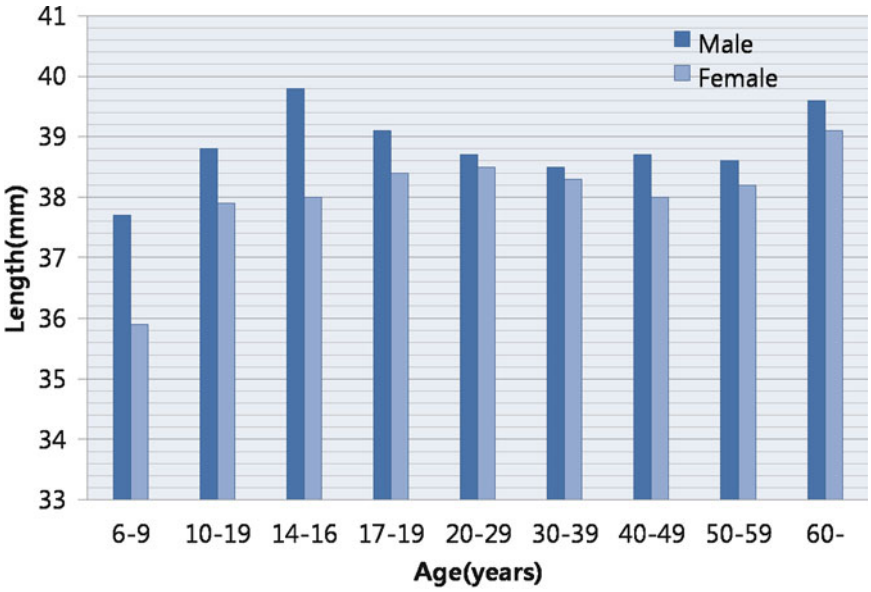

Fig. 35.6 Intercanthal distance. The intercanthal distance was 38.4 ± 3.0 mm in male subjects and 38.2 ± 2.8 mm in female subjects

35.9 Interpupillary Distance

Kim et al. reported the mean values of the interpupillary distance to be 59.9 mm in male subjects and 63.5 mm in female subjects (Kim et al. 1988). Park et al. reported mean values of 65.0 mm in male subjects and 63.2 mm in female subjects (Park et al. 1989). Hwang et al. reported a mean of 63.5 mm for beautiful women and 63.6 mm for average looking women (Hwang et al. 1996). Park et al. reported mean values of 65.8 mm in male subjects and 65.1 mm in female subjects between 20 and 24 years of age (Park et al. 1990). Cho et al. reported mean values of 69.4 mm in male subjects and 66.6 mm in female subjects, which proved greater in male subjects than in female subjects ($p < 0.05$). This review also showed that the interpupillary distance increased until 17 and 19 years of age, without change shown by age after that time (64.6 ± 2.9 mm in male subjects and 63.6 ± 2.9 mm in female subjects) (Fig. 35.7).

35.10 Vertical Dimension of Open Upper Eyelid

For the vertical dimension of upper eyelid, Kim et al. reported a mean value of approximately 18 mm in Asian male and female subjects between 12 and 26 years of age (Kim et al. 1985). For the vertical dimension of the open upper eyelid, Park et al. reported 10.3 mm in male subjects and 10.0 mm in female subjects (Park et al. 1990). This article reported mean values of 12.3 mm in male subjects and 12.5 mm in female subjects for open eyelid with no statistically significant difference according to sex. After reaching the peak at 17–19 years of age, it increased slightly after subjects reached their sixties ($p < 0.05$) (Fig. 35.8).

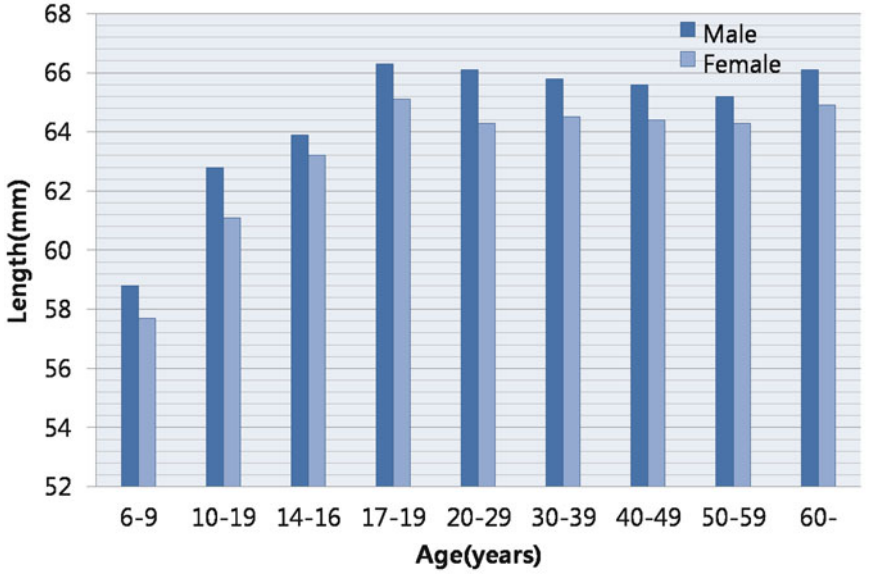

Fig. 35.7 Interpupillary distance. The interpupillary distance was 64.6 ± 2.9 mm in male subjects and 63.6 ± 2.9 in female subjects

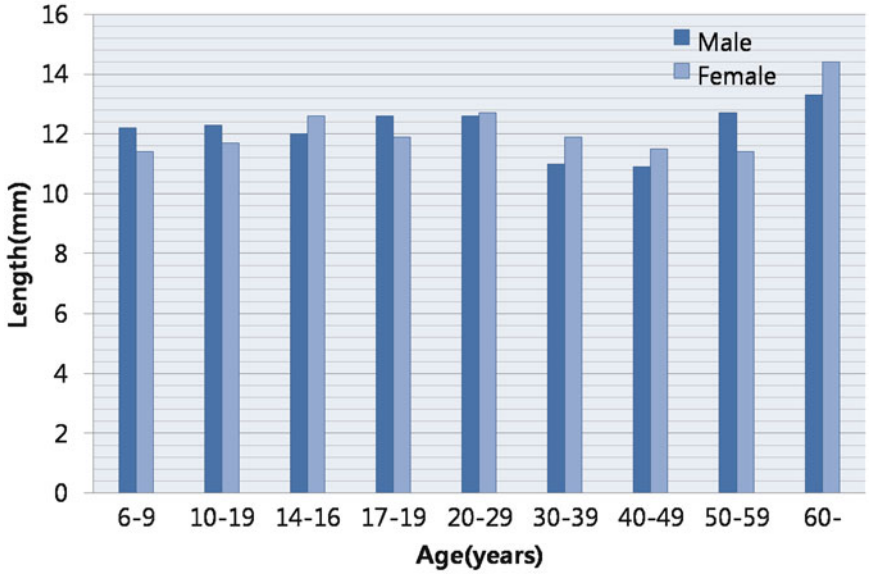

Fig. 35.8 Height of the opened upper eyelid. The height of the open upper eyelid was 12.4 ± 2.4 mm in male subjects and 12.0 ± 1.9 mm in female subjects

35.11 Applications to Other Areas of Health and Disease

In particular, for unilateral ptosis surgery, the size and shape of the normal eyelid might be used as a guide during surgery. However, for double-eyelid blepharoplasty (which is a ptosis correction surgery frequently performed, in cases of bilateral operation), the normal anthropometric value of eyelids becomes important to guide surgery.

Summary Points

- The horizontal dimension of the palpebral fissure was 27.0 ± 1.8 mm in male subjects and 26.8 ± 1.7 mm in female subjects.
- The vertical dimension of the palpebral fissure was 8.0 ± 1.0 mm in male subjects and 8.2 ± 1.1 mm in female subjects.
- The slant of the palpebral fissure was 7.9° ± 2.4° in male subjects and 8.8° ± 2.3° in female subjects.
- The height of the open upper eyelid was 12.4 ± 2.4 mm in male subjects and 12.0 ± 1.9 mm in female subjects.
- The height of the double fold in the closed eye was 6.6 mm in male subjects and 6.5 mm in female subjects.
- The intercanthal distance was 38.4 ± 3.0 mm in male subjects and 38.2 ± 2.8 mm in female subjects.
- The interpupillary distance was 64.6 ± 2.9 mm in male subjects and 63.6 ± 2.9 in female subjects.
- A double fold was found in 36.1%, in total, with higher incidence in females (41.3%).
- The epicanthus appeared in 42.2% in total, and the most common type was epicanthus tarsalis. The growth pattern can be classified as continuously increasing, decreasing, and stationary after reaching the peak level.
- The peak level of growth was attained at 10–13 years of age for the vertical dimension and the slant of palpebral fissure; at 14–16 years of age for the intercanthal distance; and at 17–19 years of age for the horizontal dimension of palpebral fissure, the height of upper eyelid, and the interpupillary distance ($p < 0.05$).

Table 35.1 Key points of anthropometry of the eyelid

The eight measured items are as follows:

1. Horizontal dimension of the palpebral fissure (HDPfi): the distance between the medial canthus and the lateral canthus.
2. Vertical dimension of the palpebral fissure (VDPfi): the distance between the open upper eyelid margin and the open lower eyelid margin.
3. Slant of the palpebral fissure: based on the line connecting the right and left medial canthus, and the angle of the line between the medial and lateral canthus of an eye.
4. Type and height of the double fold.
5. Type and height of the epicanthus.
6. Intercanthal distance (ICD): the distance between the right and left canthus.
7. Interpupillary distance (IPD): the distance between the right and left pupils.
8. Height of open upper eyelid: the perpendicular distance between the highest point of open upper eyelid margin and the lower margin of the eyebrow.

This table lists eight measured items and their definitions.

Chapter 36
Neck Circumference: Its Usage in Medicine and Biology

Bernhard Fink

Abstract Neck circumference, measured as the distance around the neck, is a simple and timesaving screening measure to identify obesity in both men and women. It is positively correlated with the components of the metabolic syndrome and obstructive sleep apnea. Furthermore, neck circumference is positively associated with traditional anthropometric measures of body circumferences and indices, such as the body mass index and the waist-to-hip ratio, and other physiological and biochemical measures of cardiovascular risk. It is positively correlated with systolic and diastolic blood pressure, triglycerides and glucose levels and has been used as a clinical predictor of menstrual irregularity, hirsutism, infertility, and insulin resistance. This has led to and increased interest in this measure with regard to its usefulness in clinical and epidemiological studies, but also from biological studies, interested in the possibility of an early predisposition for cardiovascular risk through early sex-steroid exposure. This chapter briefly reviews the reported associations with neck circumference and suggests possible applications also in non-clinical studies.

Abbreviations

AHI	Apnea/hypopnea index
BMI	Body-mass index
CHD	Coronary heart disease
FAI	Free androgen index
MS	Metabolic syndrome
MI	Myocardial infarction
NC	Neck circumference
NHR	Neck-to-height ratio
OHS	Obesity hypoventilation syndrome
OSA	Obstructive sleep apnea
PCOS	Polycystic ovary syndrome
PIH	Pregnancy-induced hypertension
T	Testosterone
WC	Waist circumference
WHR	Waist-to-hip ratio

36.1 Introduction

Among the several anthropometric measures, such as body mass index (BMI, kg/m²) and waist-to-hip ratio (WHR, waist circumference divided by hip circumference), most of which have been shown to be increased in people suffering from metabolic syndrome (MS) and obstructive sleep apnea (OSA), neck circumference (NC) appears to be another simple screening measure. The usefulness of this measure has been demonstrated in recent reports using relatively large samples of obese and overweight patients (Ben-Noun et al. 2001; Ben-Noun and Laor 2003, 2006), and some reports found NC even superior in predicting MS, than, for example, measures of waist circumference (WC) (Onat et al. 2009). In addition to the reported relationship between NC and cardiovascular risk factors (e.g., Ben-Noun and Laor 2003, 2006), increased NC has also been observed in patients who suffer from obstructive sleep apnea (Davies et al. 1992; Pływaczewski et al. 2008; but see Dancey et al. 2003).

Further examination of potential risk factors for the development of MS and OSA revealed that NC was also a good clinical predictor of menstrual irregularity, hirsutism, infertility, insulin resistance, and polycystic ovary syndrome (PCOS) in obese pre-menopausal women (Dixson and O'Brien 2002). These results have also motivated non-clinical studies to study associations between NC and other anthropometric traits, such as the digit ratio 2D:4D, that is, the ratio of the lengths of the second and fourth digits, a supposed proxy of prenatal and adult concentrations of testosterone (T) (Manning et al. 1998) and implications for the risk of coronary heart disease (CHD) (Fink et al. 2006). While the number of clinical studies that have used NC in examining predictors of obesity and sleep apnea is still low compared to those that report the use of traditional anthropometric measures, such as BMI and WHR, they support the usefulness of this measure without other more complex techniques, particularly when examining larger groups of patients.

36.2 The Measurement of Neck Circumference

Neck circumference is defined as the measure of the distance around the neck. It is usually measured with a tape measure (see Fig. 36.1a). A simple (household) tape measure may suffice to measure NC accurately, but some companies (e.g., Seca® and Prestige Medical®) provide quite useful retractable

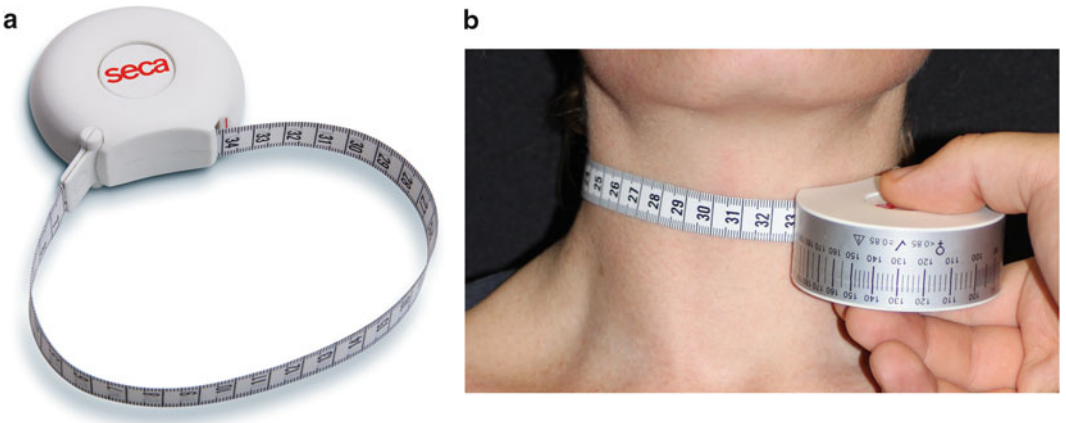

Fig. 36.1 (**a**) Retractable non-stretching tape measure for determining body circumference. Image courtesy of Seca® GmbH & Co. KG, Germany. (**b**) Image of neck circumference measurement. (Image courtesy of B. Fink, University of Goettingen)

Table 36.1 Measuring neck circumference

- Use a non-stretching tape measure.
- The head should be held erect with the eye facing the measurer.
- Measure at the most prominent portion of the thyroid cartilage (Adam's apple).
- Carefully follow the surface of the skin.

tape measures, usually made of non-stretching Teflon, with increments down to 0.1 cm or 1/16 inch, for measuring circumference. For careful and proper assessment, the participant (or patient) should be instructed to hold the neck erect (in the resting position) with the eyes facing forward to the measurer (see Fig. 36.1b). While NC is basically an easy-to-measure trait, some caveats remain. The neck can be very broad because of excessive prominence of the trapezius, skin folds or webs. In the presence of such anatomy, the tape measure should carefully follow the surface of the skin to reflect the circumference accurately. The horizontal plane at which measurement occurs should be carefully selected at the most prominent portion of the thyroid cartilage (Adam's apple) (Hall et al. 1989) (Table 36.1).

