Chapter 88
Anthropometry and Mortality in Older Women: Potential Survival Benefit of Overweight and Obesity

Chantal Matkin Dolan, Michelle Hansen, and Kathryn Fisher

Abstract This chapter examines the reported relationship between body mass index (BMI kg/m^2) and other measures of anthropometry, such as fat mass and waist circumference, and the risk of all-cause mortality in older women. The World Health Organization (WHO) and the NHLBI have defined overweight as body mass index (BMI) 25.0–29.9 kg/m^2 and obesity as BMI of 30.0 kg/m^2 or greater and stated that all individuals who are overweight or obese are at risk for increased morbidity and mortality. The application of this single set of cutpoints to define mortality risk associated with overweight and obesity is controversial, particularly when applied to older women. Some studies support a linear relation while the majority of studies of older women have reported a J- or U-shaped relation between BMI and mortality in older women. Other studies have reported a "flattening" of this J- or U-shape relation between BMI and mortality among very elderly women. The totality of the evidence suggests that the BMI associated with lowest risk of mortality in older women is much higher than in younger women and that it includes overweight and possibly moderately obese women. The WHO and NHLBI guidelines are not appropriate when interpreting BMI levels and risk of mortality in older women, since many of the women categorized as overweight or obese are at the lowest risk of mortality. There does appear to be some survivor effect or protective effect of increased adiposity for risk of mortality in older women. Recent data suggests, however, that the possible protective effect of obesity on mortality may not provide protection against disability. More data are needed to understand fully the nature of the relation between anthropometry and risk of mortality and the link with morbidity and disability. There continues to be a striking lack of information on the risk of increased adiposity and mortality in non-White women. Although there is very little data on other measures of anthropometry other than BMI, BMI is highly correlated with other measures of anthropometry and is an easy and practical method of studying these relationships.

88.1 Introduction

In recent years, the prevalence of overweight and obesity, particularly in USA, has reached dramatically high, even epidemic, levels. According to recent estimates, more than 68.3% of the US adult population is overweight or obese (Flegal et al. 2010). In 2008, among women over 60 years of age, 68.6% were considered overweight and 33.6% were obese (see Table 88.1). Although these levels have dramatically increased over the past several decades, there does appear to be some leveling off of the prevalence rates of overweight and obesity in the most recent data suggesting that, perhaps, a "steady state" of overweight and obesity has been reached in the USA (Flegal et al. 2010). Because such large proportions of the female population are considered overweight or obese and as these proportions are not likely to decrease in the near future, it is important to understand the mortality risk associated with being an older overweight or obese woman.

In 1998, in an expert panel report, the National Heart Lung and Blood Institute (NHLBI) defined overweight as a body mass index (BMI) of 25.0–29.9 kg/m^2 and obesity as a BMI of 30.0 kg/m^2 or greater, and stated that all individuals who are overweight or obese are at risk for increased morbidity and mortality (NHLBI 1998). These guidelines were applied to adults of all ages, of both sexes, and across racial/ethnic groups. The World Health Organization (WHO) has also adopted these same cut-points to identify overweight and obesity (WHO 1998).

Several studies have shown that the risk of mortality associated with high BMI levels is greater for younger women than for older women (Lew and Garfinkle 1979; Lindsted and Singh 1997; Stevens et al. 1998, 1999; Calle et al. 1999; Thinggaard et al. 2010). In addition, the shape of the relationship between BMI and risk of mortality in women has been debated. Several studies have shown a J- or U-shaped relation between BMI and mortality in older women, suggesting elevated risk for mortality at the both low and high levels of BMI (Lew and Garfinkle 1979; Waaler 1984; Folsom et al. 1993; Durazo-Arvizu et al. 1997; Sempos et al. 1998; Bender et al. 1999; Calle et al. 1999; Dey et al. 2001; Katzmaryzk et al. 2001; Flegal et al. 2005; Corrada et al. 2006).

This chapter examines the reported relationship between BMI and other measures of anthropometry and adiposity, such as fat mass and waist circumference (WC), and the risk of all-cause mortality in older women. Particular attention is paid to large cohort studies that have included multiple indicators or measures of anthropometry and adiposity.

Table 88.1 Prevalence of obesity and overweight for adult women in the United States, % (95% confidence interval [CI]) (Flegal et al. 2010)

	All Women		Women 60 years and older	
	BMI ≥ 25 (Overweight and obese)	BMI ≥ 30 (Obese)	BMI ≥ 25 (Overweight and obese)	BMI ≥ 30 (Obese)
All	64.1 (61.3–66.9)	35.5 (33.2–37.7)	68.6 (64.4–72.7)	33.6 (30.2–36.9)
Non-Hispanic White	61.2 (56.7–65.7)	33.0 (29.3–36.6)	67.6 (62.2–73.1)	31.4 (27.3–35.5)
Non-Hispanic Black	78.2 (74.5–81.9)	49.6 (45.5–53.7)	78.2 (70.7–85.8)	50.5 (40.5–60.5)
All Hispanic	76.1 (72.0–80.1)	43.0 (37.9–48.2)	80.7 (77.3–84.1)	46.7 (41.0–52.3)
Mexican–American	76.9 (71.8–81.9)	45.1 (38.9–51.2)	82.6 (77.2–88.0)	48.1 (43.0–53.3)

88.2 Measuring Adiposity in Large Epidemiologic Studies

Most large epidemiologic studies measure adiposity by indirect anthropometric measures of obesity, such as BMI, rather than by more direct but relatively expensive measures of fat mass and lean mass, such as from bioelectrical impedance analysis (BIA) or dual X-ray absorptiometry (DXA). The inability to distinguish lean and fat mass using BMI may be particularly important among older women, who, on average, have a higher percentage of fat mass than younger women with the same BMI (Stevens et al. 1999). The loss of spinal height with age among women may also affect the relationship between BMI and fat mass in older women. However, BMI is easily calculated from weight and height (kg/m^2), and can be estimated based on actual measurements of height and weight in a clinical setting, self-reported height and weight, or recorded height and weight in various medical or population databases.

In addition to being an indirect measure of adiposity, BMI does not detect differences in body fat distribution, which may be important because of the link between abdominal or central adiposity and increased risk of heart disease (Han et al. 1996). Waist circumference and waist-to-hip (WHR) ratio have been used to indicate central adiposity. Although relatively easy to measure, WC or WHR must be collected and measured by trained personnel and cannot typically be self-reported or easily collected from stored records, such as height and weight for BMI calculations. Very few large epidemiologic studies examining obesity and mortality risk in older women have measured central adiposity using either WC or WHR.

Likewise, there are limited data on the relationship between the risk of mortality in older women and direct measures of body fat, such as percent body fat, fat mass, or lean mass, using either BIA or DXA measurements. The BIA technique assumes a two-compartment model of body composition (fat mass and lean mass). Based on the principle that tissues that contain water and dissolved electrolytes conduct electricity, the observed electrical impedance of body tissues can be used to estimate the total body water content, lean mass, and fat mass.

DXA uses a three-component model of body composition and is able to estimate bone mineral content in addition to fat mass and lean mass. By using the attenuation of radiation beams at two different energies, DXA can estimate the composition of body tissue (Mazess et al. 1990). Although considered superior to BIA, DXA is not considered a true gold standard because, like all measures of body composition, it is subject to measurement error and relies on various assumptions.

Thus, because of its low cost and ease of use and interpretability, BMI has been the predominant measure used in studies of adiposity and mortality in older women.

88.3 BMI and Mortality Among Older Women

Several, large, prospective cohort studies have reported a U-shaped relation between body size and mortality among women (Lew and Garfinkle 1979; Waaler 1984; Harris et al. 1988; Folsom et al. 1993; Durazo-Arvizu et al. 1997; Lindsted and Singh 1997; Durazo-Arvizu et al. 1998; Sempos et al. 1998; Allison et al. 1999; Calle et al. 1999; Singh et al. 1999; Dey et al. 2001; Katzmaryzk et al. 2001; Lahmann et al. 2002; Bigaard et al. 2004; Flegal et al. 2005; Corrada et al. 2006; Dolan et al. 2007; Thinggaard et al. 2010). In addition, many of the studies report that the lowest mortality risk in older women is often observed in BMI categories, including overweight and/or even obese women.

Both the American Cancer Society Study (Lew and Garfinkle 1979), which included over 400,000 women aged 30 years and older, and a study from Norway of over 900,000 women aged 15–90 years reported a U-shaped relation between BMI and mortality (Waaler 1984). However, neither the American Cancer Society Study nor the Norwegian study adjusted for smoking. The Nurses Health Study, which includes over 115,000 women aged 30–55 years at baseline, reported that, after adjusting for smoking, the association between BMI and mortality was linear (Manson et al. 1995). They suggested that the U-shaped relation between BMI and mortality reported in the literature could be due to smoking. It is possible that the mortality risk associated with BMI may be more linear in middle-aged women, as shown in the Nurses Health Study, but J- or U-shaped in older women.

However, other studies of women in age groups similar to the Nurses Health Study have controlled for smoking and still reported a U-shaped relation between body size and mortality, including a large cohort of female nonsmokers aged 25–64 years in Finland, the Iowa Women's Health Study, and the Framingham Heart Study (Rissanen et al. 1991; Folsom et al. 1993; Harris et al. 1988)]. A reanalysis of the Framingham Heart Study data concluded that the U-shape was not due to smoking and that the BMI associated with minimum mortality was similar for smokers and nonsmokers (Sempos et al. 1998). The American Cancer Society Cancer Prevention Study II that included more than 588,000 women and 14 years of follow-up data also had a U-shaped relation between BMI and mortality. This relationship was evident for smokers and nonsmokers, although the shape of the curve was flatter for nonsmokers (Calle et al. 1999). Data from a study including a cohort of 6,523 Alameda County Study women up to the age of 75 years concluded that only the underweight and moderately to extreme obese are at increased risk of mortality, more evidence of the U-shape (Strawbridge et al. 2000). The author asserted that the NHLBI guidelines categorize too many people as overweight and do not sufficiently account for sex, race and ethnicity, age, and other differences and fail to consider the health risks of low body weight.

This lower relative risk (RR) of mortality among older women was also observed in data from the American Cancer Society (Calle et al. 1999; Stevens et al. 1999). However, the authors of the Cancer Prevention Study II concluded that there was a consistent increase in mortality observed with increasing weight, supporting the use of a single recommended range of body weight throughout life (Calle et al. 1999). Others maintained that the data did not support age-independent standards and, among older women, only BMI values greater than 28.0 kg/m^2 were associated with increased mortality (Durazo-Arvizu et al. 1997).

A study among Seventh Day Adventists reported that the risk of mortality associated with high levels of BMI was lower for older women (55–74 years old) compared to younger women (30–54 years old) (Lindsted and Singh 1997). In one study from Finland, BMI was not an important predictor of mortality in women 65 years or older (Rissanen et al. 1991). Further, in a recent analysis of the Finnish Twin Cohort, there was no linear association apparent between BMI and mortality in older women (Korkeila et al. 2009). Data from the Leisure World Cohort Study, a population-based cohort from California including 8,571 women, suggested that being underweight or obese was a risk factor

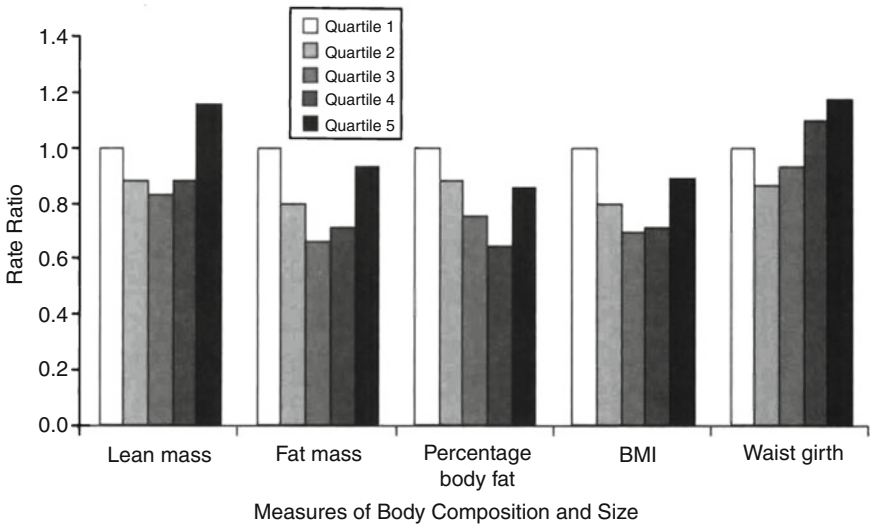

Fig. 88.1 Graphical representation of the linear spline Cox regression for age groups (Thinggaard et al. 2010, ©2010 The Author)

for mortality among those aged 75 years and older (Corrada et al. 2006). Overweight was a risk factor for mortality only in those under 75 years of age, demonstrating the different risks associated with adiposity in the elderly.

Data from the Jerusalem Longitudinal Study also supported a different relation between obesity and risk of mortality in the elderly than in younger populations. They reported that obesity was not associated with increased mortality risk in women when examined at 70, 78, and 85 years of age (Stessman et al. 2009).

In a recent analysis from the Longitudinal Study of Aging Danish Twins, Thinggaard et al. examined the relationship between mortality and BMI and concluded that, in older women, the highest risk of mortality was consistently observed in the underweight and overweight subjects (Thinggaard et al. 2010). They also reported that the U-shaped relationship decreased or flattened with advancing age among women (from age 70 to 95 years) in this Danish cohort (Fig. 88.1). Low BMI was consistently associated with higher mortality than even the highest levels of BMI. This somewhat disputes other data. Although this was a large population-based cohort with high participation rates, it is important to note that the authors did not control for initial health or other risk factors that could potentially confound the relationship.

88.4 Results from Meta-Analysis Studies

In 2007, a large meta-analysis on the association between BMI and risk of mortality in older women and men calculated the summary relative riskRR for all-cause mortality associated with the WHO- and NHLBI-defined BMI categories of overweight and obesity (Janssen and Mark 2007). Overall, the summary RR for all-cause mortality was 1.02 (95% confidence interval (CI) = 0.98–1.05) for overweight women and 1.18 (95% CI = 1.13–1.24) for obese women. BMI in the overweight range (25.5–29.9 kg/m^2) was not associated with an increased risk of mortality in older women, and there was only a modest risk associated with mortality in obese women (BMI ≥ 30 kg/m^2).

Table 88.2 Cohort studies between 1989 and 2009 identifying optimal BMI ranges in older women

Source, year/study	Applicable age or age range (y)	Optimum BMI (kg/m^2)

Rissanen et al., 1989/Social Insurance Institute of Finland Survey	≥75	28–31

Another meta-analysis of BMI and mortality confirmed excess mortality among obese women but not among overweight women (McGee 2005). For women in the overweight BMI category, relative to women in the normal-weight category, McGee calculated an RR of 0.968 (95% CI = 0.925 to 0.987). The RR associated with the obese BMI category relative to normal weight was 1.275 (95% CI = 1.183, 1.373). In their models, the author controlled for age, but this analysis did not specifically address the risk in older women. In a review of the evidence regarding the NHLBI and WHO guidelines, Heiat et al. concluded that the data do not support the inclusion of the BMI range between 25 and 27 (part of the overweight category) as a risk factor for all-cause mortality in older women and that most studies show a negative or no association between BMI and mortality (Heiat et al. 2001).

Combining data from studies included in the published meta-analyses and reviews and more recently published data, Table 88.2 shows the BMI ranges that are associated with lowest risk of mortality in several large epidemiologic cohort studies (Janssen and Mark 2007; McGee 2005; Heiat et al. 2001).

In most studies, the BMI in the "optimum range" and thus associated with the lowest mortality risk included or exceeded the BMI categorization for overweight and, in some cases, included the BMI categorization for obese. To this point, in another study combining data from five prospective cohorts in USA, more than 80% of deaths attributable to obesity were among individuals with a BMI greater than 30 kg/m^2, the lower cut-point for obesity (Allison et al. 1999).

88.5 Using Different Measures of Body Composition and Anthropometry to Assess Risk of Mortality

Although BMI has been criticized as a potentially biased measure of anthropometry in older women, most of the large cohort studies only use BMI. In order to more fully understand the nature of the relation between overweight and obesity and risk of mortality in older women, we identified three relatively recent, large cohort studies that included multiple measures of anthropometry and adiposity including BMI (indirect measure of adiposity), BIA (direct measure of adiposity), and WC or WHR (measure of central adiposity): The Study of Osteoporotic Fractures (SOF), The Malmö Diet and Cancer Study, and The Melbourne Study (Dolan et al. 2007; Lahmann et al. 2002; Simpson et al. 2007).

88.6 The Study of Osteoporotic Fractures

One of the few studies to examine the risk of mortality and multiple measures of adiposity in the same cohort is based on data from The SOF, a large, prospective, cohort study of fractures among predominantly white women age 65 years and older, who were being followed up as part of a study on hip fractures. Details of the SOF cohort and its study design have been previously published (Cummings et al. 1990). Direct body composition measures included fat mass (kg), lean mass (kg), and percent body fat and were calculated using BIA. BMI and WC (cm) were also measured.

Women aged 65 years and older were recruited from September 1986 to October, 1988, from community-based listings in the geographic areas of Baltimore, Maryland; Minneapolis, Minnesota; Portland, Oregon; and the Monongahela Valley area near Pittsburgh, Pennsylvania. Most of the participants (greater than 98%) were white.

BMI (kg/m^2) was calculated based on measured weight and height. Waist girth (cm) was measured using an inelastic tape measure. Fat mass, lean mass, and percent body fat were calculated from BIA. During the follow-up period, 945 deaths occurred among the 8,029 women who had complete anthropometric measures. All of the measures of body composition and anthropometry were quite highly correlated with one another.

Body measures were categorized into quintiles, and Cox proportional hazards regression models were used to estimate the RR of mortality associated with each body measurement category. There was a U-shaped relation between each of the body-size measures and mortality that persisted when adjustments were made for potential confounding factors, including age, self-reported health, smoking, grip strength, non-thiazide diuretic use, and femoral-neck BMD (Fig. 88.2). Among nonsmokers, the patterns of associations between quintiles of body-size measures and mortality were similar to the results for the entire cohort (Fig. 88.3). The U-shaped relationship between body-size measures and mortality persisted after further controlling for hypertension and diabetes and when exclusions were made for women who died within the first 2 years of follow-up, or for women who had lost greater than 10% of their body weight since age 50 years. Thus, the U-shaped relationship was not likely the result of uncontrolled confounding due to smoking or preexisting medical conditions.

In the SOF cohort, the lowest risk was consistently observed among women falling in the middle of the distributions of all the body composition and anthropometric measures. In this population of older women, BIA, the more costly measure of body composition, did not provide an obvious advantage or difference in predicting mortality over BMI or waist girth.

The BMI values for the two quintiles at lowest risk were between 24.6 and 29.8 kg/m^2, and the optimal value was estimated to be 29.3 kg/m^2. These results cautioned against applying the recent National Institutes of Health classifications for overweight and obesity to older women with BMI greater than 25 kg/m^2, as many of these women are in the lowest risk group for mortality. The results

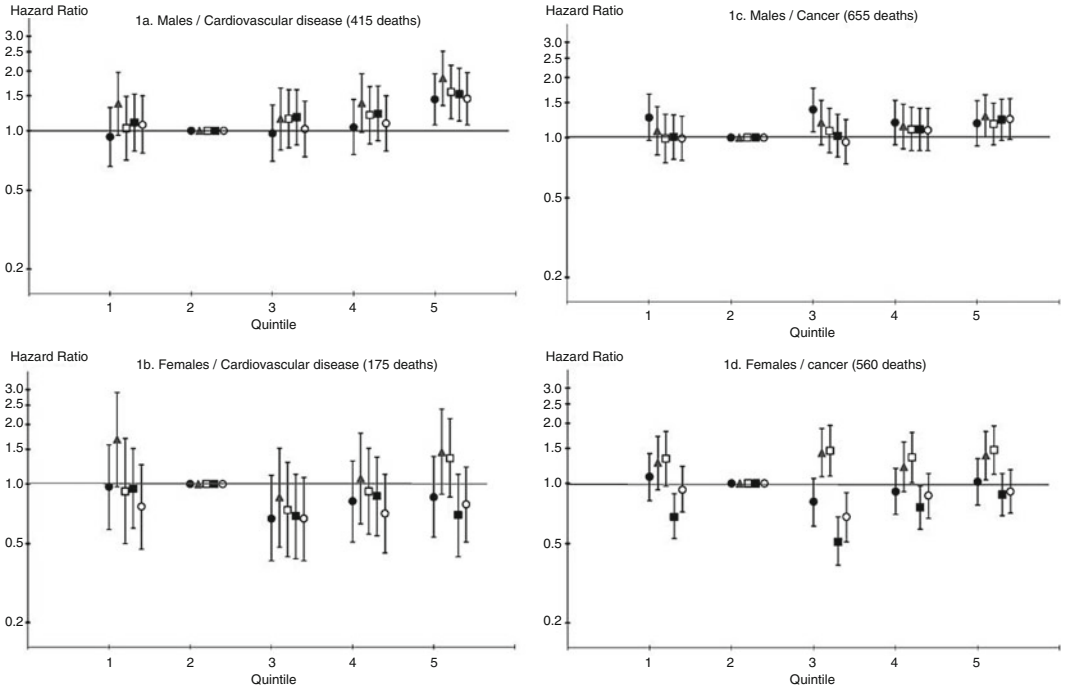

Fig. 88.2 Quintiles of body composition measures and mortality risk in women aged 65 years and older: study of osteoporotic fractures (SOF); Baltimore, MD; Minneapolis, MN; Portland, OR; Monongahela Valley Area, PA; 1986–1997 (Dolan et al. 2007, ©2007 APJH)

showing minimum mortality in the middle of the distribution of BMI and body composition levels are consistent with data from the NHANES-I Epidemiologic Follow-up Study, which demonstrated a broad range of BMI values associated with low risk of mortality (Durazo-Arvizu et al. 1998).

88.7 The Malmö Diet and Cancer Study

The Malmo Diet and Cancer Study is one of only two other large cohort studies besides the SOF cohort that examined the association between adiposity and all-cause mortality, using multiple measures of adiposity in older women. The study was a prospective population-based cohort study among residents of Malmo, Sweden (Lahmann et al. 2002). BMI (kg/m^2) was calculated based on measured weight and height. The waist and hip circumference of each participant were measured by trained personnel and used to construct the WHR. BIA analyses were conducted to estimate lean body mass and percent body fat. Body measures were categorized into quintiles, and Cox proportional hazards regression models were used to estimate the RR of mortality associated with each body measurement category. The lowest quintile was used as the reference category. Models were adjusted for potential confounders including age, height, smoking status, and physical activity.

The final female cohort included 17,035 women born between 1923 and 1950, with complete data for all measurements. Participation rate was approximately 40%. The study found a direct, positive, linear relationship between percent body fat and mortality in the middle-aged women (45–59 years of age). Among older women (60–72 years of age), the study observed a J-shaped association between percent body fat and risk of mortality, with the women in the quintiles 2–5 at lower risk than women in the bottom quintile. The lowest risk for percent body fat was observed in the second quintile RR = 0.47 (95%

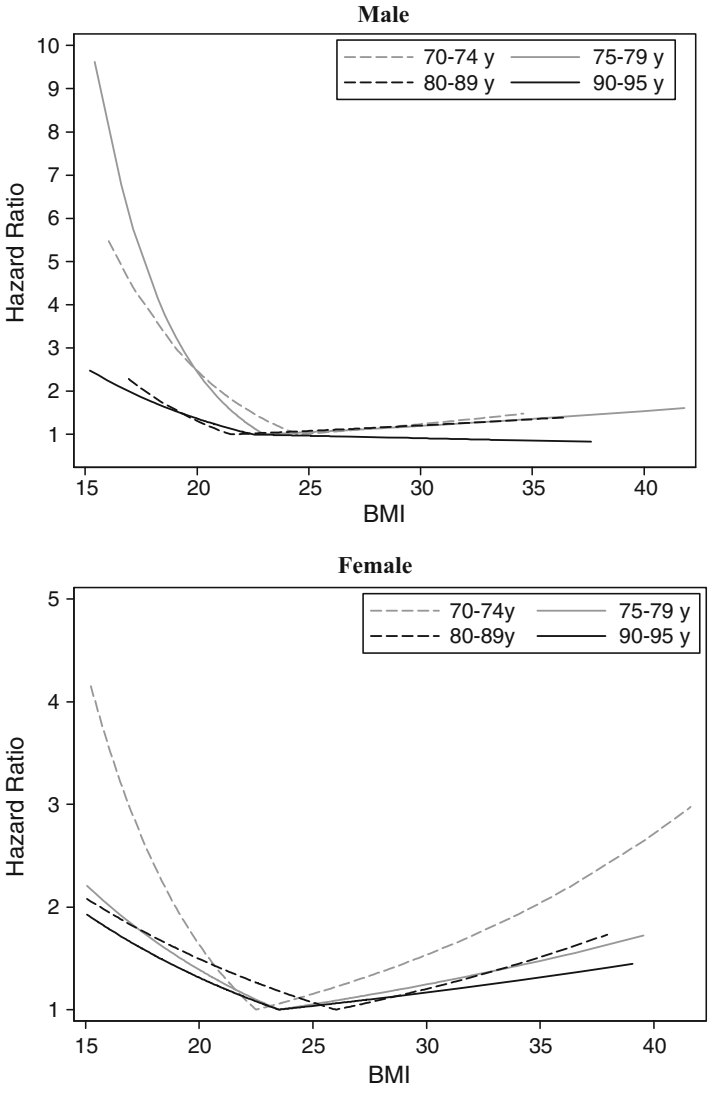

Fig. 88.3 Adjusted rate ratios (RRs, with 95% confidence intervals [CIs]), by quintile of body composition measures in women aged 65 years and older: SOF; Baltimore, MD; Minneapolis, MN; Portland, OR; Monongahela Valley Area, PA; 1986–1997 (Dolan et al. 2007, ©2007 APJH)

CI = 0.30–0.74), corresponding to body fat between 27% and 30%. A U-shaped association was observed between lean mass and mortality, though none of the RRs was statistically significant. A J-shaped association was observed for BMI and mortality risk, though, like lean mass, no significant associations were observed between BMI and risk of mortality. The authors noted that there was no evidence of excess mortality in the WHO- and NHLBI-defined overweight category of 25.0–29.9 kg/m^2 when compared to the normal weight category (BMI 18.5–24.9 kg/m^2). When they analyzed the WHR quintiles, they observed a positive linear association between central adiposity and mortality risk. The highest risk of mortality in older women was observed in the highest quintile of the WHR (RR = 2.13 (95% CI = 1.52 to 3.00). These observations were not due to early death or preexisting illnesses.

These data from the Malmo Diet and Cancer Study support the J- or U-shaped relation between percent body fat, lean mass, and BMI and risk of mortality. However, in this study, only RR estimates for quintiles of percent body fat were statistically significant. The WHR, by contrast, demonstrated

a strong direct linear relation with mortality risk. The authors concluded that central adiposity and WHR constitute a more useful measure of estimating mortality risk in older women than either the more commonly used BMI or the expensive BIA estimates of percent body fat and lean mass.

88.8 The Melbourne Collaborative Cohort Study

The Melbourne Collaborative Cohort Study also examined the relationship between multiple measures of body composition and anthropometry and risk of mortality in a cohort including older women (Simpson et al. 2007). The study participants were recruited from the Melbourne metropolitan area between 1990 and 1994. Weight, height, WC, and hip circumference were measured at baseline using standard protocols. BIA was conducted to estimate fat mass and percent fat mass. The final cohort included 24,344 women with 99% in the age range 40–69 years. There were 1,166 deaths during a median follow-up period of 11 years.

Each body composition and anthropometric measure was divided into quintiles. Cox proportional hazards regression models were used to estimate the hazard ratios (HRs) for mortality risk for each anthropometric and body composition measure, using the second quintile as the referent group. The models were stratified for previous history of illness at baseline and adjusted for age, country of birth, physical activity, alcohol intake, education, and smoking status based on descriptive characteristics.

Results from the regression models showed that the association between BMI, WC, fat mass, and percent body fat all had a U-shaped association with mortality risk, whereas WHR demonstrated a linear relationship with mortality (see Fig. 88.4). Women in the highest quintile of WC and WHR had increased risk of mortality compared to women in the referent group (HR = 1.3 (95% CI = 1.1–1.6) and HR = 1.5 (95% CI for HR = 1.2–1.8), respectively). They observed little or no increased risk in the highest quintiles of BMI, fast mass, and percent body fat. They concluded, like the Malmo Diet and Cancer Study, that measures of central adiposity were better predictors of mortality risk than BMI or BIA measures of body composition.

88.9 Measures of Central Adiposity: Are They Better than BMI or Measures of Body Composition at Predicting Mortality Risk?

Interestingly, none of the three large cohort studies that have examined the association between multiple measures of adiposity (including central adiposity) and the risk of mortality were able to detect a clear advantage of using the BIA-estimated percent body fat, fat mass, or lean mass, the more expensive and direct measures of body composition. Both the Malmo Diet and Cancer Study and the Melbourne Collaborative Cohort Study observed a strong, direct, linear (not U-shaped) relation between WC (Melbourne Collaborative Cohort Study) or the WHR (Malmo Diet and Cancer Study) and risk of mortality. By contrast, the SOF study observed a U-shaped relation between all of the measures of anthropometry (including WC) and mortality in older women. Waist circumference was not a stronger predictor of mortality than BMI or body composition measures in the SOF data set.

Unfortunately, studies examining the association of central adiposity and mortality risk in older women are limited. One other large cohort study has examined the association between central adiposity in older women (though they did not include direct measures of adiposity, such as BIA). The Rotterdam Study was a population-based cohort study in Ommoord, the Netherlands (Visscher et al. 2001). Study participants were recruited from 1990 to 1993 and included 3,694 women 55–102 years of age with a mean follow-up period of 5.4 years. There were 477 deaths during this period. BMI was calculated based on measured height and weight (kg/m^2). Waist and hip circumference

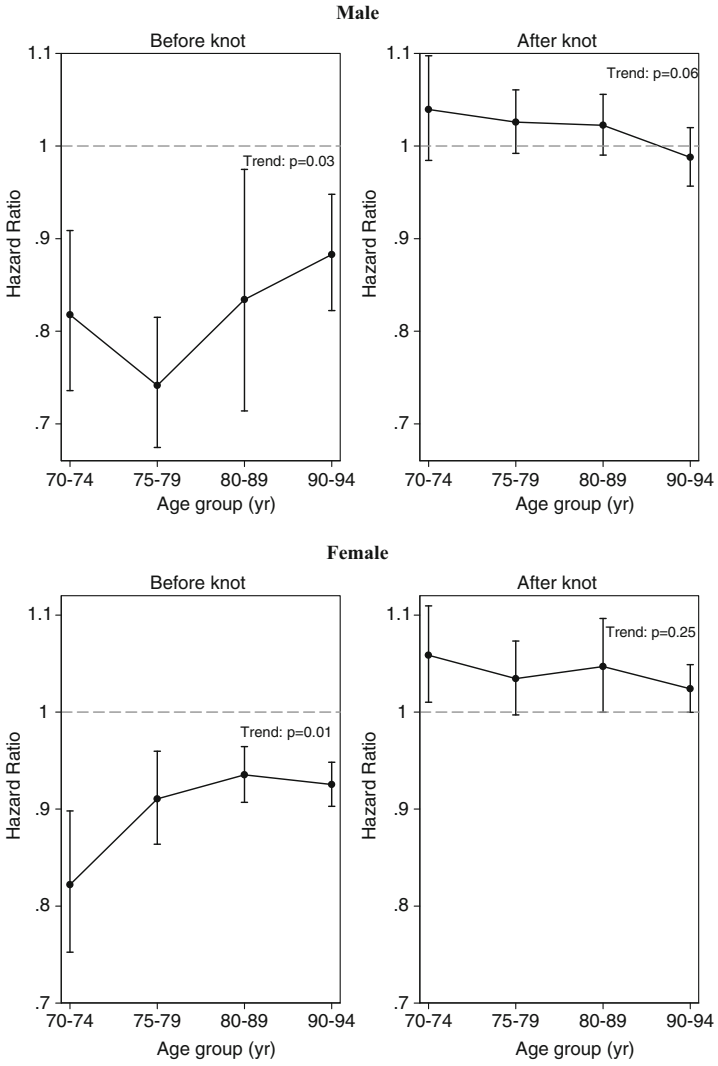

Fig. 88.4 Anthropometric risk factors for all-cause mortality (Simpson et al. 2007, ©2007 NAASO)

were measured by trained study personnel. All the measures of body size were divided into quintiles for analysis. Age-adjusted Cox proportional hazards regression models were used to estimate the RR for each body measure. The second quintile was designated as the reference category. Analyses were stratified by smoking status (never, former, and current).