36.3 Neck Circumference as a Measure of Central Obesity

Body obesity and MS, defined by a cluster of clinical conditions associated with an enhanced propensity toward the development of type 2 diabetes and hypertension, are considered as a major risk factor for CHD, which itself is associated with an increased risk for stroke and early mortality (Cruz and Goran 2004; Jiamsripong et al. 2008a, b) (Table 36.2).

There are numerous methods of assessing obesity. In terms of anthropometrics, some of the most frequently used and reported measures associated with obesity are BMI and WC. For example, Balkau et al. (2007) reported measures of BMI and WC in a total of 168,000 primary care patients from 63 countries, aged 18–80 years, and found a significant increase of both measures in patients with CHD. However, there is considerable concern in the literature with regard to the optimum cut-off points of these anthropometric indices in predicting cardiovascular risk factors, also because of variation in definitions for different ethnic groups (e.g., Bouguerra et al. 2007; Al-Lawati and Jousilahti 2008).

While by tradition, BMI has been the most widely used index to determine the prevalence of overweight in, and across, populations as well as associated risk factors, most studies nowadays use more than one anthropometric measure to evaluate central obesity. In addition to BMI and WC, WHR, and to a lesser extent, the waist-to-height ratio (sometimes also referred to as waist-to-stature ratio, WSR), are the most prominent among the indices mentioned earlier. It is generally concluded that these measures perform the same way as indicators of body fatness, but is has also been reported that they are more closely related to each other than with percentage body fat (as measured by measured by dual-energy X-ray absorptiometry) (Flegal et al. 2009). In the attempt to determine whether BMI, WC, or percent body fat best predicts MS, Shen et al. (2006) evaluated these measures in 1,010 healthy white and African-American men and women. It was found that WC could significantly predict health risk indicators, followed by BMI, but no significant prediction could be made through the body fat percentage (Table 36.3).

There will probably be an ongoing controversy over the usefulness of the various anthropometric indices in predicting obesity and the associated health risks, including morbidity and mortality, which might not be resolved eventually in favor of only one measure. A more plausible scenario and

Table 36.2 Key features of the metabolic syndrome

- Central obesity (visceral adiposity with overweight and increased fat deposits mainly around the waist)
- High blood pressure
- Fasting hyperglycemia (diabetes mellitus type 2 or impaired fasting glucose, impaired glucose tolerance, or insulin resistance)
- Decreased HDL cholesterol
- Elevated triglycerides

valuable advice is perhaps the consideration of one or another measure (or also the combination of some) with reference to the study question in focus. While some clinical setting may allow a more detailed assessment of subjects, physicians and scientists working in the field on demographic, epidemiological or anthropological questions may face time constraints, thus seeking a simple, quick to asses, but also accurate measure of obesity.

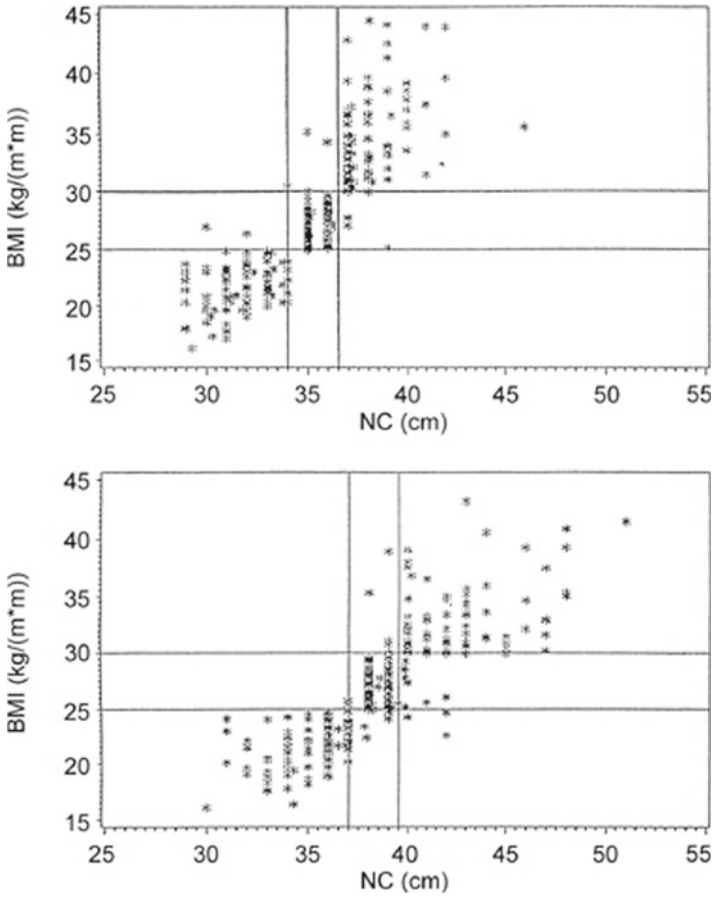

Fig. 36.2 Optimum cut-off points of NC as reported by Ben-Noun et al. (2001). NC of ≥37 cm for men and ≥34 cm for women identified most of the subjects with a BMI ≥25. NC of ≥39.5 cm for men and ≥36.5 cm for women identified most of the subjects with a BMI ≥30. (Adapted with permission from Macmillan Publishers Ltd)

Ben-Noun et al. (2001) and Ben Noun and Laor (2003, 2004, 2006) suggested that NC could be such a measure. In their first study (Ben-Noun et al. 2001), they aimed to identify overweight or obese patients solely by measuring the circumference of the neck. In a sample of 460 men and 519 women, NC was measured along with circumferences of the waist and hip, and age, height and weight were recorded to subsequently calculate BMI. In both, men and women, NC correlated positively and significantly with age, weight, and waist and hip circumferences, and also with indices of BMI and WHR in both men and women. Moreover, it was found that NC greater than or equal to 37 cm in men, and 34 cm in women, was the best cut-off level for determining the subjects with a BMI greater than or equal to 25, and an NC greater than or equal to 39.5 cm in men, and greater than or equal to 36.5 cm in women, performed best in identifying subjects with a BMI greater than or equal to 30 (Fig. 36.2). More recently, Onat et al. (2009) reported similar cut-off points of 39 cm in men and 35 cm and 35.5 cm, respectively, in women as corresponding to MS and OSA.

Ben-Noun and Laor (2003) studied NC in relation to potential risk factors for CHD, that is, anthropometric indices (BMI and WHR), systolic and diastolic blood pressure (SBP and DBP), and biochemical measures of lipoprotein, glucose, cholesterol, and uric acid levels. Higher NC was

associated with higher values and levels of all measures, leading the authors to conclude that NC is correlated positively with components of MS, and thus likely to increase CHD. In a follow-up study, Ben-Noun and Laor (2004) further examined the associations of NC with SBP and DBP, in a sample of 155 men and 209 women with no known major medical conditions. NC was positively and significantly correlated with changes in SBP and DBP in both men and women. Furthermore, significant positive associations of NC were also found with other components of MS, such as triglycerides and glucose levels, which again leads to the conclusion that NC is a useful measure in predicting MS and cardiovascular risk (for a similar study, see Ben-Noun and Laor 2006). Severe obesity, however, is associated with physiological and biochemical changes, including androgen excess and insulin resistance, which are also features of, for example, the polycystic ovary syndrome (PCOS) in women (Table 36.4).

Dixson and O'Brien (2002) examined these relationships in combination with anthropometric measures by studying their changes in a sample of 107 severely obese pre-menopausal women after 1-year post-obesity surgery. NC and age were independent predictors of higher free androgen index (FAI) by explaining 36% of the variability, while WHR was not a significant predictor. NC was further a clinical predictor of menstrual irregularity, hirsutism, infertility, insulin resistance, and the PCOS, with NC lesser than 39 cm, 39–42 cm, and greater than 42 cm, reflecting, respectively, a low, intermediate, and high risk for developing PCOS and MS. Similar observations were made by Laakso

et al. (2002), who tested the association of NC with abdominal and general obesity, as well as with insulin resistance-related factors, showing that neck NC was associated with measures of metabolic disorders (e.g., blood lipids, insulin, and glucose concentrations) related to insulin resistance. Taken together, NC seems to be a good predictive measure of hyperinsulinemia and raised androgens in obese pre-menopausal women, thus making it additionally useful in clinical screening for persons at an enhanced risk for insulin resistance.

36.4 Neck Circumference and Obstructive Sleep Apnea

Obesity is also a risk factor for obstructive sleep apnea (OSA) and the obesity hypoventilation syndrome (OHS), leading to increased morbidity and mortality, with reduced quality of life (Table 36.5).

Katz et al. (1990) provided the first study of the association between NC and sleep apnea (as defined by the apnea/hypopnea index, AHI). They found that NC (together with BMI) accounted for 39% of the variability in AHI, and reasoned that the association of obesity and OSA is via fat deposition in the neck (see also Davies et al. on the combination of features and symptoms in the clinical diagnosis of OSA).

The current literature supports this early observation and the suggestion that NC shows the strongest association with OSA (but see Onat et al. (2009) on the superiority of NC over WC in Turkish men, but not women; and Pływaczewski et al. (2008) on comparison to BMI). Moreover, the frequency and severity of sleep apnea in the sleep clinic population seems to be greater in men than in women. With reference to the original suggestion by Katz et al. (1990), there is some support for the claim of a sex-dependent fat distribution in the neck from magnet resonance imaging. Whittle et al. (1999) reported that the neck soft-tissue volume was greater in men than women, although no significant difference was observed for the volume of fat (Fig. 36.3).

More recently, Dancey et al. (2003) investigated this observation in relation to the gender differences in NC. Sleep apnea was examined together with NC in a sample of 2,753 men and 1,189 women. Men had significantly higher AHI and NC, although the difference in NC was less pronounced when adjusted for height (neck-to-height ratio, NHR). However, NHR was found to be the best predictor of AHI, accounting for about 19% of the variability, and a higher slope in men than women.

Mortimore et al. (1998) compared anthropometric measures of BMI and NC in addition to resonance images of the neck in obese and non-obese age-matched subjects with sleep apnea, and found excess fat deposition in even relatively non-obese patients with sleep apnea, especially anterolateral to the upper airway (Fig. 36.4a, b).

The effect of neck circumference on symptoms of OSA may be even increased in physically demanding situations accompanied with hormonal changes, such as pregnancy. Ursavas et al. (2008) investigated self-reported snoring in pregnant women, and the relationship of snoring, obesity and

Table 36.5 Key features of obstructive sleep apnea

- Sleep-disordered breathing
- Loud snoring that stops when a person tries to breathe
- Hypersomnia (excessive amounts of sleepiness, also during the daytime)
- Often associated with obesity, large neck circumference, mood swings or depression, and concentration difficulties

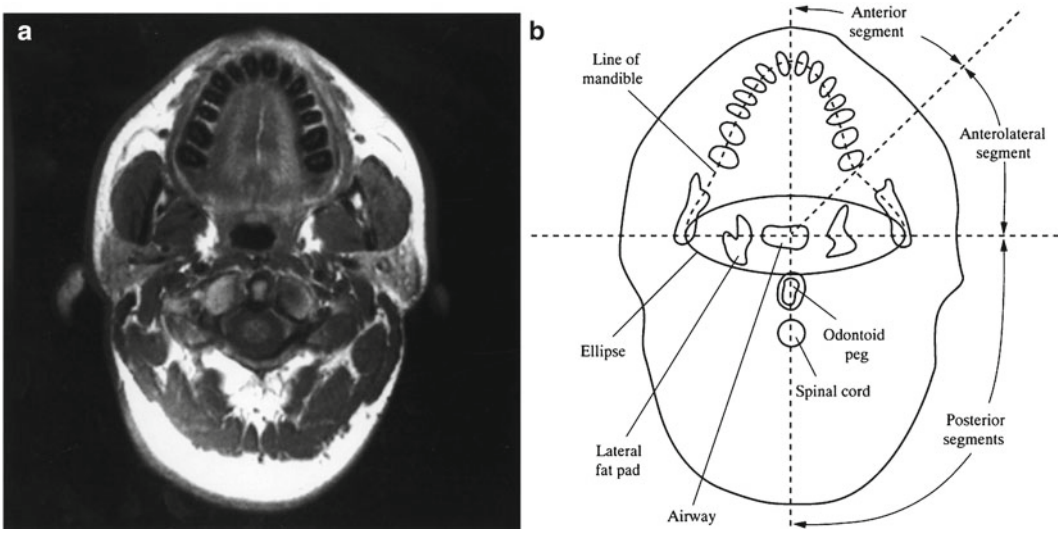

Fig. 36.3 (**a**) Representative transverse T1-weighted magnetic resonance image (MRI) of the neck of a normal man. (**b**) Schematic representation of the MRI illustrating the segmental divisions used for analysis of neck fat volumes, the subdivision of the anterior and anterolateral segments by the line of the mandible, and the position of the ellipse used for analysis of fat volumes close to the airway. NC to pregnancy-induced hypertension (PIH) and preeclampsia in a sample of 469 pregnant and 208 (age-matched) non-pregnant women. It was found that habitual snoring was increased in pregnant women, and that NC, age, smoking during pregnancy, and weight before delivery were independent risk factors for its prevalence.

36.5 Applications to Other Areas of Health and Disease

Most studies on the significance of NC have considered the predictive nature and usefulness of this trait (compared to or in combination with traditional anthropometric measures) in the clinical study of cardiovascular risk factors and sleep apnea. Given that NC has turned out to be a valuable measure, which not only shows strong associations with other body indices (such as WHR and BMI), but also correlations with physiological and biochemical measures, it may serve as additional measure for medical, epidemiological, and social anthropological studies. However, with the rise of the evolutionary biological and psychological study of human physical appearance (see for review Fink and Penton-Voak, Gangestad and Scheyd 2005), health, and its perception, NC researches in related disciplines may find it to be an additional (and perhaps less offensive) measure than some subjects consider BMI and WHR to evaluate physical condition.

The fact that NC shows considerable sexual dimorphism may be of particular interest in this context. Some 15 years ago, Antoszewska and Wolański (1992) examined 37 somatic traits and ratios in a sample of 1,034 newborns, and compared them with those of adults. Head and neck showed a moderate sexual dimorphism, like, for example, the length of the upper extremities or the breadth of the hips. Sexual differences in physical measures were basically more pronounced in adults than in newborns. While studies use MRI to capture possible differences in fat deposition, recent research also considered anthropometrical properties of the head and neck to explain this sexual dimorphism and accompanied sex specific syndromes. Vasavada et al. (2008) found that the geometric differences of men and women in neck anthropometry (an average of 9–16% smaller in females) were even greater than those in head anthropometry (an average of 3–6% smaller in females) and that there were also significant strength differences. Hence, it was concluded that male necks are not simply scaled versions of female necks, which should be considered when studying sex differences in neck-related disorders.

While there is corroborating evidence for the sexual dimorphism of the neck, which is present even in newborns, and this relates to the neck's geometry as well as to the differences in soft tissue and possibly fat depositions, the cause of this dimorphism remains to be investigated. Sex differences in body composition and the expression of physical traits are well known in humans, although their early development is rarely considered (however, see, for a recent study, Fields et al. 2009). One measure that has received considerable attention in recent years in medicine and biology is the ratio of the lengths of the second (index finger) and fourth (ring finger) digits, also referred to as 2D:4D or digit ratio, a supposed proxy of prenatal and adult concentrations of T (Manning et al. 1998). Digit ratio has been related to numerous physical and behavioral traits that show sex differences, including face and body shape, and anthropometric measures. It is beyond the scope of this chapter to outline the evidence in detail (however, see Manning, Chapter 48). However, digit ratio has also been studied in relation to NC, based on the possibility that T protects men against myocardial infarction (MI). Fink et al. (2006) investigated associations between 2D:4D ratios and NC in a sample of 127 men and 117 women and found positive and significant correlations in men, but not in women, after controlling for the effect of BMI, that is, men with higher 2D:4D (indicating less T) had thicker necks. Given that 2D:4D is supposed to be determined in utero, the link between digit ratio and NC suggests the possibility of a predisposition for men toward CHD via 2D:4D as proxy to early sex-steroid exposure. If this association can be confirmed also in clinical studies, it will be interesting to see how well other factors that characterize MS, such as obesity, insulin resistance, hyperlipidemia, and hypertension, all of which increase the risk of CHD, correlate with digit ratio. Such a link would argue for the significance of early sex-steroid exposure on the development of CHD and shed further light on sex differences in its prevalence.

Summary Points

- Neck circumference is the measure of the distance around the neck.
- Neck circumference correlates positively with age, weight, and waist and hip circumferences, and also with indices of body mass index and waist-to-hip ratio in both men and women.
- Men – on average – have larger neck circumference than women.
- Men with a neck circumference ≥37 cm and women with a neck circumference ≥34 cm are considered overweight and men with a neck circumference ≥39.5 cm and women with a neck circumference ≥36.5 cm are obese.
- Neck circumference correlates with some physiological and biochemical measures associated with the metabolic syndrome and risk factors in coronary heart disease.
- Neck circumference is positively associated with systolic and diastolic blood pressure, triglycerides and glucose levels.
- Neck circumference is a clinical predictor of menstrual irregularity, hirsutism, infertility, and insulin resistance.
- Neck circumference shows strong associations with obstructive sleep apnea.
- Obstructive sleep apnea patients have excess fat deposition, especially anterolateral to the upper airway.
- Neck circumference is a risk factor for pregnancy-induced hypertension.
- Neck circumference correlates with digit ratio (2D:4D), a proxy of prenatal and adult concentrations of testosterone.

Chapter 37
Prediction of Upper and Lower Extremity Tissue Masses Using Surface Anthropometric Measures and DXA

David M. Andrews and Timothy A. Burkhart

Abstract This chapter reviews the few studies that have reported regression equations that enable the prediction of upper and lower extremity soft and rigid tissue masses of living people, including lean (muscle), fat, and bone mineral content, from surface anthropometric measures such as segment lengths, breadths, circumferences, and skinfolds. Predicted tissue masses from the upper extremity segments (arm, forearm, forearm and hand) and lower extremity segments (thigh, leg, leg and foot) were validated against those obtained from full body Dual Energy X-ray Absorptiometry (DXA) scans. Twenty-four tissue mass prediction equations for the upper and lower extremity segments have been compiled which are highly predictive of measured tissue masses from DXA, with adjusted R^2 values ranging from 0.67 to 0.97. The studies that have evaluated the reliability of the methods used to develop the prediction equations are also reviewed. Almost 90% of the between- and 100% of the within-measurer reliability coefficients for the segment anthropometric measurements needed as inputs to the tissue mass prediction equations were found to be greater than 0.75 in magnitude, signifying good to excellent reliability. The reliability of manually segmenting tissue masses of the upper and lower extremities from DXA scans using analyst-assigned regions of interest was also assessed, and values were very high, ranging in magnitude from 0.991 to 1.000 across all tissue types and segments. In general, the low errors in predicted tissue masses and high reliability coefficients for the measured anthropometric measurements reported herein indicate that the methods used to develop and validate the tissue mass prediction equations are robust and appropriate for a variety of applications involving living people.

37.1 Introduction

Impacts to the upper and lower extremities, which are common during sport and recreational activities such as in-line skating and running, have been associated with musculoskeletal injuries and disorders in humans, including fractures to the distal upper extremity (Jaffe et al. 1997), joint and back pain (Light et al. 1980; Voloshin and Wosk 1982), articular cartilage degeneration and osteoarthritis (Radin et al. 1973), and tibial stress fractures (Milner et al. 2006).

In order to better understand the mechanisms by which injuries occur to the body during such activities, numerous biomechanical models have been developed and proven useful. However, traditional rigid link-segment and mass/spring/damper biomechanical models do not incorporate both soft (e.g., fat, muscle, and skin) and rigid (bone) tissues of body segments, even though the effect that soft tissues have on impact dynamics has been described in the literature (Gruber et al. 1998; Pain and Challis, 2006).

Widespread incorporation of soft and rigid tissues into biomechanical models has been limited in part because of the lack of tissue-specific mass data in the literature for living subjects. These types of data have traditionally been obtained from cadaver segmentation studies (e.g., Clarys et al. 1999), but the application of these limited data to living subjects, particularly younger adults and women, is questionable. Imaging technologies, such as Dual Energy X-ray Absorptiometry (DXA) (Table 37.1), have been shown to be valid and reliable for body composition analysis (Haarbo et al. 1991; Durkin et al. 2002; Ball et al. 2004), but the cost of scanning, and the limited availability of DXA for research applications can be significant hurdles to overcome, for many researchers.

The limitations associated with obtaining person-specific tissue masses punctuate the importance of having an inexpensive, readily accessible, accurate, and reliable method of quantifying tissue masses in vivo, in order to improve our understanding of injury mechanisms and to facilitate biomechanical modeling of impact applications.

It is reasonable to assume that the magnitude of the different tissue masses within body segments is related to the dimensions of those segments. Consequently, if there was a strong relationship between surface anthropometric measurements and the internal tissue masses for each segment, then, obtaining person-specific tissue masses for integrating into biomechanical models would facilitate the evaluation of applied biomechanical problems in order to quantify the associated risk and to develop strategies for injury prevention.

To date, an extensive array of upper and lower extremity surface anthropometric measures, including segment lengths, breadths, circumferences, and skinfolds have been taken from 168 healthy, young men and women, and used to develop in vivo soft and rigid tissue mass prediction equations for the upper and lower extremities (Holmes et al. 2005; Arthurs and Andrews 2009)

Table 37.1 Key features of dual energy X-ray absorptiometry (DXA)

1. Dual energy X-ray absorptiometry is a diagnostic imaging technique used to measure bone density and body composition
2. Two X-ray beams of alternating high (140 keV) and low (70 keV) intensity are passed through the body
3. Tissue masses including lean tissue (muscle and skin), fat tissue, and bone mineral content are calculated by measuring the attenuation of the beams and incorporating the calibration coefficients for the different tissues
4. The patient dose from DXA (approximately 0.37 μSv) is relatively low compared to the annual dose from natural background radiation (2,400 μSv per annum) and from other imaging techniques, such as chest X-rays (50 μSv) and lateral spine X-rays (820 μSv)

This table lists the key features of DXA, including the system for attaining body composition masses
keV kiloelectron volt, measures the intensity of energy, where 1 keV = 1×10^{-16} J, μSv micro Siverts, a unit of radiation

Table 37.2 Key features of regression analysis and prediction equations

1. Regression analysis is a statistical technique that is used to show the relationship between variables
2. In multiple linear regressions, the independent relationship that each descriptor (input) variable has on the dependent (output) variable is investigated
3. The technique is based on finding the line that best fits the data in the form of $y = b + m_1x_1 + ...m_nx_n$
4. In general, variables are included or removed from the equation until the addition or subtraction of variables does not result in an improvement in the explained variance (R^2) of the output variable
5. Prediction equations are validated by calculating the error and relationship between a gold standard measurement of the output variable and the value of the variable calculated from the prediction equation
6. A limitation of prediction equations is that they can only be used on populations with similar characteristics to the population used to generate the equations

This table lists the key features of regression analysis and the steps involved in creating prediction equations
y the output variable, b the y intercept or constant, m_1 the slope (i.e., prediction equation coefficient) of the line that describes the relationship between the first input variable x_1 and the output variable y, m_n the slope (i.e., prediction equation coefficient) of the line that describes the relationship between the n^{th} input variable x_n and the output variable y

(Table 37.2). The following chapter summarizes the procedures used to develop and validate the tissue mass equations using DXA, and provides a compilation of the prediction equations that currently exist. The reliability of the measurement methods used to collect the surface anthropometric measurements needed as inputs into the prediction equations, and of the manual segmentation of body segments from the DXA scans using regions of interest (ROIs) by trained analysts, is also presented.

37.2 Practical Methods and Techniques

37.2.1 Tissue Mass Prediction Equations from Anthropometric Measurements

Numerous equations have been developed over the years for the purpose of determining body composition (Clarys and Marfell-Jones 1986b). However, only a few have used DXA as a reference method for generating and validating equations that predict in vivo soft and rigid tissue masses of the segments of the upper and lower extremities (Holmes et al. 2005; Arthurs and Andrews 2009). The basis for these equations is an array of surface anthropometric measurements of the upper and lower extremities, including segment lengths, breadths, circumferences, and skinfolds.

37.2.1.1 Participants

Tissue mass prediction equations were developed in two separate studies: one for the upper extremities (Arthurs and Andrews 2009) and one for the lower extremities (Holmes et al. 2005). A total of 168 healthy, young participants (upper extremities: 50 M, 50 F; 21.8 (6.2) years old, 70.4 (9.5) kg, 1.71 (1.94) m; lower extremities: 26 M, 42 F; 21.9 (2.6) years old, 65.4 (10.6) kg, 1.69 (0.09) m) were measured and scanned using DXA.

In order to facilitate the development and validation of the tissue mass prediction equations, participants were randomly assigned to two groups: a generation sample used to develop the prediction equations (Arthurs and Andrews (2009): $n = 76$: 38 M, 38 F; Holmes et al. (2005): $n = 52$: 20 M, 32 F), and an independent validation sample used to assess their accuracy (Arthurs and Andrews (2009): $n = 24$: 12 M, 12 F; Holmes et al. (2005): $n = 16$; 6 M, 10 F).

37.2.1.2 Surface Anthropometric Measurements

Comprehensive bilateral anthropometric measurements of the upper and lower extremities were taken from participants by trained measurers while they stood in anatomical position in a private room near where the DXA scans were performed within the hospital facilities. A total of six lengths, six circumferences, eight breadths, and four skinfolds were taken from each of the upper and lower extremities, using standard anthropometric measuring equipment, including flexible measuring tapes, anthropometers (Layfayette Instrument Company, Layfayette, IN), and skinfold calipers (Slimguide, Creative Health Products, Plymouth, MI). A full list of the measurements taken can be found in Holmes et al. (2005), Burkhart et al. (2008), and Arthurs and Andrews (2009), but the subsamples of measurements (and descriptions) that were ultimately used as inputs into the tissue mass prediction equations are included in Tables 37.3 and 37.4.

37.2.1.3 DXA Scanning and Scan Analysis

The magnitudes of the actual tissue masses in the upper and lower extremity segments were quantified by having each participant undergo a whole body scan for less than 5 min using DXA (Hologic QDR 4500/W (Holmes et al. 2005), and GE Lunar Prodigy Advance (Arthurs and Andrews 2009)). Participants were scanned in a supine position with upper extremities by their sides. DXA scan files were analyzed using the software that came with each scanner. Segments on each image were manually sectioned by trained analysts using custom regions of interest (ROIs) via segmentation guidelines similar to those used on cadavers by Clarys and Marfell-Jones (1986a) and Dempster (1955). For the upper extremities, arm, forearm, and forearm and hand segments were sectioned (see Table 37.5 for sample ROIs). Comparable sections were taken for the lower extremities, resulting in thigh, leg, and leg and foot segments (Table 37.6).