Among elderly women, high levels of body fatness measured by BMI, WC, or WHR did not predict increased mortality risk. Although the quadratic term for BMI was significant in the regression models for never-smoking elderly women suggesting a U-shaped relation, the individual RR did not appear elevated at either the lowest quintile or highest quintile of BMI.

Thus, in the Rotterdam Study, none of the measures were predictors of mortality risk in these elderly women and the measures of central adiposity did not provide an advantage over BMI. The study may have been limited in size and ability to control for other potential risk factors, such as underlying or preexisting disease.

The data on the association between the measures of central adiposity and mortality risk are quite limited and somewhat contradictory. Although both the Malmo Diet and Cancer Study and the

Melbourne Collaborative Cohort Study suggested that central adiposity measures were strong, linear predictors of mortality in elderly women, neither the SOF cohort nor the Rotterdam Study supports these conclusions. In a study including older Chinese women, Woo et al. concluded that both WC and BMI had an inverse association with mortality and that WHR was not a useful predictor of mortality risk (Woo et al. 2002). Hopefully, more studies will include measures of WC or WHR, so that the relation between central adiposity and risk of mortality is more clearly understood.

Because the link between obesity and risk of mortality is so widely studied and has such significant public-health implications, it would be useful to identify the single body-size measure that best predicts mortality. It is difficult to conclude from the available literature that which of the measures of body composition and anthropometry "best" predicts mortality. Although the data are limited, the three large cohort studies that measured body composition, central adiposity, and BMI in older women concluded that the more direct specific measures of body composition by BIA did not provide a clear advantage over either BMI or the central adiposity measures. The additional cost and difficulty of obtaining BIA or DXA favor the use of BMI and WC, both of which are relatively easy and inexpensive to measure.

88.10 Anthropometric Measures and Mortality in Non-White Ethnic or Racial Groups

The vast majority of the studies examining anthropometric measures and risk of mortality in older women have been in white women in USA, Europe, and Australia. Very few studies have been conducted in older women of other racial or ethnic groups. Data regarding older black women are particularly limited. Using data from the NHANES I Epidemiologic Follow-up Study and the National Health Interview Survey showed that the BMI values associated with minimum mortality risk and the U-shaped association with mortality were very similar among blacks and whites (Durazo-Arvizu et al. 1997). In another analysis of the NHANES data, the optimum BMI range for lowest mortality risk was higher for black women than for white women, although similar risks were associated with high and low BMI for older black and white women (Cornoni-Huntley et al. 1991). Studies in older Asian women are also quite limited. It has been suggested that a lower cut-point to define obesity may be needed in Asian populations (WHO 2000); however, recent data from a cohort of Koreans reported that the obesity-related mortality was similar to that observed in whites (Oh et al. 2004).

88.11 Summary and Conclusions

In summary, it is possible to draw some conclusions about the association between measures of anthropometry and risk of mortality in older women. First, there is strong evidence that the relationship between adiposity is different for older women than younger women. Evidence suggests that the BMI associated with lowest risk of mortality in older women is higher than in younger women and that it includes overweight and, possibly, moderately obese women. There is also substantial support for the U-shaped relation between BMI and mortality in older women, suggesting that women at the lower and higher ends of the BMI spectrum are at greater risk than those in the middle part of the distribution. There is also evidence that this U-shape is attenuated with age and "flattens" with advancing age.

88.12 Practical Application to Future Studies of Anthropometric Measures and Mortality in Older women

Because BMI is easy to measure and calculate, the bulk of the studies examining the association between adiposity and mortality in women has been based on BMI data. In general, in studies with available data, the more direct measures of body composition, such as fat mass, lean mass, or percent body fat estimated by BIA, did not prove to be substantially better at predicting mortality risk in older women than the BMI data in the studies that had BIA-estimated measures of body composition. Although some studies have suggested that measures of central adiposity may be stronger predictors of mortality in older women than BMI, others have not observed that central adiposity is different or better than BMI. In order to more fully understand the complex relation between measures of body size and adiposity and risk of mortality in older women, more studies are needed that measure both BMI and central adiposity.

The vast majority of the large cohort studies on anthropometry and mortality in older women have been confined to populations of white women in USA, Europe, and Australia. More data on other ethnic/racial groups in different areas of the world are needed to better understand the relationship of measures of anthropometry and mortality risk in non-white populations.

88.13 Application to Clinical Guidelines for Overweight and Obesity

Several of the large prospective cohort studies and meta-analyses have concluded that the NHLBI and WHO guidelines for BMI cut-points defining overweight and obesity should be interpreted with caution and are not appropriate when applied to older women. Many studies have found that there is a wide range of optimum BMI levels for minimum mortality risk and that this range includes BMI values in the overweight category and, even in some studies, the obesity category. The totality of the data do not support the classification of older women, who have a BMI of 25–29.9 kg/m^2, as overweight and at risk for increased mortality, as these ranges were associated with the lower risks of mortality in most studies.

88.14 Application to Other Areas of Health and Disease

Among older women, there does appear to be some survival benefit associated with increased adiposity. The reasons for this survival advantage are not well understood. It is possible that those women susceptible to the effects of excess body weight died at younger ages. It is also possible that the excess weight confers some type of real survival advantage in older women, whether through biologic activity of fat cells or through other means. More research is needed to understand the biological mechanism related to this survival advantage.

This review has not addressed the risk of cause-specific mortality or the association between anthropometry and body size and risk, or morbidity, or disability. These results that show a lower risk of mortality among overweight or even obese women in some cases should not be applied to risk of morbidity. Interestingly, a recent examination of the association between obesity on risk of both mortality and disability showed that the protective effect of obesity on mortality did not extend to disability (Lang et al. 2008), thus suggesting a potentially very important paradox and difficult public-health problem in which overweight and obese women may have some type of mortality protection but without an accompanying protection against morbidity or disability.

Table 88.3 Key features of three large cohort studies that included multiple measures of anthropometry and adiposity and risk of mortality in older women

Cohort	Study population	Body-size measures included	Average length of follow-up period	Number of deaths during follow-up period	Variables controlled for in analyses	Study Results
SOF (Dolan et al. 2007)	• Predominantly white (98%) women aged 65 and older • From Baltimore, MD, Minneapolis, MN, Portland, OR, and near Pittsburgh, PA • Recruited from voter registration lists, driver's license and ID card information, and HMO membership lists • Baseline dates: September 1986–October 1988 • $N = 9704$ • Mean Age: 73.2 years • Mean BMI: 26.2 kg/m^2	• BIA (Lean Mass, Fat mass, and % Body Fat • BMI (Height and Weight) • Waist circumference (WC)	8 years	945	• Age • Smoking status • Alcohol use • Femoral-neck bone density • Self-reported health status • Physical activity level • Grip strength • Non-thiazide diuretic use	U-shaped relations were observed between all measures of body size and mortality throughout the age ranges in the study. For BMI, the lowest mortality rates were in the range 24.6 to 29.8 kg/m^2. Results not attributable to smoking or measures of preexisting illness.
Malmö Diet and Cancer Study (Lahmann et al. 2002)	• Men and women aged 45–73 years • Randomly sampled from Sweden's National Population Registry • Baseline dates: 1991–1996 • $N = 16{,}814$* • Mean age: 59.2 years* • Average BMI: 25.5 kg/m^{2*}	• BIA (Lean Mass, % Body Fat) • BMI (Height and Weight) • Waist-to Hip Ratio (Waist and Hip circumference)	5.7 years	392*	• Age • Height • Smoking status • Physical activity level	The association between % body fat and mortality was modified by age. Weaker associations were seen for BMI than for % body fat. WHR stronger predictor of mortality in women Results not explained by bias from early death or preexisting illness.

Melbourne Collaborative Cohort Study (Simpson et al., 2007)	• Men and women aged 27–75 years from the Melbourne metropolitan area (99.3% of subjects were 40–69 years of age) • Recruited through electoral rolls and advertising • Baseline dates: 1990–1994 • *N* = 24,344* • Median BMI: 25.9 kg/m^{2*}	• BIA (Fat Mass, % Body Fat) • BMI (Height and Weight) • Waist-to-Hip Ratio (Waist and Hip Circumference) • WC	11 years	1166*	• Age • Country of birth • Physical activity level • Alcohol use • Education • Previous history of heart attack, angina, diabetes, stroke, and cancer • Smoking status	U-shaped relation between WC and mortality. WHR was positively, linearly related to mortality risk Little or no increased mortality risk for BMI, fat mass, or % body fat

*Women

Summary Points

- The relation between anthropometric measures and mortality is different for older women than younger women; the BMI associated with the lowest risk of mortality is higher among older women than younger women.
- The BMI ranges associated with minimum mortality in older women include WHO and NHLBI categories of overweight and, in some studies, obesity.
- Direct measures of body composition, such as BIA-measured fat mass, lean mass, and percent body fat do not appear to provide an advantage over BMI or measures of central adiposity in predicting mortality risk.
- Limited data on measures of central adiposity and risk of mortality are inconsistent. More research is needed to better understand the association between central adiposity and mortality risk in older women.
- Most of the studies on anthropometry measures and mortality risk in older women have been conducted in white populations in USA, Europe, and Australia. More studies are needed to understand the association of anthropometry and mortality risk in non-white populations.
- The results showing a protective effect of increased adiposity on mortality do not necessarily extend to morbidity or disability.

Chapter 89
Postmenopausal Anthropometric Relationship Between Arm Span and Height in Osteoporosis

Demet Ofluoglu

Abstract Osteoporosis is a skeletal disorder characterized by compromised bone strength predisposing a person to an increased of risk fracture. The most frequently observed osteoporotic fracture is a vertebral fracture, resulting in vertebral deformities. In the aging population and especially osteoporotic women, changes in body composition and some anthropometric measurements have been noted. Loss of height increased with age and is frequent in middle-aged women. It is caused by decreasing height of the intervertebral discs and joint cartilage, less pronounced foot arches and postural changes. Another important cause of the age-related height loss is the reduction in vertebral height due to osteoporotic vertebral fractures and structural changes, these being more frequent in women. Arm span is recommended as an acceptable measure for height in clinical situations where it is difficult to measure standing height limited by contractures, fractures, scoliosis, amputation, quadriplegia, paraplegia, coma, or existing osteoporotic fractures. Arm span is a valid measure of height in young and middle-aged adults. Arm span measurements can be used in estimation of youth height and age related loss in stature. Measurement of height loss is a good clinical indicator of vertebral fracture. Greater than 6 cm height loss can be a finding for osteoporotic vertebral fractures, therefore a spinal X-ray should be obtained. The sensitivity and specificity of the arm span – height differences for having osteoporosis is high. Therefore, arm span – height differences can be used for the initial screening of vertebral deformities in postmenopausal women. This chapter discusses the relationship between height and arm span differences in postmenopausal osteoporotic women.

Abbreviations

AS	Arm span
ASHD	Arm span – Height Differences
DEXA	Dual energy X-ray absorptiometry
FEV1	Forced expiratory volume in one second
FVC	Forced Vital Capacity
SD	Standard deviation
VD	Vertebral deformity

89.1 Introduction

Osteoporosis is commonly seen in people over 50 years of age, and is a major cause of fractures. In the earlier part of 2000, the estimated worldwide incidence of osteoporotic fractures was nine million (Johnell and Kanis 2006). The incidence of osteoporotic fractures will continue to increase as the population ages. The most frequently observed osteoporotic fracture is in the spine, which causes vertebral deformities. These can lead to morbidity in the form of chronic back pain, loss of height, kyphosis, and functional impairment (Rea et al. 2000).

Anthropometry has been used over the centuries to distinguish the differences between the human races. It plays in important role in industrial design, clothing design, architecture, as well as in medicine. Some diseases and their expression, such as marfanoid stature, can be identified with anthropometric measurements.

Changes in body composition and some anthropometric measurements have been noted in the aging population and in osteoporotic women. In this chapter on postmenopausal osteoporosis, the relationship between arm span and height will be discussed.

89.2 Osteoporosis: Definition, Risks, and Management

Osteoporosis is a skeletal disorder characterized by compromised bone strength, predisposing a person to an increased risk of fracture. Bone strength primarily reflects the integration of bone density and bone quality (Brown and Fortier 2006; Kanis et al. 2008). Approximately one in four women and one in eight men have osteoporosis, according to fracture data in Canada (Jackson et al. 2000).

Osteoporosis is becoming a major public-health problem, as the population ages all over the world. The prevalence of osteoporosis increases with age, from approximately 6% at 50 years of age to over 50% above 80 years of age (Looker et al. 1997). Generally, osteoporosis is called a silent bone disease till a fracture occurs. However, patients can suffer back pain, loss of height, and postural disorders, such as kyphosis of the spine. The major problem (in osteoporosis) is fractures, the highest incidence being vertebral, followed by wrist and hip fractures (Rea et al. 2000). A 50-year-old Caucasian woman has a residual lifetime fragility fracture risk of 40% for vertebra, hip, or wrist (Brown and Fortier 2006).

There are many risk factors associated with osteoporosis, such as age, sex, low body mass index, glucocorticoid treatment, smoking, alcohol intake, inflammatory disease, and thyroid disorders (see Table 89.1) (Kanis et al. 2008). The main cause of postmenopausal osteoporosis is estrogen withdrawal. Figure 89.1 shows a postmenopausal osteoporotic woman. However, coexistence of other risk factors can facilitate the development of postmenopausal osteoporosis.

The diagnosis of osteoporosis requires a thorough history and physical examination, including family history of osteoporosis, type and location of musculoskeletal pain, general dietary calcium intake, and level of physical activity and height and weight measurements (see Table 89.2) (Sinaki 2000). However, the objective of bone mineral measurements is to provide diagnostic criteria, prognostic information on the probability of future fractures, and a baseline on which to monitor the natural history of the treated or untreated patient (Kanis et al. 2008). Typically, osteoporosis is not visible on conventional radiographs until at least 25–30% of bone mineral has been lost. There are many methods to evaluate bone mineral density; however, the most commonly used technique is dual energy X-ray absorptiometry (DEXA) (Sinaki 2000). The technique has high precision and

Table 89.1 Common risk factors for osteoporosis

Age: over 65 years
Fragility fracture after age 40 years and/or family history of osteoporotic fracture
Early menopause (before age 45 years)
Nutritional factors:
Malnutrition
Anorexia/bulimia
Vitamin deficiency (C or D)
Vitamin overuse (D or A)
Calcium deficiency
High sodium intake
High caffeine intake
High protein intake
High phosphate intake
Alcohol abuse
Sedentary lifestyle, immobility, and smoking
Gastrointestinal diseases (liver disease, malabsorption syndromes, alactasia, and subtotal gastrectomy) or small-bowel resection
Nephropathies
Chronic obstructive pulmonary disease
Malignancy (multiple myeloma and disseminated carcinoma)
Drugs: phenytoin, barbiturates, cholestyramine, and heparin
Endocrine disorders: Acromegaly, hyperthyroidism, Cushing's syndrome, hyperparathyroidism, diabetes mellitus, and hypogonadism

Age, fracture history in both patients and their family, early menopause, malabsorption syndrome, hypogonadism, and primary hyperparathyroidism are very important risk factors for osteoporosis. Bone mineral density should be measured in women under the age of 65 years with these risk factors or for all women age 65 years and older because of the high risk of osteoporosis and fracture after that age

accuracy. According to World Health Organization criteria, bone mineral density is classified as follows: *T*-score > -1 standard deviation (SD), normal; *T*-score -1 to -2.5 SD, osteopenia; *T*-score of -2.5 SD or less, osteoporosis. A *T*-score at or below -2.5 and the presence of one or more fragility fractures is termed severe or established osteoporosis (see Table 89.3) (Wahner 1996; Brown and Josse 2002). The treatment of osteoporosis is planned according to this classification and severity. Apart from the many types of drugs available for the treatment of osteoporosis, exercises and the prevention of bone loss are an important part of the management.

Prevention is as important as the treatment of osteoporosis. The goal for osteoporosis in both prevention and treatment is the same: maintaining bone health to ensure a low risk of fracture and to improve the quality of life. Prevention begins in childhood and continues throughout life. The more the subjects build up bones during their early years, the less likely they are to develop osteoporosis later on. The factors for prevention of osteoporosis include avoiding the risk factors of osteoporosis, good nutrition (adequate intake of calcium and vitamin D), regular physical activity (at least 30 min walking three times a week), healthy habits and behaviors, good posture, and medications. When combined, these factors support and strengthen one another to help prevent or manage osteoporosis.

The treatment goal of osteoporosis includes maximizing the development of the skeleton, preventing fractures, relieving the symptoms of fractures, improving the balance, and the ability to move and be active. Once osteoporosis is diagnosed, in addition to diet and exercise, medications are often prescribed for people at high risk of developing osteoporosis and those who have been diagnosed

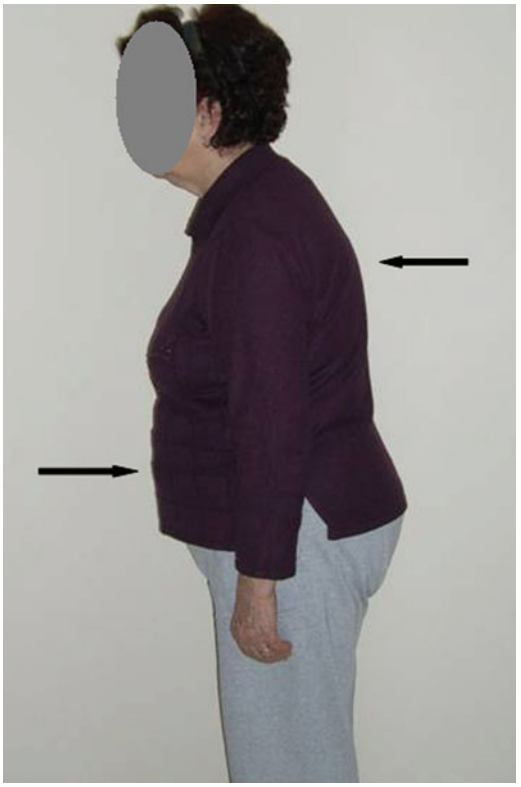

Fig. 89.1 A postmenopausal osteoporotic woman. She was a 73-year-old woman with osteoporosis. The figure indicates increased kyphosis and abdominal protrusion due to thoracic kyphosis. She complained of back pain and loss of height by at least 5 cm. Her height and arm span were 165 and 172 cm, respectively. She had low bone mineral density in her DEXA measurement and two osteoporotic vertebral compression fractures in her T 12 and L 1 vertebrae

Table 89.2 Diagnostic evaluation for osteoporosis

History and physical examination
Radiography of chest and spine
Bone mineral density (hip and spine)
Complete blood cell count
Chemistry group

Total thyroxine
Immunoreactive parathyroid hormone
25-Hydroxyvitamin D and 1,25-dihydroxyvitamin D
Urinalysis and 24-h urine
Biochemical markers of bone turnover

Evaluation of osteoporosis in postmenopausal women should include the assessment of clinical risk factors for low bone mineral densitometry and bone mineral densitometry testing. The gold standard method to diagnose for osteoporosis is DEXA. Hip and spine measurements by DEXA should be used for both risk assessment and follow-up, as they provide the most accurate and precise measurements of BMD

with the disease. Most prescription medications for osteoporosis are called antiresorptives. The term refers to action of slowing or stopping the breakdown of bone tissue. Other medications include drugs to build new bone and increase bone mass. All these types of medications should be supplemented with daily calcium and vitamin D. After menopause, a woman needs to take 1,000 mg/day elemental calcium and 800 IU/day vitamin D.

The key features of osteoporosis are summarized in Table 89.4.

Table 89.3 Osteoporosis classification according to bone mineral density

T-score > –1	Normal
T-score between -1 and – 2.5	Osteopenia
T-score < –2.5	Osteoporosis
T-score < –2.5 and at least one fragility fracture	Established osteoporosis

WHO classification of osteoporosis according to DEXA. WHO has proposed four diagnostic categories for postmenopausal Caucasian women according to DEXA. The choice of this 2.5 standard deviation (SD) cutoff by the WHO was based on epidemiological data

WHO World Health Organization

Table 89.4 Key features of osteoporosis

- Osteoporosis is a systemic skeletal disorder characterized by a low BMD and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk.
- All postmenopausal women older than 50 years should be assessed for the presence of risks factors for osteoporosis.
- The prevalence of osteoporosis increases with age, from approximately 6% at 50 years of age to more than 50% above 80 years of age.
- There are many risk factors associated with osteoporosis, such as age, sex, low body mass index, glucocorticoid treatment, smoking, alcohol intake, inflammatory disease, and thyroid disorders. The main cause of postmenopausal osteoporosis is estrogen withdrawal.
- The gold standard method for diagnosing osteoporosis is measurement of bone mineral densitometry with DEXA.
- Osteoporotic fractures are a major cause of morbidity in the population. Common sites for osteoporotic fracture are the spine, hip, and wrist. Vertebral fractures may cause acute pain and loss of function but may also occur without serious symptoms.
- The goals of osteoporosis management should be fracture-risk assessment and fracture prevention.

This table lists the key features of postmenopausal osteoporosis

89.3 Practical Methods Measurement of Height and Arm Span

Height is measured as follows: subjects should remove their shoes, stand facing away from and against the wall (buttocks, back, and head against the wall) and hold their head erect. The point at the top of the head should be indicated on the wall and, then, the distance between floor and the point should be measured with the same device each time. However, a standard measurement device can be used (see Fig. 89.2). For arm-span measurement, the subjects should be standing as mentioned earlier and arms spread in a straight line parallel to the floor, as shown in Fig. 89.3. The distance between the right- and left-hand tip of the middle finger is taken as the arm span.

Osteoporosis is commonly seen in people after 50 years of age and is associated with increased risk for fracture and thus has a major impact on the affected patients and on societies. It is the major cause of vertebral, wrist, and hip fractures. The associated morbidity and mortality of osteoporotic fractures are very significant. The most frequently observed osteoporotic fracture is vertebral fracture, which causes vertebral deformities. These deformities are associated with increased morbidity and symptoms, such as loss of height, kyphosis, back pain, functional impairment, depression, and reduced survival rates (Rea et al. 2000).

Changes in body composition and some anthropometric measurements have been noted in the aging population and in osteoporotic women. It is well known that vertebral fracture and loss of height in osteoporotic women are closely linked (Ettinger et al. 1994). Only one-third of these vertebral fractures give rise to symptoms (Versluis et al. 1999). It is therefore necessary to establish a screening method to detect existing vertebral fractures in asymptomatic individuals. There is an excellent correlation between arm span and height in the human body. Arm span is a valid measure

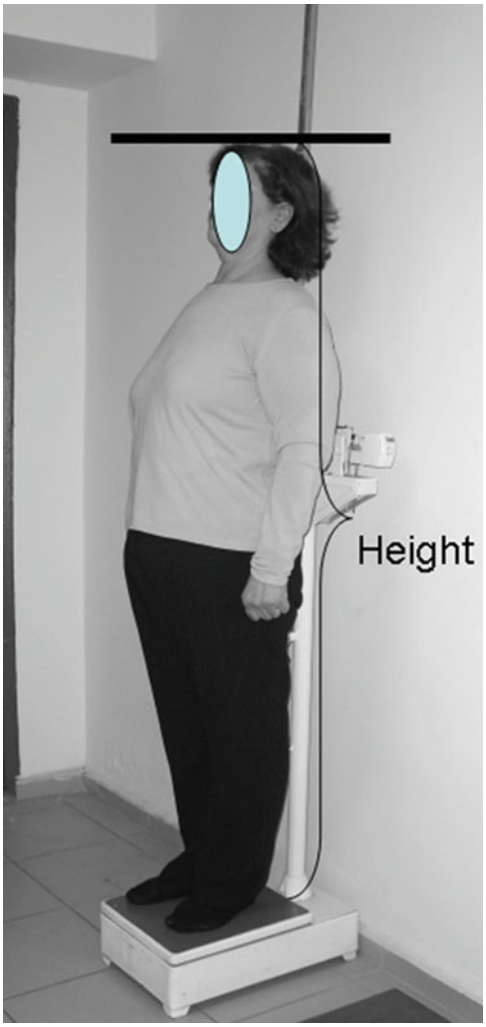

Fig. 89.2 Measurement of height. Height measurement of an example of a woman with osteoporosis. The subjects should remove their shoes, stand facing away from and against the device upright, and hold their head erect. The point at the top of the head should be indicated on the device upright; the distance between floor and the point is the "height"

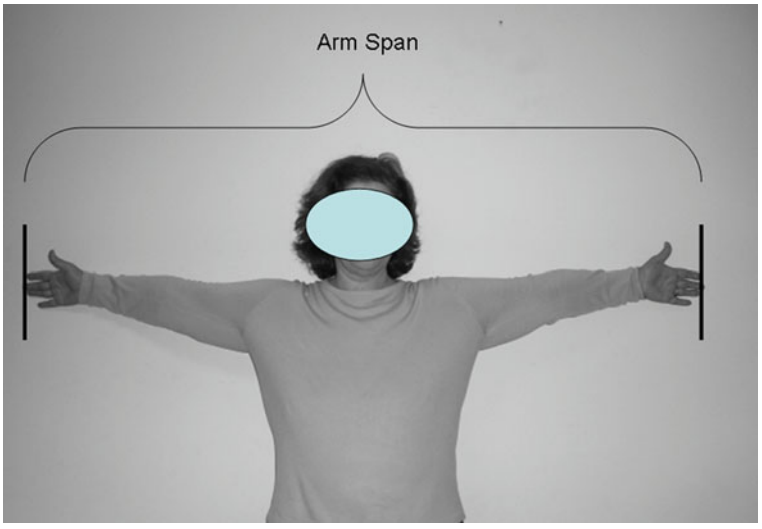

Fig. 89.3 Measurement of arm span. Arm-span measurement of an example of a woman with osteoporosis. The subjects should remove their shoes, stand facing away from and against the wall, and hold their head erect. Arms should be spread in a straight line parallel to the floor. The distance between the right- and left-hand tip of the middle finger is taken as the arm span of the subjects

of height in young and middle-aged adults. Hence, arm-span measurements can be used in the estimation of youth height and age-related loss in stature. This method can be used as a screening tool to determine height loss due to osteoporotic vertebral fracture in patients with osteoporosis.

89.4 The Relationship Between Arm Span and Height

Marcus Vitruvius Pollio was a Roman writer, architect, and engineer who realized that the proportions of the greatest work of anthropometric measurements of the human body, and observed a relation between arm span and height. Leonardo da Vinci depicted his Vitruvian Man as the "Diagram of Man" (Versluis et al. 1999).

Age, gender, and race have been associated with differences in arm span and height. Men have greater differences between arm span and height than women. Normally, the differences between arm span and height are not more than 2 cm in young men and women (Brown et al. 2000). The authors found that there was an excellent correlation between arm span and height.

Steele and Chenier investigated the relation between arm span and height of 591 black and white women in their study (Steele and Chenier 1990). They found that the arm span in black women was 8.7 cm longer than height, whereas the relation was 3.3 cm in white women. However, they showed that there was a good correlation between arm span and height in both black and white women.

Rabe et al., in their study, examined interrelationships of height and arm span in elderly women and men (Rabe et al. 1996). They found that there was good correlation between arm span and height in both female and male groups. Their data graphics for female and male elderly are shown in Figs. 89.4 and 89.5, respectively.

89.5 Arm Span and Height Ratio in Postmenopausal Osteoporotic Women

In postmenopausal osteoporosis, the most common fracture is in the vertebrae, and the prevalence of these fractures increases with age, even though only one-third of these vertebral fractures give rise to symptoms (Versluis et al. 1999). It is therefore necessary to establish a screening method to detect

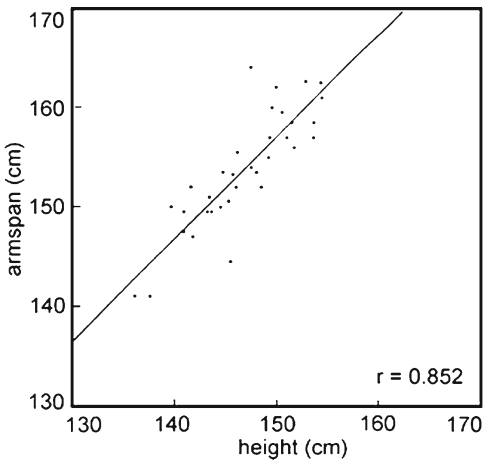

Fig. 89.4 Correlation between height and arm span in elderly females. The figure shows a good correlation between arm span and height in the female group (Reprinted from Rabe et al. 1996. With permission)

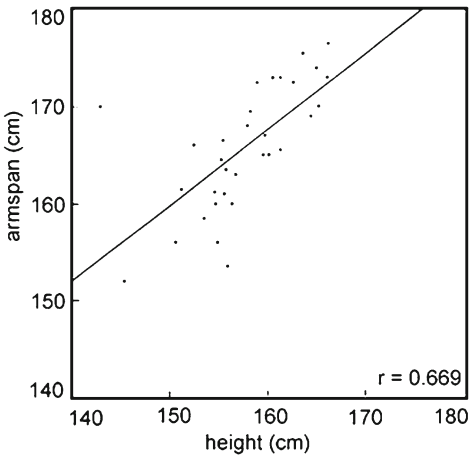

Fig. 89.5 Correlation between height and arm span in elderly males. The figure shows a good correlation between arm span and height in the male group (Reprinted from Rabe et al. 1996. With permission)

existing vertebral fractures in asymptomatic individuals. It is well known that vertebral fracture and loss of height in osteoporotic women are closely linked (Ettinger et al. 1994).

Late in the 1990s, Verhaar et al. studied 36 postmenopausal women with established osteoporosis and 25 women without osteoporosis to identify the usefulness of arm span–height differences (Verhaar et al. 1998). They found that there was a very good correlation between arm span and height in osteoporotic women, and the sensitivity and specificity of the arm span–height differences for having osteoporosis were 81% and 64%, respectively.

Mohanty et al. studied the relationship between anthropometric measurements and standing height of 505 healthy women between the ages of 20 and 29 (Mohanty et al. 2001). They found that arm span was the most reliable body parameter for predicting the height of an individual. They also concluded that arm span was a useful predicting factor for age-related loss in stature. Jalzem and Gledhill investigated the relationship between arm span and height in individuals aged 0.5–56 years (Jalzem and Gledhill 1993). They concluded that height can be predicted reliably from arm measurements.

We published data comparing the relationship between arm span and height in 70 postmenopausal women and 70 young healthy women (Ofluoglu et al. 2008). Mean age of the postmenopausal women (group I) was 64.4 ± 8.6 years and 27.3 ± 3.5 years in young healthy women (group II). Mean height was 152 ± 5.1 cm and 161.5 ± 5.9 cm in groups I and II, respectively. Mean arm span was 159.6 ± 6.3 cm in group I and 163.5 ± 6 cm in group II. The demographic characteristics of these subjects are shown in Table 89.5. The mean arm span–height difference was significantly higher in postmenopausal women when compared to healthy young women (7.7 ± 3.6 and 2 ± 2.9 cm, respectively; $p < 0.001$) (see Table 89.6). We concluded that the arm-span measurements can be used for the estimation of youth height and age-related loss in stature in postmenopausal women.

Recently, Abe et al. evaluated the efficacy of using arm-span height differences, wall–occiput distance, and rib–pelvic distance separately and in combination to screen for undiagnosed vertebral fractures in 116 middle-aged elderly Japanese women (Abe et al. 2008). The mean arm-span–height differences for those participants with and without vertebral deformities were 7 ± 4.1 and 4.2 ± 4.2 cm, respectively. They found that sensitivity and specificity for use of arm span–height differences were 85% and 52%, respectively. They concluded that arm span–height differences effectively predicted vertebral deformities. Some of their important data are shown in Tables 89.7 and 89.8.