37.2.1.4 Statistical Analyses

Statistical differences and homogeneity of variance between the generation and validation samples were evaluated using one-way ANOVAs and Levene's test, respectively. Pearson correlation coefficients were computed between all of the anthropometric measurements to establish if any measurements could be eliminated prior to regression analysis. The inclusion of highly correlated variables (i.e., $r \geq 0.70$)

Table 37.3 Description of the upper extremity anthropometric measurements used as prediction equation inputs (see equations in Table 37.7), and the associated mean (SD) measurements

Anthropometric variables		Description	Mean (SD) (cm)	Mean difference (cm)	
				Between	Within
$x1$	Sex	0 for females; 1 for males			
$x2$	Height (m)				
$x3$	Body mass (kg)				
$x4$	Elbow circumference	Distance around the epicondyles of the humerus	26.3 (2.7)	0.15	0.04
$x5$	Med. arm length	Distance between the axilla and the joint space just distal to the medial epicondyle of the humerus	24.4 (0.4)	1.28	0.21
$x6$	Styloid circumference	Distance around the radial and ulnar styloids	16.7 (1.6)	0.09	0.06
$x7$	Lat. forearm length	Distance between the lateral aspect of the elbow joint space and the distal aspect of the radial styloid	25.8 (1.5)	1.07	0.10
$x8$	Pos. forearm skinfold	Vertical fold on the posterior aspect of the forearm	0.6 (0.1)	0.03	0.01
$x9$	Med. forearm length	Distance between the medial aspect of the elbow joint space and the distal aspect of the ulnar styloid	25.7 (1.2)	0.13	0.28
$x10$	Pos. arm skinfold	Vertical fold on the posterior aspect of the arm midway between the acromion and olecranon processes	1.5 (0.4)	0.03	0.01
$x11$	Ant. arm skinfold	Vertical fold on the anterior aspect of the arm midway between the acromion and olecranon processes	0.8 (0.3)	0.25	0.04
$x12$	Prox. arm breadth	Distance across the arm between the axilla and deltoid	10.4 (0.7)	1.99	0.18
$x13$	Med. forearm skinfold	Vertical fold on the medial aspect of the forearm	0.6 (0.2)	0.04	0.01
$x14$	Prox. arm circumference	Distance around the arm at the level of the axilla and deltoid	31.2 (4.8)	0.87	0.26
$x15$	Mid-forearm circumference	Distance around the forearm between the elbow joint and styloids	24.0 (2.9)	1.28	0.19
$x16$	Mid-forearm breadth (M-L)	Distance across the forearm at the level of maximum circumference in the frontal plane	8.0 (1.0)	0.17	0.03

(Modified from Holmes et al. 2005; Burkhart et al. 2008; Arthurs and Andrews 2009)

The mean absolute between- and within-measurer errors (cm) for the upper extremity anthropometric measurements were found to be small overall. The variables listed (e.g., $x1$) correspond to the input variables to the tissue mass prediction equations shown in Table 37.7

Table 37.4 Description of the lower extremity anthropometric measurements used as prediction equation inputs (see equations in Table 37.7), and the associated mean (SD) measurements

Anthropometric variables		Description	Mean (SD) (cm)	Mean difference (cm)	
				Between	Within
*x*17	Prox. mid-thigh length	Distance between the anterior level of the pubis symphysis and the medial aspect of the femur midway between the superior iliac crest and the tibial plateau	24.4 (3.8)	1.76	0.58
*x*18	Lat. thigh length	Distance between the superior iliac crest and the lateral aspect of the tibial plateau	57.3 (1.7)	0.73	0.17
*x*19	Ant. mid-thigh skinfold	Vertical fold on the anterior aspect of the thigh midway between the superior iliac crest and the tibial plateau	1.9 (0.8)	0.25	0.03
*x*20	Mid-thigh breadth (M-L)	Distance across the femur and overlying tissue midway between the superior iliac crest and the tibial plateau	15.5 (0.2)	0.08	0.11
*x*21	Prox. mid-calf length	Distance between the medial aspect of the tibial plateau and the medial malleoli	16.6 (0.6)	3.94	0.56
*x*22	Med. mid-calf skinfold	Vertical fold on the medial aspect of the unweighted calf at the level of maximum circumference	1.3 (0.5)	0.04	0.04
*x*23	Mid-calf breadth (M-L)	Distance across the tibia and fibula at the level of maximum calf circumference	10.5 (0.0)	0.03	0.07
*x*24	Prox. thigh circumference	Distance around the femur and overlying tissue just inferior to the gluteal fold	58.5 (0.6)	1.15	0.19
*x*25	Mid-thigh circumference	Distance around the femur and overlying tissues midway between the superior iliac crest and the tibial plateau	53.8 (1.3)	0.58	0.73
*x*26	Mid-thigh breadth (A-P)	Distance across the femur midway between the superior iliac crest and the tibial plateau in the sagital plane	16.8 (0.6)	0.14	0.22
*x*27	Knee circumference	Distance around the outmost projections of the tibia	33.9 (3.4)	0.43	0.10
*x*28	Mid-calf breadth (A-P)	Distance across the tibia and fibula at the level of maximum calf circumference	10.9 (0.3)	1.35	0.03
*x*29	Malleoli breadth	Distance between the most lateral and medial projections of the tibia and fibula	6.9 (0.7)	0.19	0.03
*x*30	Lateral leg length	Distance between the lateral aspect of the tibial plateau and the inferior base of the lateral malleoli	41.8 (2.1)	0.58	0.47
*x*31	Malleoli circumference	Distance around the most lateral and medial projections of the tibia and fibula	25.6 (2.1)	0.19	0.03
*x*32	Ankle circumference	Distance around the tibia and fibula, just superior to the malleoli	26.5 (1.6)	0.85	0.22

Modified from Burkhart et al. (2009)
The method of lower extremity manual segmentation was found to be highly reliable between and within measurers. Reliability was assessed using intra-class correlation coefficients (ICC) with high reliability occurring at an ICC of ≥0.75

was assessed in terms of how difficult and reliable (Burkhart et al. 2008) they were to collect. Prediction equations were then developed for wobbling mass (WM), bone mineral content (BMC), fat mass (FM), and lean mass (LM) for the individual upper and lower extremity segments using forward/backward multivariate linear regression analysis. Anthropometric measurements were added and eliminated via the regression analyses until the final models that explained the most variance were generated.

37.2.1.5 Prediction Equation Accuracy

Anthropometric data from the independent group of participants in the validation sample were input into the developed equations to assess equation accuracy. Accuracy of the predicted tissue masses was assessed via absolute errors (g) and percentage (%) errors with respect to the measured tissue masses from DXA. Simple linear regression was performed to quantify the amount of variance (R^2 values) in measured tissue masses explained by the predicted masses.

37.2.2 Reliability of Measurement Methods

Two studies are reported here that determined the between- and within-measurer reliability of the upper and lower extremity anthropometric measurements needed to develop the tissue mass prediction equations described herein. Between- and within-measurer reliability was also quantified for the process of manually segmenting the upper and lower extremities from DXA scans using the ROI option available in the scan software.

37.2.2.1 Surface Anthropometric Measurements

Fifty healthy, young adults (25 M, 25 F; 22.5 (2.79) years old, 72.3 (13.3) kg, 1.72 (0.09) m) were recruited from the University of Windsor student population. Anthropometric measurements, including six lengths, six circumferences, eight breadths, and four skinfold thicknesses, were taken from the right upper and lower extremities, by two trained measurers using the standard anthropometric measuring equipment described previously (flexible measuring tape, anthropometer, and skinfold calipers). A full list of the measurements taken can be found in Burkhart et al. (2008), but a sample of the measurements and the descriptions that incorporate the anatomical landmarks used to measure them, are included in Tables 37.3 and 37.4. Prior to measurement, anatomical landmarks were identified using 0.64 cm diameter colored stickers, as participants stood in anatomical position. After all anthropometric measurements were recorded, the stickers were removed, and the procedure was repeated by the same measurer without reference to the first set of measurements. Separately, and without feedback, the second measurer repeated the measurement protocol.

37.2.2.2 Manual Segmentation from DXA Scans

Using enCORE software (2006, GE Healthcare, v. 10.51.006), custom ROIs were traced manually over the DXA scan images by three trained measurers to segment the upper and lower extremities of the 100 participants described in Arthur and Andrews (2009). Sample ROIs for the upper and lower extremities are included in Tables 37.5 and 37.6, respectively. The criteria for determining the ROI borders were adapted from the segmentation methods presented by Clarys and Marfell-Jones (1986a) and Dempster (1955). The measurers segmented each segment twice independently using the original DXA scans (i.e., no ROIs or personal information were included on the scans to help the measurers). Segmentations for all participants were completed by each measurer before repeating the procedure, and the order in which the measurers segmented the upper and lower extremities was randomized. Segment tissue masses, including WM, BMC, FM, and LM, from within each ROI were recorded for analysis.

37.2.2.3 Statistical Analyses

Errors in tissue masses were expressed as percentage (%) errors (the difference in tissue masses between trials (within-measurer error) and between measurers (between-measurer error), divided by the mean tissue masses of each segment (Burkhart et al. 2008)). Intraclass correlation coefficients (ICCs) were used to quantify between- and within-measurer reliability. Good to excellent reliability was accepted for ICCs ≥ 0.75 (Portney and Watkins 2000).

37.3 Results

37.3.1 Tissue Mass Prediction Equations from Anthropometric Measurements

The generation and validation samples for the upper and lower extremities were compared and standard data preparation techniques were utilized in order to reduce the number of input variables prior to multiple regression analysis (see Statistical Analyses section above).

A total of 24 tissue mass prediction equations were generated for the upper and lower extremities (4 tissues × 6 segments) (Table 37.7) from a total of 32 anthropometric variables, including sex,

Modified from Holmes et al. (2005) and Arthurs and Andrews (2009)
The small absolute (g) and percentage (%) errors combined with the high agreement (Adj. R^2) between the actual (measured from DXA) and predicted (from tissue mass equations) tissue masses validate the use of prediction equations for calculating segmental bone mineral content, fat mass, and lean mass of the upper and lower extremities

height, and body mass (Tables 37.3 and 37.4). Equations with the lowest number of predictor variables that explained the most variance in tissue mass outputs (highest adjusted R^2) comprised the final regression models. The final equations incorporated three to eight variables and exhibited high adjusted R^2 values, ranging from 0.84 to 0.97 and 0.67 to 0.92 for the upper and lower extremities, respectively.

The mean absolute errors between the predicted and the measured tissue masses were small in general, ranging from < 1.0 g for several tissues in the upper extremity, to just over 270 g for the FM of the thigh (Table 37.8). Mean percent errors ranged from 0.1% to 12.5% across both extremities, with only 2 of 24 error measures > 10.0% in magnitude. The predicted and measured tissue masses were highly correlated in general with strong linear relationships and high R^2 values ranging from 0.68 to 0.97 and 0.49 to 0.95, for the upper and lower extremity segments, respectively (Table 37.8).

37.3.2 Reliability of Measurement Methods

37.3.2.1 Surface Anthropometric Measurements

Over 70% of the between-measurer differences in the upper and lower extremity anthropometric measurements used for the tissue mass prediction equations were < 1.0 cm in magnitude, whereas all within-measurer measurement differences were less than this amount for the same variables (Tables 37.3 and 37.4). Averaged across measurement type, length measurements had the highest between- and within-measurement differences for both the upper and lower extremities at 1.35 and 0.34 cm, respectively. Skinfold measurement differences were the lowest on average, at 0.11 and 0.02 cm.

Almost 90% of the between-measurer ICCs for the upper and lower extremity anthropometric measurements used in the tissue mass prediction equations demonstrated good to excellent reliability, with more than half being greater than 0.90 (Table 37.9). Within-measurer ICCs were higher on average than between-measurer ICC, with all within-measurer coefficients demonstrating good to excellent reliability.

37.3.2.2 Manual Segmentation from DXA Scans

The overall percentage errors across all segments and tissue types were relatively small between measurers, ranging between 1.1% and 6.0%, with the maximum values being in the upper extremity for the forearm (4.79%) and BMC (6.0%) (Fig. 37.1). All of the within-measurer errors were less than 5.0% in magnitude. The largest mean within-measurer errors were found in the upper extremity for the arm with shoulder segment (4.5%) and for FM (4.1%).

In all cases, the mean between- and within-measurer ICCs for the upper and lower extremities (ranging from 0.991 to 1.000) far exceeded the 0.75 criterion set as good to excellent reliability (Tables 37.5 and 37.6). The ICC values across the different segments and tissue types were consistently very high, but were highest in the lower extremity for the leg and foot segment and for BMC.

37.4 Discussion

The methods by which regression equations for predicting upper and lower extremity soft and rigid tissue masses in living subjects were developed and validated by using surface anthropometric measures and DXA have been described. In general, the prediction equations were shown to result in tissue masses that compared very favorably to those measured using DXA. The reliability of the anthropometric measures used as inputs to the prediction equations, and of the tissue masses resulting from the manual segmentation of the DXA scan images, were also highlighted, and were very high in magnitude across all tissue types and segments.

In general, the predicted tissue masses from the developed equations were highly correlated with the masses measured from DXA and comparable to previous efforts in the literature (Jackson and Pollock 1977; Lean et al. 1996). Although the errors in anthropometric measurements and tissue mass predictions were small overall, it is important to acknowledge and evaluate those aspects of the procedures and techniques, which might have contributed negatively, even in a small way, to the outcomes. Therefore, the following discussion will be focused on specific issues related to the regression procedures used, and the sources of error associated with obtaining the anthropometric measures

Table 37.9 Between- and within-measurer reliability coefficients (ICCs) for the anthropometric measurements used as inputs to the tissue mass prediction equations

Anthropometric variables		ICCs	
		Between	Within
$x1$	Sex		
$x2$	Height (m)		
$x3$	Body mass (kg)		
Upper extremity			
$x4$	Elbow circumference	0.985	0.986
$x5$	Med. arm length	0.846	0.802
$x6$	Styloid circumference	0.985	0.975
$x7$	Lat. forearm length	0.881	0.865
$x8$	Pos. forearm skinfold	0.894	0.908
$x9$	Med. forearm length	0.887	0.817
$x10$	Pos. arm skinfold	0.957	0.962
$x11$	Ant. arm skinfold	0.867	0.878
$x12$	Prox. arm breadth	0.590	0.872
$x13$	Med. forearm skinfold	0.960	0.946
$x14$	Prox. arm circumference	0.942	0.899
$x15$	Mid-forearm circumference	0.929	0.960
$x16$	Mid-forearm breadth (M-L)	0.939	0.934
Lower extremity			
$x17$	Prox. mid-thigh length	0.814	0.911
$x18$	Lat. thigh length	0.939	0.943
$x19$	Ant. mid-thigh skinfold	0.967	0.968
$x20$	Mid-thigh breadth (M-L)	0.856	0.892
$x21$	Prox. mid-calf length	0.266	0.768
$x22$	Med. mid-calf skinfold	0.942	0.960
$x23$	Mid-calf breadth (M-L)	0.623	0.937
$x24$	Prox. thigh circumference	0.964	0.974
$x25$	Mid-thigh circumference	0.883	0.873
$x26$	Mid-thigh breadth (A-P)	0.920	0.896
$x27$	Knee circumference	0.966	0.994
$x28$	Mid-calf breadth (A-P)	0.850	0.938
$x29$	Malleoli breadth	0.983	0.981
$x30$	Lateral leg length	0.894	0.889
$x31$	Malleoli circumference	0.972	0.952
$x32$	Ankle circumference	0.991	0.994

Modified from Burkhart et al. (2008) and Arthurs and Andrews (2009)
Anthropometric measurements were found to be highly reliable between and within measurer. Results are presented as ICCs and high reliability was attained at a value ≥0.75

(used as regression inputs) and during the quantification of criterion tissue masses from DXA scan images (that have been used for validation purposes).

37.4.1 Regression Procedures

In determining the full range of anthropometric measurements that would be originally considered as inputs into the regression analyses, a mix of measurement types was targeted, as it was the intent

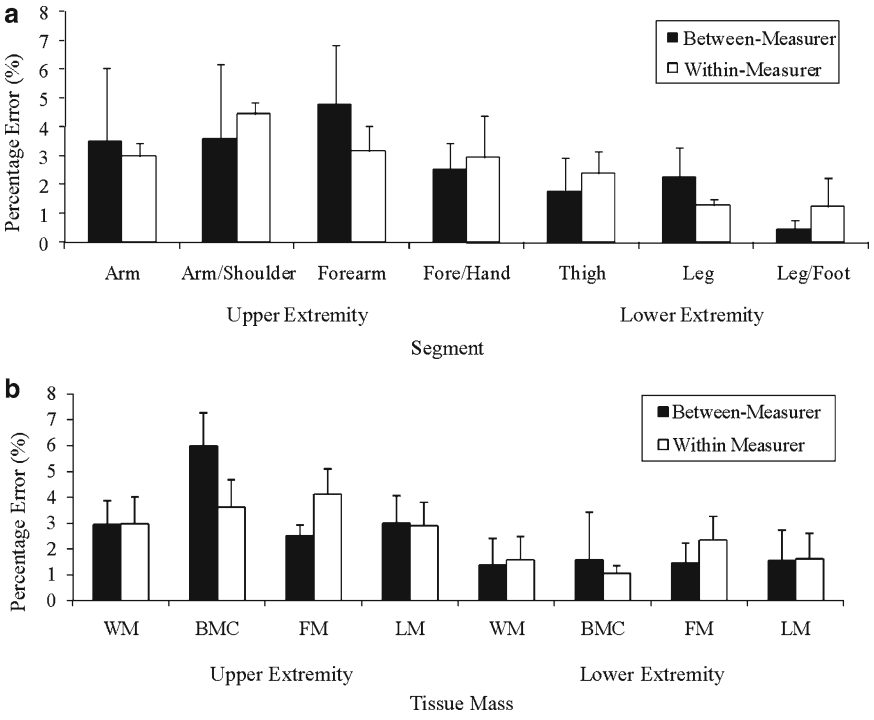

Fig. 37.1 Between- and within-measurer errors associated with specific segments (**a**) and tissue masses (**b**) from manually segmented DXA scans. Manual segmentation of DXA scan images resulted in small between- and within-measurer percentage errors. Results are shown as mean (SD) percentage errors (Modified from Burkhart et al. 2009)

to be able to predict both soft and rigid tissue masses equally well. Consequently, measurements such as circumferences and skinfolds, were selected because it was thought that these types of measurements would be more reflective of soft tissue mass than lengths and breadths. Lengths and breadths were also selected, as they have been conventionally associated with the prediction of BMC (e.g., Clarys and Marfell-Jones 1986b).

The decision of which variables to include in each regression analysis depended, in part, on how highly correlated the variables were. The most reliable (as per Burkhart et al. 2008) of two highly correlated variables would have been selected for inclusion in the regression analysis. In a few cases, input variables were eliminated based on the relative ease with which the type (e.g., breadths and lengths), and direction of the measurements (e.g., medio-lateral and antero-posterior) were taken. For example, if medial and lateral arm length had been equally predictive, the lateral arm length might have been selected because it is easier for the measurer to obtain and did not require the axilla to be landmarked, which was uncomfortable for some participants. If the reliability and ease of measurement of two highly correlated variables were similar, they were run separately to determine which resulted in the equation that explained the most variance. In these ways, the number of input variables was reduced while keeping the most reliable and easily measured variables available for equation generation.

37.4.2 Surface Anthropometric Measurements

The methods used to take the anthropometric measurements in this work are a potential source of systematic bias that may have resulted in the within-measurer differences that were reported. Measurement differences in circumferences, breadths, and skinfolds specifically can result when the soft tissues beneath and between the measuring tape and calipers are compressed. This effect is most evident when measurements around fleshy parts of segments (e.g., proximal arm or thigh circumference) are compared to those around bony processes with little underlying soft tissue (e.g., styloid or malleoli circumference).

The between-measurer differences in anthropometric measurements may be explained, in part, by the method used for anatomical landmark identification. For example, in the reliability study described herein, the sticker placed at the mid-leg location was used as a point of reference for four different anthropometric measurements for the leg (including mid-calf breadth and medial mid-calf skinfold: Table 37.4). Small variances in the placement of the mid-leg sticker between measurers would therefore have had a significant overall effect on multiple measurement outcomes, which would in turn have contributed to reduced equation prediction power (Burkhart et al. 2008).

37.4.3 Manual Segmentation from DXA Scans

The development and validation of the tissue mass prediction equations presented in this chapter were dependent on the use of DXA as the criterion method by which the living tissue masses of the participants were quantified. DXA has been shown previously to be a valid and reliable method for body composition measurement by a number of authors (e.g., Haarbo et al. 1991; Ball et al. 2004). Of particular importance to the current work is that DXA can also provide accurate estimates of both soft and rigid tissue masses for the whole body from a single scan. Despite the advantages of using DXA, all methods have limitations which can contribute to errors in tissue mass estimates.

Systematic bias in the DXA tissue masses could have resulted from reduced image quality caused by participants moving during scanning (Cawkwell 1998) and by the level of training of the measurers who carried out the segmentations (Atkinson and Nevill 1998). Discerning soft tissue edges and joint spaces may have been particularly affected by movement. However, this source of error was limited as much as possible by having very quick scans and vigilant technicians. Further, while no research on expertise using DXA has specifically studied manual segmentation, Lewiecki et al. (2006) comment on the importance of utilizing highly trained and qualified personnel to improve the quality of bone mineral density analysis. To this end, the three analysts in the current work received extensive training and demonstrated very high between- and within-measurer reliability on the tissue masses obtained from DXA, as a result.

Errors in the rigid tissue mass estimates (BMC) were likely caused, in part, by visualizing joint geometries, and determining where the proximal and distal borders of the ROIs were placed during segmentation. As the DXA images only provided a frontal view of the participants, any bony landmark on the posterior aspect of joints and segments would not be able to be accounted for by the analyst. The wider the joint space between segments, the easier was the segmentation. The lower mean percentage errors for the lower extremity segments may be attributed to the fact that the joint space between the femoral condyles and the tibial plateau is generally wider and more easily discernable on the scans than the elbow joint space in the upper extremities.

Soft tissue measurement errors are more attributable to the placement of the medial and lateral borders of the ROIs. A limitation of the imaging software used in this work was the inability to draw smooth curved lines. Consequently, if different body parts are pressed tightly together in an image, soft tissue from one segment might be incorrectly attributed to another segment when using ROIs. The closer the segments are to each other, the harder it is for the analyst to slice the segments cleanly. The upper extremities were most affected by this issue due to the arms being held along the sides during scanning, positioning that was done in order to keep the arms within the scan boundaries on the DXA machine bed. This may also help explain why the percentage errors in upper extremity tissue masses were greater on average compared to the lower extremity.

The validity of DXA under different physiologic conditions, including hydration, must also be considered as a contributing factor to soft tissue mass errors. DXA has been shown to overestimate fat content when the people being scanned are hydrated more than average, as DXA assumes that the hydration of fat-free tissue remains constant (Laskey and Phil 1996). Although hydration was not controlled in the experiments described herein, its overall effect was deemed to be minimal based on previous evaluations (e.g., Lohman and Going 1998).

37.4.4 Recommendations for Future Research

The work presented herein is limited in several important ways. The most important limitation is that the generalizability of the prediction equations developed to date (Holmes et al. 2005; Arthurs and Andrews 2009) is restricted to healthy, young adults (17–30 years of age). Body composition has been shown to fluctuate with age (Baumgartner 2000), sex (Daniels et al. 1997), and health status (Poehlman et al. 1995). To improve the generalizability of the equations, large numbers of working-age and older adults and children with body compositions characteristic of the general population, from underweight to overweight, need to be sampled. Current work has also been limited to the extremities due to the challenges of working with the trunk and head. How the masses are actually distributed within the segments is also not represented by the developed equations. Mass distribution will have a significant effect on the determination of body segment parameters, such as radius of gyration and moment of inertia, which play a major role in biomechanical analyses of dynamic human movements.

More work is also needed to determine the impact that the anthropometric measurement errors have on the predicted tissue masses quantified using the developed equations. Learning what measurements are most difficult to carry out will help during training. Knowing how much error in the predicted tissue masses can result as a function of how well the anthropometric measurements are taken is critical in terms of providing the user an idea of how much variability in tissue masses can be expected compared to other measurement techniques.

The impact of factors, such as body mass and overall body fat percentage, on soft tissue mass estimation using manual ROIs in DXA software, also needs to be investigated further. The range of body masses and body fat percentages in this work was fairly limited compared to the general population, and may contribute to greater errors when larger and heavier people are analyzed.

37.4.5 Applications to Other Areas of Health and Disease

The developed prediction equations provide a means by which the mass of the soft and rigid tissues of the upper and lower extremities of young people can be determined using simple surface anthropometric measurements, without the need for expensive imaging technologies. Although the exposure to radiation during a whole body DXA scan is very small compared to other X-ray based technologies (Haarbo et al. 1991), bypassing the need to scan living subjects in order to obtain regional tissue mass composition information has definite health benefits to the subject and technician. Having the ability to predict the mass of tissues other than fat, to which traditional skinfold measurement techniques are restricted, helps to extend their use to other health applications. For example, bone tissue degeneration, that is characteristic of osteoporosis, could be monitored over time without the need to scan individuals repeatedly. Being able to determine the ratio of bone mineral content to muscle or fat within a segment may also have implications for injury risk prediction, as the soft and rigid tissue properties may play an important role with respect to the development of stress fractures in some athletes (Milner et al. 2006).

Summary Points

- A total of 24 tissue mass prediction equations for the segments of the upper and lower extremity that use surface anthropometric measurements such as lengths, breadths, circumferences, and skinfolds as inputs were presented.
- Soft (e.g., wobbling mass, lean mass, and fat mass) and rigid (bone) tissue mass estimates from the predicted equations compared very well to measured tissue masses from DXA.
- Accurate and reliable person-specific tissue mass information can therefore be obtained without the need to scan participants with technologies such as DXA.
- The anthropometric measurements used as inputs into the equations were found to have excellent reliability between and within measurer.
- The process of manually segmenting DXA images using regions of interest for obtaining the upper and lower extremity soft and rigid tissue masses of living subjects was also found to have excellent between- and within-measurer reliability.
- More prediction equations need to be developed for other populations including older adults and children, for people of varying body compositions, and for other body segments such as the trunk and head.

Acknowledgments The authors wish to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for funding this research. Thanks also to Diagnostic Imaging at Windsor Regional Hospital and Nuclear Medicine at McMaster University Medical Centre for the use of their facilities, equipment, and technical support, and to the people who agreed to participate in the studies described in this chapter.

Chapter 38
Demographic Trends in Mid-Arm Circumference in Children and Adults over a 35-Year Period

R.J. Prineas, Y. Ostchega, and D.S. Reed-Gillette

Abstract Upper mid-arm circumference, measured in a standard way, has been used as an indicator of nutrition, for tracking malnutrition and obesity in populations and as a guide to proper sized cuff selection in the indirect measure of blood pressure. There are few published national data from which to observe changes in arm circumference over time that are gender-specific, in a wide range of ages from infancy through old age. The present chapter presents such detailed tables for the United States for the first time. The span of time covered is 35 years, from 1971 to 2006. Arm circumference adjusted for age and gender increased steadily over the earlier parts of this period but shows some signs of leveling off in the most recent periods. The increase over time has been greater among children and young adults than among older age groups. The increase in mid-arm circumference is mirrored both by an increase in stature and an increase in obesity. Detailed age-sex-specific tables are presented

Abbreviations

BMI	Body mass index
MA	Mexican American
NHANES	National Health and Nutrition Examination Survey
NHB	Non-Hispanic black
NHW	Non-Hispanic white

38.1 Introduction

Mid-arm circumference reflects the stature and nutritional status of individuals. It is an anthropometric measurement that is of importance in establishing obesity patterns and blood pressure measurement standards in populations. This measurement, on the right arm, has been a standard anthropometric measure in all National Health and Nutrition Examination Surveys (NHANES) of the National Center for Health Statistics, Centers for Disease Control and Prevention in the USA.

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_38,

We previously reported on trends in the USA for mid-arm circumference in adults from 1988 to 2002 (Ostchega et al. 2005) and in children from 1988 to 2004 (Prineas et al. 2007). Among adults, mid-arm circumference increased significantly for both males and females between the two adult surveys (NHANES III and NHANES 1999–2002) for all year age groups (those 20 years or older through 60 years and older). The greatest increase occurred in the 20–59-year age group. The overall increase was true for blacks and whites, but not for Mexican-American women.

Among children (ages 7–17 years), the periods examined were NHANES III and NHANES 1999–2004. Across these two surveys, girls 7–12 and 13–17 years of age, and boys 7–12 years of age showed significant increase in mid-arm circumference. We now extend these findings by examining earlier surveys (NHANES I and NHANES II) and later NHANES periods including 2003–2006, that is, for a 35-year time span. Further, we have extended the data to include infants and the end of childhood ages so that children of ages 1–19 years are tabulated and analyzed separately from adults 20 to 74 years of age.

38.2 Data Sources

38.2.1 Populations Surveyed

The National Health and Nutrition Examination Survey (NHANES) program of the National Center for Health Statistics, Centers for Disease Control and Prevention, includes a series of cross-sectional nationally representative health examination surveys beginning in 1960. In each survey, a nationally representative sample of the US civilian non-institutionalized population was selected using a complex, stratified, multistage probability cluster sampling design (US Department of Health and Human Services 2006). A home interview was followed by a physical examination in a mobile examination center. Beginning in1999, NHANES became a continuous survey. The procedures followed to select the sample and conduct the interview and examination were similar to those for previous surveys (Lewis et al. 2003).