By contrast, some other studies did not support the difference between arm span–height for prediction of vertebral deformities. Versluis et al. investigated the differences between arm span and

Table 89.5 Subjects' demographic characteristics (Reprinted from Ofluoglu et al. 2008. With permission)

	Group I	Group II	*P* value
Age (year) (mean ± SD)	64.4 ± 8.6	27.3 ± 3.5	<0.0001
Height (cm) (mean ± SD)	152 ± 5.1	161.5 ± 5.9	<0.0001
Arm Span (cm) (mean ± SD)	159.6 ± 6.3	163.5 ± 6	<0.0001
Height–Arm span Differences (cm) (mean ± SD)	7.7 ± 3.6	2 ± 2.9	<0.0001

There were significant differences between the two groups regarding demographic characteristics. However, most importantly, the study showed a significant difference in height–arm span ratio between osteoporotic women and young women

Table 89.6 Correlation analysis of the parameters (Reprinted from Ofluoglu et al. 2008. With permission)

	R value	*P* value

height in relation to the presence of vertebral deformities in 494 women (Versluis et al. 1999), found no differences, and concluded that this method cannot be used for the detection of vertebral deformities. Recently, Uzunca et al. agreed with the Versluis et al. conclusion. They studied 90 postmenopausal women and their data showed that measurement of arm span–height differences cannot

Fig. 89.6 An example of osteoporotic vertebral fracture. *Arrow* indicates osteoporotic L1 vertebral compression fracture

estimate presence of osteoporosis and related fractures (Uzunca et al. 2008). Although Wang et al. found that there was a strong relationship between arm span and standing height in healthy young men and women and in healthy elderly men and women, the difference between arm span and standing height alone predicted only 49–62% fracture cases in women and men (Wang et al. 2004). Therefore, they suggested that the predictive ability of the difference between arm span and height to identify vertebral fractures was limited (Fig. 89.6).

89.6 Application to Other Areas of Health and Disease

Height is a very important parameter for (1) determining basic energy requirements, (2) standardizing measures of physical capacity, and (3) adjusting drug dosage. However, in some situations, such as scoliosis, arthritis, lower-limb amputations, and vertebral fractures, the exact height cannot be measured directly. Estimation of height can be made using arm span. Therefore, arm span can be used for estimating exact height in certain diseases to adjust drug dosage, assess pulmonary function, etc. Tan et al. showed correlation between arm span–height ratio and FEV1 and FVC (Tan et al. 2009). They concluded the importance of arm-span measurements in lung-function assessment.

89.7 Conclusion

Height loss increases with age and is frequent in middle-aged women. It is caused by decreasing height of the intervertebral disks and joint cartilages, less pronounced foot arches, and postural changes. Another important cause of the age-related height loss is the reduction in vertebral height

due to osteoporotic vertebral fractures and structural changes, which are more frequent in elderly women (Tobias et al. 2007). Low bone mineral density and bone loss are strongly associated with height loss. Forsmo et al. showed that there was a significant relationship between the increased rate of height loss and bone loss (Forsmo et al. 2007). Besides low bone mineral density, one vertebral fracture is associated with height loss of about 2.5 cm (Ismail et al. 1999; Siminoski et al. 2006; Tobias et al. 2007).

Arm span has been suggested as a useful predictor of standing height (Jalzem and Gledhill 1993; Mohanty et al. 2001). Measurements of arm span are not affected by height loss and vertebral deformities. Thus, in case of a disease that affects height, such as osteoporotic vertebral fractures, the patient's arm span should be longer than height. The sensitivity of this method is quite high (81%), whereas specificity is about 64% (Verhaar et al. 1998). Therefore, other diseases which affect height should be taken into account. However, apart from vertebral deformities, other factors may contribute to variations in arm span–height differences. For example, degenerative disk disease may lead to height loss in the elderly, leading to differences between arm span and height.

As a result, arm span is a valid measure of height in young and middle-aged adults. Its measurements can be used to estimate youth height and age-related loss in stature, making it a potential tool for screening for vertebral deformities in postmenopausal women, as well as for some other fields in health and disease.

Summary Points

- Osteoporosis is a skeletal disorder characterized by compromised bone strength, predisposing a person to an increased risk of fracture. Osteoporosis is becoming a major public-health problem as the population ages all over the world.
- There are many risk factors associated with osteoporosis. The main cause of postmenopausal osteoporosis is estrogen withdrawal. The gold standard method for diagnosing osteoporosis is measurement of bone mineral densitometry with DEXA. The goals of osteoporosis management should be fracture risk assessment and prevention of fracture.
- The most important complication of osteoporosis is osteoporotic fractures. They are a major cause of morbidity in the population. The most frequently observed osteoporotic fracture is a vertebral fracture, which causes vertebral deformities.
- Vertebral deformities are associated with increased morbidity and symptoms, such as loss of height, kyphosis, back pain, functional impairment, depression, and reduced survival rates. However, only one-third of these vertebral fractures give rise to symptoms.
- Height loss increases with age and is frequent in middle-aged women. An important cause of the age-related height loss is the reduction in vertebral height due to osteoporotic vertebral fractures and structural changes, which are more frequent in the elderly women.
- There was an excellent correlation between arm span and height. Normally, the difference between arm span and height is not more than 2 cm in young men and women. Therefore, the arm span–height ratio can be used as a screening method to detect existing vertebral fractures in especially asymptomatic individuals with osteoporotic vertebral fractures. This method is inexpensive and reliable.
- If a postmenopausal woman has a historical height loss greater than 6 cm, kyphosis, or acute incapacitating back pain, a spinal radiograph with a specific request to rule out vertebral fractures should be obtained.

Key Points

See Table 89.9.

Table 89.9 Key facts of arm span and height ratio

• Arm span helps to estimate height accurately.
• Arm span is recommended as an acceptable measure for height in clinical situations, where it is difficult to measure standing height.
• An increased arm span to height ratio is an indication of possible loss of height.
• Greater than 6 cm height loss can be a finding for osteoporotic vertebral fractures; therefore, a spinal X-ray should be obtained.
• The sensitivity and specificity of the arm span–height differences for having osteoporosis are high.

This table lists the relationship and the importance of arm span and height ratio for postmenopausal osteoporotic women

Acknowledgments Thanks to Professor Abe and coauthors for sharing some of their data about arm span and height in the study cited earlier and thanks to the Editor of Journal of APJCN for giving permission to show some figures of the study by Rabe et al. in the chapter.

Chapter 90
Relationship Between Plasma Hormones and Anthropometric Measures of Muscle Mass in Postmenopausal Women

Fábio Lera Orsatti, Erick Prado de Oliveira, and Roberto Carlos Burini

Abstract The muscle undoubtedly pertains to a complex mechano-biological system that primarily enables efficient locomotion but is also involved in other vital physiological functions. Aging is accompanied by progressive reduction in muscle mass (sarcopenia). Sarcopenia is a progressive process that occurs in healthy individuals. Sarcopenia is usually associated with functional impairment and physical disability, especially in women, and is the direct cause of reduction in muscle strength. Muscle mass and strength start declining over the perimenopausal years and this phenomenon seems to be partly estrogen-dependent. The role of estrogen in sarcopenia remains unclear. Epidemiological studies suggest that as estrogen declines with age there is an increase in the levels of pro-inflammatory cytokines suspected to be involved in the sarcopenia process such as tumor necrosis factor alpha and interleukin-6 (IL-6). These cytokines cause an imbalance in muscle tissue synthesis in favor of excess protein breakdown. Epidemiological studies suggest a relationship between low levels of testosterone and loss of muscle mass, strength and function. In post-menopausal women testosterone increases muscle mass. Despite evidence that DHEA supplementation results in an increase of blood testosterone levels in women and increase of IGF-1 in men, few studies have reported an effect in muscle size, strength or function. Insulin-like growth factor-1 (IGF-1) and growth hormone (GH) decline with age. GH replacement therapy lowers fat mass and increases lean body mass. The aging muscle is capable of synthesizing IGF-1 but it may be less sensitive to IGF-1 and could have an attenuated ability to synthesize an isoform of IGF-1 promoting satellite cell proliferation. Exercise may reverse the resistance of aging muscle to IGF-1.

90.1 Introduction

The muscle pertains to a complex mechanobiological system that primarily enables efficient locomotion but is also involved in other vital physiological functions (Sievanen 2005).

Principal hormones and muscle and bone tissue have coexisted from the very beginning of the evolution of the present forms of complex life. Over millions of years, these three physiological modules have embodied in such a universal biological protocol that is fit and efficient for all foreseen locomotive and physiological demands that may occur in various forms of life. The muscle is an example of this evolutionary process, as it provides the body not only with a practical locomotive apparatus and protection for internal organs, but also with a reservoir for amino acids needed for physiological functions – several vital functions integrated within a single organ (Sievanen 2005).

Aging is accompanied by progressive reduction in muscle mass (sarcopenia) (Pierine 2010; Data from our laboratory – Fig. 90.1). Sarcopenia is a progressive process that occurs in healthy individuals.

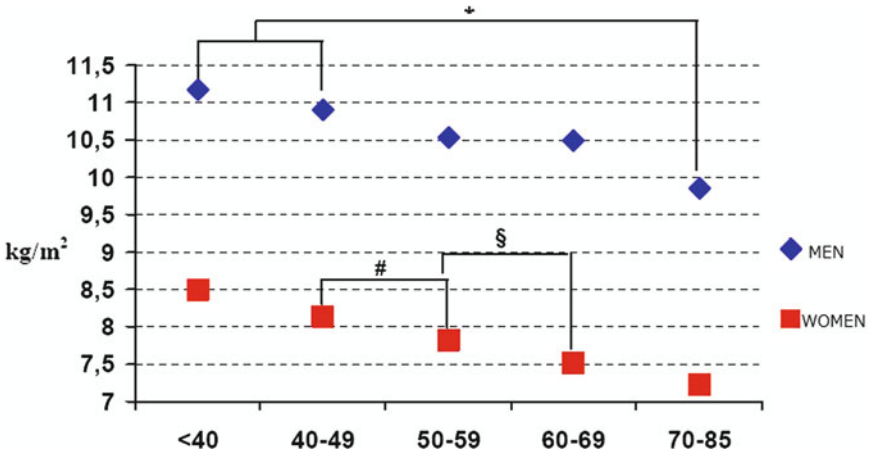

Fig. 90.1 Average of muscle mass index (kg/m^2) according to gender and age. * = $P < 0.001$, # = $P < 0.01$ and § = $P < 0.03$. $n = 734$ (170 men and 564 women)

It is usually associated with functional impairment and physical disability, especially in women, and is the direct cause of reduction in muscle strength. It is widely accepted that the age-related loss of muscle mass has a significant detrimental impact on motor performance in old age. Muscle performance is an important determinant of functional capacity and quality of life among elderly women, and is also involved in the maintenance of balance. Age-related changes in muscle and bone are likely to contribute to an increased risk of falls, an important source of death and injury in elderly people. Therefore, the maintenance of good muscle strength in aging women can prevent fragility fractures and lessen the burden of osteoporosis. The growing population of elderly citizens and the age-related motor handicap have enormous socioeconomic effects on the modern healthcare system (Sirola and Rikkonen 2005).

90.2 Relationship Between Muscle Mass and Hormones in Postmenopausal Women

Several factors such as diet, lifestyle, and metabolic and hormonal parameters influence body composition in postmenopausal women. Menopause may induce a phase of rapid decreases in aerobic fitness, muscle strength, and balance, especially in sedentary women. Muscle mass and strength start declining over the perimenopausal years, and this phenomenon seems to be partly hormone dependent (Figs. 90.2 and 90.4a).

The role of estrogen in sarcopenia remains unclear (Sirola and Rikkonen 2005). Theoretically, estrogen has a direct anabolic action on skeletal muscle that contains estrogenic receptors. However, this effect may also be mediated through the conversion of estrogens into testosterone. Thus, both may inhibit the production of catabolic cytokines (interleukins-1 and -6 and TNF), suggesting that the loss of these hormones at menopause has direct or indirect effects on muscles (Kamel et al. 2002) (Figs. 90.2 and 90.4).

Epidemiological and interventional studies suggest that estrogens prevent the loss of muscle mass. (Greising et al. 2009) accomplished a systematic review and meta-analysis of the research literature (23 relevant studies were found) that compared muscle strength in postmenopausal women, who were or were not on estrogen-based hormone therapy (HT). They concluded that overall, estrogen-based treatments were found to beneficially affect strength.

Conversely, none of five recent clinical trials reported an increase in muscle mass after hormone replacement therapy (HRT) (Jacobsen et al. 2007). Estrogens increase the level of the sex hormone binding protein, which reduces the level of serum free testosterone (Gower and Nyman 2000); thus, HRT should decrease rather than increase muscle mass. The increase in sex hormone binding globulin (SHBG) with age results in lower levels of free or bioavailable testosterone (Morley et al. 1997) (Fig. 90.2).

Estrogen and tibolone increase muscle strength, but only tibolone appears to increase lean body mass and decrease total fat mass (Jacobsen et al. 2007). Tibolone is a synthetic steroid with estrogenic, androgenic, and progesterogenic activity. HRT and tibolone may both react with the intranuclear receptor in the muscle fibers (Wiik et al. 2005), and tibolone may also act by binding androgen receptors in the muscle fibers and increase free testosterone and growth hormone.

Total testosterone decreases by 1% per year and bioavailable testosterone by 2% per year from the age of 30 years onward in males. In women, testosterone levels decrease rapidly from age 20 to 45 years (Morley and Perry 2003). Epidemiological studies suggest a relationship between low levels of testosterone and loss of muscle mass, strength, and function (Rolland et al. 2008).

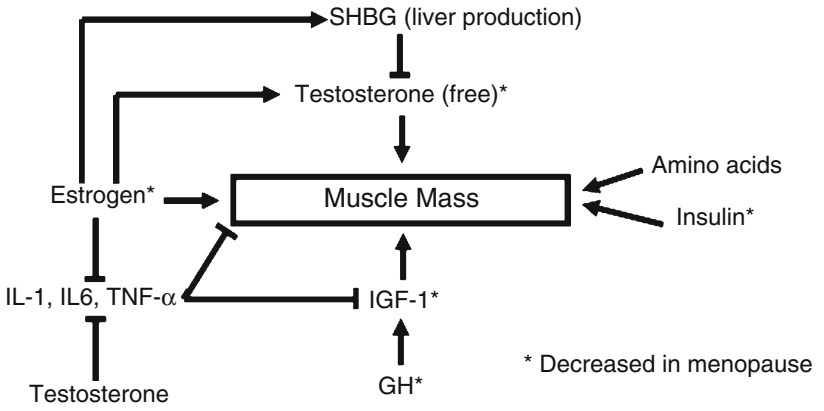

Fig. 90.2 The summary of the hormonal control of the muscular mass. *SHBG* sex hormone binding globulin; *IGF-1* insulin-like growth factor-1; *GH* growth hormone; *IL* interleukin; *TNF-α* tumor necrosis factor-α

Table 90.1 The relationships between muscle strength, muscle mass, and serum hormone concentrations in 37 postmenopausal women

	Muscle strength–leg extension (kg)
Muscle mass (kg)	0.72*
Cortisol (μg/dl)	–0.05
DHEA (μg/dl)	0.36*
Testosterone total (ng/dl)	0.40*

DHEA Dehydroepiandrosterone, * = $P < 0.05$

We observed positive correlation between serum DHEA and testosterone total and leg press strength in 37 postmenopausal women (Table 90.1, data not published). Clinical and experimental studies support the hypothesis that a low testosterone level predicts sarcopenia, resulting in lower protein synthesis and a loss of muscle mass (Galvao et al. 2007).

On the other hand, in the elderly, some interventional studies report a modest increase in lean mass and most report no increase in strength (Borst 2004). Besides, testosterone increases muscle mass and strength by stimulating satellite cell production (Bhasin et al. 2003). In postmenopausal women, testosterone increases muscle mass (Morley and Perry 2003). In supraphysiological doses, testosterone increases muscle mass and strength in young subjects under resistance training (Borst 2004).

Progressive strength training not only in young and middle-aged adults but also in older men and women can lead to substantial increases in muscle mass and strength performance. Heavy resistance exercise is well known to be a potent stimulus for acute increases in circulating anabolic hormones in younger men. In women, the acute response in serum testosterone is lower than in men, whereas no response at all is necessarily observed in older women (Orsatti et al. 2008).

Hakkinen et al. (2001) showed that individual concentrations of serum free testosterone correlated with the individual averaged total CSA of the QF muscle before the training ($r = 0.69$, $P < 0.05$) and after the 21-week training period ($r = 0.65$, $P < 0.05$). The individual concentrations of serum free testosterone correlated with the individual muscle fiber areas of type II before the training ($r = 0.86$, $P < 0.001$) and after the 21-week training period ($r = 0.79$, P, 0.01). The individual mean concentrations (averaged over the 21-week period) of serum testosterone correlated with the changes in the CSA of QF muscle over the 21-week training ($r = 0.64$, $P < 0.05$). The data showed that the individual gains in the CSA of the trained muscles were minor in those older women who demonstrated lower basal

Table 90.2 The relationships between individual changes in serum hormones concentrations (Δ%) and the individual changes in muscle mass (Δ%) during the 4-month resistance training in 21 postmenopausal women

	Muscle mass, kg (Δ%)
Cortisol, μg/dl (Δ%)	–0.09
Testosterone, ng/dl (Δ%)	0.49*
DHEA, μg/dl (Δ%)	0.55*
Estradiol, pg/ml (Δ%)	0.03

Corrected for age and time of menopause; Δ = variation between the final and initial moments, *DHEA* dehydroepiandrosterone, * = $P < 0.05$

Table 90.3 The relationships between serum hormones concentrations in 86 postmenopausal women

	DHEA, μg/dl
Cortisol, μg/dl	0.04
Testosterone, ng/dl	0.08
IGF-1, ng/dl	0.31*
Estradiol, pg/ml	–0.10

DHEA Dehydroepiandrosterone; *IGF-1* Insulin-like growth factor-1; * = $P < 0.05$

testosterone concentrations compared with those with higher testosterone concentrations ($r = 0.64$, $P < 0.05$). The findings strengthen the suggestion that basal concentrations of blood testosterone may be of great importance; even so, a low level of testosterone may be a limiting factor in older women, for both strength development and overall training-induced muscle hypertrophy, when typical total body heavy resistance training programs are taken into account. In this study, only the serum levels of testosterone were measured. It is possible that, even though the blood testosterone levels would remain unaltered, strength training can induce changes, for example, at the receptor level. In our studies, we observed relationships between individual changes in serum total testosterone and DHEA (dehydroepiandrosterone) concentrations (Δ%) and the individual changes in muscle mass (Δ%) during the 4-month resistance training in 21 postmenopausal women (Table 90.2, data not published).

Dehydroepiandrosterone (DHEA) levels decline steeply with aging, and lower levels are associated with low muscle mass and strength in postmenopausal women (Haren et al. 2007). Despite evidence that DHEA supplementation results in an increase of blood testosterone levels in women and increase of IGF-1 in men, few studies have reported an effect in muscle size, strength, or function (Percheron et al. 2003). We also observed positive correlation between serum DHEA and IGF-1 in 86 postmenopausal women (Table 90.3, data not published).

Insulin stimulates skeletal muscle protein synthesis. The weight gain that frequently occurs during middle age results in a decline of the anabolic action of insulin, potentially predisposing to muscle loss, but the presence of amino acids, especially for high intakes, may stimulate the anabolic effect of insulin (Rasmussen and Phillips 2003).

Insulin-like growth factor-1 (IGF-1) and growth hormone (GH) decline with age. GH replacement therapy lowers fat mass and increases lean body mass (Rolland et al. 2008). The aging muscle is capable of synthesizing IGF-1, but it may be less sensitive to IGF-1 and could have an attenuated ability to synthesize an isoform of IGF-1, promoting satellite cell proliferation. Exercise may reverse the resistance of aging muscle to IGF-1 (Clavel et al. 2006).

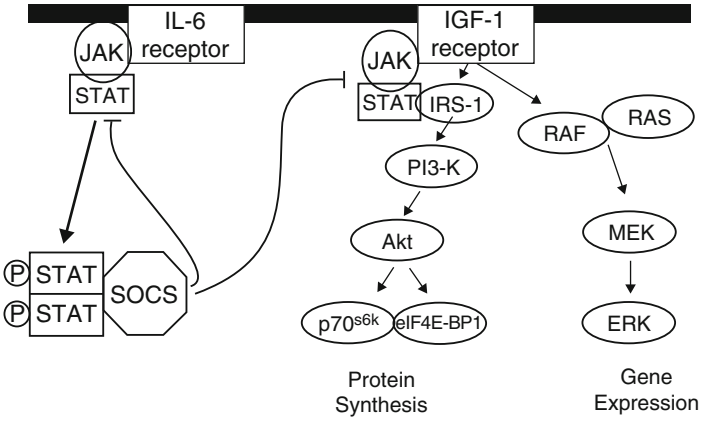

Fig. 90.3 Potential interactions of signaling elements serving the IL-6 and insulin-like growth factor (IGF)-I receptors. *MEK* mitogen-activated protein kinase kinase; *JAK* Janus kinase; *RAS* renin–angiotensin system; *SOCS* suppressors of cytokine signaling

IGF-1 activates satellite cell proliferation and differentiation and increases protein synthesis in existing fibers (Musaro et al. 1999). There is evidence that IGF-1 acts on muscle tissue by interacting with androgens (Chen et al. 2005). Former sedentary postmenopausal women submitted to resistance training for 16 weeks gained on average 1.8 kg of muscle mass, which was positively associated with the increase in plasma IGF-1 ($r = 0{,}45$, $P < 0.05$) (Orsatti et al. 2008). In addition, there is a negative correlation between the individual serum IGF-1 initial and individual change in IGF-1 (delta %) in RT ($r = -0.62$). These data indicated the possibility that women who demonstrated low basal IGF-1 levels were more sensitive at resistance training. Several IGF binding proteins (IGFBP) have been described, but it seems that only IGFBP-5 is reported to be an important modulator of myogenesis (Cobb et al. 2004).

In a study among obese postmenopausal women, the administration of GH alone or in combination with IGF-1 caused a greater increase in fat-free mass and a greater reduction in fat-mass than that achieved by diet and exercise alone (Thompson et al. 1998). In the elderly, most studies report that GH supplementation does not increase muscle mass or strength (Borst 2004). GH increases mortality in ill, malnourished persons, and potential serious and frequent side effects, such as arthralgia, edema, cardiovascular side effects, and insulin resistance occur with GH supplementation (Blackman et al. 2002).

There is some evidence that increased fat mass and reduced circulating levels of sex hormones with aging contribute to the age-related increase in pro-inflammatory cytokines that contribute to catabolic stimulation (Janssen et al. 2004). Epidemiological studies suggest that, as estrogen levels decline with age, there is an increase in the levels of pro-inflammatory cytokines, such as tumor necrosis factor alpha and interleukin-6 (IL-6), suspected to be involved in the sarcopenia process (Kramer et al. 2004).

Studies have reported an association between measures of muscle strength and muscle mass and blood levels of TNF-α, IL-6, and C-reactive protein (CRP). High levels of IL-6 and CRP were associated with an increased risk for loss of muscle strength (Schaap et al. 2006) (Fig. 90.2). These cytokines cause an imbalance in muscle tissue synthesis in favor of excess protein breakdown. A chronic elevation in inflammatory cytokines or other pro-inflammatory proteins could result in predisposition to sarcopenia (Roubenoff and Hughes 2000).

High levels of cytokines may also result in loss of muscle mass through increased activation of the ubiquitin–protease pathway and lower production of IGF-1. TNF-α stimulates muscle loss through the activation of the apoptosis pathway. Recent research has demonstrated that intracellular signaling components associated with several pro-inflammatory cytokines have the potential to interact with signaling pathways that regulate anabolic processes in skeletal muscle (Adams 2010) (Figs. 90.3, 90.4B).

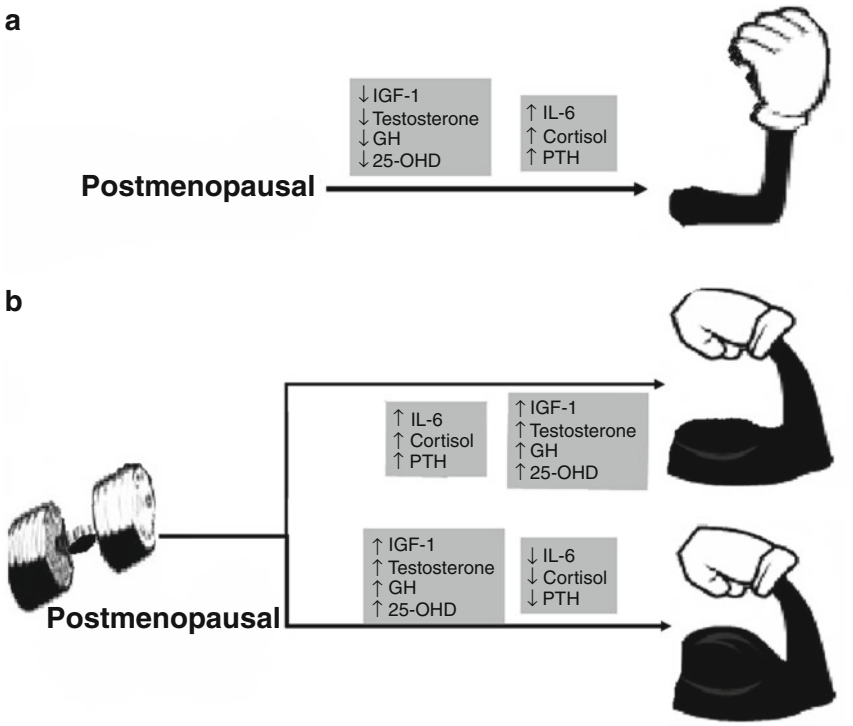

Fig. 90.4 (**a**) Hormone and muscular mass during aging. (**b**) Association between plasma hormones and anthropometric measures of muscle mass during resistance training in postmenopausal women. *GH* Growth hormone; *IGF-1* Insulin-like growth factor-1; *IL* interleukin; *TNF-α* tumor necrosis factor-α

IL-6 signaling may inhibit IGF-I signaling via increased SOCS (suppressors of cytokine signaling). Treatment with IL-6 has been reported to reduce the interaction between IRS-1 and PI3K in skeletal muscle. In addition, IL-6- induced increase in the expression of SOCS1 or SOCS3 can result in ubiquitin-mediated degradation of IRS-1 (Adams 2010) (Fig. 90.3).

GH is able to induce IGF-1 mRNA production and increased suppression of cytokine signaling-2 (SOC-2) in myoblast cell experimentation studies. SOC-2 has been reported to be a major modulator of GH action. It is a cytokine-inducible protein that inhibits cytokine production through a negative feedback mechanism (Leroith and Nissley 2005).

Chronic medical conditions, such as chronic obstructive pulmonary disease (COPD), heart failure, and cancer are associated with an increased serum level of pro-inflammatory cytokines and loss of body weight, including lean mass. This condition can occur in younger adults or elderly persons and is called cachexia. This acute hypercatabolism differs from the long-term age-related process that leads to sarcopenia. However, aging is also associated with a more gradual, chronic, increased production of pro-inflammatory cytokines, particularly IL-6 and IL-1, by peripheral blood mononuclear cells (Roubenoff et al. 1998).

The Longitudinal Aging Study has shown that lower 25-hydroxyvitamin D (25-OHD) and higher PTH levels increase the risk of sarcopenia in older men and women (Visser et al. 2003).

Cross-sectional studies have shown that low 1,25-hydroxyvitamin D and low 25-OHD are related to lower muscle strength, increased body sway, falls, and disability in older men and women. Vitamin D metabolites can influence muscle cell metabolism in three ways: by mediating gene transcription, through using rapid pathways not involving DNA synthesis, and by the allelic variant of the vitamin D receptor (Janssen et al. 2002).

Levels of parathyroid hormone (PTH) increase with age. PTH may also have a direct effect on skeletal muscle because its administration has been shown to impair production, transfer, and utilization of energy in skeletal muscle of rats (Baczynski et al. 1985), and it influences skeletal muscle protein and amino acid metabolism in rats (Garber 1983). PTH is also known to increase free intracellular calcium concentrations in muscle tissue (Begum et al. 1992), which may disrupt muscle structure or function. An indirect effect can also be hypothesized. The hormone is known to induce the production of IL-6 and IL-6sR in rat liver and increase circulating levels of these cytokines in vivo (Mitnick et al. 2001).

90.3 Applications to Other Areas of Health and Disease

Muscle plays a central role in whole body protein metabolism by serving as the principal reservoir for amino acids to maintain protein synthesis in vital tissues and organs, in the absence of amino acid absorption from the gut, and by providing hepatic gluconeogenic precursors. Furthermore, altered muscle metabolism plays a key role in the genesis, and, therefore, the prevention, of many common pathologic conditions and chronic diseases. Hence, it is important for nutritional, exercise, and metabolic areas.

90.4 Perspectives

As sarcopenia affects an increasing amount of the menopausal women, the importance of developing strategies for its prevention grows. The mechanisms behind this condition are complex and involve a variety of factors. To obtain efficient and practical methods of treatment for menopause, a better understanding of the interaction between factors, such as exercise, hormonal secretion, and inflammation, is necessary.

Summary Points

- Sarcopenia (reduce muscle mass) is usually associated with functional impairment and physical disability, especially in women, and is the direct cause of reduction in muscle strength. This decline starts during the perimenopausal years and seems to be partly estrogen dependent.
- On the other hand, estrogens increase the level of the sex hormone binding protein, which reduces the level of serum free testosterone. The increase in sex hormone binding globulin (SHBG) with age results in lower levels of free or bioavailable testosterone, decreasing muscle mass.
- In women, testosterone levels decrease rapidly from age 20 to 45 years. Clinical and experimental studies support the hypothesis that a low testosterone level predicts sarcopenia, resulting in lower protein synthesis and a loss of muscle mass.
- Insulin-like growth factor-1 (IGF-1) declines with age. IGF-1 activates satellite cell proliferation and differentiation and increases protein synthesis in existing fibers. The aging muscle is capable of synthesizing IGF-1, but it may be less sensitive to IGF-1 and could have an attenuated ability to synthesize an isoform of IGF-1.
- Epidemiological studies suggest that, as estrogen declines with age, there is an increase in the level of pro-inflammatory cytokines, such as tumor necrosis factor alpha and interleukin-6 (IL-6), suspected to be involved in the sarcopenia process. High levels of cytokines result in a loss of muscle mass and decreased performance.

Key Features

Table 90.4 Key points

1. It is widely accepted that the aging-related loss of muscle mass, strength, and quality has a significant detrimental impact on motor performance in old age, especially in women, and on the ability to recover from falls, resulting in an increased risk of fractures and dependency.
2. A number of factors have been implicated in the pathogenesis of sarcopenia, including hormonal decline (both reproductive hormones and the hypothalamic-GH-insulin like growth factor-I axis) and low-grade systemic inflammation.
3. Thus, the aging-related motor handicap and the growing population of elderly citizens have enormous socioeconomic effects on the healthcare system.

Table 90.5 Key facts

1. The steroidal hormones estrogen and androgen have anabolic effects on muscle mass.
2. The steroidal hormone cortisol has catabolic effects on human muscle mass.
3. Dehydroepiandrosterone (DHEA) is a steroidal precursor of androgens and estrogen.
4. DHEA, androgens, and estrogens decrease upon aging.
5. Cortisol increases with age.

Chapter 91
Anthropometric Measurements in Adults and Elderly: Cuban Perspectives

Aline Rodrigues Barbosa and Raildo da Silva Coqueiro

Abstract Despite the economic crisis in Cuba over the last few decades, the government has sought to ensure social equality as a development strategy on the basis of universality and free access to social services, health included. Anthropometric measurements are associated with health status and socioeconomic conditions in population groups, as they reflect the exposition to deprivation or excessive food, insufficient physical activity, and occurrence of diseases. This chapter presents and discusses information about anthropometric characteristics of adult and elderly (inclusive centenarian) Cuban individuals. According to the analyzed studies, between 1982 and 2001, there was a reduction in the prevalence of underweight and an increase of overweight/obesity in adults aged 20–59 years. In adult and elderly subjects, the greatest prevalence of underweight is observed in men and overweight/obesity in women. Around the age of 70, there is a reduction in muscle mass and fat mass, which is more prevalent among women and the oldest age groups. The elderly of Cuba have different anthropometric characteristics than those of other cities of Latin America and developed countries. Among centenarians, values for BMI and arm and calf circumferences were greater for men. A significant number of Cuban individuals, independent of age group and sex, present vulnerable nutritional status, in view of the high prevalence of underweight and overweight/obesity. Data from these studies may be used for surveillance and for planning actions that intend to prevent or improve nutritional inadequacy in the Cuban population.

91.1 Introduction

The Republic of Cuba, with Havana as its capital city, is an archipelago with a land area of 110,860 kg/m^2 located in the entrance of the Gulf of Mexico, in the Caribbean Sea. The country has the most advanced demographic transition in Latin America and the Caribbean. Its population in 2007 was 11,265,000, out of which 18.7% were aged 60 years and older and 17.5% were younger than 15 years of age (Pan-American Health Organization [PAHO] 2008).

This "premature" aging has direct consequences on changes in the socioeconomic structure, and, more specifically, on matters related to health and disease standards among the population. A reduction in morbidity–mortality due to infectious diseases can be observed, as well as an increase in the prevalence of non-transmittable diseases and injuries (Fraga 2006).

Politics in this country have maintained social equality goals as a development strategy, based on universality and free availability of social services, including health. Basic levels for food and goods of primary necessity are assured, and vulnerable groups receive special treatment (PAHO 2008).

It is widely known that Cuba suffers a strong and long-lasting economic embargo by USA and its allies since 1961, shortly after the Cuban Revolution. However, severe sanctions, in response to the issuing of the Cuban Democracy Act in the early 1990s – when the country could no longer rely on the support of the socialist bloc due to the collapse of the Soviet Union – were to cause one of the worst economic crises ever experienced by the Cuban population. The result was an abrupt reduction of foreign trade, as well as a decline in the availability of fuel, raw material, and other essential goods, such as food and medication (Porrata et al. 2000; Jímenez 2003; Yudkin et al. 2008).

The effects of the economic crisis over public health in Cuba have been documented in the literature; they include a decline in nutritional levels and a rise in infectious disease and total mortality rates (Rodríguez-Ojea et al. 2002). The policy of preferential access to essential goods for children and for women of childbearing age became an example throughout the world, but resulted in the creation of other vulnerable groups. One of the most affected was the elderly individual group (Porrata et al. 2000).

Due to the social and economic context of the past decade in Cuba, the health aspects of the population have drawn the attention of the international scientific community (Barceló et al. 2006; Yudkin et al. 2008). Population data from Cuba provide a unique opportunity to examine the health conditions of a population under the effects of the longest economic embargo in modern history. Furthermore, they can help evaluate the capability of a health system, which, despite political and economic adversities, allows universal access (Garfield and Santana 1997).

Anthropometric measurements and indices are related to health status and socioeconomic conditions in population groups as they reflect the exposure to deprivation or excessive food, insufficient physical activity, and occurrence of diseases (World Health Organization [WHO] 1995).

Anthropometric information on Cuban individuals is still not well known. According to information from the WHO Global InfoBase (2008), between 1982 and 2002, three national studies were carried out (1982, 1995, and 2002) involving Cuban adults. Recently, anthropometric data on elderly individuals from Havana (Coqueiro et al. 2009) and on centenarians living in a province in Central Cuba

This table lists the studies analyzed in this chapter, including location, year of collection, sex and number of participants (*n*), and age group and anthropometric variables
M male; *F* female; *BMI* body mass index; *SABE* Survey on Health and Well-Being of the Elderly

(Prado Martinez et al. 2009) were published. This chapter presents and discusses information about the anthropometric characteristics of adult and elderly Cuban individuals. The analysis is limited to population studies that were published in the last 2 decades and are available online (Table 91.1).

91.2 Overview of Anthropometry

Anthropometry is a noninvasive method used to evaluate size, proportions, and body composition (bone, muscle and adipose tissue). The relevance of anthropometric measurements and indices, in all life cycles, has lately been reinforced, as they relate with the health status and socioeconomic conditions of individuals and/or population. As body dimensions in all ages reflect the general health and welfare conditions of individuals and populations, anthropometry can also be used to predict performances, health, and survival (WHO 1995).

The use of anthropometry helps characterize the nutritional status that expresses the degree by which physiological needs for nutrients are being met, maintaining adequate body composition and functions. This means that the type and amount of food ingested, the energetic needs of the body, and the efficiency of the biological use of nutrients should all be balanced (Kuczmarski et al. 2005). Whenever a factor interferes in any step of this process, risks of nutritional inadequacy are imminent.

Changes in nutritional status, either by malnutrition or by excessive food, contribute to an increase of morbidity–mortality in individuals of all ages, especially in the elderly (WHO 1995).

Adult individuals (20–59 years of age) represent that proportion of the population that is related, almost totally, with the capability of production and services upon which individuals in the phase of growth (under 20 years of age) depend. This makes nutritional/anthropometric evaluations in this group relevant for any population, in both developed and developing countries (Berdasco 2002).

Elderly persons are rather susceptible to nutritional problems, mainly due to factors concerning physiological alterations, social conditions, occurrence of chronic diseases, use of several medications, problems with food intake (chewing and swallowing), depression, and alterations in mobility with functional dependence (Kuczmarski et al. 2005).

Moreover, with advancing age, alterations can be observed in body composition, which can be assessed by anthropometric measurements. After 20–30 years of age, relative body fat seems to increase until around the age of 70 years, when it starts to reduce (WHO 1995). Even when the percentage of body fat remains constant, intra-abdominal fat tends to increase, whereas subcutaneous fat tends to decrease. Concomitantly to the increase in body fat, after 20–30 years of age, fat-free mass progressively decreases. The fat-free mass peak is reached around the age of 20 years, and it reduces by up to 40%, primarily in the skeletal muscle, from 20 to 70 years of age, growing in intensity from that age onward (Hughes et al. 2004; Santos et al. 2004; Barbosa et al. 2005).

91.3 Adults

91.3.1 Body Mass Index Category

In adult individuals of all ages, the body mass index (BMI), obtained through the division of body mass (BM) by height [BMI = BM (kg)/height $(m)^2$], is the most commonly used indicator for identifying subjects at risk of being underweight and overweight. This anthropometric indicator can be applied to large population groups and in clinical practice because of its ease of attainment and interpretation, low cost, and little inter- and intra-evaluator variation.

In Cuba, two national surveys carried out in 1982 (Berdasco 1994) and 2001 (Acosta Jiménez et al. 2005) presented BMI data from adult individuals. The 1982 survey measured height and weight in 31,662 adults (20–59 years of age), out of whom 11,912 were men and 19,750 were women. The Second National Survey on Risk Factors and Chronic Diseases, conducted in 2001 (Acosta Jiménez et al. 2005), presented data from 22,851 subjects aged 15 years and older, 19,519 of them being adults (over 20 years of age). The prevalence of underweight (BMI < 18.5 kg/m^2) and overweight/obesity (BMI ≥ 25 kg/m^2) was available from each survey.

Comparing data from both national surveys performed in Cuba, in 1982 and 2001, it can be observed that the Cuban population faced a challenge (Figs. 91.1 and 91.2, for women and men, respectively). In 1982 (Berdasco 1994), underweight was higher than 11% in all age groups, in both genders, and was greater in the youngest age group (20–29 years). In 2001 (Acosta Jiménez et al. 2005), the prevalence of underweight was nearly half of that of 1982.

In women, the subsequent shift to lower BMI categories resulted in increases by 16.2, 8.5, 7.6, and 2.4 percentage points in the normal weight category (BMI > 18.5 and < 25 kg/m^2) for age groups 20–29 years, 30–39 years, 40–49 years, and 50–59 years, respectively. In men, the alterations resulted in an increase of overweight/obesity by 8.7, 8, 2.9, and 10.2 percentage points for the same age groups. In both surveys, overweight/obesity was most prevalent in women, in all age groups. However, although that prevalence remained similar in women, data from 2001 showed that men were more susceptible to overweight/obesity than women were.

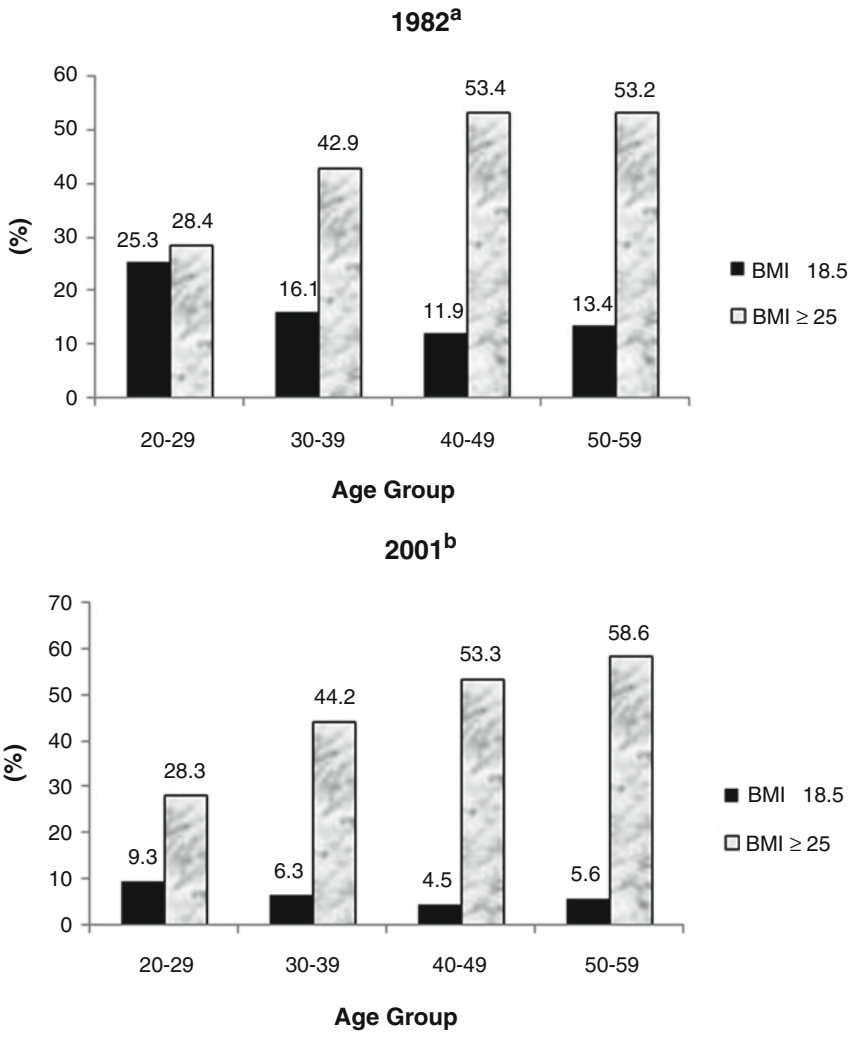

Fig. 91.1 Distributions of body mass index categories in women of Cuba, according to age group, in 1982 and 2001. In 2001, the prevalence of underweight was nearly half of that of 1982, in all age groups ([a]Adapted from Berdasco 1994. With permission; [b]Adapted from Acosta Jimènez et al. 2005. With permission)

Data from the study by Berdasco (1994) probably reflect the modifications since the 1960s, after the Cuban Revolution, which resulted in social changes. Furthermore, the implementation of a health policy led to progressive improvements in the health situation. The socialist nature of the revolution created a rationed distribution system that intended to allow equitable access to food (72% of the supply of energy and proteins), with regulated prices subsidized by the State. This phase lasted until 1989. During this period, there was greater meat and fat consumption and a decrease in the consumption of carbohydrates and fibers, as well as a decline in labor-intensive activities, which resulted in an increase of the number of people with overweight/obesity (Porrata et al. 2000).

In 1989/1990, following the disintegration of the Soviet Union and the Eastern Europe socialist countries, Cuba was mired in a severe economic crisis. There was a 25% decrease in food availability *per capita* and a rise in non-labor physical activity (Jiménez 2003). These shifts in diet and physical activity had a great impact on the nutritional status of the population. Although there are no data

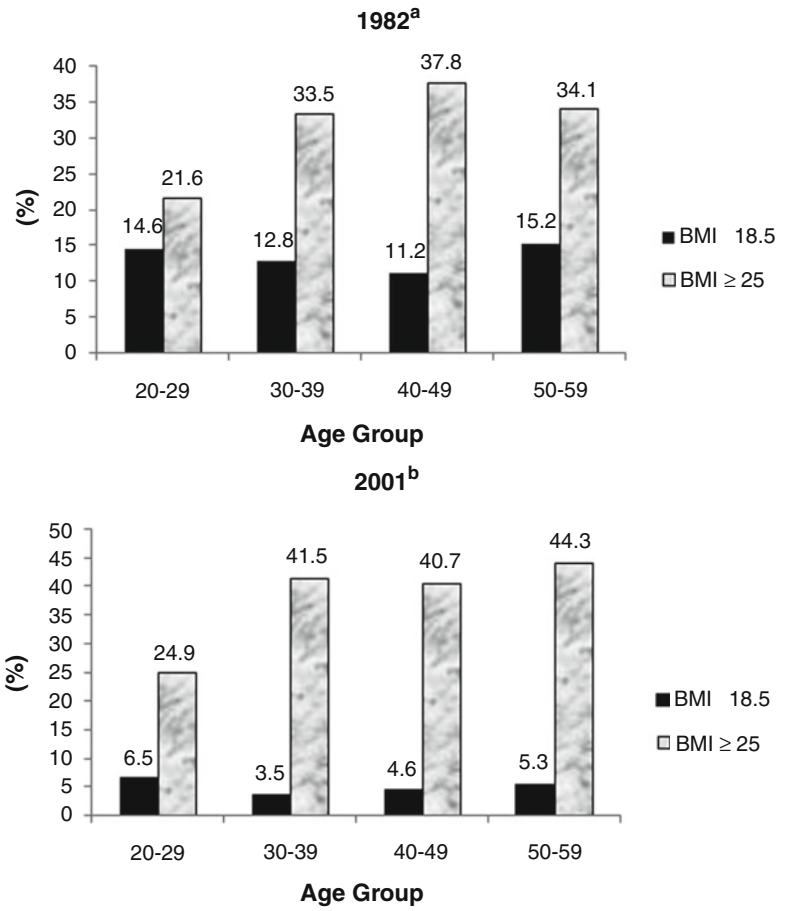

Fig. 91.2 Distributions of body mass index categories in men of Cuba, according to age group, in 1982 and 2001. The prevalence of underweight declined between 1982 and 2001, whereas the overweight/obesity BMI prevalence rates (BMI ≥ 25) grew ([a]Adapted from Berdasco 1994. With permission; [b]Adapted from Acosta Jimènez et al. 2005. With permission)

available online, according to Rodríguez-Ojea et al. (2002), between 1982 and 1994, there was an increase in the prevalence of underweight and normal BMI and a reduction in the number of individuals with overweight/obesity.

From 1996 to 1998, as the Cuban economy gradually recovered, there was an increase in food availability *per capita*, albeit still at lower levels than those observed in the 1980s (Jiménez 2003). Therefore, the data from the 2001 National Survey (Acosta Jiménez et al. 2005) reflect the recovery period, which is made evident by the reduction in the prevalence of underweight (approximately 50%) in men and women aged 20–59 years. Although women in all age groups present a greater frequency of BMI ≥ 25 kg/m^2, a comparison of data from 1982 and 2002 shows that men were more susceptible to overweight/obesity.

Data from the 2001 National Survey (Acosta Jiménez et al. 2005) showed that the prevalence of obesity (BMI ≥ 30 kg/m^2) grows with increasing age, up to 50–59 years, and affects 7.9% of men and 15.4% of women aged 20 years and older (Fig. 91.3).

When the data for Cuban residents were compared with data from another developing country, it was found that the prevalence of obesity was respectively smaller in Brazilian women (13%) and

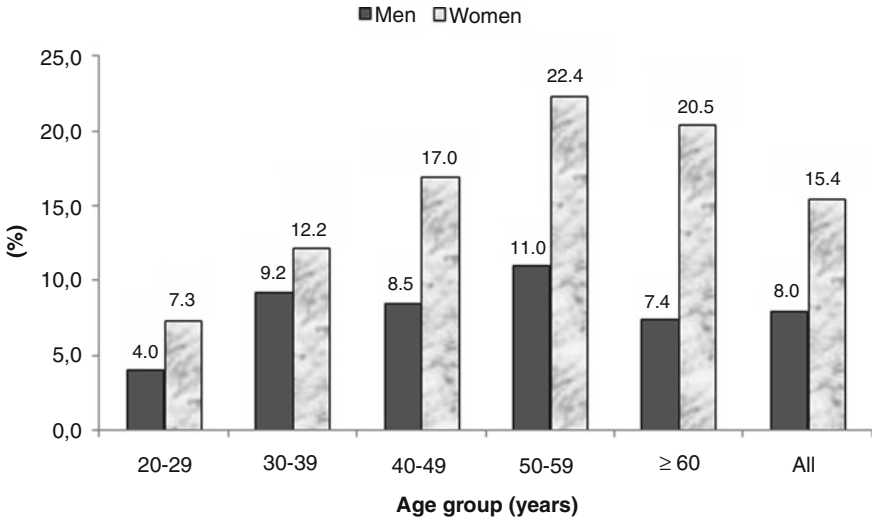

Fig. 91.3 Obesity prevalence rates (BMI ≥ 30), by age group, among men and women Cubans (2001). In men and women, obesity prevalence rates (BMI ≥ 30) grow with increasing age, up to 50–59 years (Reprinted from Acosta Jimènez et al. 2005. With permission)

greater in men (8.8%) (Monteiro et al. 2007). Similarly, between 1975 and 2003, Brazil found its increase in the rate of obesity to be greater in men (92% for males and 63% for females) in the first 14-year period examined (1975–1989). A further increase in obesity among men (70%) and among those in lower-income groups in the second period (1989–2003) was also observed.

Changes in the Cuban population's nutritional status, as a consequence of the collapse of the Eastern European countries and the Soviet Union, show that the reduction in food consumption and the increase in physical activity patterns had a positive impact on mortality trends. Conversely, the increase in the prevalence of overweight/obesity observed in 2002, which is due to undesirable changes in diet composition and reduction in physical activity levels, has important policy implications as it is associated with the increase of chronic disease risk. Thus, the promotion of a healthy diet and an active lifestyle is part of the program "Propositos, Objetivos y Metas para mejorar la salud de la población Cubana para el año 2010" (Rodríguez-Ojea et al. 2002).

91.4 Older Adults

91.4.1 Weight and Height

Height and body mass are routine measurements at health screenings, physical examinations, and nutritional assessments, and are affected by the aging process. An individual's weight can vary normally due to daily fluid retention or loss. In older persons, a weight loss ≥ 5% of the body weight in the last month or ≥ 10% in the last 6 months indicates an associated risk to a subsequent mortality (American Academy of Family Physicians [AAFP] 2002; Kuczmarski et al. 2005). Adult height is an indicator for the nutrition and health environment experienced in early life. Height changes with aging due to alterations in the skeletal integrity. BMI is an indicator frequently used to assess nutritional status in the elderly (WHO 1995).

All measurements were greater in younger groups, compared to older ones (‡$p = 0.000$; ANOVA)
SD standard deviation

The study carried out by Coqueiro et al. (2009) used data from the *Survey on Health, Aging and Well being in Latin America and the Caribbean* (SABE) (Pélaez et al. 2004) and analyzed anthropometric characteristics in 1,905 elderly individuals (≥60 years) from Havana, comprising 1,197 women and 708 men. Results have shown greater height values for men and younger age groups, according to what was expected. Women (Table 91.2) and men (Table 91.3) presented a difference of 5 cm in mean height between the 60–64-year age group and the oldest individuals (≥80 years) (Fig. 91.4).

The proportion of height reduction with increasing age is not yet well defined: values seem to vary from 0.5 cm to 3 cm per decade, after the age of 60 (WHO 1995; Perissinotto et al. 2002; Santos et al. 2004; Barbosa et al. 2005), more markedly in the oldest individuals and in women. Such alterations are consequences of vertebral compression, changes in intervertebral disk thickness and shape, loss of muscle tone, and posture changes and osteoporosis (WHO 1995).

As observed for height, data from Havana (Coqueiro et al. 2009) show that BM and BMI were greater in the youngest as compared with the oldest elderly (Tables 91.2 and 91.3, for women and men, respectively). The reduction in BM values, with increasing age, was stronger in women, as observed in other studies with elderly individuals in Latin America (Santos et al. 2004; Barbosa et al. 2005) and developed countries (WHO 1995; Perissinotto et al. 2002).

Usually, BM tends to reach a plateau around the age of 65 in men and 75 in women, when it begins to decrease. It is believed that reductions with increasing age are consequences of the loss of total body water and general cellular mass (WHO 1995; Hughes et al. 2004), not to mention the likely cohort effect and selection bias, due to institutionalization or premature death of persons with overweight or obesity.

91.5 Body Mass Index

Among the elderly of Havana (Coqueiro et al. 2009), reductions in BMI values occurred after the ages of 65 and 70, for men (Table 91.3) and women (Table 91.2), respectively. Differently from Havana, recent studies have shown that significant declines in BMI seem to occur from the age of 75 in men and women (Kuczmarski et al. 2000; Perissinotto et al. 2002; Barbosa et al. 2005) (Table 91.4).

BMI values were lower for the elderly in Havana for both sexes and the same age groups as compared with results from other studies in Latin America (Santos et al. 2004; Barbosa et al. 2005). Differences were more expressive when data were compared with those of USA (Kuczmarski et al. 2000) and Italy (Perissinotto et al. 2002). In the study carried out by Acosta Jimènez et al. (2005), of elderly subjects (60 years and older) sampled nationally, the percentile distributions presented for BMI (Table 91.7) were slightly higher, from 1.0 to 0.2 points, compared to men and women from Havana (Coqueiro 2008).

Although a lower BMI provides evidence of less obesity among Cubans, it may be a sign of greater nutritional vulnerability. This concern becomes apparent in the classification of nutritional status (Figs. 91.5 and 91.6, for women and men, respectively). Results from Coqueiro (2008) have

Table 91.4 Key features of American Academy of Family Physicians (AAFP)

- The AAFP is one of the biggest health organizations in the USA, with over 94,600 members in 50 states (http://www.aafp.org).
- The AAFP, in a partnership with the American Dietetic Association and the National Council on Aging, developed the Nutrition Screening Initiative, a project that aims to promote good nutrition, working along with physicians, politicians, and population.
- The Nutrition Screening Initiative provides tools and recommendations for nutritional status evaluation and a guide to nutrition in chronic disease management for older adults.

This table lists key facts of the AAFP including partner organizations in the development of strategies for good nutrition in elderly adults

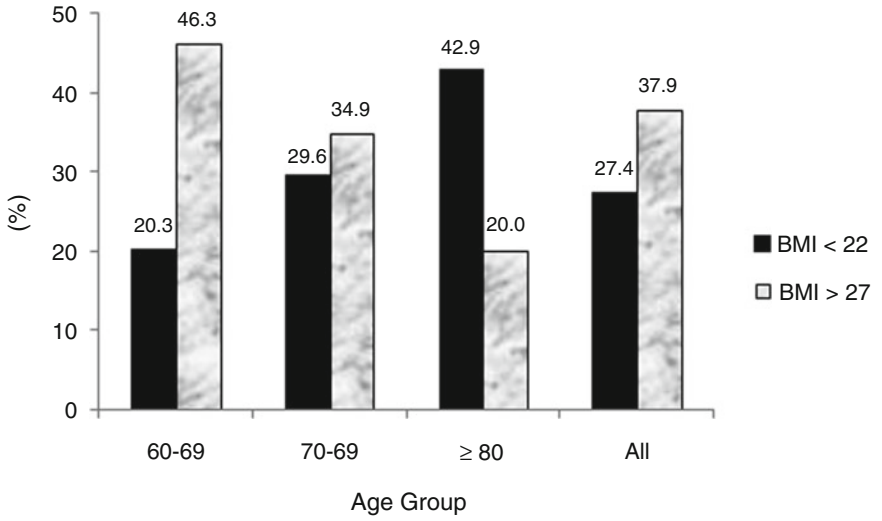

Fig. 91.5 Distributions of body mass index categories in elderly women of Havana, according to the age group (SABE Survey), Havana, Cuba, 2000. Overweight (BMI > 27 kg/m^2) is more frequent among the youngest age group (60–69 years) (Adapted from Coqueiro 2008. With permission)

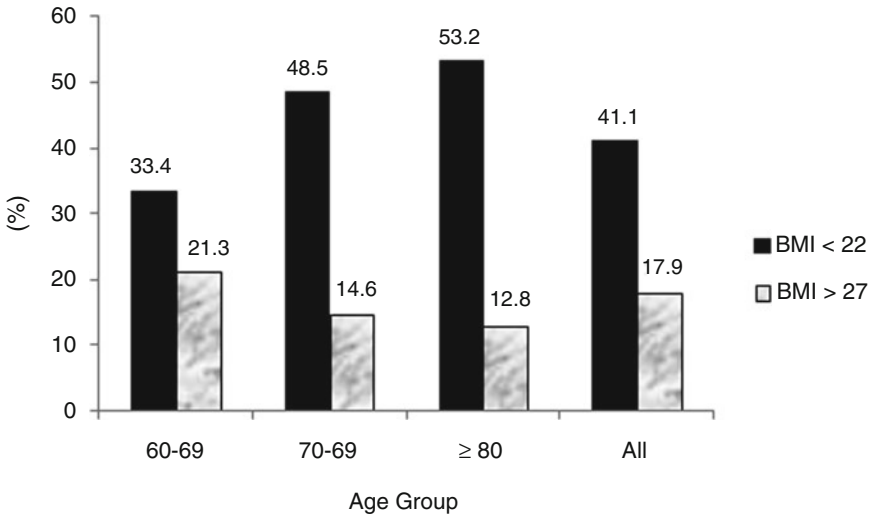

Fig. 91.6 Distributions of body mass index categories in elderly men of Havana, according to the age group (SABE Survey), Havana, Cuba, 2000. Underweight (BMI < 22 kg/m^2) is more prevalent among the oldest age group (≥80 years) (Adapted from Coqueiro 2008. With permission)

shown that underweight (BMI < 22 kg/m^2) and overweight (BMI > 27 kg/m^2) presented high proportions in the elderly of Havana. With increasing age, there is an increase in the number of underweight persons, with a greater prevalence for males, in all age groups, when compared to women. Overweight was most frequent in women, in all age groups.

When the results of Coqueiro (2008) are compared with those from researches that used the same cutoff points, it can be noted that Cuba was the country with the greatest prevalence of underweight. Prevalences of approximately 12% (according to the distribution of the reference curves) in Italy (Sergi et al. 2005) and 13.4% in the USA (Diehr et al. 1998) were observed.

Data from the elderly of the countries that took part in the SABE survey show that BMI < 22 kg/m^2 corresponds approximately to the 10th and 25th percentile, respectively, for women and men of São Paulo, Brazil (Barbosa et al. 2005). In Santiago, Chile, this value is closest to percentile 10, for both sexes (Santos et al. 2004). BMI > 27 kg/m^2 corresponds approximately to percentiles 50 and 75 for women and men of São Paulo, respectively (Barbosa et al. 2005), whereas in Santiago, this value is closest to percentile 50 for both sexes (Santos et al. 2004). This means that the prevalence is greater for underweight and lower for overweight among the Cuban elderly, when compared to the elderly individuals of other Latin American cities.

There is no consensus in literature about optimal values to classify underweight and overweight in older persons. WHO (2006) presents BMI values under 18.5 kg/m^2 as a sign of underweight and values over 24.9 kg/m^2 and from 30 kg/m^2 onward indicate overweight and obesity, respectively, for adults of all ages. However, it recommends that the values 23, 27.5, 32.5, and 37.5 kg/m^2 are to be used in public policies, making international comparisons easier.

The *Nutrition Screening Initiative* suggests BMI values < 22 kg/m^2 and > 27 kg/m^2 as indicative of underweight and overweight, respectively (AAFP et al. 2002). Sergi et al. (2005) have suggested that BMI ≤ 22 kg/m^2 should be adopted as a classification of individuals at risk. The PAHO (2001) has used the BMI value ≤ 23 kg/m^2 to classify underweight and values 28 ≤ BMI < 30 kg/m^2 and BMI ≥ 30 kg/m^2, respectively, for overweight and obesity.

It is known that any BMI value corresponds to more fat in the elderly body composition, when compared to the BMI in younger adults; this is probably due to the reduction of thin body mass, mainly muscle mass, with increasing age. This means that the application of the same classification used for adults may underestimate the prevalence of overweight in the older adults. Moreover, several studies show that, in elderly, the curves of mortality related to BMI differ from those observed in young and middle-aged adults, and point out different values for the classification of underweight and overweight. Independently of the cutoff point used, underweight and overweight are factors associated with morbidity–mortality in the elderly (Allison et al. 2002; Sergi et al. 2005).

Independently of the cutoff point used, the percentile BMI distribution values for the Cuban elderly indicate a nutritional risk for a large proportion of these individuals and an direct relationship between underweight and age.

Several factors can justify the greater underweight risk in the oldest age groups, such as smell and taste reduction, teeth and mouth problems, reductions in physical activity levels and a consequent reduction in nutrition and energy needs, social isolation, and functional dependence, which can discourage or complicate the preparation of food. Moreover, polypharmacy, which is frequent in the elderly, may result in nutritional disorders and harm nutrient absorption and use (Kuczmarski et al. 2005).

Underweight is associated with an increased risk of hospitalization and delay in illness recovery and higher costs for the public health service, with physical, functional, and psychological impairment. Although underweight seems to be a better predictor of negative outcomes than obesity, overweight/obese elderly subjects are certainly at risk of disability, morbidity, and mortality (Sergi et al., 2005).

91.6 Indicators of General and Central Adiposity and Muscle Mass

Circumferences and skinfold-thickness measurements allow a fairly accurate assessment of distribution and reserves for body fat and muscle mass. With increasing age, there is a reduction in muscle mass, which can be observed by measuring arm and calf circumferences (AC and CC, respectively) and arm muscle circumference (AMC). Moreover, the adipose tissue is redistributed: there is an increased tendency in the intra-abdominal level and a reduction in subcutaneous fat in the limbs, which can be assessed by measuring waist circumference (WC) and triceps skinfold thickness (TSF), among others (Kuczmarski et al. 2000; Santos et al. 2004; Barbosa et al. 2005).

The data on the elderly of Havana (Coqueiro et al. 2009) show that women (Table 91.5) have presented more subcutaneous fat (greater TSF values), whereas muscle mass indicators (AMC and CC) were slightly greater for men (Table 91.6). Differences between the extreme age groups (60–64 years and ≥ 80 years) in AC, TSF, AMC, and CC mean values, as observed in weight, were greater for females (in percentage). These results suggest that elderly women undergo slightly more intense reductions in subcutaneous fat and muscle mass when compared to men, although at the age of 80 women continue to have more subcutaneous fat, as observed in other studies with elderly subjects (Kuczmarski et al. 2000; Barbosa et al. 2005). Probably, since women are predominant among the oldest individuals, and report more chronic non-transmittable diseases (Barceló et al. 2006), they are more adversely affected in nutritional conditions.

In the study carried out by Coqueiro et al.(2009), more than 5% of women aged 75 and older and men aged 65 and older present inadequate AC (≤ 22 cm) and over 10% of the elderly present a CC lower than 31 cm, considered malnourished or at risk of malnutrition (Guigoz 2006). Even though these measurements consider bone and adipose tissues, they indicate muscle reserve and are regarded as a valid nutritional screening instrument for malnutrition in the elderly. The values of these

SD standard deviation

measurements in the elderly of Havana were lower than the ones observed in the SABE survey carried out in São Paulo, Brazil (Barbosa et al. 2005) and may indicate a greater risk of malnutrition among Cubans.

As for central adiposity (WC), data from Havana (Coqueiro et al. 2009) showed a reduction in the values from ages older than 70 in women and 75 in men. In other Latin American countries (Santos et al. 2004; Barbosa et al. 2005) that took part in the SABE Survey, this reduction occurred at a greater age (by 10 years for both genders), similar to what was observed for BMI.

A comparison between WC values from the elderly individuals analyzed in the 2001 National Survey (Acosta Jiménez et al. 2005) and those from Havana (Coqueiro 2008) shows that men from Havana, throughout the percentile distribution, had higher percentile values by 2–4 points (Table 91.7). In women, WC median values were similar in both studies. Percentile distribution values for WC in Cubans were, in both surveys, lower than those observed in the elderly of Santiago, Chile (Santos et al. 2004). Despite the fact that risk values for metabolic disorders and cardiovascular

diseases in the elderly are not established, when the cutoff points proposed by Lean et al. (1995) (WC ≥ 88 for women and 102 for men) are considered, it can be observed that approximately 50% of women and 10% of men, from both studies, are at risk.

The characteristics of the studies (Coqueiro 2008; Coqueiro et al. 2009; Acosta Jiménez et al. 2005) do not make it possible to infer whether the nutritional status attributes of the elderly of Cuba relate with the economic and political status of the country. However, it is known that the major economic crisis of the 1990s resulted in a reduction of over 35% in the Cuban population's *per capita* energy ingestion (Jímenez 2003). As the Cuban policy of access to essential goods prioritized children and women in childbearing age, the eldest age groups became quite vulnerable, mainly due to the lack of food and medication (Garfield and Santana 1997). It seems reasonable to consider that the data from 2000 to 2001, with its high underweight rate, may be a consequence of the years of food deprivation.