Since 1960, there have been eight periodic surveys; this chapter will focus on the first, second, and third National Health and Nutrition Examination Surveys (NHANES I, 1971–1974; NHANES II, 1976–1980; and NHANES III, 1988–1994), and on two periods of the current continuous surveys (NHANES 1999–2002 and NHANES 2003–2006). The age range for NHANES I was 1–74 years; for NHANES II, 6 months to 74 years; and for NHANES III, 2 months and older; for NHANES 1999–2002 and NHANES 2003–2006, there were no age limits. Trends in mean arm circumference are based on comparisons of data on children and adults aged 1–74 years from five surveys: NHANES I (1971–1974) (n = 20,685); NHANES II (1976–1980) (n = 19,899); NHANES III (1988–1994) (n = 25,871); NHANES 1999–2002 (n = 17,014); and NHANES 2003–2006 (n = 16,773).

In NHANES III and in the current survey, the race/ethnic group based on self-report was categorized as non-Hispanic white (NHW), non-Hispanic black (NHB), Mexican American (MA), or other. In previous national surveys, the group was based on observation, and categorized as white, black, or other. In NHANES II, but not in previous surveys, information on Hispanic origin was also collected. Subjects in NHANES II were also categorized as non-Hispanic white, non-Hispanic black, or other. However, NHANES II did not have an adequate sample size to permit separate estimates for Mexican Americans. Therefore, arm circumference and its relationship with race ethnicity (NHW, NHB, and MA) was analyzed using NHANES III and current continuous NHANES data only.

38.2.2 Measurements and Indices Used in the Tables of This Chapter

Mid-arm circumference has been measured consistently in the same standard way since NHANES I (1971–1974), as detailed below under Sect. 38.4. Height in centimeters and weight in kilograms were measured in the mobile examination center following a standard protocol (for height: using a stadiometer with the examinee without shoes; for weight: using a platform balance Toledo scale, with the examinee without shoes and heavy outer clothing). Body mass index (BMI) was calculated as weight in kilograms divided by the square of height in meters (kg/m^2).

38.3 Applications to Other Areas of Health and Disease

Mid-arm circumference is a necessary measurement for the selection of correct cuff size for measuring blood pressure. The cuff-bladder width to mid-arm circumference ratio (CW/AC) affects the determination of blood pressure level with the usual indirect clinical measurement methods (Rastam et al. 1990; Sprafka et al. 1991). As early as the 1950s, Smirk (1957) showed that the effect of this soft-tissue factor was independent of the underlying tissue whether it be fat or muscle, and this has recently been confirmed for muscular arms (Fonseca-Reyes et al. 2009).

38.4 Practical Methods and Technique

38.4.1 Measuring Mid-Arm Circumference

(a) Standard measurement of the mid-upper arm circumference involves the examinee standing erect with the right arm by the side and flexed 90° at the elbow. Then, the arm is measured from the outer edge of the acromial process to the olecranon process of the ulna. The instructions for the measuring technician are: mark the outer edge of the acromial process first, then place the tape (a steel or non-stretchable tape checked against a standard) on the mark, and locate the midpoint between the acromial and olecranon processes. Mark this midpoint carefully. This is the level at which the measurement is taken to the nearest 0.1 cm. The tape should fit snugly against the skin in the whole circumference of the arm without indenting the skin. The right arm is chosen as standard in national statistical studies.

(b) Comparison of mid-arm circumference between a reference population and study population, or for an individual and a reference population standard, can best be expressed as a *Z*-score (also known as a standard deviation score), rather than as a percentile comparison. *Z*-score = (observed value) - (median reference value)/standard deviation of reference population. A fixed *Z*-score interval indicates fixed mid-arm circumference difference for persons of a given age and gender (WHO 1995). From a group of *Z*-scores in population-based applications, the mean and standard deviation of the *Z*-scores can be calculated. The problem arises then as how to construct a standard population for reference of individuals and study populations. This can no longer rest on NHANES II data that were earlier used by WHO because the population is now no longer well nourished, in that, a great proportion of the population is now obese.

(c) Estimating mid-arm circumference from self-reported anthropometric parameters may be used for inter-population comparison of mid-arm circumferences when one population has

no direct measurements. Tables are available derived from earlier data from NHANES surveys that give separate equations for men and women based on *self-reported* mid-arm circumference (AC) (Ostchega et al. 2006) such that for men: AC cm = 32.52145 + 0.10975 × (weight) – 0.26057 × (height) – 0.03028 × (age); and for women: AC cm = 30.22126 + 0.13534 × (weight) – 0.34121 (height) + 0.09014 × (age) – 0.00082565 × (age^2). These equations differ from those using *measured* height and weight (Ostchega et al. 2004), where for men: AC cm = 31.76749 + 0.22626 × (weight) – 0.10109 × (height) + 0.05092 × (age) – 0.00081813 × (age^2); and for women: AC cm = 39.29946 + 0.26410 × (weight) – 0.18230 × (height) + 0.01972 × (age) – 0.00104 × (age^2) + 0.00045901 × (weight × age) + 0.00037509 × (height × age).

38.4.2 Estimating the Correct Blood Pressure Cuff-Bladder Width from the Mid-Arm Circumference

Cuff-bladder width should be equal to 120% of the diameter of the mid-upper arm in children and adults (Frohlich et al. 1988; Guntheroth and Nadas 1955; Park et al. 1976). This translates to 38% of the circumference of the upper mid-arm [$120\%D = (C \times 120\%)/\pi = 38\%C$, where C = circumference and D = diameter of arm] (Prineas and Elkwiry 1992).The American Heart Association (Frohlich et al. 1988) has used the approximation of 40% for the CW/AC in the past and have also has given useful directions for estimating the correct cuff-bladder width, given the mid-arm-circumference measurement:

(a) "If the manufacturer provides the width of the inflatable bladder … mark this measurement in indelible ink on the cuff. If not, measure the width of the *inflatable bladder* … (Do not measure the cuff width [i.e. the cuff containing the bladder] which is wider).
(b) Multiply the bladder width in centimeters by 2.5 [which gives the reciprocal of CW/AC of 0.4 or 40%]. This calculation is the correct arm circumference for the bladder. Measuring distally from the index line of the cuff, mark this with a line C [from the top to the bottom of the cuff] which indicates the ideal arm circumference."

Then, an acceptable range of mid-arm circumferences can be marked on the cuff with appropriately placed lines on either side of line C. The ranges that are acceptable will depend upon the range of cuff sizes available, but should be within ±4% of a CW/AC of 40% (the ideal ratio) (Prineas 1991). For CW/AC ratios that are too small, the diffusion of the cuff pressure during inflation requires a higher pressure to collapse the brachial artery, and, so, a falsely high blood pressure recording will result. Similarly, a CW/AC ratio that is too large will result in falsely low estimates of blood pressure level (see illustrations in Prineas 1991). The acceptable mid-arm circumference range marked on the cuff is also critical, and probably should be of the order of 38% ± 5%, that is, 33–43%. A larger range than this could lead to unacceptable systematic blood pressure differences between the smallest and largest arm circumference enclosed by the same cuff (Rastam 1990).

Earlier recommendations for appropriate cuff-bladder width, which are still erroneously quoted, required that the cuff size be determined in children both by mid-arm circumference and upper arm length (AL). Such a requirement would require the AC/AL be a constant ratio, which is not the case. In more than 10,000 children aged 6–10 years, the AC/AL ratio varied from 0.4 to 1.9 and was not linearly related to age or height (Prineas and Elkwiry 1992).

Rational standardization of cuff sizes needs to be agreed upon by the interested parties including institutions, manufacturers, and regulatory agencies working together. Despite repeated calls for such action, this has still not been achieved.

38.5 Distributions of Mid-Arm Circumference by Age, Race, and Sex for Children (1–19 Years of Age) and Adults (20–74 Years of Age) in the USA for Five Survey Periods from 1971 to 2006

In the tables below, the *p*-values are for trend of mid-arm circumference measures between surveys, where NHANES I is the reference. Because there is an interaction between age-group*survey, the trend is calculated separately for each age group and gender. Further, the *p*-values need to be adjusted using a Bonferroni adjustment; so, for youth, the significant alpha will be .05/19 = .00263 ~ .002 or .003, for adults .05/5 = .01.

38.5.1 Changes in the Distributions of Mid-Arm Circumference for the Men, Women, Children, and the Total Population by Age Group, Separately

Table 38.1 ((a) children, (b) adults) is a *key summary table* that shows the changes from NHANES I through NHANES 2003–2006. Table 38.1 a for children has a range of 7,620–11,805 sample sizes examined cross-sectionally at five separate time points. For all five survey periods, for all ages (increasing from a mean of 22.25–23.45 cm), and for boys and girls separately, there is a significant steady increase in mid-arm circumference across the survey periods (*p*-value for trend <0.001). However, for ages 1–2 years, the increase is not sustained from NHANES III to NHANES 2003–2006, and there is an actual decrease from NHANES 1999–2002 to NHANES 2003–2006. For ages 3–15 years, the increase is not sustained from NHANES 1999–2002 to the NHANES 2003–2006 survey.

Table 38.1b similarly summarizes the changes for adults from age 20 years through 74 years by three age groups. The sample sizes at each of the five surveys vary from 7,962 to 14,066. Again, the mid-arm circumference increases significantly overall (from 30.68 to 33.14 cm), for each of the three age groups and for men and women separately (*p*-value for trend <0.001). However, for women of ages 60–74 years, the increase is observed across all surveys until 2002; but later, there is a small decrease. Figures 38.1a and 38.1b show the relation of mid-arm circumference with age for males and females separately. It can be seen that there is a steady increase in arm circumference from childhood to adulthood, and a slight decline in old age, across all surveys.

38.5.2 Percentiles of Mid-Arm Circumference by Detailed 1-Year Age Groups for Infants and Children (1–19 Years) for All and for Males and Females Separately for NHANES I and for NHANES 2003–2006

Tables 38.2 and 38.3 show the mean and standard errors of the 1st, 5th, 10th, 25th, 75th, 90th, 95th, and 99th percentiles of age-specific mid-arm circumference for all children and for males and females separately, at two time periods: 1971–1974 and 2003–2006, a span of 32 years. The upper percentiles, 50th through 99th for the total 1–19-year olds are all greater in the later time period, so that the 50th, 75th, 90th, 95th, and 99th centimeter percentile values for 1971–1974/2003/2006 are, respectively: 21.6/22.7, 25.8/27.7, 29.3/32.1, 31.6/34.9, and 36.6/40.4. These differences are reflected generally in each gender and for each separate 1-year age groups, with a few minor exceptions. This indicates that the increase in mid-arm circumference from the early1970s to 2003–2006 is not

Age-adjusted for the entire population, by the direct method, to the US census population projected estimates for the year 2000 using the age groups 20–39, 40–59, and 60–74 years

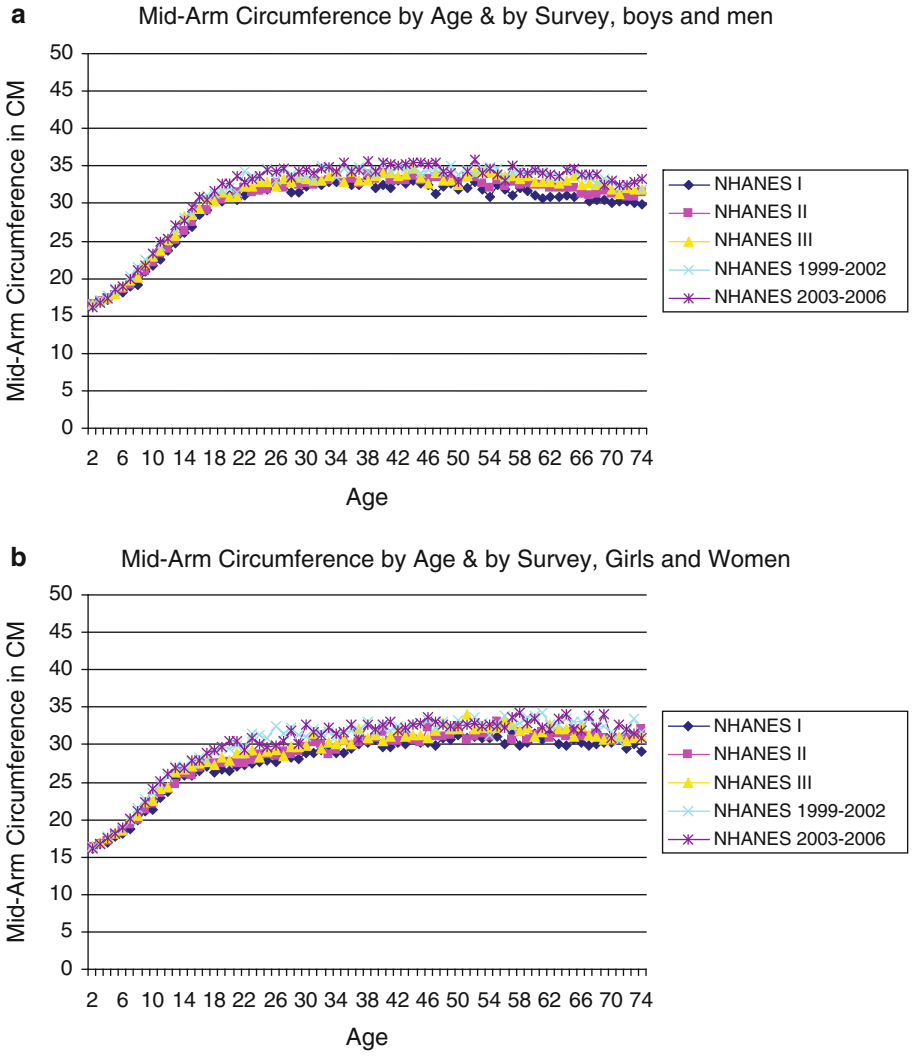

Fig. 38.1 (**a**) Males and (**b**) females, mid-arm circumference by age

just a rise in the mean levels, but is a shift to the right in the whole mid-arm circumference size distribution. There is a steady increase in the 95th percentile values for all children, and boys and girls separately from age 1 year through 19 years, at both time periods.

38.5.3 Changes in the Mid-Arm Circumference for All Children and for Boys and Girls at Each of Five Survey Periods from 1971–1974 to 2003–2006 by Separate Ages from 1 to 19 Years

Table 38.4 shows the mean and standard errors of the mean for each separate 1-year age group from 1 to 19 years, for the total, and for boys and girls separately for the survey periods 1971–1974 (NHANES I), 1976–1980 (NHANES II), 1988–1994 (NHANES III), 1999–2002, and 2003–2006.