Table 91.7 Percentile values (BMI and WC) for elderly (≥60 years) in Cuba (2001) and Havana (2000) ([a]Reprinted from Acosta Jiménez et al. 2005. With permission; [b]Reprinted from Coqueiro 2008. With permission)

	Percentile						
Variable	3	10	25	50	75	90	97
Body mass index

Waist circumference							
Female							
National Survey[a]	67.0	72.0	78.3	87.0	95.0	102.0	110.0
Havana[b]	64.5	70.3	77.7	87.0	96.0	104.0	111.3
Male							
National Survey[a]	67.0	72.0	78.3	87.0	95.0	102.0	110.0
Havana[b]	71.0	75.0	81.0	89.0	97.2	105.0	112.0

Men from Havana presented lower BMI and higher WC values than those evaluated in the National Survey. Women, in both studies, had BMI values that were quite similar

91.7 Centenarians

In a study carried out between 2004 and 2008, data from all Cubans aged more than 100 years (1,448 individuals) were analyzed. Results showed that centenarians had long-living parents, feel satisfied with life, live with their families, are mostly women, and have physical and mental limitations (Infomed 2009).

The study published by Prado Martinez et al. (2009) interviewed 134 individuals (82 women, 52 men) of 100 or more years of age living in the province of Villa Clara, Cuba. The maximum age recorded for both genders was 106 and, above 102 years, the sample size lessened by 50%. Information from approximately 125 individuals was collected, concerning weight, height, knee height, BMI, AC, and CC (Table 91.8).

Data on the nutritional status of centenarians are basically scarce and a comparison pattern is not yet available. BMI for the Cuban centenarians was 1.1 points lower than that observed in Italians of the same age (21.1 × 22.2 kg/m^2) (Paolisso et al. 1999).

When comparing data on the centenarians (Table 91.8) with the elderly aged 80 years and older (Tables 91.2 and 91.3, for women and men, respectively), a reduction can be observed in all measurements. Differences in stature were 7 and 10 cm, for men and women respectively, whereas the weight was approximately 9 kg lower. Average BMI for the centenarians was 13% (women) and 1.5% (men) lower to that observed in the individuals from Havana (≥ 80 years). Values related to muscle mass (AC and CC) were 11% and 17% lower in women and men, respectively. Although there are no values of normality for centenarians, according to the values suggested by Guigoz (2006), centenarian men and women presented inadequate AC and CC figures. It is worth noting that, although the average BMI for men was close to the value that is considered normal, according to AAFP et al. (2002), standard deviation was quite high, which indicates a large variability in the measurements.

Table 91.8 Anthropometric characteristics of the Cuban centenarian population of Villa Clara province (Reprinted from Prado Martinez et al. 2009. With permission)

	Male			Female			Total		
Variables	*n*	Mean	SD	*n*	Mean	SD	*n*	Mean	SD
Weight (kg)	42	50.32	12.06	53	42.58	8.35	95	46.00	10.77
Height (cm)	49	153.82	13.11	76	143.36	7.86	125	147.51	11.44
Knee Ht(cm)	49	49.73	6.90	76	46.45	4.96	125	47.75	6.04

The mean values of all anthropometric measures and indexes were greater in men
Knee Ht knee height; *BMI* body mass index; *AC* arm circumference; *CC* calf circumference; *SD* standard deviation

Key Features

Table 91.9 Key features of calf circumference

- Calf circumference (CC) is a sensitive indicator of lean mass loss among the elderly.
- Among the elderly, CC (<31 cm) provides information on muscle-related disability and physical function (Rolland et al. 2003).
- This measurement is more affected in cases of malnutrition.
- Malnutrition in older adults is common and is associated with poor clinical outcomes.
- The cutoff of 30.5 cm provides a good diagnostic capacity of the nutritional status of a hospitalized elderly person (Bonnefoy et al. 2002).

This table lists key facts of the CC including main uses

91.8 Final Considerations

Cuba is a country with unique social–political and health characteristics and presents a rather advanced demographic transition. The several transformations that occurred in the past decades seem to have reverberated as changes in the individual nutritional/anthropometric characteristics.

Between 1982 and 2001, there was a reduction in the number of underweight adults and an increase in the prevalence of overweight/obesity. The reduction in the frequency of underweight was found to be greater in the young age groups, whereas the rise in overweight/obesity was more pronounced in the 50–59-year age group, with disparity between men and women. The proportion of individuals with an inadequate nutritional status (underweight and overweight/obesity) is rather high.

The elderly of Cuba, specifically those from Havana, present different anthropometric characteristics than the ones featured in other cities of Latin America and developed countries. Such differences can be related to political, social, economic, and lifestyle issues, among other factors. However, the nature of the analyzed data (cross-sectional) does not allow the establishment of a cause-and-effect relation. Alterations in body dimensions that occur with increasing age differ between men and women. There is a loss of muscle mass, as well as a redistribution and reduction of fat mass, which are observed to be more severe in women. Many of the anthropometric differences are remarkable from age 70 onward.

According to the analyzed results, it is possible to conclude that a great number of the Cuban individuals, independently of age group and sex, present a vulnerable nutritional status, in view of the high prevalence of underweight and overweight/obesity.

91.9 Applications to Other Areas of Health and Disease

This material provides relevant empirical arguments that can be used for the development of health and social policies for nutritional surveillance, concerning overweight/obesity prevention as much as underweight, which are prevalent among individuals of all ages.

Anthropometry is a noninvasive, low-cost method used in research and clinical practice. Certain anthropometric measurements can be correlated with other body dimensions and are comparable to dimensions measured in other studies/populations.

BMI is the most important anthropometric index for the assessment of nutritional status, in individuals of all ages. Weight, BMI, AC, AMC, TSF, and CC are variables of currently used nutrition instruments developed for the elderly (Kuczmarski et al. 2005; Guigoz 2006). Underweight is an independent predictive factor of short-term mortality in older adults, and obesity causes serious medical complications and can exacerbate the age-related decline in physical function and lead to frailty (Sergi et al. 2005; Villareal et al. 2005). Particularly for very old persons, indicators of muscle mass may be helpful in determining their need for interventions, such as nutrition programs and assistance in activities of daily living (Kuczmarski et al. 2000).

Data from this chapter may be used for comparison and evaluation of the nutritional status of adults and elderly individuals from Cuba, including centenarians, whether in clinical practice or in epidemiological studies. Moreover, the data can be used for comparisons between different populations from developed and developing countries.

Summary Points

- The use of anthropometry helps characterize the nutritional status that expresses the degree by which physiological needs for nutrients are being achieved to maintain adequate body composition and functions.
- Sex and age are determining factors for anthropometric characteristics.
- In young adults (20–39 years), the prevalence of underweight is greater for women.
- On the basis of two population-based surveys conducted in Cuba (1982 and 2001), we identified clear changes in the prevalence of underweight and overweight/obesity in the 20–59-year-old population.
- In 1982, underweight was frequent in over 11% of men and women (25% of 20–29-year-old women). In 2001, there was a reduction of approximately 50% in underweight prevalence, in both genders. Men were more susceptible to overweight/obesity than women were.
- In Havana, in 2000, there were nearly two obese elderly women for each obese elderly man. For each obese man, there were two underweight; for women, the proportion was closer to 1/1.
- With increasing age, there is a reduction in height, body mass, muscle mass, and fat mass, which differed for each sex; this reduction is greater among women.
- Many of the anthropometric differences are remarkable from age 70 onward.
- Underweight and overweight presented high proportions in the elderly population of Cuba.
- When comparing data on the centenarians (mean) with the elderly aged 80 years and older, a reduction can be observed in all anthropometric measurements.

Chapter 92
Anthropometric Indices and Nutritional Assessments in the Elderly: Brazilian Perspectives

Aline Rodrigues Barbosa, Lúcia Andréia Zanette Ramos Zeni,
and Ileana Arminda Mourão Kazapi

Abstract Anthropometry is a low-cost, easy-to-perform method that allows diagnosis, stratification, and monitoring of the nutritional status of the elderly, indicating that it is useful to assess the health conditions of the elderly population. Brazil is going through a rapid aging process and some studies, carried out in the last 20 years, presented the anthropometric characteristics and the nutritional status of the Brazilian elderly individuals (≥60 years). The data from the population-based and household studies have been discussed in this study. According to earlier studies, sex and age are factors that determine the anthropometric changes. The patterns of alterations with increasing age in anthropometric characteristics are similar; however, the intensity of the alterations varies between populations and studies. With increasing age, there is a reduction in the stature and body mass, which is more intense for women. In addition, there is a reduction in muscle mass and subcutaneous fat, which is greater for men and women, respectively. Along with the loss of muscle mass, there is a greater accumulation of central adiposity in women. However, after the age of 75 years, central adiposity reduction occurs more rapidly in men. Overweight or obesity is more prevalent among women and underweight is more common in men, irrespective of their age. With increasing age, there is a reduction in the prevalence of obesity and an increase in the prevalence of being underweight, which is more evident after the age of 75 years. Data from earlier studies can be used for surveillance and for planning actions that intend to prevent or improve nutritional inadequacy in the Brazilian elderly population.

92.1 Introduction

Population aging is a phenomenon observed in many parts of the world. In Brazil, this process began only from the 1960s on, when a decrease in the fertility rates was noticed in some regions. This reduction became stronger in the following decades, and its association with the decrease in mortality led to a change in the Brazilian age composition, as the country experienced an aging process, with an increase in life expectancy (Carvalho and Garcia 2003).

In 1940, the average life expectancy was 39 years and 43 years for men and women, respectively. In 2008, the average woman had a life expectancy of 76.6 years, whereas men lived up to 69.0 years. The percentage of elderly individuals in the population was 2.5% in 1940, which reached 9.5% in 2008, corresponding to an absolute number of approximately 18 million individuals (Instituto Brasileiro de Geografia e Estatística [IBGE] 2008).

Demographic changes have been occurring at a rapid and more intense pace: according to the predictions, by 2025, Brazil will have the world's sixth greatest population of individuals aged 60 years and older, in absolute numbers (Carvalho and Garcia 2003). It is believed that the Brazilian population's average life span will increase by a few more years, reaching 81.29 years by 2050 (IBGE 2008).

This phenomenon of population aging has an impact on the prevalence of chronic diseases, which are most frequent in adult and elderly individuals. It is also an important issue for investigating, monitoring, and planning public policies, owing to the inevitable growth in the demand on the health system (Tavares and Anjos 1999).

One change that is rather evidenced with increasing age is body composition, which can influence the nutritional status of elderly individuals. With aging, there is a progressive increase in fat mass, with a greater deposit in the upper body. The amount of fat in the limbs decreases. Reductions are observed in height, body mass (BM), and lean body mass, especially in relation with muscle mass decrease (Kuczmarski et al. 2000; Santos et al. 2004; Barbosa et al. 2005; Coqueiro et al. 2009).

In this context, anthropometry is useful to assess the health conditions of the elderly individuals, as many disorders are associated with dietary and nutritional problems (Barbosa et al. 2007; Munaretti 2009). Traditionally, anthropometric measurements (e.g., BM, height, circumferences, and skinfold thickness) are used for the physical examinations of the elderly in clinical studies, especially in population studies. These measurements, which are low cost and easy to perform, allow for the diagnosis, stratification, and monitoring of the nutritional status in the elderly. They can also estimate, fairly accurately, the subcutaneous fat or muscle reserve in certain parts of the body (Tavares and Anjos 1999). However, the utility of these indicators depends on the availability of reference data related to age, sex, and age group, specific to each population (World Health Organization [WHO] 1995).

In Brazil, not many population studies, carried out in different regions of the country, attempted to identify the anthropometric characteristics in the elderly. These studies have their differences concerning height, body mass, adiposity, and muscle mass, according to sex, age group, and region.

The purpose of this study is to examine the anthropometric characteristics and the nutritional status in Brazilian elderly individuals, by analyzing the data from the population-based- and household studies that were carried out in the last 20 years (Tables 92.1 and 92.2).

SABE Survey Survey on Health and Well-Being of the Elderly

Table 92.2 Key features of Survey on Health, Aging and Well being in Latin America and the Caribbean (SABE)

- During 1999 and 2001, the PAHO coordinated the SABE project. This is a multicenter study, carried out in seven countries (Argentina, Barbados, *Brazil*, Chile, Cuba, Mexico, and Uruguay).
- In each participant country, the SABE project was coordinated by a team of researchers, consisting of a main investigator and their associates.
- Project goals were to collect information on the health conditions of elderly individuals (chronic and acute diseases, disability, nutritional status, physical and/or mental impairment, etc.) and to evaluate differences related with gender, age group, socioeconomic conditions, and use and accessibility of services, among others.
- SABE is the first survey of its kind in the region and was simultaneously and rigorously comparable for the purpose of compiling information of persons aged 60 and older.
- Anthropometric data were obtained by health professionals who received special training, including a video for standardization and better visual presentation of the anthropometric techniques to be used in all countries.

This table lists the key facts of the SABE Survey including the participant countries, research coordination, and main goals. PAHO, Pan American Health Organization

92.2 Body Mass and Height

Decline in the BM and height with age has been observed in studies throughout the world (WHO 1995; Kuczmarski et al. 2000, Perissinotto et al. 2002; Santos et al. 2004; Coqueiro et al. 2009), although the pattern of change is different and varies with sex. Usually, men tend to reach a plateau in their BM by the age of 65 years, decreasing from then on. In women, the raise usually continues until around 75 years of age, and then starts to reduce (WHO 1995; Kuczmarski et al. 2000). Such a reduction is more strongly related to the decrease in the muscle mass in men, and in body fat in women. For subjects aged 80 years and older, body water is the most important cause for BM reduction (Stenn 1988). With respect to height, there has been no agreement on the value of its reduction with increasing age; it appears to reduce by 0.5–3 cm per decade after the age of 60 years, and becomes steeper in older ages for both the sexes (WHO 1995; Perissinotto et al. 2002).

In the elderly, BM assessment is considered when the person presents an illness. In the absence of confounding factors, BM < 80% of the recommended value (using age-adjusted norms) can be considered as low BM (Andres et al. 1985), necessitating an assessment over time. This indicates that unintentional weight loss in 1 month (2%), 3 months (5%), or 6 months (10%) may also be owing to associated nutritional compromise (Jensen et al. 2001; Huffman 2002; American Academy of Family Physicians [AAFP] 2002).

Although BM and height are the commonly recorded anthropometric measurements, only two Brazilian studies presented these values for older adults (Tables 92.3 and 92.4, showing data for the elderly in São Paulo and Rio de Janeiro, respectively).

Data from São Paulo (Barbosa et al. 2005) showed that BM was lower in the oldest than in the youngest individuals, and was higher in men than in women in all age groups, similar to that observed in the Rio de Janeiro study (Santos and Sichieri 2005) and in other studies on elderly populations (Perissinotto et al. 2002; Santos et al. 2004; Velasquez-Alva et al. 2004; Coqueiro et al. 2009).

Furthermore, some factors appear to contribute to such a reduction in body weight with increasing age, such as selection bias, institutionalization or earlier death of overweight or obese individuals (a relation impossible to assess in a household survey), cohort effect, and reduction in total body water and muscle mass (WHO 1995; Perissinotto et al. 2002, Barbosa et al. 2005).

A comparison between the two extreme age groups (60–64 years and ≥80 years group) showed that the reductions in the mean BM were 13.6% (9 kg) for women and 11.2% (7.9 kg) for men in São Paulo (Barbosa et al. 2005). For the elderly in Rio de Janeiro (Santos and Sichieri 2005), the differences in the mean BM values were 8% (5 kg) and 10% (6.4 kg) for men and women, respectively,

Table 92.3 Body mass, height, and body mass index for men and women (≥60 years). Survey on Health and Well-Being of the Elderly (SABE), São Paulo, Brazil, 2001 (Reprinted from Barbosa et al. 2005. With permission)

Body mass, height, and body mass index (BMI) were significantly lower in the oldest than in the youngest individuals (‡$p \leq 0.001$; ANOVA). In general, mean body mass and height in women were less than those reported for men at each age group. Mean BMI was higher in women than in men (*$p \leq 0.001$; †$p = 0.007$; Student's *t*-test)
SD standard deviation

between the 60–69 years and the >80 years age groups. Furthermore, divergences concerning the values of reduction may be related to the extension of the age groups and sample characteristics. It is worth mentioning that, for the oldest individuals, the BM values were similar among the women in both the studies and were greater for men in Rio de Janeiro.

Table 92.4 Anthropometric values for men and women (≥ 60 years). Rio de Janeiro, Brazil (1995/1996) (Reprinted from Santos and Sichieri 2005. With permission)

Variables	60–69 years		70–79 years		≥80 years	
	Mean	SE	Mean	SE	Mean	SE
Men						
Height (m)	1.67	0.61	1.65	0.73	1.65	1.61
Body mass (kg)	70.5	1.00	67.6	1.25	65.5	1.92
Body mass index (kg/m^2)	25.2	0.32	24.5	0.42	24.0	0.64
Waist circumference (cm)	89.9	1.08	90.1	1.28	90.5	1.94

Arm muscle circumference (cm^2)	39.8	0.78	39.2	0.93	37.1	1.85

There was a significant difference between men and women ($p < 0.001$) in all the analyzed anthropometric variables. For men, body mass, arm circumference (AC), and arm muscle circumference (AMC) values were greater in younger groups compared with older ones. For women, AC and AMC did not show a variation with age
SE standard error

This difference in BM reduction between the sexes was observed in the elderly in Mexico City (Velasquez-Alva et al. 2004), Havana (Coqueiro et al. 2009), and Santiago (Santos et al. 2004). This may be because women are predominant among the elderly and report more chronic diseases (Friedmann et al. 2001), and, hence, are more adversely affected by nutritional conditions.

In the above-mentioned studies (Barbosa et al. 2005; Santos and Sichieri 2005), height reduction differed between the sexes. Women from São Paulo and Rio de Janeiro showed statistically significant differences between the age groups, whereas for men, the differences were not significant. In a study carried out by Barbosa et al. (2005), throughout the percentile distribution, the reductions varied from 1 to 3 cm/decade for women, whereas for men, the variations in percentiles were from 1 to 2 cm/decade. Among the elderly in Rio de Janeiro, the reduction was 2 cm/decade, and no changes were observed between men aged 70–79 years and 80 years and older.

The differences between men and women with regard to height reduction with aging were also observed in other populations (Perissinotto et al. 2002; Santos et al. 2004; Coqueiro et al. 2009), and some previously discussed factors (Barbosa et al. 2005) appeared to justify these divergences. The loss of muscle tone and greater muscle contraction, as well as alterations in intervertebral disks, vertebral bodies, and postural modifications, may be more intense among women, as osteoporosis is more frequent among them. Similarly, the effects of the differences between the cohorts and the secular height trend are also considered to be important, which may reflect the influences from the intrauterine period until the end of development, when improvements in the living conditions and population health may have affected men and women differently. In the developed countries, the positive secular height trend was more evident in men than in women (WHO 1995), but the same cannot be stated for the elderly in São Paulo and Rio de Janeiro.

The mean height values for the elderly in São Paulo (Barbosa et al. 2005) were lower than those observed in men and women from Rio de Janeiro (Santos and Sichieri 2005), in spite of the difference

between the analyzed age groups. It is presumed that environmental and sample selection aspects may have contributed to such differences.

A comparison of the data from the National Survey on Health and Nutrition (PNSN), carried out between July and September 1989 (WHO 1995), with those from São Paulo (Barbosa et al. 2005) and Rio de Janeiro (Santos and Sichieri 2005) showed a slight height difference (0.5–3 cm) between the sexes in the same age groups (60–69 years and 70–79 years), with higher values in the elderly of the last study. This height increase may reflect the cultural differences and an improved quality of health and nutritional status in the population, and may also be owing to the sampling differences, as the PNSN covered individuals from various regions of Brazil, with different socioeconomic and cultural characteristics.

When compared with international studies, the height values for women in São Paulo (Barbosa et al. 2005) were greater than those observed in the elderly females in Santiago (Santos et al. 2004) and Mexico City (Velasquez-Alva et al. 2004), and were lower than observed for the women of Havana (Coqueiro et al. 2009). Men from São Paulo and Rio de Janeiro showed height values similar to those of the elderly from Santiago, and greater than those from Mexico City and lower than those from Havana.

92.3 Body Mass Index and Nutritional Status

The relation between height and BM has proven itself a good way to assess nutritional status in adults. The body mass index (BMI = BM(kg)/height $(m)^2$) is mentioned as most advantageous due to its ease of calculation, bad correlation with height and good correlation with the body fat, as well as the fact that it relates with morbidity–mortality (WHO 1995). BMI is used as a measure of underweight, overweight, and obesity, being one the most important anthropometric measures for both initial and follow-up assessments of nutritional status (Kuczmarski et al. 2000).

Data from older adults of São Paulo show that BMI values (Table 92.3) were greater among women, in all age groups, and lower in the oldest age groups, as shown in other studies on elderly populations (Barreto et al. 2003; Velasquez-Alva et al. 2004; Santos et al. 2004; Santos and Sichieri 2005; Coqueiro et al. 2009). The reduction was more pronounced after the age of 75 years, converging with the trend observed in developed countries (WHO 1995; Kuczmarski et al. 2000).

Mean BMI was greater for the men and women of São Paulo (Barbosa et al. 2005), when compared to the Brazilian elderly sample (Tavares and Anjos 1999) analyzed in the PNSN/89, or to men and women of Bambuí-MG (Barreto et al. 2003), and also the women from Rio de Janeiro (Table 92.4), in the study by Santos and Sichieri (2005).

Divergences in BMI values between studies carried out in Brazil can be explained by differences in socioeconomic development, lifestyle, health conditions, sampling process, as well as possible differences in migration patterns among the analyzed populations.

In Brazil, as well as in developed countries, the rating of the elderly according to BMI is still rather debated, and there are disagreements among several studies as to the values used (Barreto et al. 2003; Santos and Sichieri 2005; Barbosa et al. 2007; Menezes et al. 2008; Silveira et al. 2009). It is known that any BMI value corresponds to more fat in the body composition of the elderly, when compared to adults, probably due to the reduction of muscle mass with age (WHO 1995). This means that using the same cutoff point utilized for adults may underestimate the prevalence of obesity in the elderly. Moreover, the reduction in height (the denominator for the BMI equation) with age may cause an "artificial" raise in the index, without a real increase in adiposity (Sorkin et al. 1999).

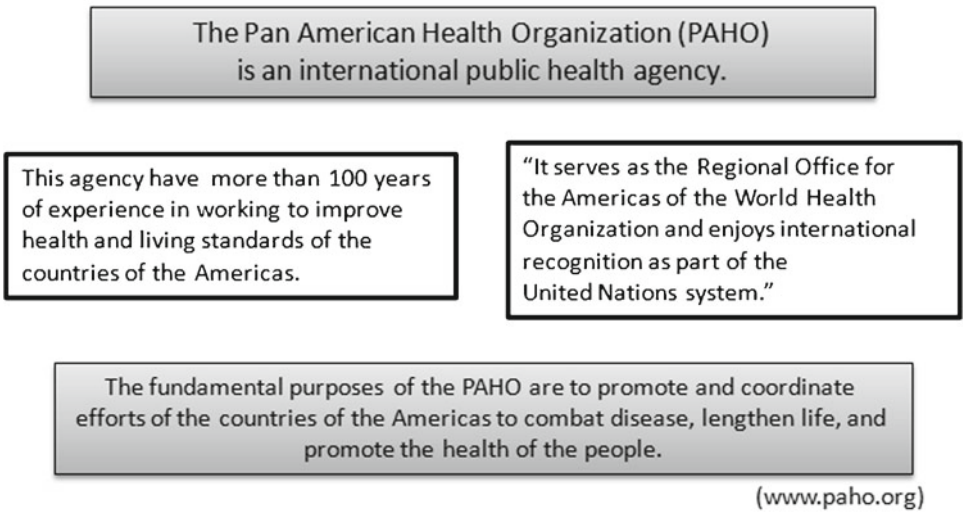

Fig. 92.1 Key features of Pan American Health Organization. This figure presents the key facts of the PAHO, including the main goals

Body mass index values ≤23 kg/m^2 rated as underweight, ≥28 for overweight, and ≥30 kg/m^2 for obesity were used by the PAHO (2001) in the data on elderly individuals from the Survey on Health, Aging and Well being in Latin America and the Caribbean (SABE). In Brazil, the Ministry of Health (2008) recommends BMI values <22 kg/m^2 and >27 kg/m^2 (AAFP et al. 2002), as indicating underweight and overweight, respectively (Fig. 92.1).

Data from several studies indicate that the relation between BMI and all causes of mortality is similar to an U-shaped curve; this means that there are health hazards for both underweight and overweight, and recommendations for a healthy life must take these hazards into account (Troiano et al. 1996; Sergi et al. 2005).

Likewise, the lack of studies involving elderly persons from developing countries suggests the need for larger investigations in order to delimit underweight and overweight/obesity for this group of individuals.

The WHO (1995) recommends, for adults and elderly individuals, the following rating: underweight (BMI < 18.5 kg/m^2), overweight (BMI > 25 kg/m^2), and obesity (≥30 kg/m^2), even though it acknowledges the limitation of its use for subjects over 69 years, due to the lack of data for older individuals. The values 23, 27.5, 32.5, and 37.5 kg/m^2 are to be used in public policies, making international comparisons easier (WHO 2006).

In Barreto et al. (2003), underweight (BMI > 20 kg/m^2) and obesity (BMI ≤ 30 kg/m^2) were determined by the mean BMI ± a standard deviation from what was verified for the sample. The authors observed that 14.4% of the individuals were underweight and 12.8% were obese. The prevalence of obesity was greater among women and those with higher income and educational levels. As in other studies, there was a reduction in the obesity prevalence with increasing age. However, this reduction was only significant in women. Due to the lack of cutoff points for the elderly population, the authors also calculated underweight and obesity by the cutoff point BMI < 23 or >28 kg/m^2 (Troiano et al. 1996) and observed that the prevalence of underweight in this community would be 35% and of obesity 24.8%.

Data from Rio de Janeiro (Santos and Sichieri 2005) showed a greater proportion (54.6%) of overweight women (BMI ≥ 25 kg/m^2), compared to men (47.9%). In the three analyzed age groups

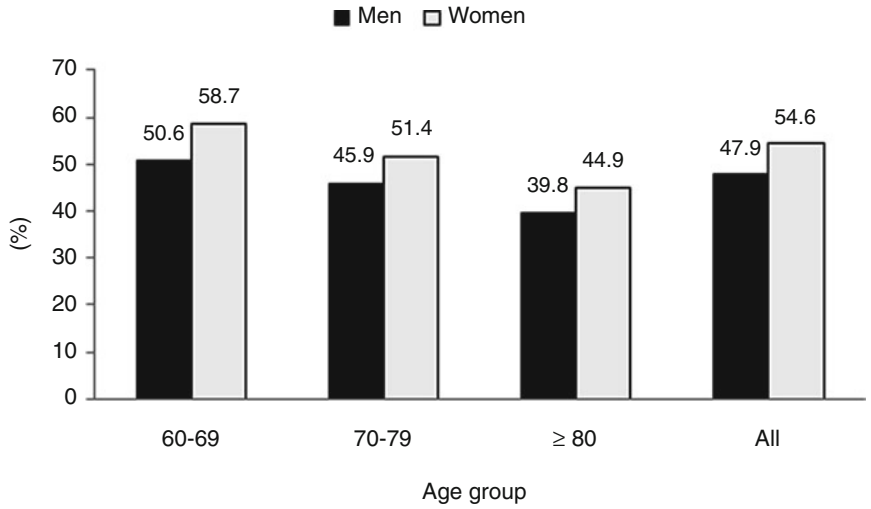

Fig. 92.2 Prevalence of overweight (BMI ≥ 25) in the elderly of Rio de Janeiro, according to sex and age group. The prevalence of overweight was greater in women than in men, in all age groups (Adapted from Santos and Sichieri 2005, With permission)

(60–69 years, 70–79 years, and ≥80 years), a greater proportion of overweight was observed among women (Fig. 92.2). For men, the overweight prevalence decreased with age, and this reduction was lower for women. The prevalence of underweight (BMI ≤ 18.5 kg/m^2), especially in women, was lower than that observed for Brazil in 1989 (Tavares and Anjos 1999).

The evaluation of the nutritional status in the elderly of São Paulo (Barbosa et al. 2007) shows that men and women, with increasing age, present a raise in the number of underweight individuals (BMI < 23 kg/m^2), with a greater prevalence for males, in all age groups, when compared to women (Fig. 92.3). The difference between sexes in the underweight prevalence was more pronounced for the group aged 80 and over. Obesity was most frequent in women, in all age groups, and there was no difference in the percentage of obese men and women between age groups 60–69 and 70–74. The reduction in the proportion of obese elderly was only verified concerning the oldest age group (≥80 years).

When data from São Paulo (Barbosa et al. 2007) were compared with data from Bambui (Barreto et al. 2003), using the cutoff points suggested by Troiano et al. (1996), it was found that the prevalence of underweight is greater for the elderly of Bambui, whereas the obesity frequency is greater for older adults of São Paulo.

According to Campos et al. (2006), the prevalence of the categories of nutritional status among men was 6% for underweight (BMI ≤ 18.5 kg/m^2), 31.9% for overweight (25.0 ≤ BMI < 30), and 5.6% for obesity (BMI ≥ 30 kg/m^2). For women, prevalences were, respectively, 5.4%, 32.7%, and 16.3%. With increasing age, the chance of obesity and overweight decreased, and the chance of underweight increased. A comparison with data from the PNSN/89 (WHO et al. 1995; Tavares and Anjos 1999), carried out seven years earlier, shows that the prevalence of underweight decreased, whereas those of adequate weight and obesity remained stable.

Data from the elderly of Fortaleza (Menezes et al. 2008) show similar proportions of normal weight between sexes (47.4% for men and 47.2% for women). Men presented a lower prevalence (13.5%) of overweight (based on the percentile distribution of Kuczmarski et al. 2000) when compared to women (21.9%). The study did not show data according to age group, specifically for each sex (Fig. 92.4). Analysis of all the elderly individuals showed that the 60–69 age group was the one with the greatest proportion of underweight (36%). The overweight proportion was similar among

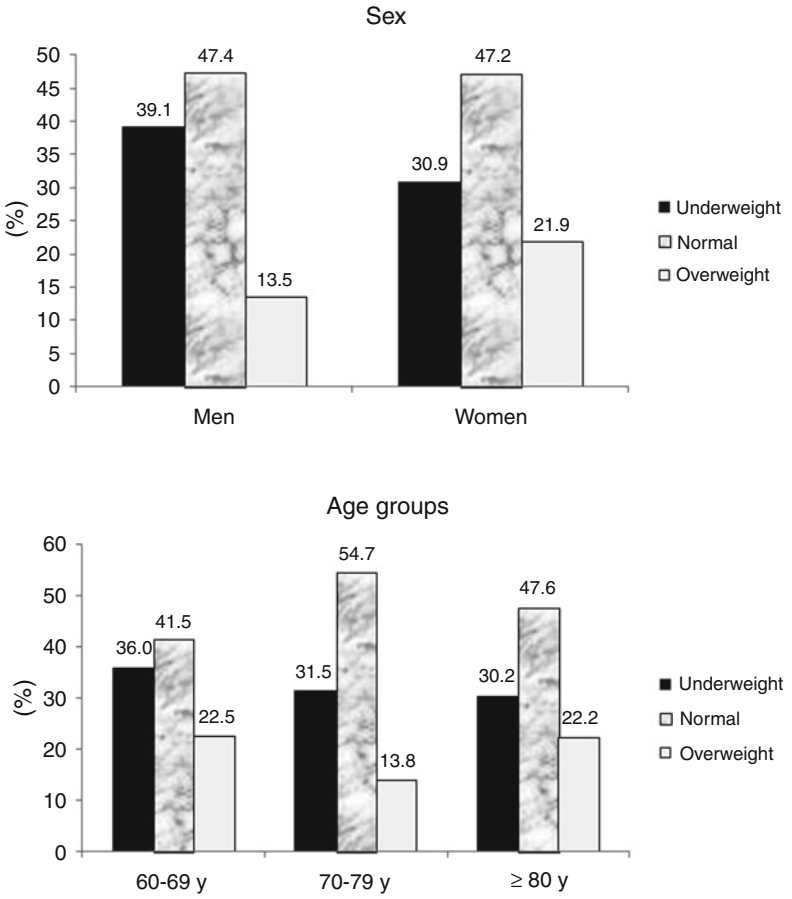

Fig. 92.3 Prevalence of underweight and obesity according to age group for men and women. Survey on Health and Well-Being of the Elderly (SABE), São Paulo, Brazil, 2001. Underweight (BMI < 23 kg/m^2); obesity (BMI ≥ 28 kg/m^2). For both genders, the prevalence of obesity was similar between groups aged 60–69 and 70–79 and the underweight frequency was greater in the oldest individuals. Differences were statistically significant for men and women ($p \leq 0.001$) (Reprinted with permission from Barbosa et al. 2007)

groups aged 60–69 (22.5%) and over 80 (22.2%). Probably, the fact that there was no stratification by sex may have contributed to the high prevalence of underweight within the youngest age group.

According to Silveira et al. (2009), the prevalence of obesity (BMI ≥ 30 kg/m^2) was 25.3%, classed into 30.8% in women and 17.4% in men. Using the BMI > 27 kg/m^2 cutoff point, the prevalence was 48.0%, 53.4%, and 40.1%, respectively. The oldest subjects show lower obesity prevalence. Underweight, independently of the cutoff point (BMI < 18.5 kg/m^2 or BMI < 22 kg/m^2), was more prevalent in men. The results, in spite of being based on self-referred information on body mass and height, are consistent with other studies carried out in Brazil.

A comparison between the several studies made in Brazil is hard to make, mainly due to the different cutoff points used to rate nutritional status, as well as differences in age-group extension. Results have shown that the nutritional profile for the Brazilian elderly, in the past decade, is characterized by a high prevalence of individuals with adequate weight and by a low prevalence of underweight. The prevalence of overweight/obesity has been increasing, similar to what was observed in developed countries, and is much more associated with females and with the urban population.

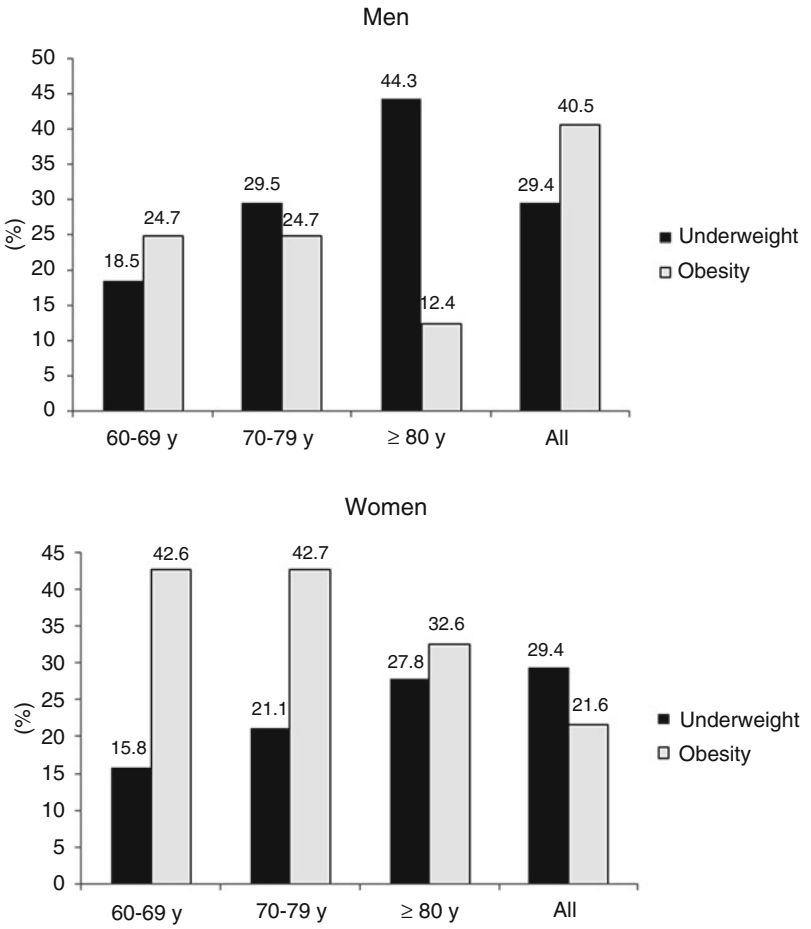

Fig. 92.4 Distributions of body mass index categories in elderly of Fortaleza/CE, according sex and age group. Fortaleza, Ceará, Brazil (2003). Underweight was more common among men and the youngest age group (60–69 years). There was a statistically significant difference between sexes ($p \leq 0.001$) (Adapted from Menezes et al. 2008. With permission)

92.4 Central Adiposity

Several studies have been pointing out a progressive increase of individual body fat with increasing age (until 75 years), as well as a redistribution of body fat. There is a greater deposit in the abdominal area and an internalization of subcutaneous fat, and it is possible to observe increase in waist circumference measurements (Perissinott et al. 2002; Santos et al. 2004).

The waist circumference (WC) is an indicator used to assess fat deposition in the central region, which characterizes the visceral abdominal obesity. Abdominal obesity is considered a major metabolic cardiovascular risk factor (e.g., high blood pressure, plasma lipids, and insulin resistance) (Lean et al. 1995), including in the elderly (Okosun et al. 2000; Munaretti 2009). However, there is still no agreement on the best cutoff point to identify the risk in elderly individuals and different populations (Okosun et al. 2000).

The study carried out by Barbosa et al. (2005) showed that WC decreased, with aging, more rapidly in men than in women (Tables 92.5 and 92.6, respectively), and lower values were observed in the more advanced age groups, as was showed by Santos and Sichieri (2005) in Rio de Janeiro

SD standard deviation

(Table 92.4). In men, differences between age groups were significant. For women, there were no significant differences between age groups (Barbosa et al. 2005), as was observed by Perissinotto et al. (2002) in Italian elderly subjects.

Men and women from São Paulo (Barbosa et al. 2005) presented WC values (mean and percentiles) lower than those observed in elderly individuals in Chile (Santos et al. 2004) and Italy (Perissinotto et al. 2002) and greater than in Cuba (Coqueiro et al. 2009). When compared to the elderly of Rio de Janeiro (Santos and Sichieri 2005), men and women from São Paulo presented higher values, in spite of age-group extension.

Based on risk indicators for cardiovascular disease and metabolic disorders (WC ≥ 88 and 102 for women and men, respectively) (Lean et al. 1995), WC data from São Paulo indicate that approximately 25.0% and 50.0% of elderly men and women, respectively, from all age groups, may be at risk. Compared to the Cuban elderly (Coqueiro et al. 2009), the percentage of individuals at risk was greater for males and females in São Paulo.

Arm and calf circumference, muscle circumference, and triceps skinfold thickness were significantly higher in the youngest elderly (‡$p \leq 0.001$; ANOVA). For waist circumference, there were no significant differences between age groups

SD standard deviation

Using data from the SABE Survey, São Paulo, and considering the cutoff points from which men and women should avoid gaining weight (WC ≥ 94 cm for men and ≥ 80 cm for women) (Lean et al. 1995), the study carried out by Munaretti (2009) showed an independent association between WC and hypertension. The prevalence of individuals with inadequate WC values was 56.1% in men and 83.9% in women from São Paulo, which is greater than that observed in Rio de Janeiro (Santos and Sichieri 2005), being 39.2% and 65.9%, respectively (Fig. 92.5).

92.5 Body Fat and Muscle Mass Indicators

With aging, there is a redistribution of body fat and fat-free mass. The amount of fat in the upper and lower limbs decreases, and it is possible to observe reductions in the arm circumference (AC) and triceps skinfold (TSF) measurements. A decrease in the fat-free mass can be observed, especially concerning

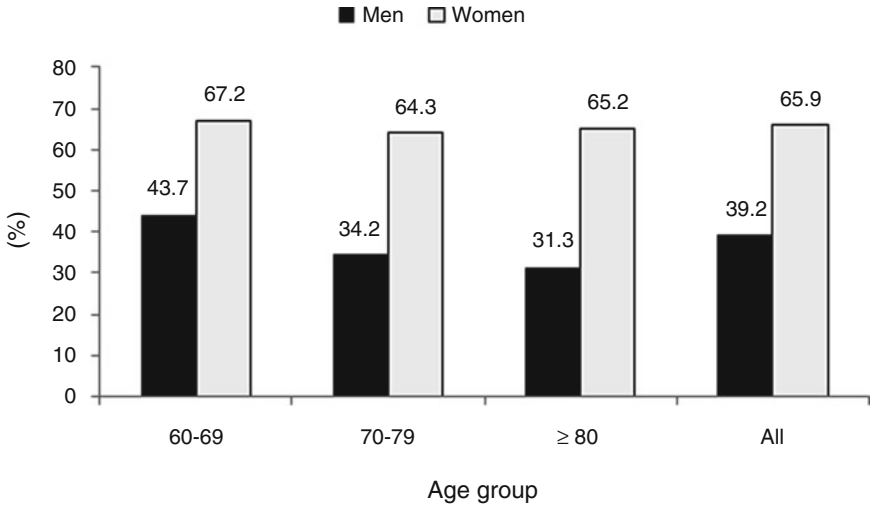

Fig. 92.5 Distributions of overweight (WC ≥ 94 e ≥ 80 cm)* in the elderly of Rio de Janeiro, according to sex and age group. *waist circumference for men and women, respectively. In all age groups, the prevalence of overweight was greater for women (Adapted from Santos and Sichieri 2005. With permission)

the reduction of muscle mass, the body's largest protein reserve (WHO 1995). Reductions in muscle mass can be identified in a decrease in calf circumference (CC) and in the arm's muscle circumference (Perissinotto et al. 2002; Barbosa et al. 2005; Menezes and Marucci 2007; Coqueiro et al. 2009); these regions provide estimates of the protein reserves, and can also indicate muscle use, or lack thereof.

Arm muscle circumference (AMC), AC, and CC estimate muscle reserves (the first two estimate arm muscle tissue and the last represents leg muscle tissue) and are considered good indicators for malnutrition in the elderly; also, CC has lately been recommended as a sensitive measurement for muscle mass loss in these individuals (WHO 1995). However, although AC and CC are anthropometric variables recommended for verifying muscle mass reserves, they represent the sum of bone, muscle, fat, and epithelial tissues for arms and legs, respectively, and should not be used independently (Menezes and Marucci 2007).

For the elderly of São Paulo (Barbosa et al. 2005), in all age groups, AC and TSF values were greater for women than men, whereas the latter presented greater AMC values. Calf circumference values were similar between men and women (Tables 92.5 and 92.6, respectively). Probably, such similar values occur due to gender-related differences in the proportion between fat and muscle mass. With increasing age, both sexes showed significant reductions in all measurement values.

The data from the elderly of Fortaleza (Menezes and Marucci 2007) show (Table 92.7) that TSF and AMC values were greater for men and women, respectively, as observed in the elderly of São Paulo (Barbosa et al. 2005) and Rio de Janeiro (Santos and Sichieri 2005). Arm circumference values were similar in both sexes. As the age groups increased, there was a significant reduction in AC and AMC values for men, and in TSF and AC for women.

A comparison between the data on the elderly of São Paulo, Fortaleza, and Rio de Janeiro is difficult, due to the difference in age-group intervals (shorter in São Paulo) and the lack of a percentile distribution by Santos and Sichieri (2005). However, it can be noticed that the differences are more evident for AC and TSF values, which are greater among men and women from Rio de Janeiro. It can also be observed that differences appear to be greater among women and younger age groups. As for the oldest age group, mean and percentile AMC values were rather close, in male and female elderly from Fortaleza and São Paulo.

70–79	121	22.3	3.0	17.8	18.8	20.1	22.1	24.3	25.9	28.1
≥*80*	47	22.0	3.1	16.2	18.2	19.8	21.6	24.5	26.1	27.0

With increasing age, there was a significant reduction in arm circumference and triceps skinfold thickness (TSF) values, for men and women, respectively (*p <0.001; ANOVA). The mean value for arm muscle circumference and TSF was greater among men and women, respectively (‡$p \leq 0.001$; Student's t-test)
SD standard deviation

In the elderly of the three studies (Barbosa et al. 2005; Santos and Sichieri 2005; Menezes and Marucci 2007), AC values appear to indicate a greater quantity of subcutaneous fat for women, as females present greater TSF and lower AMC values. With increasing age, subcutaneous fat reduction is stronger for women and muscle mass loss is greater for men. In spite of these reductions, even the oldest men (≥80 years) continue to present greater muscle mass values (AMC) and women still present more subcutaneous fat (TSF), as was assessed in elderly individuals from other countries (Kuczmarski et al. 2000; Santos et al. 2004; Coqueiro et al. 2009).

92.6 Final Considerations

The data from the analyzed studies show that reductions in BM, height, and BMI with increasing age are reflected in the other anthropometric measurements, and show a stronger reduction in the oldest age group – although it should be stated that it is also the most heterogeneous group.

The patterns of alterations in anthropometric characteristics with increasing age are similar; however, the intensity of the differences varies between the populations, even in the same country. Anthropometric comparison of different populations should be carried out with caution because normal effects of aging result from both genetic differences and exogenous factors (socioeconomic and lifestyle differences, among the other factors) (Barbosa et al. 2005).

Bambuí, São Paulo, and Rio de Janeiro, in the southeast; Fortaleza, in the northeast; and Pelotas, in the south, are cities with diverse socioeconomic and environmental characteristics. São Paulo and Rio de Janeiro are the two most populous cities of Brazil, and the former is the capital of the state with the biggest industrial park and economic production in the country. Fortaleza is the capital of the state of Ceará, and its service sector comprises the largest part of the wealth produced in the state. Bambuí is a small town with 77.6% urban and 22.4% rural population (21,850 inhabitants), whereas Pelotas is a city with nearly 300,000 inhabitants and a 93.2% urbanization rate (IBGE 2009).

Besides the differences between the populations, other factors, such as method characteristics, number of participants, criteria for inclusion or exclusion of the sample, and the way in which the results are presented (Menezes and Marucci 2007), limit the comparisons.

92.7 Applications to Other Areas of Health and Disease

Anthropometry is a noninvasive, low-cost, and easy-to-apply method. Arm muscle circumference and CC, which estimate the muscle reserve, are considered as good indicators of undernourishment in the elderly, and CC has been considered as a sensitive measurement tool to measure the muscle mass loss in elderly individuals (WHO 1995). Weight change, BMI, TSF, AC, and CC are the essential components of several nutrition screening instruments developed for the elderly (Jensen et al. 2001; Huffman 2002; Guigoz 2006). Waist circumference has been used to identify central adiposity (visceral), and is also a measurement used to verify the risk of developing cardiovascular diseases and metabolic disorders.

The information from early studies may be used to compare and assess anthropometric characteristics (e.g., nutritional status, central adiposity, subcutaneous fat reserve, and muscle mass) in the elderly, in either clinical practice or epidemiological studies. If there is a lack of reference values for the Brazilian elderly, then these data can be used as a reference for the elderly individuals in other regions of the country, rather than comparing with the international data. The data can also be used for planning actions that intend to prevent or improve the nutritional inadequacy in the elderly, as well as for verifying the improvements achieved by the implemented actions.

92.8 Key Points of Anthropometry of Brazilian Elderly

The elderly have heterogeneous anthropometric characteristics that are specific to the location (city/region). Anthropometric alterations such as reductions in height, BM, BMI, increase in the proportion of body fat, changes in skin texture, and loss of muscle tissue, may be universal, but how they occur and their incidence may vary considerably within and between the groups of elderly individuals (whether genetically similar or not) owing to the action of environmental factors on normal aging effects.

Summary Points

- Sex and age are the determining factors in anthropometric changes.
- With increasing age, there is a reduction in height and BM, which are different for each gender. This reduction is greater among women.
- Muscle mass in the limbs decreases progressively and fat centralization increases with increasing age, especially in women.
- After 75 years, waist circumference (central adiposity) decreases more rapidly with aging in men than in women.
- Women accumulate more subcutaneous fat and have less muscle mass than men. With increasing age, subcutaneous fat reduction is greater in women, and the loss of muscle mass is greater in men.
- Independent of the cutoff point used to evaluate the nutritional status (BMI), overweight/obesity is more prevalent in women, and underweight is more common in men.
- With increasing age, there is a reduction in the prevalence of obesity and an increase in the prevalence of underweight, which is more evident after the age of 75 years.

Chapter 93
Assessment of Sarcopenia

Daniel Bunout, Gladys Barrera RN, Pia de la Maza, Laura Leiva RT, and Sandra Hirsch

Abstract Sarcopenia is defined as the loss of muscle mass that occurs during normal aging and is associated with functional impairment. This is a dynamic concept that should consider the reduction of muscle mass over time but, for practical purposes, we must rely on cross-sectional measures to determine the presence of a significant loss of muscle mass. Double energy X ray absorptiometry is a reasonably accurate and inexpensive method to determine body composition. Knowing the body composition of a representative sample of older subjects in a specific community, regression equations to predict muscle mass can be derived to determine which individuals are sarcopenic using the residuals method. Functional measures should also be incorporated in the assessment of sarcopenia. The most popular assessments include walking capacity, the ability to rise from a chair and the measurement of muscle strength using dynamometers. A lower muscle mass and function in older subjects are risk factors for mortality and disability. Physical training is the only intervention capable of reverting the adverse consequences of sarcopenia.

93.1 Definition and Pathogenesis of Sarcopenia

Sarcopenia is defined as the loss of muscle mass that occurs during normal aging (Bales et al. 2002). It is associated with a deterioration of muscle strength and walking capacity leading to dependence. The causes are not completely known, but it is probably related to oxidative damage of muscle, nutritional or endocrinological changes that occur during the aging process.

Accumulation of reactive oxygen species in tissues is closely related to the aging process and caloric restriction the only experimental procedure that may retard the aging process, considerably reduces the accrual of these species (Zainal et al. 2000). The most probable target of oxidative damage is mitochondrial DNA, which leads to derangements of oxidative phosphorylation.

Several nutritional factors have been implicated in sarcopenia. Older people have higher protein requirements than young adults and they tend to fall in a negative nitrogen balance. Amino acid supplementation increases lean body mass (Dillon et al. 2009). Also, vitamin D deficiency, highly prevalent in the elderly, may also play a role in muscle loss (Bunout et al. 2006). Somatopause or

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_93,

the decline in growth hormone secretion with aging has also been related to sarcopenia and the supplementation with ghrelin, an enhancer of pulsatile growth hormone secretion (Nass et al. 2008), reverts it. Finally successive bouts of weight loss during late life contribute to muscle loss. Even if lost weight is regained, there is always a net loss of muscle, which is replaced by fat (Lee et al. 2009).

Whatever the cause of sarcopenia, the therapeutic options to revert it or decrease its functional consequences are limited to exercise training, the only intervention that has shown universal benefits for older subjects with sarcopenia, in a variety of scenarios (Bunout et al. 2005). This is a simple, safe and thrifty intervention that should be widely recommended to older people. Its drawback is the lack of compliance with exercise sessions. Probably, better educational campaigns encouraging older subjects to engage in physical activities and sports will partially overcome these limitations.

93.2 Measurement of Muscle Mass and Function

93.2.1 Muscle Mass

Anthropometry is practically useless as an assessment method of sarcopenia since it must relay on the estimation of body fat, using calipers to measure skin fold thickness. This measurement has a low inter observer concordance and a very low correlation with body fat measured with more accurate methods, such as those described below To determine the total or appendicular amount of muscle in an individual, radiological methods or densitometry, should be used.

Double energy X-ray absorptiometry (DEXA) is a relatively inexpensive method to assess body composition and it is accurate if used in a homogeneous group of subjects in terms of age and health status (Williams et al. 2006). The case of subjects in whom shifts in body hydration produce significant errors in the estimation of body compartments is different (Georgiou et al. 1997). This method gives a good estimate of fat free mass, which also can be divided easily in different body segments to calculate appendicular (limb) and truncal composition. A recent study compared DEXA with magnetic resonance imaging to determine the amount of skeletal muscle mass in older women, obtaining a correlation of over 0.9 between both methods (Chen et al. 2007).

Bioelectrical impedance is another inexpensive method that relies on the fact that body impedance is inversely proportional to body water content. When multi-frequency bioelectrical impedance is used, the concordance with DEXA measurements is acceptable, if local regression equations are generated for the population that is being studied (Shafer et al. 2009).

Computed tomography and magnetic resonance are highly accurate to measure body composition, but also very expensive. These methods measure not only the amount of muscle but also its quality. In older subjects, there is a progressive fat infiltration of muscle (Cree et al. 2004), which not only replaces functional muscle fibers but also damages the remaining ones. This infiltration may be recognized as a reduction in radiological density of muscle in computed tomography (Goodpaster et al. 2000) or using magnetic resonance spectrometry, that is a far more exact method (Torriani et al. 2005). Probably, in the future the radiological density of muscle will have to be added to volume measures to obtain a better prediction of muscle strength. The disadvantage of these methods is that their cost precludes their widespread application in clinical or epidemiological settings and must be reserved for research purposes.

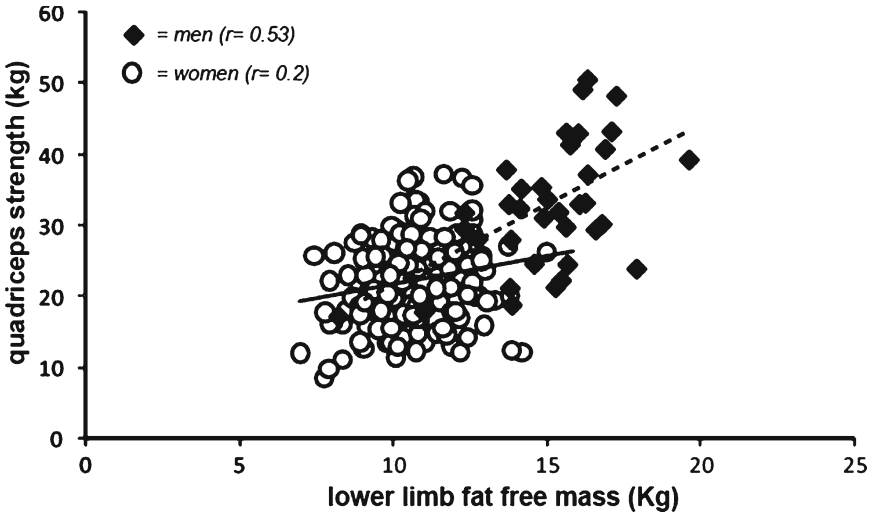

Fig. 93.1 Correlation between lower limb fat free mass measured by Double energy X Ray Absorptiometry (DEXA) and quadriceps strength in a group of healthy men and women. There is a positive correlation between quadriceps strength and lower limb fat free mass in both men and women. However, the correlation coefficients are low

93.2.2 Muscle Function

Functional measures have also been used as surrogate measures of muscle mass and quality in the elderly. The main parameters used are:

Muscle strength measurement using dynamometers: The most widely used is hand grip strength. We have used it to predict the muscle mass of older subjects (Arroyo et al. 2007), but it must be borne in mind that the correlation of strength with mass, although significant, is weak. The strength of other muscles such as quadriceps and biceps can be measured using hand held dynamometers or quadriceps tables but still, the correlation with muscle mass is low (Fig. 93.1).

1. *Walking capacity assessment using the 6 or 12 min test*, which consists in recording the maximal distance that a subject can walk at a constant pace in a flat surface during 6–12 min (McGavin et al. 1967). It was originally devised to evaluate patients with respiratory diseases, but has proven very useful to assess the functional capacity of older subjects. Moreover, during a 3 year follow up, we observed a close association between the evolution of fat free mass and walking capacity in this age group (Fig. 93.2). Although the association of walking capacity with muscle mass is low, other authors reported that it has a good prognostic value for future disability in the elderly (Tainaka et al. 2009).
2. *Composite functional tests*: The most popular are the timed up and go (Rockwood et al. 2000) and the short physical performance battery (Guralnik et al. 1995). Both are based on the assessment of the capacity of standing up from a chair, walking a short distance and being able to maintain a standing position. These tests are very useful to predict frailty and are relatively simple to use, but their association with muscle mass is weak, at best. An interactive program with Spanish versions of these tests can be found in: http://www.inta.cl/Estudiantes/programas/ProgramasInteractivos.htm.

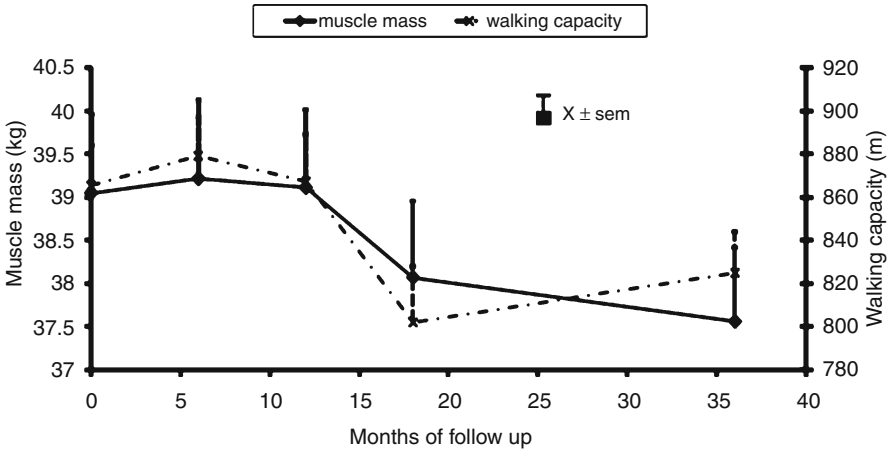

Fig. 93.2 Association between the evolution of walking capacity measured using the 12 min test and total fat free mass measured by Double energy X Ray Absorptiometry (DEXA) in a group of 86 older subjects followed up for 3 years. This figure shows repeated assessments during a 36 months follow up. A close concordance between the evolution of total fat free mass and walking capacity, was observed

93.3 Defining Cutoff Points to Diagnose Sarcopenia

Sarcopenia is a functional concept, since it encompasses muscle mass loss throughout time. Therefore, from a purist's point of view, the real way of diagnosing sarcopenia is to follow up older subjects after a lapse of more than 1 year and to define the muscle mass attrition that they have experienced. We have followed subjects for 3–5 years to calculate it. The mean loss of fat free mass, measured by DEXA is 221 ± 399 and 521 ± 454 g/year in females and males, respectively (Bunout et al. 2007) (Fig. 93.3). However the dispersion of values is high, and there is a group of subjects that do not lose fat free mass.

However, this type of follow up is normally done only in research facilities. What clinicians and epidemiologists require is to predict which subjects are sarcopenic, based on cross sectional assessments. This cross sectional definition of sarcopenia can be done in several ways:

93.3.1 Statistical Definition

This means to define as sarcopenic those individuals with a low amount of muscle mass, compared to subjects of the same age and gender or compared to young counterparts, which becomes the "gold standard" for muscle mass. Most authors have divided the amount of appendicular muscle mass by the squared height in meters, in a manner analogous to body mass index (appendicular fat free mass index). Afterwards, they defined as sarcopenic those individuals who have an appendicular skeletal muscle mass/height^2 two standard deviations below reference values of young individuals. This is similar to the t- score calculated to define osteoporosis (World Health Organization 1994). To test the value of this assessment, they have calculated the association of this parameter with functional measures such as muscle strength and gait speed. Using this definition of sarcopenia, its observed prevalence in subjects aged 60 years or more ranges from 15% to more than 50% in the oldest individuals.

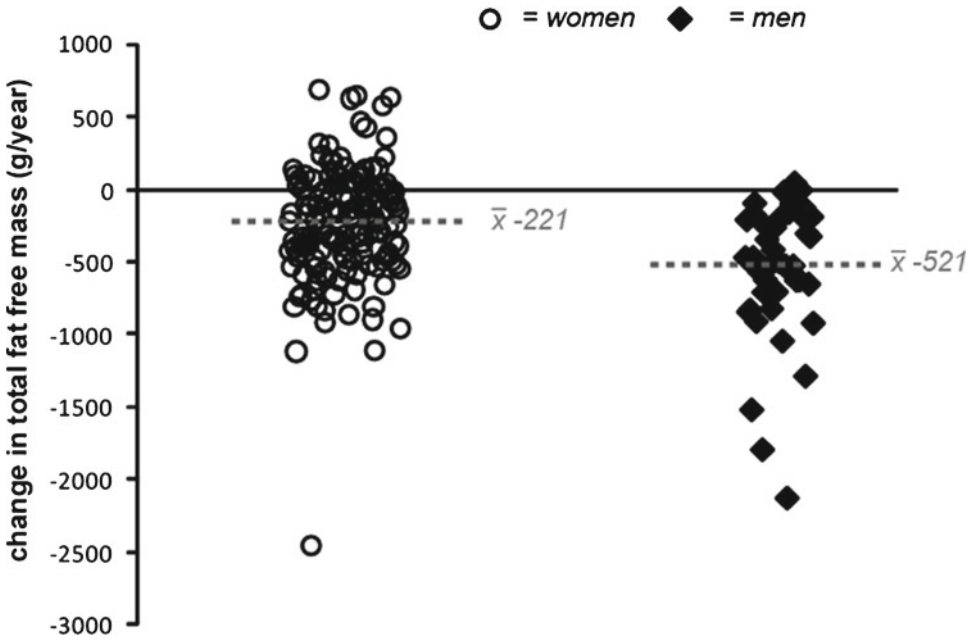

Fig. 93.3 Loss of fat free mass measured by Double energy X Ray Absorptiometry (DEXA) in 148 women and 45 men aged 70 years or more, followed for a mean of 5 years. The figure show the individual changes in total fat free mass in a group of healthy older men and women followed with repeated measurements during 5 years. There is a great dispersion of values and a small group of subjects that did not lose fat free mass during the follow up

The problem with this method is that a reference database with body composition data of young individuals of the same ethnicity and socioeconomic condition is required to calculate the t-score. This information is not always available or reliable.

To overcome this drawback, the other alternative is to calculate the amount of muscle and relate it to peers of the same age, overcoming the requirement of data from young people. When performing the calculations in this manner, gender-specific tables must be generated since there is a huge difference in the amount of muscle between men and women. Secondly, the amount of total or appendicular lean body mass must be corrected by height (dividing by the height or the squared height). Again, the ideal is to have a large set of data to obtain confident results.

A simpler method of determining which individuals are sarcopenic is to define sex-specific quartiles or quintiles and to consider as sarcopenic those individuals located in the lower quintile of lean body mass. Another way to perform the same calculation is to determine a regression equation in which the dependent variable is lean body mass and the independent variables are all those that are predictors of the former in an univariate analysis. Once the regression equation is obtained, the residuals or the difference between the actual and predicted lean body mass may be calculated (Fig. 93.4). The cutoff point where a residual becomes significant must be decided. In a recent paper, we compared the quartiles and residuals of lean body mass in a group of healthy elderly subjects followed for 4.8 years. Both methods resulted as significant predictors of fat free mass loss, assessed during the follow up. Therefore, even without having available data of young subjects, sarcopenic individuals can be identified as those that have the lowest amounts of lean mass, when compared to their peers. As an example, Table 93.1 depicts the cutoff values for fat free mass, to consider a subjects as sarcopenic, based on equations derived from subjects studied by the authors (Bunout et al. 2007).

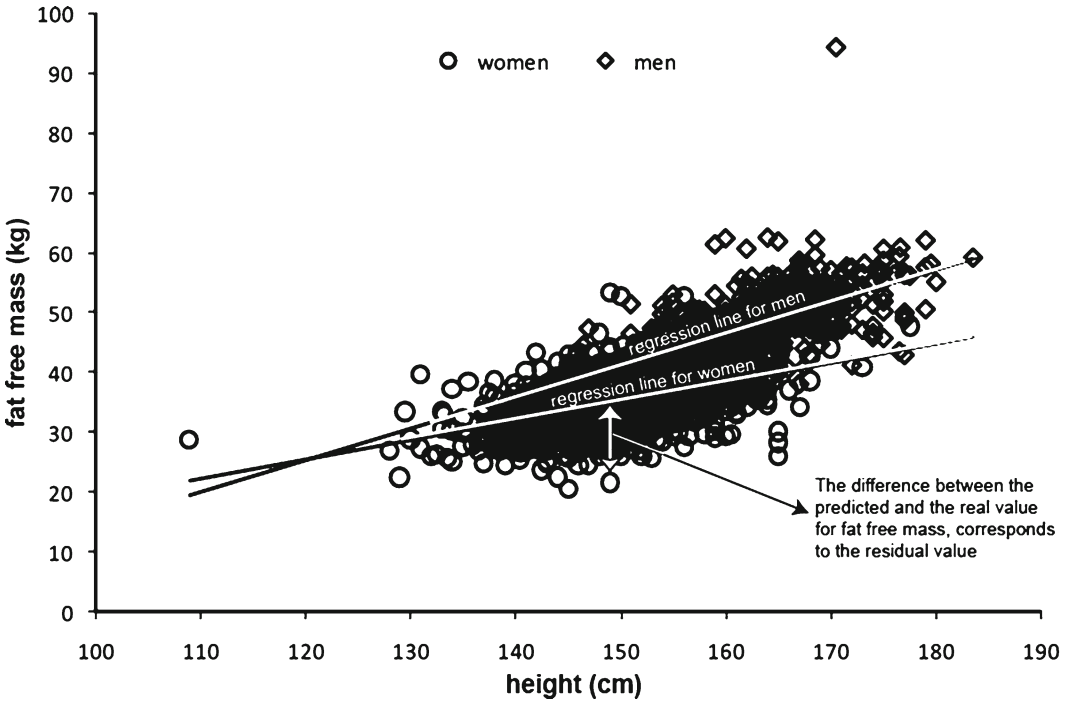

Fig. 93.4 An example of how to calculate residual values of fat free mass using a regression equation with height and age as independent factors. A regression equation for fat free mass is calculated for each gender, using height and age as independent factors. The difference between the measured and the predicted value (*arrow*) corresponds to the residuals and is used to diagnose sarcopenia, using cutoff points that are specific for each population of individuals

93.3.2 Prognostic Definition

Even though we can identify those subjects that have lost the greatest amount of muscle mass, the real reason to identify those individuals are prognostic or therapeutic issues. As mentioned before, the only available treatment for sarcopenia that is universally accepted is exercise and it should be prescribed to all individuals. Therefore, the identification of sarcopenia from a therapeutic point of view is worthless. However, the use of sarcopenia as a prognostic indicator of mortality or disability is attractive. Moreover, a working definition of sarcopenia should ideally be based on prognostic indicators rather than on statistical parameters. The most commonly used end points to determine prognosis are mortality and disability.