There is a significant trend, overall, for the five survey periods, with a steady increase in mid-arm circumference for ages 5, 10, 12, 13,15, 17, 18, and 19 years. For ages 2 and 3 years, there is no significant increase across the time span, and, for 1-year olds, the increase ceases after NHANES III (1988–1994). For ages 4, 6, 7, 8, 9, 11, 14, and 16 years, the increase ceases after the 1999–2002 survey. The changes are generally reflective for boys and girls. So, infants show no sustained increase in mid-arm circumference, whereas the older (17-, 18-, and 19-year old) children show a sustained increase across all five surveys.

38.5.4 Mid-Arm Circumference Trends by Race

Comparable race/ethnicity categorizations (only for adults) are only available for the last three surveys: 1988–1994, 1999–2002, and 2003–2006. During that time, age-sex-adjusted mid-arm circumference was greatest among African-Americans and increased by the greatest amount compared to non-Hispanic whites and Mexican Americans. The measurements in centimeters for African Americans at each successive survey were 33.22, 34.39, and 38.4, respectively, compared with equivalent values for non-Hispanic whites: 31.94, 32.96, and 33.06; and for Mexican Americans: 32.43, 32.8, and 32.9.

38.5.5 Mid-Arm Circumference Trends Adjusted for BMI, Age, Race, Sex, and Triceps Skinfold Thickness for Children Aged 2–19 Years and Adults Aged 20–74 Years

Tables 38.5 and 38.6 show the effect of adjustment for BMI and triceps skinfold thickness (measured on the same arm as the mid-arm circumference), considering the trend in mid-arm circumference across all survey periods. Table 38.5 has the results of weighted regression analysis for children aged 2–19 years across survey periods, with multivariable adjustment for age, gender, BMI, and triceps skinfold thickness. There are significant increases in mid-arm circumference from NHANES I through NHANES 1999–2002, but no further significant increase was observed for the last survey in 2003–2006, confirming the results displayed earlier. However, the change is most affected by BMI, followed by triceps skinfold thickness, which, although statistically significant, has only a minor role. Stated differently, together, BMI and triceps skinfold values alone explain. Eighty-three percent of the variation in mid-arm circumference values (R^2 = 0.834); removing triceps skinfold values from the model reduces the explained variability by.005% (R^2 = 0.829). This is an indication that total body size, including muscle and bone, has a greater effect on mid-arm circumference than does triceps skinfold thickness. Table 38.6 shows similar results for men and women aged 20–74 years of age, with the exception that the increase of the mid-arm circumference values continues across all survey periods, and that obesity has a greater effect in this population sample than in children. Similar to the findings in youth, BMI alone is associated with most of the explained variance in mid-arm circumference (R^2 = 0.78); adding triceps skinfold thickness to the adult model containing BMI actually reduces the amount of explained variation in mid-arm circumference values by 2% (R^2 = 0.76).Indeed, triceps skinfold thickness is more correlated with the independent variable BMI (r = 0.57) than with the outcome variable mid-arm circumference (r = 0.44), explaining the decrease in R^2 value when triceps skinfold thickness is added to the adult model."

Triceps skinfold	0.11	0.002	<.001
BMI	0.61	0.004	<.001

BMI trends and mid-arm circumference trends (except for extreme levels) match each other almost exactly, as can be seen in Fig. 38.2a, b for males and females, respectively. Further demonstration of the importance of generally increased body size and not just obesity of the upper arm can be seen in Fig. 38.3a (males), b (females), where much of the overall observed increase of mid-arm circumference across the five surveys is mitigated by adjustment for triceps skinfold thickness, but not so markedly, as for BMI, when separate adjustment is made for each of these parameters. This suggests that effects of underlying tissues other than fat, such as bone and muscle increase, also add to the observed changes in mid-arm circumference. Regardless of the origins of the increase in arm size, there is a need to be aware of changing requirements of blood pressure cuff sizes to appropriately match mid-arm circumference and avoid overestimate of actual blood pressure levels. In population samples, this could result in false, secular trends of blood pressure level estimates. Also, rather than reflecting optimal nutrition, US current mid-arm circumference measurements reflect levels of obesity to be prevented in the future.

Summary Points

- Mid-arm circumferences for males and females, from childhood to age 74 years have increased successively from 1971–1974 to 2003–2006, over a 35-year period in five surveys in the USA.
- Mid-arm circumference increases from age 1 year to adulthood and decreases slightly but steadily from age 50 years to older ages.

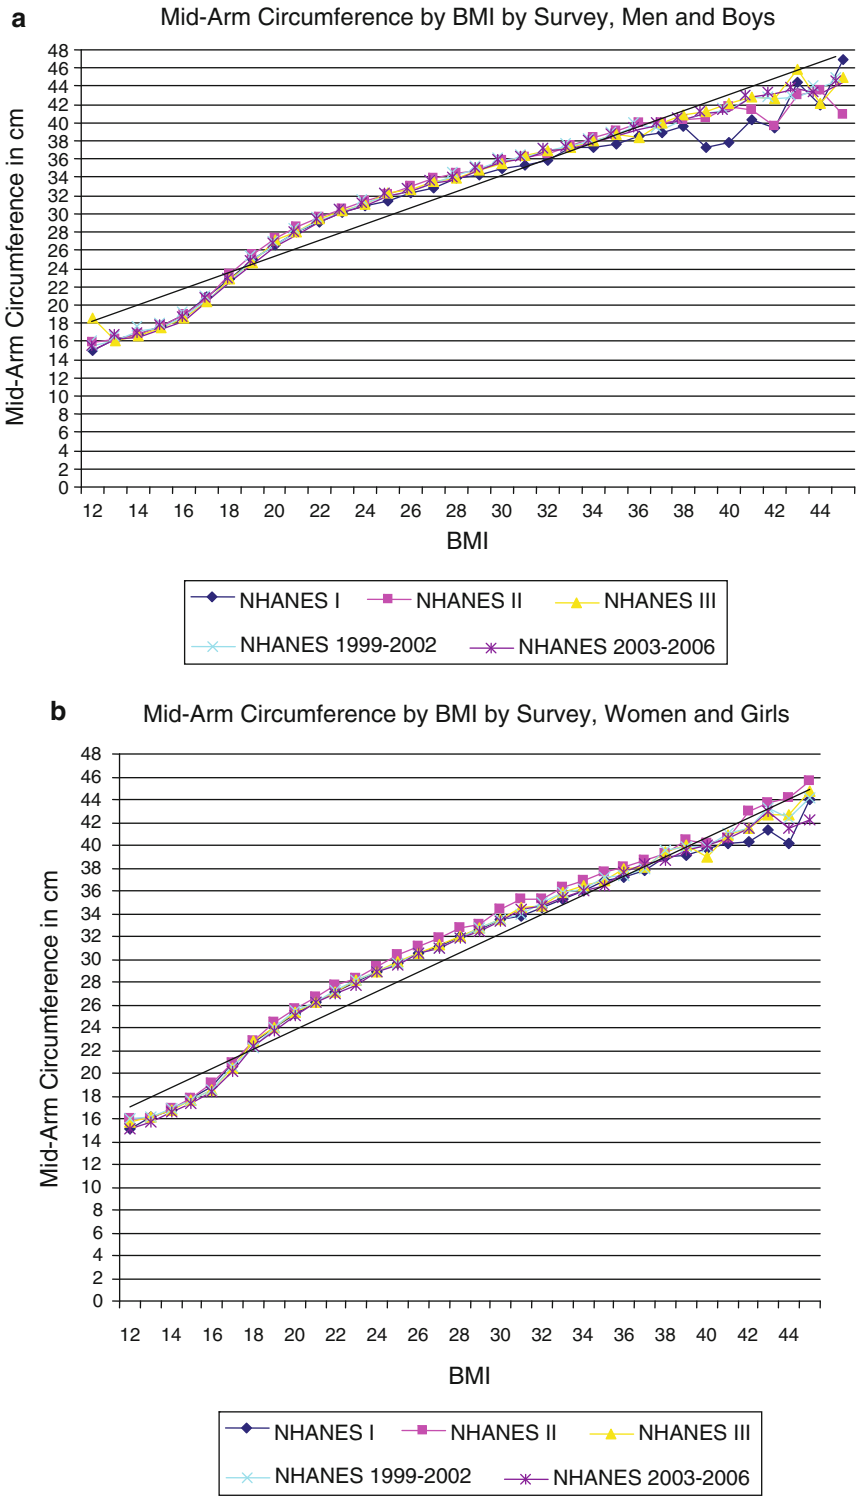

Fig. 38.2 (**a**) Males and (**b**) females mid-arm circumference by body mass index (BMI)

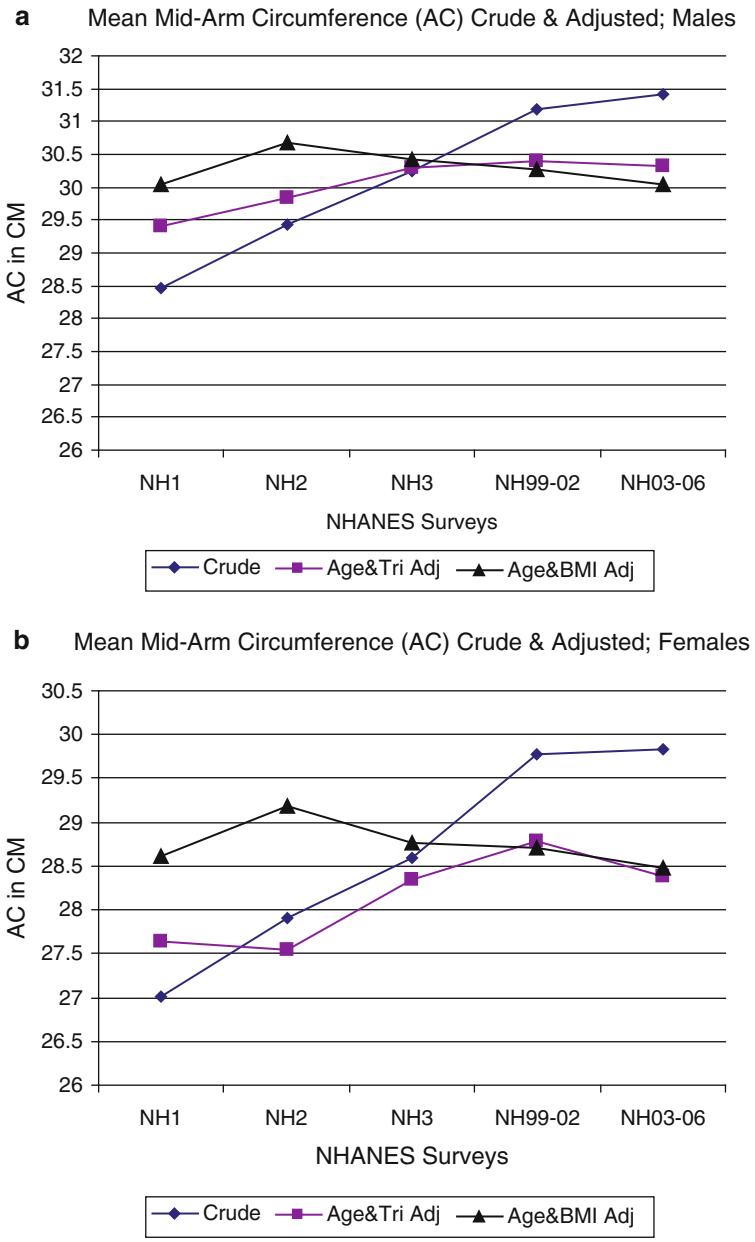

Fig. 38.3 (**a**, **b**) Mid-arm circumference by survey, adjusted separately for Age and Triceps Skinfold Thickness (Tri) and Age and Body Mass Index (BMI)

- The increase in mid-arm circumference is due to a shift to the right in the distribution of mid-arm circumference measurements.
- Infants show no sustained increase in mid-arm circumference, whereas the older children (17-, 18-, and19-year olds), like adults, show a sustained increase across a 35-year period.
- In more recent times, from 1988–1994 through 2003–2006,African Americans exhibit larger mid-arm circumferences and greater increase in size over the period than do non-Hispanic whites or Mexican Americans.

- The increase in mid-arm circumference over the past three and a half decades is modified by the increase in triceps skinfold thickness and BMI.
- The increase in mid-arm circumference size is almost entirely due to the parallel increase in BMI.

Acknowledgments We are grateful to the US Centers for Disease Control for access to public use documents regarding the NHANES surveys.

Chapter 39
Anthropometric Wrist and Arm Circumference and Their Derivations: Application to Amyotrophic Lateral Sclerosis

Luciano Bruno de Carvalho-Silva

Abstract ALS is a degenerative disorder described as the loss of upper and lower motor neurons. ALS patients have an unfavourable prognosis that may influence alterations in the body mass. As a way of following up the clinical evolution of individuals with ALS, nutritional evaluation techniques are frequently used, however, they are not specific for ALS. In this review, we discuss the main anthropometric techniques emphasizing the circumferences, as well as their applications and limitations in ALS patients. All available articles were investigated, and anthropometry is suggested as a good tool, nevertheless, having some limitations and observations. Wrist and arm circumferences and their derivations are good indicators of these individuals' nutritional state and body composition. It should be noted that these patients typically have asymmetry, a low body mass index and an increase of fat mass. An equation is available for the calculation of fat-free mass in ALS patients. Among the complementary techniques, the bioelectrical impedance analysis at a frequency of 50 kHz is the most suitable. A strong correlation between this bioelectrical method and the measurement of circumferences and their derivations was observed. Therefore, the use of circumferences is suggested in the evaluation and follow-up of ALS patients.

Abbreviations

ALS	Amyotrophic lateral sclerosis
AMA	Arm muscle area
BIA	Bioelectrical impedance
BMI	Body mass index
BSF	Bicipital skinfold
DXA	Dual X-ray absorptiometry
FFM	Fat-free mass
MAC	Mid-arm circumference

39.1 Introduction

'Amyotrophy' refers to the atrophy of muscle fibres, which are denervated as their corresponding anterior horn cells degenerate, leading to weakness of affected muscles and visible fasciculations. 'Lateral sclerosis' refers to hardening of anterior and lateral corticospinal tracts, as motor neurons in these areas degenerate, and are replaced by gliosis (Rowland and Shneider 2001; Wijesekera and Leigh 2009). Amyotrophic lateral sclerosis (ALS) is characterised by progressive paralysis, secondary to the compromise of both the upper motor neurons and lower motor neurons. Individuals with ALS lose skeletal muscle mass secondary to denervation. This neurologically induced muscle mass loss is inevitable as the disease progresses; so, tracking muscle wasting is one way to monitor disease progression (Gubbay et al. 1985; Nau et al. 1997; Nelson et al. 2000).