Mortality: Longitudinal studies have shown that muscle strength measured using a hand grip dynamometer or functional capacity measured using walking speed are better predictors of 6 years mortality than muscle mass measured by DEXA or 24 h urine creatinine excretion (Metter et al. 2002). Other studies have demonstrated that frailty, defined as a low muscle strength, a low walking speed or a low amount of appendicular muscle mass, increased the risk of mortality among men older than 65 years by a factor or two (Cawthon et al. 2007).

We recently analyzed the data of 1,500 elderly subjects that had a measurement of muscle mass and were followed for a median of 5 years. Among subjects older than 74 years, the amount of appendicular fat free mass was a significant predictor of mortality (Fig. 93.5).

(a) *Disability*: As stated before, the correlation between muscle mass and strength is generally low (Bunout et al. 2004). However if a functional parameter is used as endpoint, such as walking capacity, muscle strength becomes an excellent predictor of disability (Arroyo et al. 2007).

Table 93.1 Prediction of sarcopenia based on fat free mass measured by Double energy X Ray Absorptiometry (DEXA) and equations published in Aging (2007) 19:295

		Females		Males	
Age (years)	Height (cm)	Predicted fat free mass (kg)	Sarcopenic if fat free mass is below (kg)	Predicted fat free mass (kg)	Sarcopenic if fat free mass is below (kg)

	160	36.5	33.9	45.3	42.7
	170	38.9	36.2	49.3	46.7
	180	41.2	38.6	53.3	50.7
	190	43.6	40.9	57.3	54.7
85	150	33.6	31.0	40.0	37.4
	160	35.9	33.3	44.0	41.4
	170	38.3	35.7	48.0	45.4
	180	40.6	38.0	52.0	49.4
	190	43.0	40.4	56.0	53.4
90	150	32.6	30.0	36.7	34.1
	160	35.0	32.3	40.7	38.1
	170	37.3	34.7	44.7	42.1
	180	39.7	37.0	48.7	46.1
	190	42.0	39.4	52.7	50.1

An 8 year follow up study showed that the risk of developing disability, determined using a mailed questionnaire, was 27% higher in elderly men and women with a low muscle mass (Janssen 2006). Another study observed a relationship between health-related quality of life in older people and hand grip strength (Sayer et al. 2006). There is also an association between weakness and poor function and the risk of hospitalization in older subjects (Cawthon et al. 2009).

(b) *Composite indexes*: There is always a temptation to combine several parameters in a single score to obtain better prognostic yields in the evaluation of patients. Sarcopenia is not the exception and a group of authors developed an index that combines measures of muscle mass, strength and function, demonstrating its validity for epidemiological research (Miller et al. 2009). The problem with this type of composite indexes is that they must be validated in each new population where they will be used; they are seldom used by clinicians, who prefer simple and single measurements to assess risk.

(c) *Sarcopenic obesity*: Recently, the concept of sarcopenic obesity has been incorporated and several studies and have observed that obesity, defined as a percentage of body fat over 35%, is a better predictor of physical disability than sarcopenia and that the latter, in the absence of obesity, is not associated with physical difficulties (Rolland et al. 2009).

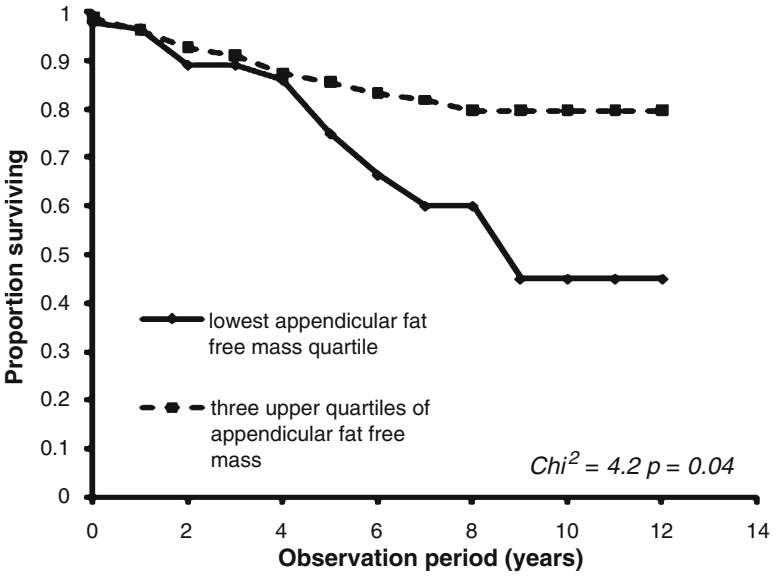

Fig. 93.5 Mortality of elderly subjects according to their appendicular fat free mass measured by Double energy X Ray Absorptiometry (DEXA). Mortality of healthy older subjects was recorded during a 12 year follow up. Subjects aged over 74 years in the lowest quartile of appendicular fat free mass had a significantly higher mortality than their counterparts without sarcopenia

We have some doubts about the real influence of obesity on the risk of elderly subjects. These apprehensions are based on the observation that mortality among this age group is higher among those with a low body mass index and the factor that is related to mortality is the presence of excessive visceral fat (Price et al. 2006). Probably, extreme degrees of obesity influence the functional performance of older subjects, but a body mass index between 27 and 30 kg/m^2 appears more as a protective rather than a risk factor.

93.4 Conclusions

Sarcopenia is a dynamic process whose importance lies in its functional consequences and its association with mortality among older people. Therefore we need to determine the cutoff points to define sarcopenia based on prognostic rather than statistical factors. According to the literature and our own experience, the assessment of muscle mass in the elderly can be performed reliably and economically using double energy X-ray absorptiometry (DEXA) equipment. On the other hand, the measurement of hand grip strength and walking capacity are simple to use functional measures. A set of data of an important number of elderly subjects should be obtained in every country to define sex and age stratified quartiles or quintiles. Subjects in the lowest quartile or quintile of any of the functional or mass measures may be considered, without fear of sinning, as sarcopenic. This assumption is based on data from all the prospective studies on sarcopenia. Obviously, the ideal is to follow the subjects to determine local risk factors for disability or mortality, but this is not always feasible.

Finally, it is important to remember again that the best measure to prevent muscle loss and its consequences is to recommend physical activity to all older subjects.

Summary Points

- Sarcopenia is defined as the loss of muscle mass that occurs during normal aging and is associated with functional impairment
- The only intervention considered useful thus far to prevent the consequences of sarcopenia is physical training
- Anthropometry is not useful to assess sarcopenia
- Double energy X ray absorptiometry should be used to assess body composition in the elderly
- The short physical performance battery (SPPB), the timed up and go (TUG), the 6 min walk and hand grip dynamometry are good functional indicators of disability associated with sarcopenia
- Sarcopenia is a risk factor for disability and mortality

Key Points

- Sarcopenia is a dynamic concept indicating a loss of muscle mass with aging
- Sarcopenia is associated with a higher risk of disability and mortality
- Measurement of muscle mass is best achieved by double beam X-ray absorptiometry (DEXA)
- The determination of cutoff points to diagnose sarcopenia can be accomplished using regression equations based on local data.

Key Features of Dynamometers

- These are simple devices used to measure muscle strength
- They are hand held and will measure the strength of specific muscle groups
- The most commonly used are those that measure the hand grip strength
- There are also dynamometers that measure the strength of proximal muscles of upper and lower limbs

Key Features of 6 or 12 min Walk

- This test is a simple measure of endurance
- It only requires a flat surface such as a football or baseball field
- The perimeter of the field must be measured
- The number of laps that a subject is capable of walking in 6 or 12 min at a constant pace is recorded
- A walking speed of less than 1 m/s is considered abnormal
- This measure is a good predictor of future disability

Chapter 94
Body Mass Index and Cardiac Events in Elderly Patients

John A. Batsis and Silvio Buscemi

Abstract Body Mass Index has been challenged as an anthropometric measurement in elderly patients. Recent data, even in elderly patients, has demonstrated that elevated body mass index affords a worse long-term prognosis, although the magnitude of this relationship weakens as one ages. Underweight patients, possibly due to elements of sarcopenia and/or frailty, are also at a higher risk of overall mortality. A number of inflammatory mediators may be responsible for such factors which likely contribute to the increased risk of cardiovascular events observed. Although body mass index has been implicated in the development of heart failure, coronary artery disease and mediates its effects through other cardiovascular risk factors, it appears that it may indeed be protective in elderly patients who are overweight or mildly obese. Conversely, low body mass index may be harmful, a concept known as the obesity paradox which has been observed in a number of settings including congestive heart failure following cardiac surgery and in particular following hip fracture repair. This chapter examines the impact of body mass index on overall mortality and cardiovascular events in elderly patients. Although there are similarities between older patients and those of young and middle age, there are striking differences which will be delineated in this review.

Abbreviations

BIA	Bioelectrical impedance
BMI	Body Mass Index
CABG	Coronary artery bypass graft
CV	Cardiovascular
CRP	C-reactive protein
DEXA	Dual energy x-ray absorptiometry
IL-6	Interleukin 6
TNFα	Tumor necrosis factor α

94.1 Introduction

Obesity has been deemed a modifiable cardiovascular risk factor according to the American Heart Association. Obesity not only mediates traditional cardiovascular risk factors, including hypertension, diabetes, and dyslipidemia, but also reduces insulin sensitivity, enhances free fatty acid turnover and promotes systemic inflammation, all of which induce atherosclerosis and lead to the development of coronary artery disease (Domfeld and Maxwell 1985; Gregg et al. 2005; Grundy et al. 2005). Other adverse effects of obesity are listed in Table 94.1 (Lavie et al. 2009). The impact of obesity on non-cardiac outcomes has been covered in other chapters of this Handbook.

94.2 Challenges and Limitations of BMI in Elderly Patients

Both the World Health Organization and the National Institutes of Health use body mass index (BMI) to define and classify patients with obesity (Quetelet 1871). However, the diagnostic performance of BMI has repeatedly been challenged for some very important reasons, particularly in elderly patients (Jackson et al. 2002). There are conflicting results when examining the correlation between BMI and key clinical outcomes, such as mortality, disability and cardiovascular events. In addition, the ability of BMI to accurately discriminate adiposity has also been called into question. BMI is calculated by using total body mass in kilograms, divided by the square of height (kg/m^2). This calculation incorporates both adipose tissue and lean mass, both of which have biochemical and mechanistic differences in terms of bodily function and outcome measures (Smalley et al. 1990). BMI can overestimate adiposity in younger patients with increased musculature, but can underestimate adiposity in elderly patients who have age-related reduction in lean mass and increasing amounts of fat deposition.

Previous studies using bioelectrical impedance (BIA) have demonstrated the poor relationship between BMI and adiposity (Blew et al. 2002). Although BIA has been used to accurately assess adiposity in nationally representative databases because it is reproducible and easy to perform, unfortunately it is impractical in a primary care office setting. One significant limitation in using BMI in elderly populations is that it simply cannot account for differences in fat mass and lean mass (Bales and Ritchie 2002; Dey et al. 1999). In elderly patients, lean mass and percent body fat correlate with BMI to a lesser degree than a corresponding younger cohort (Prentice and Jebb 2001). The calculation of absolute values of BMI in the elderly is influenced by changes that commonly occur as people age in both the numerator (weight) and the denominator (height). Weight often changes either intentionally or not, and loss of height occurs, both physiologically and pathologically, such as with vertebral compression fractures. Due to reduction in height with age, the possibility exists that BMI in the elderly is falsely elevated and may thus be a poor predictor of CV events. Furthermore, because of changes in body composition in the elderly occurring even in the female sex, the comparison of what BMI represents in these populations may not be equal across sex and age. Hence it may seem inappropriate to extrapolate data obtained in young and middle age patients to an elderly cohort (Prentice and Jebb 2001). In this respect, it has also been proposed that the optimal range of BMI in elderly people should be increased with respect to that considered for younger subjects (Beck and Ovesen 1998; Villareal et al. 2005).

By using BMI, inherent misclassification of patients that are obese may occur, particularly in the primary care setting where this anthropometric measurement is commonly utilized. Other anthropometric measures, including waist circumference, waist-hip ratio or hip circumference, have been proposed to be used in lieu of BMI as a means of identifying and defining obesity, particularly in elderly patients (Price et al. 2006). Studies have demonstrated that death may be better predicted by

waist circumference than BMI, both in men and women (Folsom et al. 2000; Heitmann et al. 2000). Ideally, methods including CT scanning, dual-energy x-ray absorptiometry (DEXA) and BIA, or hydrostatic measures, can all assess adiposity with greater accuracy and precision (Fogelholm and van Marken Lichtenbelt 1997). Despite this advantage, these modalities have significant disadvantages including increased cost, subjecting patients to possible radiation and harm and being clinically impractical in a busy office setting.

94.3 Body Mass Index and Mortality

94.3.1 Studies Using the National Health and Nutrition Examination Surveys (NHANES)

The relationship between BMI and mortality appears to be "U" or "J" shaped. This was well characterized in a study using data obtained from NHANES which examined BMI categories and subsequent risk of all-cause mortality in a cross-sectional manner (Flegel et al. 2005). In elderly patients, stratified between ages 60 and 69 and >70, underweight patients appear to have a higher relative risk of mortality

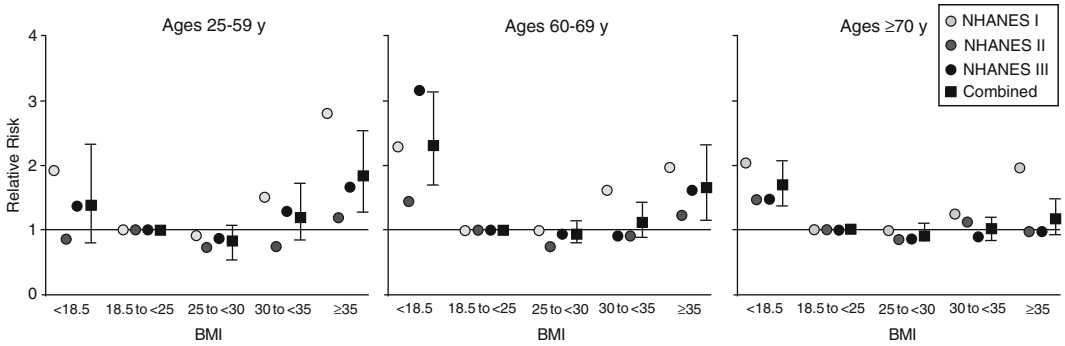

Fig. 94.1 Relative risks of mortality by BMI category, survey, and age BMI indicates body mass index, measured as weight in kilograms divided by the square of height in meters. The reference category with relative risk 1.0 is BMI 18 to <25. Error bars indicate 95% confidence intervals (Obtained with permission from Flegal et al. 2005. Table 94.2 Key features of the National Health and Nutrition Examination Survey (NHANES)

1. Assesses health and nutritional status of adults and children in the United States
2. Began collecting data in the 1960's in the United States population and is now a continuous program
3. Examines a nationally representative sample of ~5,000 persons yearly
4. Data includes questionnaires, an examination and laboratory component
5. Findings from the survey data are used in determining prevalence of major diseases and risk factors in disease-related epidemiology
6. Important in guiding health policy to help improve health status and prevent future health problems

than normal BMI patients, even higher than obese patients (Fig. 94.1). Examining cause-specific mortality using NHANES data (Table 94.2), the same group ascertained that for cardiovascular disease, obesity (BMI>30 kg/m^2) was positively associated with excess mortality and significantly increased mortality from both coronary heart disease and other forms of cardiovascular disease including cancers considered obesity related, than other BMI categories (Flegal et al. 2007) (Fig. 94.2). In this analysis, underweight or overweight patients were not at any different risk. Other studies confirm that obesity may have a higher hazard ratio than under or overweight.

94.3.2 Accuracy of BMI in Elderly

In general, BMI has often been challenged as an accurate anthropometric measure in predicting the risk of mortality in elderly patients. Results of studies have often been conflicting with regard to type of risk. Much of the controversy stems from biases and confounding variables. When data are corrected for smoking, a linear relationship has resulted between BMI and the risk of mortality (Ajani et al. 2004). However, some studies showed that an increased BMI value in elderly patients has a protective effect in terms of mortality risk. These confusing results are probably the consequence of many potential specific biases; for example, a history of weight change may influence mortality risk. Some studies provide evidence that the median survival is reduced in those subjects who have reached an increased BMI in elderly (Whitlock et al. 2009). Other studies showed an increased risk in those elderly subjects who lost weight (Strandberg et al. 2009). A significant problem is the difficulty in

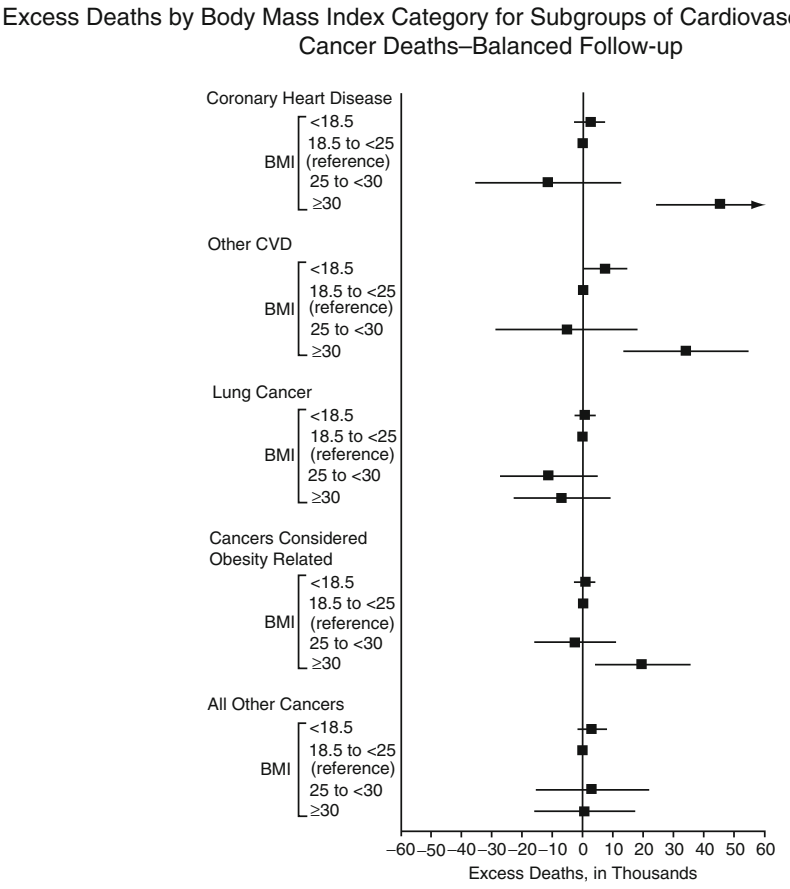

Fig. 94.2 Excess deaths by body mass index category for subgroups of cardiovascular disease and cancers BMI, body mass index, calculated as weight in kilograms divided by height in meters squared; *CVD* cardiovascular disease. Error bars indicate 95% confidence intervals (Obtained with permission from Flegal et al. 2007. Copyright © 2005 American Medical Association. All rights reserved)

establishing whether the body weight change is intentional or unintentional in this class of subjects. Furthermore, death events related to an increased BMI may occur earlier in life and it may be the case that those subjects who reach the elderly age group are less prone to cardiovascular complications.

94.3.3 Overall and Cardiac Mortality in Elderly – Meta-Analyses

Most studies examining overall or cardiac mortality have used BMI as a surrogate for obesity, and this is no exception in elderly patients. Many studies were retrospective cohorts, or prospective cohorts that were otherwise underpowered to prove any causal association between these entities. Stevens et al suggested that approximately 400 events in each age category are needed to detect a relative risk of 1.5 (Stevens et al. 1998). A recent meta-analysis determined the association between obesity and overall mortality and cardiovascular events in all patients (Romero-Corral et al. 2006). In this analysis, over 40 studies with a mean follow-up of 3.8 years were identified, consisting of 250 and 152 patients. Their results suggested that patients with a low BMI, defined as a BMI ≤ 20, had a

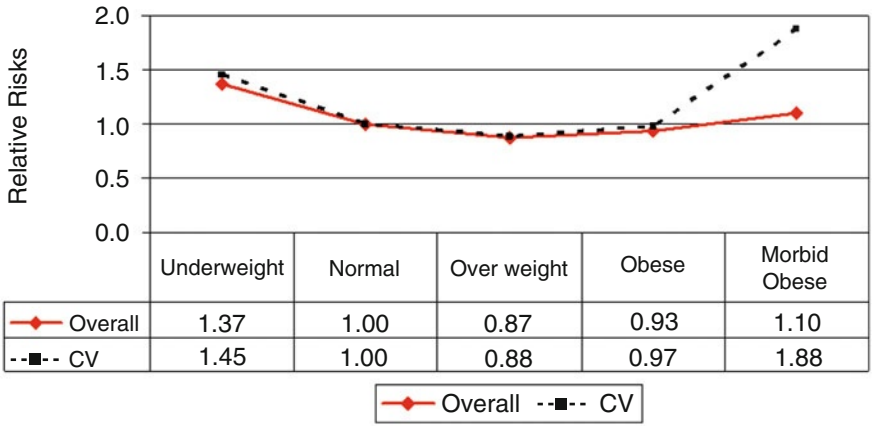

Fig. 94.3 Mortality in coronary artery disease patients. Adjusted relative risks in each category of BMI (<18.5, 18.5–24.9, 25–29.9, 30–34.9, 35+) for mortality in patients with coronary disease. Overall mortality and cardiovascular specific mortality risks are demonstrated. The referent category is patients with a normal BMI (18.5–24.9 kg/m^2). (Reprinted and adapted from Romero-Corral et al. (2006) © 2006. With permission from Elsevier)

higher risk of overall and cardiovascular mortality than patients with a BMI between 25–29.9 kg/m^2 (Fig. 94.3). There was no increased risk for patients with a BMI between 30–35 kg/m^2 other than in those with a history of having a coronary artery bypass graft (CABG). Class II+III obese patients (BMI ≥ 35 kg/m^2) had higher cardiovascular mortality but not overall mortality. Although this study did not differentiate between age groups, it provides important information about the utility of BMI as a discriminatory anthropometric variable. As is mentioned subsequently, elders with low BMI may have an element of sarcopenia, or decreased muscle mass (Lauretani et al. 2003). This entity is known to be an independent mortality predictor in elders. However, this population is also known to have reduced exercise tolerance and reduced functional status both of which are associated with increased overall mortality (Roubenoff 2000b). Nonetheless, morbidly obese patients, with increased amounts of excess body fat, had significantly higher risks for cardiovascular events, confirming the importance of excess adiposity on the impact of cardiovascular events (Eckel et al. 2002).

One of the many challenges in examining the impact of BMI on mortality or cardiovascular events, particularly in looking at the elderly, is adjusting for potential confounding variables. In a recent meta-analysis, a definitive collaborative study analyzed the relationship between BMI and cause-specific mortality in over 900,000 adults in 57 prospective studies predominantly from Western nations (Whitlock et al. 2009). There were 6.5 million years of person-follow-up. This was a study of epic proportions demonstrating that BMI between the ages of 35 and 89 years in both sexes, as a surrogate for obesity, is associated with increased overall mortality. Their data suggested that all-cause mortality, between a BMI 15–50 kg/m^2 demonstrated a J-shaped association in both males and females at all age levels, including 60–69 years, 70–79 years and 80–89 years. These associations persisted in 70–79 year olds between smokers and non-smokers (mortality risk ratio <2.5). They also demonstrated that in patients with a BMI between 25–50 kg /m^2, the effects of BMI and smoking were additive for vascular mortality and all-cause mortality. They additionally ascertained relative risk of different diseases according to BMIs as demonstrated in the Figs. 94.4–94.6. The author's overall conclusions from this study hold true, even in elderly patients, that BMI may indeed be a strong predictor of overall mortality at opposite ends of the optimal 22.5–25 kg/m^2 range. They suggested a causal association between BMI and vascular disease above this range. In addition,

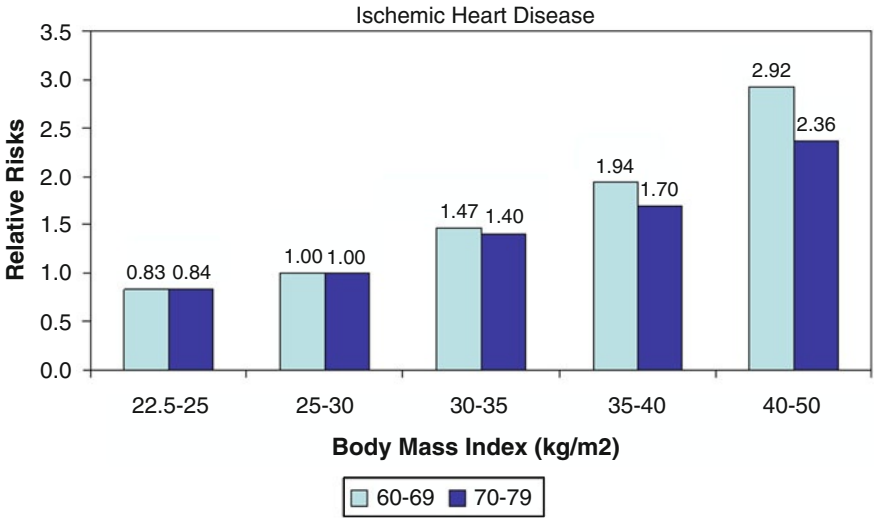

Fig. 94.4 Assumed causal relative risks for mortality estimates – ischemic heart disease. Figure represents relative risks for mortality estimates for ischemic heart disease. Body Mass Index and cause-specific mortality in 900,000 adults: collaborative analyses of 57 prospective studies, © 2009, with permission from Elsevier)

the authors confirmed that cause-specific mortality is due primarily to ischemic heart disease, stroke, diabetes and liver disease in patients with high BMIs. The low-normal BMI (18.5–22.5) group also has an increased risk of death as well.

An accompanying editorial provided possible explanations for these findings (Lopez-Jimenez 2009). First, there may be a protective effect of fat storage on acute disease or chronic wasting. This reserve of adiposity may be absent in the low-normal BMI group. Secondly, the amount of lean mass which is required not only for overall homeostasis but also oxygen consumption is limited in these patients, both of which are important contributors to survival. However, the authors do demonstrate that this inverse relationship between lower BMI and mortality is predominantly related to smoking-related pulmonary diseases. Although the associations presented in this study were slightly weaker in the 70–79 year age group, particularly from mortality of ischemic heart disease, this may transpire from the reduced associations of blood pressure and dyslipidemia with mortality or possibly due to age-related muscle loss and the impact on metabolic variables (Lewington et al. 2002, Lewington et al. 2007).

The third important meta-analysis published to date specifically identifies elderly patients, aged 65 years and older (Janssen and Mark 2007). They ascertained that elderly overweight patients with a BMI of 25–29.9 kg/m^2 were not associated with a significantly increased risk of mortality while those who were moderately obese, BMI 30–34 kg/m^2 had only a modest increase in mortality (RR 1.10 [1.06–1.13]). They also concluded in the oldest old (age > 75 years), an elevated BMI had no impact on the risk of death. These results preceded the definitive meta-analysis discussed above, but the authors state valid conclusions as to why they observed these results. First, patients with an elevated BMI may have already died at an early age; thus, those still alive may be resistant, for whatever reason, to the effect of an elevated BMI, the phenomenon of selective survival. Second, one cannot ascertain the differences between lean mass and excess body fat in these patients, both of which impact mortality and cardiovascular events(Kyle et al. 2001a, b; Roubenoff et al. 1995). The limitations of this work were that it used population-based and retrospective analyses and had a number of missing studies in their criteria.

94.4 The Risk of CV Events Associated with Underweight and Obesity in Midlife and in the Elderly

Despite obesity being a well-established risk factor for cardiovascular (CV) events, few studies have specifically addressed this point in elderly patients. In general, it is difficult to distinguish the independent effect of obesity on CV morbidity from those of obesity-related conditions such as metabolic syndrome, diabetes, hypertension or dyslipidemia and, even more, when they are pharmacologically or surgically treated (Batsis et al. 2007). In this context, abdominal obesity measured by means of waist circumference, has been confirmed to be an independent risk factor for heart failure even in older people (Nicklas et al. 2006). On the contrary, a low BMI was independently associated with an increased risk of silent cerebral infarction in the elderly, a condition that can predict clinical overt stroke or vascular dementia (Kotani et al. 2004). Recently, data from the Chicago Heart Association study (Yan et al. 2006) were analyzed to control for the role of obesity-related CV risk factors and to address the issue of whether midlife BMI had an independent impact on CV outcomes, including mortality from diabetes and hospitalization in survivors to the age of 65 years and older. The results indicated that being obese (BMI>30 kg/m^2) but not overweight, in middle age has a higher risk of mortality in older age. In this study, however, about 2,500 subjects (6% of the participating cohort) died before the age of 65 years and no information was available about the relationships between BMI and CV risk factors in these subjects. Interestingly, the midlife prevalence (referred to the years 1967–1973) of low risk subjects with normal BMI was low (<4%), a prevalence which may have been lower currently given the increasing prevalence of obesity and its associated risk factors. Another study (Adams et al. 2006) indicated that in older adults recalled BMI at middle age was a stronger mortality predictor than current BMI. A recent study from the Framingham cohort found that the risk of all-cause mortality was not increased in obese subjects older than 70 years who were not obese at 50 years; on the contrary, elderly subjects with midlife obesity were at an increased risk, independently if they were actually obese or nonobese (Janssen and Bacon 2008). A possible study bias was that confounding information of both health risk and BMI, such as smoking, alcohol intake or socioeconomic status was not taken into consideration. However, globally considered, these observations are in agreement with the concept that current and midlife BMI provide independent information on health risk in elderly subjects with different clinical implications.

94.5 Other Anthropometric Variables and Mortality

Although outside the scope of this chapter, waist circumference and waist-to-hip ratio are other well known surrogate measures of abdominal obesity or body fat distribution. Many of the limitations that plague BMI in ascertaining obesity can be seen with these measures as well. Waist circumference changes with age because of changes in vertebral column and in truncal posture and are therefore independent in part from visceral fat size modifications. No extensive data are available that consider these potential biases.

Waist circumference and waist-hip ratio, which probably reflect the nature of both adiposity and body fat distribution measures, generally provide improved prediction of mortality risk among the elderly (Pischon et al. 2008; Price et al. 2006; Visscher et al. 2001). Some studies demonstrated an inverse association between BMI and mortality while the latter was positively associated with waist-hip-ratio. No extensive data are available between mortality risk and body composition in elderly subjects. However, similar to BMI, skinfold thickness was inversely associated with mortality (Kalmijn et al. 1999). When BMI and waist circumference were considered together, it showed that higher BMI values were associated

with lower mortality risk once the risk attributable to waist circumference (WC) was accounted for(Janssen et al. 2005).Therefore, taken as a whole, these data seem to indicate that in elderly subjects abdominal fat mass rather than the excess of body weight in itself, is closely associated with mortality.