In approximately 50% of patients, the disease first affects the arms (Fig. 39.1), in 25% the legs, and in 25% the onset is bulbar (Fig. 39.2). Manifestation forms progressive muscle atrophy is observed. This atrophy may mask the increase in metabolic demand, as metabolic energy is channelled to maintain pulmonary ventilation, thus causing the increase in basal energy expended by ALS patients (Nau et al. 1995; Silva et al. 2008a; Silva et al. 2008b).

Changes in body composition may be followed through anthropometry. The anthropometric assessment of muscle mass has been widely utilised in studies of malnourished populations and in the nutritional assessment of hospitalised patients (Blackburn et al. 1977; Heymsfield et al. 1994). For individuals with ALS, in addition to the body mass index (BMI) [weight (in kg)/height^2 (in m)], the determination is made on the upper extremities, although the methodology has been expanded to evaluate the lower extremities as well (Callaway et al. 1988). Typically, the circumference and skinfold thickness of the mid-upper arm are measured.

Fig. 39.1 Appendicular onset

Fig. 39.2 Bulbar onset

In such context, in the present chapter, the main uses of anthropometric parameters will be discussed, particularly the wrist and mid-arm circumference (MAC), as well as their derivations, in individuals with ALS. It is important to highlight that there are few studies available that are related to nutritional evaluation in ALS patients. However, considering the available articles addressing this issue, some research groups are mentioned for their contribution: Desport et al.

39.2 Arm and Wrist Circumference and Application to Amyotrophic Lateral Sclerosis

As ALS evolves, a decrease of muscle mass may be observed, independently from its manifestation, in addition to an increase of fat mass. Nau et al. (1997) assessed the body composition and caloric intake of 12 ambulatory males with ALS over a 6-month period. The men lost 1.5 kg of body mass during this period. Body composition analysis revealed that the mass loss was composed of a 2.0 kg reduction in lean mass and a 0.55 kg increase in fat mass. In this case, the loss in body mass underrepresented the degree of muscle wasting they had experienced, and the muscle wasting masked fat accumulation.

Several anthropometric parameters may be used for the estimate and follow-up of a patient's nutritional status. Some relevant research data are presented in Table 39.1.

The MAC is assessed on the arm extended along the body, measured at the middle point between the tip of the acromion and olecranon process, using a flexible, non-elastic, metric plastic tape (Callaway et al. 1988). In anthropometry, the circumference is very important because other nutritional status indicators may be estimated from it. Desport et al. (2003) used MAC for calculating mid-arm muscle circumference (MAMC) and follow-up of the nutritional status of ALS patients. Researchers have used circumferences as parameters for assessing these body composition modifications.

The wrist circumference is measured using a tension-gated tape measure positioned over Lister's tubercle of the distal radius and over the distal ulna (Fig. 39.3). In ALS, both sides should be measured.

Body frame size is determined by a person's wrist circumference in relation to his or her height. The body frame size is determined by measuring the wrist with a tape measure to determine whether the person is small, medium or large boned (Table 39.2)

DXA dual X-ray absorptiometry

Table 39.4 Equations for the estimate of mid-upper arm muscle circumference, arm muscle area in males and females, and fat-free mass, specifically validated for ALS patients

Parameters	Equations
MAMC	MAMC = MAC – (π × TSF)
AMA	AMA (males) = [MAC – (π × TSF)^2/4 π – 1]
AMA	AMA (females) = [MAC – (π × TSF)^2/4 π – 6.5]
	FFM Equation for ALS patients
FFM	FFMfin50 = (0.436 W) + (0.349 mean H^2/Z_{50}) – (0.695 mean TSF) + 9.245

TSF (mm) triceps skinfold, *MAC* (cm) mid-arm circumference, *MAMC* (mm) mid-arm muscle circumference, *AMA* (mm) arm muscle area, *FFM* (kg) fat-free mass, W (kg) weight, H (m) height, Z_{50}: 50 kHz.

Rio and Cawadias (2007) performed a study with 23 dieticians working in ALS/Motor Neuron Disease centres/clinics across England, Wales, Northern Ireland and Canada. By means of a standardised questionnaire, the researchers obtained information on nutritional assessment techniques, requirement equations, sources of nutritional information and perception of quality of information. The techniques used for anthropometrics evaluation are shown in Table 39.3.

Determination of upper extremity anthropometrics is simple, requires little equipment, is independent of patients' effort and is highly reproducible (Heymsfield et al. 1994; Callaway et al. 1988). In these cases, a MAC may be used. The MAC reflects the total body composition without separating the fat mass from the lean mass. This parameter is obtained from the middle point on the extended arm from the non-dominant side. Nevertheless, for individuals with ALS, due to the asymmetric characteristic, it is worth noting that measurements should be taken from both the right and left upper extremities, calculating the average between the two assessments for the correct estimate of body mass (Kasarskis et al. 1997).

Obtained from MAC, the MAMC is used to distinguish the muscle mass (Heymsfield et al. 1994), as it takes into consideration the tricipital skinfold (TSF). In ALS, as well as in other situations, the isolated TSF measurement provides an estimate of the subcutaneous fat mass.

Once the MAMC is estimated, it is possible to obtain the arm muscle area (AMA). In ALS, AMA and the percent body fat are lower among subjects closer to death (Heymsfield et al. 1982; Kasarskis et al. 1996). The equation used for the AMA estimate is the same as the one used in other clinical situations (Table 39.4).

There are no specific equations applicable for individuals with ALS. Therefore, as described before, it is advised to take the average measurements from the patient's right and left sides, especially in case of individuals with bulbar onset.

Table 39.5 Anthropometric methods for the estimate of fat mass and muscle mass

Compartments	Equations
Fat mass	Jackson and Pollock (1985)
	Durnin and Womersley (1974)
	Deurenberg et al. (1991)
	MacArdle et al. (1991)
	Siri (1961)
Muscle mass	Heymsfield et al. (1982)
	Martin et al. (1990)

In 2003, Desport et al. compared the fat-free mass (FFM) obtained by dual X-ray absorptiometry (DXA) with FFM obtained by BIA and by the skinfold-thickness technique. In this study, the FFM and fat mass of the patients were calculated from BIA, the measured resistance to a weak alternative current applied to wrist and ankles. A recent formula for FFM has been validated against a reference method in ALS, both transversally and longitudinally.

Serial body composition measurements are necessary to measure and track changes in the fat and muscle components of the body. It is common to use the loss of body mass as an estimate of both muscle atrophy and nutritional status (Nau et al. 1997). The equations frequently used to convert anthropometric values into estimates of lean and fat mass are the same as the ones utilised and validated in other clinical conditions (Table 39.5).

Research in the application of common anthropometric techniques in nutritional practice as well as in obtaining evidence for upper extremity anthropometrics in the clinical assessment of patients with ALS, Kasarskis et al. (1997) accomplished a study with 18 non-obese ALS patients with a body mass index (BMI) < 30. In this study, the use of standard, upper extremity anthropometrics was studied and these measurements were correlated with quantitative isokinetic muscle force output, computerised tomography scan muscle area, pulmonary functions and creatinine excretion. The MAC was determined using a standard tape measure. The MAMC and AMA were calculated according to Heymsfield et al. (1982). The researchers noticed that the upper extremity AMA correlated positively with quantitative measures of body weight, net muscle area and biceps and triceps muscle force generated using slow- and high-speed isokinetic dynamometry. AMA correlated well with important measures of pulmonary function including forced vital capacity, slow vital capacity, maximal voluntary ventilation, tidal volume and vital capacity. The authors concluded that the upper extremity bone-free muscle mass, as a method to quantify the progression of the muscle atrophy in ALS and the measurement of AMA, might have utility as an outcome measure for ALS progression.

Silva et al. (2008a) studied the nutritional, respiratory and functional profiles of a cohort of 20 ALS patients regularly followed up at the Neuromuscular Outpatient Clinic of Campinas State University Hospital (UNICAMP). The anthropometric parameters used were BMI, MAC, wrist circumference, MAMC, AMA and TSF and bicipital (BSF), suprailiac (SISF) and subscapular (SESF) skinfolds. The authors looked for correlations between these variables to identify determinant factors in the severity of the disease. In both appendicular and bulbar onset patients, correlations were noticed between the BMI and the following variables: mass (kg), fat, MAC, wrist circumference and TSF, SESF, SISF, the MAMC and AMA. Based on these correlations, the researchers suggested that the application of anthropometric measurements could be useful in routine monitoring of patients with ALS.

Table 39.6 Main limitations for the use of anthropometry in individuals with ALS

ALS versus Anthropometrics parameters
Abnormal fat distribution is possible in ALS.
The disease can have effects that are more marked on one side of the body than on the other.
Non-specific manner, TSF and MAC have an operator-based risk of variation.

TSF (mm) triceps skinfold, *MAC* (cm) mid-arm circumference

It is important to point out that, in ALS, there are some limitations for the use of MAC, and also the equations obtained from this parameter, as in AMA. First, in obese ALS patients (BMI>30), the accurate measurement of TSF may be difficult, which may introduce an error in the computed value of AMA. Another limitation of the use of this anthropometric parameter is related to the predominant muscle atrophy due to the 'lower motor neuron' component of the illness, thus causing the parameter to be less sensitive to 'upper motor neuron' weakness or spasticity (Kasarskis et al. 1997). As described in Table 39.6, Desport et al. (2003) correlated some of the limitations to the use of MAC in ALS patients.

Despite the presented limitations, anthropometric measurement of upper limbs may be acceptable in ALS patients, and several authors have used this technique (Kasarskis et al. 1997).

39.3 Other Estimate Methods for Body Mass Composition in ALS Patients

The most advised methods for persons with ALS include DXA, bioelectrical impedance (BIA) and anthropometry (Nau et al. 1997). DXA categorises the body into three components: bone mass, fat mass and non-fat soft tissue (lean mass minus the bone). The use of such techniques in these individuals presents some advantages and disadvantages, as shown in Table 39.7.

DXA is limited in ALS patients because it is relatively expensive and is available primarily as a research tool. Also, it may not be well tolerated by patients with respiratory muscle weakness, as it requires the person to lie flat in a supine position for about 20 min (Nau et al. 1997). BIA, which categorises the body into fat and lean mass, is based on the premise that conductance is directly related to the percentage of water, and lean mass is hydrous compared to fat (Nau et al. 1997). To perform this technique, it is expected that the individuals are normally hydrated, which may or may not apply to persons with more advanced stages of ALS. The limitation for the use of anthropometry is related to the equations for the estimate of body mass. Anthropometric equations are frequently applied on the general population so, the current equations may not apply to persons with ALS. Most equations assume the subject is in a standing or upright position, which is not always possible among persons with ALS (Desport et al. 2003).

Desport et al. (2003), accomplished a validation study on bioelectrical impedance analysis in patients with ALS. Using 32 ALS patients, the researchers compared reference measures of fat-free mass (FFM) obtained by DXA with FFM obtained by BIA, and by the circumference and skinfold techniques. BIA was performed by measuring the bioimpedances at 5, 50 and 100 kHz of each side of the body and from one side to the other. As a result of this study, an equation was developed using multivariate analysis, with impedance at 50 kHz. This equation was validated in a second population of 15 ALS patients, and with the use of two successive measurements performed on 18 patients. It was concluded that BIA is a simple method, which is valid for use in ALS patients, both for a single exam measure and for longitudinal monitoring using an equation and applying a frequency of 50 kHz.

Table 39.7 Advantages and disadvantages of the use of anthropometry, bioelectrical impedance and dual X-ray absorptiometry in individuals with ALS

Parameters	
Anthropometry	Advantages: Simple, low cost and with strong correlations between BMI, MAC, WC, TSF and BIA.
	Disadvantages: Demands professional training; may underestimate fat mass percentage; some techniques are not validated for ALS yet.
BIA	Advantages: Fast, simple and low-cost method and validated at 50 kHz frequency in ALS patients.
	Disadvantages: Varies according to the hydration degree.
DXA	Advantage: Differentiates FM from FFM.
	Disadvantage: High cost of equipment, requires the subject to be flatly supine for >10 min, which is difficult for ALS patients.

BMI (kg/m^2) Body mass index, *DXA* dual X-ray absorptiometry, *BIA* bioelectrical impedance, *FFM* (kg) fat-free mass, *TSF* (mm) tricipital skinfold, *MAC* (cm) mid-arm circumference, *WC* (cm) wrist circumference, *MAMC* (mm) mid-arm muscle circumference and *AMA* (mm) arm muscle area

39.4 Anthropometry, ALS and Its Relation to Gender and to the Presentation Form of the Illness

ALS affects mainly males, in the proportion 1.8:1, when compared to females, and among the races, whites more than the blacks. Onset usually occurs between 59 and 65 years of age. About 4–6% of cases occur in people younger than 40 years (Dietrich et al. 2000).

Individuals with ALS present progressive decreases in BMI, body fat and lean body mass. However, in cases nearing death, the proportion of fat mass is greater in females than in males (Kasarskis et al. 1996).

ALS is progressive, with death occurring on average from 2 to 5 years after onset (Li et al. 1990; Norris et al. 1993). About 8–22% survive for at least 10 years. The prognosis tends to be worse in individuals with bulbar onset, ageing and atrophy predominance (Walling 1999). In individuals with bulbar onset, respiratory insufficiency, with or without pneumonia, is usually the cause of death, generally associated with dysphagia and bronchoaspiration.

In individuals with appendicular onset, asymmetry is more commonly observed between the most and least compromised side. This difference was noted according to anthropometric evaluation data of individuals with bulbar and appendicular ALS, who were studied at the Neuromuscular Outpatient Clinic of UNICAMP. On the most compromised side, the wrist circumference was on average 0.9 cm smaller than on the other side (unpublished data). This highlights, once again, the necessity to use both sides to estimate the body composition in ALS patients.

39.5 Final Considerations

Anthropometric parameters, especially the circumferences, which allow us to estimate the body composition, are good markers of the nutritional state and alterations in the body composition of individuals with ALS. For these patients, such parameters should be used carefully, with attention to their asymmetry. It is added that MAC, wrist circumference and their derivations present strong correlations to BIA. However, it is necessary to perform longitudinal studies to identify the sensitivity and viability of different techniques during the stages of ALS.

Summary Points

- There are strong correlation between bioelectrical method and the measurement of circumference in ALS patients.
- MAC and wrist circumference are good markers of the nutritional status in ALS patients
- In individuals with ALS with appendicular onset it more common to observe asymmetry between the most and least compromised side. MAC and wrist circumference should be taken from both the right and left upper extremities, calculating the average between the two assessments.
- Abnormal fat and mass distribution may be one limitation for the use of anthropometry in individuals with ALS.
- It is necessary to perform longitudinal studies to identify the sensitivity and viability of different techniques during the stages of ALS.