94.6 Special Considerations in an Elderly Population

94.6.1 Sarcopenia and Cardiovascular Disease

Sarcopenia is defined as age-related loss of muscle mass that usually results in a decline in strength and power leading to frailty and disability. This becomes increasingly prevalent as one ages and the financial burden in one study was in excess of $18 billion annually in the United States alone (Singh et al. 2008). There is atrophy of muscle fibers, in tandem with an increase in fat mass. Although the most effective method of measuring whether a patient is sarcopenic is DEXA scanning, it is the costliest of all methods. Anthropometry, although operator-dependent, may crudely estimate the degree of sarcopenia. There has been little information published on the impact of sarcopenia specifically on cardiovascular outcomes. It appears that on a biological front, there are common underlying inflammatory pathways among sarcopenia, obesity, and insulin resistance, the latter two of which have been demonstrated to be related to adverse cardiovascular outcomes(Singh et al. 2008).The cytokine surge produced by adipocytes may directly impact patient physical function in the aging process, particularly interleukin-6 (IL-6), tumor necrosis factor α (TNF-α), and C-reactive protein (CRP) (Fig. 94.7). These components are well correlated with BMI, total mass and sarcopenia, the latter as measured by appendicular lean mass. However, whether these relationships have any impact on cardiovascular disease remains unknown.

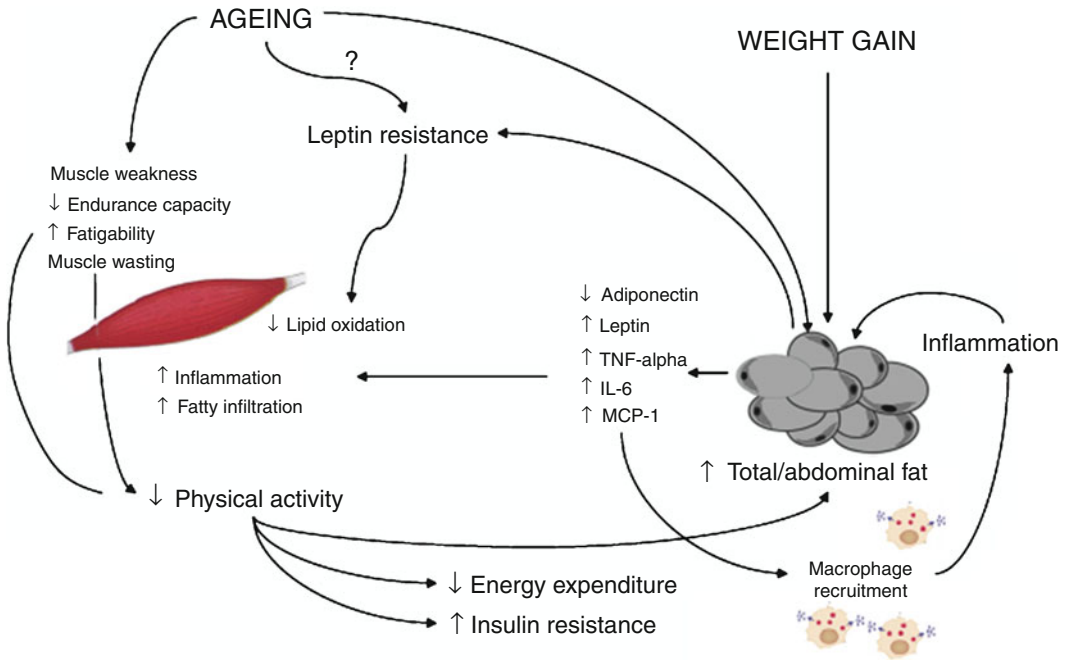

Fig. 94.7 Ageing and muscle. Inter-relationships between adipose tissue and muscle (Reprinted from Zamboni et al. (2008). With permission from Elsevier)

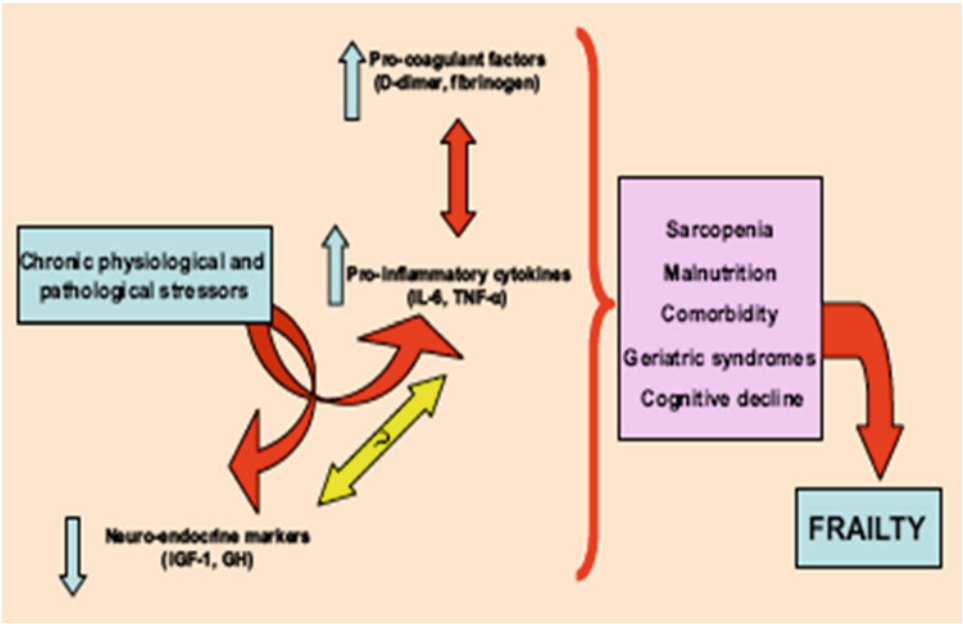

Fig. 94.8 Pathway to frailty. Pro-inflammatory signals, including IL-6 and TNF-a increase with age, as do markers of activated coagulation, including D-Dimer, fibrinogen, PAI, and Favor VIII. To the extent that these are primary processes, they may contribute to a cycle of physiologic changes that, in composite, are described as "frailty" (Reprinted from Kanapuru and Ershler (2009). With permission from Elsevier)

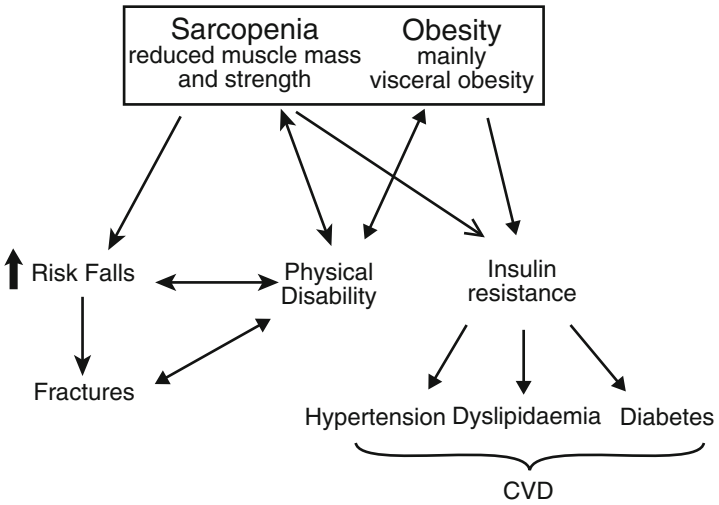

Fig. 94.9 Sarcopenia and Obesity. Possible relationships between sarcopenia, obesity, disability and cardiovascular disease. (Reprinted from Zamboni et al. (2008). With permission from Elsevier)

Patients with frailty and perhaps sarcopenia may indeed be at higher risk of developing atherosclerotic disease. This mechanism is likely mediated through a reduction in muscle blood flow as suggested by Morley (2008). Frailty and CV disease inherently share many of the same risk factors (Figs. 94.8 and 94.9). Obesity may also be associated with pre-frailty, but further studies are needed to ascertain the interplay between BMI, frailty and cardiovascular disease.

94.6.2 Frailty and Risk of Cardiovascular Events

Frailty is a construct that is difficult to define, but one that is debated in the geriatric literature. Such patients often have multiple co-morbid conditions, homeostasis is impaired in the context of acute stressors and physiologic reserves are slim, leading to an overall decline in functional status and health. The purpose of this section is not to define or debate the definitions of frailty, as these have been reviewed elsewhere, but to illustrate that such patients may be at higher risk for cardiac disease.

In epidemiologic studies, the prevalence of death from cardiovascular disease, from 1980 through 2000, fell from 542.9 to 266.8 deaths per 100,000 population among men, and from 263.3 to 134.4 deaths in women, in US adults between the ages of 25–84 years of age (Ford et al. 2007). Much of this was attributable to reductions in CV risk factors and evidence-based therapies. However, concomitant with this reduction, there continues to be a shift in population trends into the geriatric age group. In one study, it was estimated that 7% of elders are frail and this number increases to 30% in octogenarians (Fried et al. 2001). Depending on the criteria of frailty used, the prevalence can range between 6.9% in the Cardiovascular Health Study to 19% in the Longitudinal Aging Study Amsterdam (Puts et al. 2005). With the burgeoning elder population, these numbers have significant public health implications and these estimates are likely to be conservative because institutionalized patients are often excluded from these analyses. Patients with cardiovascular disease have a higher prevalence of frailty, particularly in those undergoing percutaneous coronary interventions or those with serious CAD (Purser et al. 2006). However, very little information has been published in this population group. Often, clinicians consider patients with frailty as those who are underweight, malnourished, or have poor physical performance status. One can consider a theoretical construct of patients who are frail to be equated to those who are underweight according to NHLBI criteria for obesity (Eckel et al. 2002). This has important clinical implications in that frailty predicts death, disability and institutionalization (Baumgartner et al. 2004). Two studies have determined that frailty predicts 1 year mortality and stroke after acute myocardial infarction (Krumholz et al. 2001; Lichtman et al. 2002). Although the reductions in lean mass may promote hormonal dysregulation, cytokine upsurge and increased systemic inflammation, all of which are associated with cardiovascular morbidity, further studies, specifically identifying this population, would be needed to better delineate the relationships involved.

There is an underlying inflammatory syndrome in patients who are frail, similar to that observed in sarcopenia, where many components share common links to those in cardiovascular disease. IL-6, a cytokine associated with sarcopenia and which may place patients at an increased susceptibility to infection and higher risk of disability, is often increased (Fried et al. 2001). It has also been associated with insulin resistance. Furthermore, CRP and D-dimer, both markers of inflammation, are elevated in the frailty syndrome (Fried et al. 2001, Walston and Fried 1999). CRP is an independent, non-traditional marker of CV disease and recent evidence suggests that the anti-inflammatory effects of statins in lowering CRP may indeed confer a CV disease benefit (Ridker et al. 2008). Although the study does not give particular hazard ratios, those over the age of 65 years did not have a HR or confidence intervals crossing 1.0 for their primary endpoint of nonfatal myocardial infarction, nonfatal stroke, arterial revascularization, hospitalization for unstable angina or confirmed death from cardiovascular causes following rosuvastatin administration. The subgroup results suggest that even elder patients may benefit from the CRP lowering effects of statins (Ridker et al. 2008). In a study of over 4,700 community dwelling elders, both CRP and D-Dimer were elevated in frail patients, characterized by a promotion of inflammation and enhanced markers of a potential coagulopathy (Walston et al. 2002). Indeed, much research in the cardiovascular community has focused on inflammation as a potentiating feature in the development of cardiovascular disease, much associated with pro-inflammatory cytokines and cell signaling.

94.7 Obesity Paradox

Observational studies suggested the expression of "*obesity paradox*" to indicate that among patients with chronic diseases and specifically in elderly patients, excess weight is paradoxically associated with decreased (Diehr et al. 2008) mortality. In fact, despite epidemiologic studies indicating obesity as a well established risk factor for mortality and CV disease, overweight and obesity have often resulted in protective effects not only in older subjects (Diehr et al. 2008) but also in patients with pre-existing CV disease (Curtis et al. 2005; Lavie et al. 2009), in subjects with advanced chronic kidney disease who require maintenance dialysis (Kalantar-Zadeh et al. 2005) or in those with malignancy (Chao et al. 1975) or AIDS(Roubenoff 2000a). Even more recently, it was reported that late-life obesity reduced the risk of dementia, including Alzheimer's disease, despite midlife (50 years) obesity, diagnosed on the basis of self-reported body weight, increased this risk (Fitzpatrick et al. 2009). Even those studies that reported an increased risk of death associated with increased BMI among elder subjects evidence that the relative risk of death declines with increasing age (Calle et al. 1999, Stevens et al. 1998).

The obesity paradox is an example of *reverse epidemiology*, a recently proposed construct (Kalantar-Zadeh et al. 2003) (also referred as *risk factor reversal* or *paradoxical risk factors*) indicating an alteration in the normal relation between risk factors and clinical outcomes that can result in the exact opposite of the usual association between a risk factor and the outcome found in the general population. Several potential explanations for obesity as a paradoxical risk factor in the elderly have been proposed (Strandberg et al. 2009) but, until now, a complete and satisfactory explanation has not been suggested. As previously mentioned, smoking may contribute in inducing such reverse epidemiology. In fact, the prevalence of smoking is known to be lower in the elderly. As such, patients often quit smoking later in life which leads to an increased BMI. However, the health benefits of quitting smoking far outweigh any harms of weight gain (Wannamethee and Shaper 1989).

Another possible bias may be the phenomenon of "*reverse causality*" which consists of obesity-related diseases that can lead to both weight loss and mortality, a possibility that has not been completely analyzed thus far (Flanders and Augestad 2008). Since some reports indicate that midlife overweight or obesity are associated with an adverse prognosis in old age (Adams et al. 2006), it might be the case that the progression of obesity-related diseases leads to unintentional weight loss especially in the elderly. Therefore, a significant proportion of the normal BMI group in elderly cohorts may include individuals who were once overweight or obese and experienced a sustained unintentional weight loss. Another possible interpretation may be that patients who lost weight after midlife may inherently develop "frailty", a predisposing condition to CV disease (Ahmed et al. 2007), as discussed earlier. Again, it seems that body weight history has a crucial role suggesting that those subjects who lose weight after midlife, especially unintentionally, require special attention. These data also confirm that caution should be addressed to intentional weight loss in elderly people**.** Data from the last NHANES (Olshansky et al. 2005) indicate that the excess of mortality associated with overweight and obesity is considerably lower than that reported by previous US cohort studies (Allison et al. 1999; Mokdad et al. 2004). It has therefore been proposed (Flegel et al. 2005) that as a consequence of the improved treatments for the major metabolic complications of obesity such as diabetes, dyslipidemia and hypertension, the impact of obesity may be decreasing over time, which may further explain the obesity paradox. Other possible biases have been indicated. Study sizes have sometimes been considered insufficient to perform age-specific estimates (Stevens et al. 1998) and the frequent use of self-reported weight and height to calculate BMI has been criticized (Niedhammer et al. 2000; Stevens et al. 1990). Furthermore, as reported earlier, BMI does not have the same adiposity significance at all ages in terms of body fat mass and distribution, especially in the elderly

and in females. It has been shown, in fact, that the elderly tend to have a shift of fat from peripheral to central sites without a concomitant increase in body mass index (Borkan et al. 1983), a phenomenon that is particularly true in the female sex. Peripheral body fat is considered to be associated with higher adiponectin production and with favourable cardiovascular and metabolic profile (Tanko et al. 2003; Tanko et al. 2004). Given this consideration, it seems inappropriate to compare the BMI of the elderly with those of the young and midlife ages.

Undoubtedly, the mechanisms behind the obesity paradox need to be clarified together with its clinical relevance. In fact, with the increasing prevalence of obesity and the improved life expectancy, many people may be subjected to reverse epidemiology. Whether current treatment guidelines and advice for risk factor reduction should be extrapolated to elderly patients should be further investigated.

94.8 Body Mass Index and Heart Failure

BMI has also been implicated as a predictor of heart failure in elderly patients. In a community-based, population-based study of 1,749 subjects aged 65 years and older, a BMI of ≥ 28 kg/m^2 compared to a BMI ≤ 24 kg/m^2 demonstrated a RR 1.6 of developing heart failure (Chen et al. 1999). As adiposity comprises a substantial proportion of total body weight and large volumes of fluid accompany this, the increased intravascular volume may lead to increases in cardiac contractility, cardiac output and subsequently increases hemodynamic load, leading to cardiac hypertrophy, cardiac dilation and inevitably increases the patient's risk for developing cardiac failure. The increase in left ventricular end-diastolic pressures over time leads to ventricular dilatation as well leading to increased myocardial stress, increases in myocardial mass and left ventricular hypertrophy. Alternatively, obesity may lead to excessive myocardial adipose deposition leading to a condition known as Adipositas Cordis (cardiomyopathy of obesity). An infiltrative-like cardiomyopathy may occur, ensuing not only to ventricular failure, but also to sinus node dysfunction.

Interestingly, the prognostic significance of obesity in the setting of patients with established heart failure is unclear. Patients with a low BMI may represent a cachectic group that leads to poor outcomes in this population. As described above, such a group reflects the obesity paradox or phenomenon of reverse epidemiology, whereby patients with an elevated BMI, in fact fare better clinically, than those who are not. Recently, a meta-analysis by Oreopoulos et al (2008a) identified 9 studies that met their inclusion/exclusion criteria. They determined that patients who were overweight or obese with heart failure, actually had lower all-cause mortality, than patients with normal BMI levels [RR 0.84 (0.79–0.90) vs. RR 0.67 (0.62–0.73)]. Furthermore, there were lower rates of cardiovascular mortality in the overweight (RR 0.81 [0.72–0.92]) or obese (RR 0.60 [0.53–0.69] groups than patients with a normal BMI. In fact, patients with a BMI <23 kg/m^2 (underweight/low normal), had an associated higher CV mortality (RR 1.20 [1.04–1.38]) than the other corresponding groups. This study demonstrated an inverse relationship between BMI and survival. Whether such results can be extrapolated to the extremely obese groups requires further investigation. The mean age range of the study populations examined was in the 60s, suggesting that such results may indeed be generalized to an elder population group. These authors suggest that the elevated risk of death in the low BMI groups may perhaps be due to hypoproteinemia, low energy intake, malnutrition, and possibly cachexia. Further, as chronic heart failure can be considered a catabolic state with muscle wasting, overweight or obese patients may have higher metabolic reserves than their counterparts at lower BMIs and hence can better tolerate changes in body composition, catabolic processes and metabolic stressors.

94.9 BMI and Cardiac Surgery

In a cardiac surgery population, BMI has been associated in a "U" or "J-shaped" fashion, with underweight and obese patients having higher mortality rates(Rahmanian et al. 2007; Reeves et al. 2003; Whitlock et al. 2002). This has been well documented both following cardiac surgery but also following percutaneous coronary intervention. The relationship is non-linear in nature. It appears, from other studies (Yap et al. 2007), that there are no differences in cardiac outcomes, including atrial fibrillation, myocardial infarction or heart failure, while sternal wound infections are definitively higher. Many studies are limited by sample size and a lack of information pertaining to relative confounders. In a study by the Northern New England Cardiovascular Disease Study Group that prospectively examined 11,101 patients undergoing coronary artery bypass graft (CABG), there were no differences between groups with regard to post-operative cardiac outcomes, including cerebrovascular accidents (Birkmeyer et al. 1998). In reviewing the existing literature, there is little information on the oldest old (age > 80 years). A study by Maurer et al (2002) retrospectively reviewed 1,448 patients aged >75 years undergoing cardiac surgery in the 1990's. This study divided their cohort into tertiles based on BMI and demonstrated that the patients with a low BMI had a higher incidence [OR = 1.59], of cardiovascular complications (defined as stroke, MI or arrhythmia) than subjects in higher tertiles. Although the multivariable model included many patient co-morbidity co-variates, over-adjustment of variables was a possibility. In addition, these authors hypothesize, as have others, that patients with a lower BMI have less nutritional reserve, hindering their ability to manage stressors.

In addition to cardiac surgery, examination of BMI as a predictor of outcomes following percutaneous coronary interventions (PCI) is a concern. As the prevalence of cardiovascular disease both symptomatic and asymptomatic increases with age, this procedure becomes increasingly prevalent particularly in patients with obesity. As in other populations, obesity is presumed to be a risk factor for post-operative morbidity and mortality; however, data has been conflicting at best. One study examining a registry in British Columbia, Canada, demonstrates a "U" shaped relation between BMI and mortality, which was particularly evident in underweight patients (Byrne et al. 2009). However, Oreopoulos further examined the impact of obesity on both short and long-term mortality following PCI in a meta-analysis of 22 studies (Oreopoulos et al. 2008b). Following PCI, overweight and obese patients had lower short-term or in-hospital mortality (OR 0.71 [0.62–0.81], OR 0.63 [0.54–0.73]), respectively, and lower long-term (>5 years) mortality than normal BMI patients (OR 0.66 [0.55–0.79], 0.65 [0.51–0.83]). These results were observed in post-CABG patients as well. Of note, the mean age was 66.1 years, 62.9 and 60.4, in the normal, overweight and obese categories. As in patients with heart failure, these results suggest an inconsistent protective effect of elevated BMI levels on mortality. The authors in fact excluded, in a sensitivity analysis, patients who were underweight to exclude possible confounding of their results and their outcome measures changed minimally.

94.10 BMI and Orthopedic Surgery

As the public health implications of an increasingly obese and elderly population are increasing, the need for joint replacement subsequently increases as well. Studies examining the impact of BMI on perioperative outcomes in an elderly orthopedic population have been limited to either non-cardiac complications, or have not ascertained any complications. In patients undergoing elective spine surgery, there does not appear to be any solid association between BMI and cardiac events. However, in one study of 229 patients undergoing revision total hip arthroplasty, no differences in the

(Adapted from Batsis et al. 2009. Wiley-Blackwell Publishers)

frequency of cardiac complications, defined as myocardial infarction or heart failure, between any of the obese groups (BMI > 25 kg/m^2 and BMI < 25 kg/m^2) were observed (Perka et al. 2000). This was mirrored in another study of patients undergoing total knee arthroplasty (Miric et al. 2002). Although elective arthroplasty is considered a safer procedure than that of urgent hip fracture repair, only one study has ascertained the incidence of cardiac events in a hip fracture population (Batsis et al. 2009). As BMI is known to be inversely correlated with osteoporosis and patients with a low BMI are at a higher risk of developing a fragility fracture, the magnitude of the incidence of cardiac events has not been well investigated. Obese patients were at no greater adjusted risk of having a cardiac event than patients with a normal BMI (Table 94.3). Interestingly, this study demonstrated an increased risk among underweight elders (Fig. 94.10), regardless of the multivariable model used. The authors hypothesized that their results, in a population-based study of Olmsted County, Minnesota hip fracture surgeries from 1998–2002 was a further example of the obesity paradox. In addition, such frail elders who are at a higher risk of fracturing their hips are known to have reduced functional capacity, as compared to their obese counterparts. Alternatively, there may be alterations in systemic inflammatory components that have been associated with low bone mineral density, vitamin D metabolism, and serum lipids, all of which have been demonstrated to lead to greater cardiovascular disease and mortality in geriatric patients (Bagger et al. 2007; Walston et al. 2002). The above studies likely demonstrate that elevated BMI may have a protective effect on cardiac outcomes and mortality; yet further investigation would be needed.

94.11 Application to Other Areas of Health and Disease

Further research is needed to better characterize the impact of body mass index on cardiac events in elderly patients. Easier characterization of body composition in a cost-effective and practical manner that can easily be ascertained in clinical practice should be the focus of initial work. Epidemiological

studies need to better characterize the underlying inflammatory state that is present in both underweight and obese patients and the interplay of these factors with the development of cardiovascular disease. Identification of elderly subjects at high risk will allow both primary and secondary prevention strategies with the overall goal of reducing disease burden, improving quality of life and minimizing disability.

Summary Points

- Body mass index may be an inaccurate surrogate for obesity in elderly patients but is easy to use and widely accepted
- A J-shaped or U-shaped mortality curve is observed, including in elderly patients
- Midlife obesity may afford worse outcomes than midlife overweight or normal weight patients
- Sarcopenia and/or Frailty may contribute to increased cardiovascular disease and mortality likely to be mediated by similar inflammatory mediators observed in obese patients
- Low body mass index predicts a higher cardiovascular morbidity and mortality possibly reflecting the obesity paradox in congestive heart failure, cardiac surgery and hip fracture disease states.

Key Points of Obesity in Elderly Patients

- Improved methods of measuring adiposity is necessary in elderly patients
- The prevalence of sarcopenia and/or frailty increases with age which leads to a pro-inflammatory state
- Body mass index is a strong mortality predictor even in elderly patients, although the magnitude of the effect is diminished as one ages
- Confounders complicate the ability to better utilize BMI as an anthropometric measure in assessing cardiovascular events and mortality
- The obesity paradox plays a paramount role in the pathophysiology of many disease states in elderly patients

Part XV
Anthropometry in Genetic Disease and Polymorphisms

Chapter 95
Anthropometry of Twins

Sergio Demarini

Abstract Twins are smaller than singletons at birth, due to both shorter gestational age and intrauterine growth restriction. Additionally, an intrapair discordance in birth weight is quite frequent. In twins, as in singletons, body weight and body composition vary with gestational age. However, in each pair of twins, a difference in birth weight, although correlated with, is not proportional to differences in body composition components. When compared to singletons, normally grown twins show similar body composition components. In contrast, growth-restricted twins have lower lean mass and possibly lower fat mass and bone mineral content when compared to singletons matched for gestational age. During the first 2 years of life, twins show a catch-up growth but do not reach the body size of singletons. Between 2 and 9 years of age, height in twins is only marginally lower than singletons, whereas weight gain is considerably less. Monozygotic twins are both lighter and shorter than dizygotic twins. Birth weight, parental height, zygosity, and gender are the determinants of somatic growth of twins in the first 9 years of life.

In adulthood, twins seem to have a slightly lower weight than singletons. With regard to body composition, there is a persisting correlation between birth weight and body composition components.

Abbreviations

AGA	Appropriate for gestational age
BMC	Bone mineral content
BMI	Body mass index
DXA	Dual energy X-ray absorptiometry
DZ	Dizygotic twins
FM	Fat body mass
LM	Lean body mass
MZ	Monozygotic twins
SGA	Small for gestational age

95.1 Introduction

Twin deliveries have been rising considerably in recent years, due to assisted reproduction technology. Most twins are dizygotic twins, that is, they result from a double ovum. A minority of twins are monozygotic, as they originate from a single ovum that subdivides subsequently. Spontaneous monozygotic twins appear to have a fairly stable rate at 1:250, independent of race and genetic factors. Conversely, the rate of dizygotic twins is quite variable, depending in part on factors such as maternal age, race, parity, genetics, and hormonal treatment.

Twins have an increased risk of being born preterm and perinatal mortality rate is considerably higher than in singletons. Additionally, abnormal fetal growth is quite frequent, as the incidence of low birth weight (i.e. birth weight < 2,500 g) is about 5–7 times higher than in singletons. Dizygotic twins have the same rate of congenital anomalies as singletons, whereas birth defects are about 2–3 times more common in monozygotic twins.

Monozygotic twins are genetically identical and share an almost identical intrauterine environment, whereas dizygotic twins are not genetically identical but share a very similar intrauterine environment. Consequently, twins appear to be ideal candidates to study the relative roles of genetics and environment on health outcomes.

95.2 Fetal Growth

The main determinant of fetal growth is gestational age. In normal singleton pregnancies, somatic growth is linear up to the 37th week. Twins are smaller than singletons at birth not only due to earlier delivery, but also due to decreased fetal growth. Twin fetuses grow similarly to singletons approximately up to the 32nd week of gestation: thereafter, their growth slows down. Even taking into account a shorter gestation, twins are significantly smaller than singletons at birth (Loos et al. 2005; Naeye et al. 1966). Mean birth weight for gestational age in twins and singletons is shown in Fig. 95.1. Whether intrauterine growth restriction in twins depends on limited placental supply or limited uterine size is a matter of debate. Whatever the cause, at birth, twins on average are more than 500 g lighter than singletons.

Even within twins, there are often considerable discrepancies in growth, as frequently one twin grows more than the other. Moreover, fetal growth does vary according to zygosity and chorionicity. The mean birth weight of a male twin is 2,538 g if he is dizygotic, 2,453 g if monozygotic–dichorionic, and 2,423 g if monozygotic–monochorionic. The corresponding figures for female twins are 2,443, 2,377, and 2,329 g (Loos et al. 2005). Umbilical cord insertion may influence fetal growth too: In all three categories of twins (dizygotic, monozygotic–dichorionic, and monozygotic–monochorionic), birth weight is higher if the umbilical cord insertion into the placenta is central (as is normal) than if the insertion is peripheral. Fusion of placentas also is associated to lower birth weight. In conclusion, while gestational age is the main determinant of birth weight, factors possibly associated with reduced placental function may have minor effects on intrauterine growth of twins.

95.2.1 Twins at Birth

Assessment of fetal growth is traditionally based on birth weight. Twins, however, may grow differently in utero in spite of sharing a common environment and similar genetics. Discrepant fetal growth has been defined as a birth weight difference greater of 15–30% between twins. Such discrepancy may be of clinical relevance, as it has been associated with an increased risk of both short- and long-term

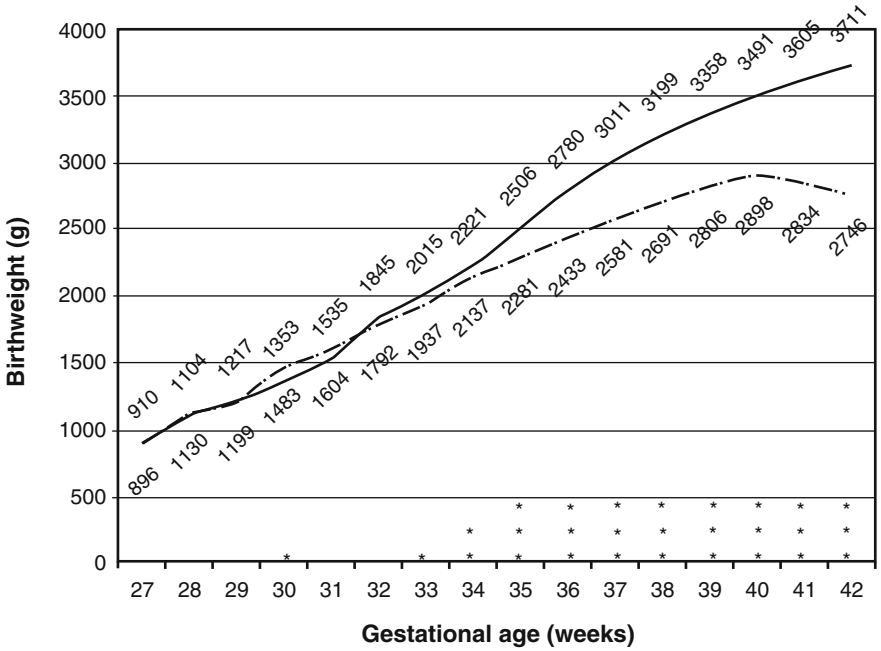

Fig. 95.1 Mean birth weight vs. gestational age for twins (*dotted line*) and singletons (*black line*) (From Loos et al. 2005)

adverse outcomes (Hollier et al. 1999; Blickstein and Lancet 1988). The use of birth weight alone does not provide information on body composition. Body composition of twins at birth was assessed in two studies, by the same group of investigators.

Koo et al. studied 48 pair of twins with birth weights from 976 to 3,135 g and a gestational age ranging from 30 to 40 weeks (Koo et al. 2002). In 29 pairs, both infants had birth weight appropriate for gestational age (between 10th and 90th percentiles). In one pair, both infants were born small for gestational age (birth weight < tenth percentile). In the remaining 18 pairs, one infant was appropriate for gestational age and the other small for gestational age. In 23 pairs, the difference in birth weight between twins was >15%. The aim of the study was to test the hypothesis that, in twins, differences in body weights are reflected by differences in the components of body composition. Body composition was studied by dual energy X-ray absorptiometry (DXA). Scans were performed at 3.8 ± 3.2 days of life, with a whole body scanner (Hologic QDR 1000/W), using a specific software, to measure bone mineral content (BMC), lean mass (LM), and fat mass (FM). In individual infants, both DXA and anthropometric measurements were higher with higher gestational age. When considering body composition components as percentage of body weight, there was an increase in BMC and FM, but a decrease in LM with increasing gestational age. With regard to intrapair differences, the percent difference in weight was correlated with percent difference in each of the body composition components. However, the percent difference in fat mass was higher than that in lean mass and bone mineral content (Table 95.1). The conclusions were that in twins, as in singletons, body weight and body composition vary with gestational age. In each pair of twins, a difference in weight, although correlated with, was not proportional to differences in body composition components.

In another study, body composition measurements of twins were compared to those of singletons (Demarini et al. 2006). There were 96 twin infants, 76 were appropriate for gestational age and 20 were small for gestational age. Each appropriate for gestational age twin was matched as closely as possible for birth weight to an appropriate for gestational age singleton. Each small-for-gestational-age twin

Table 95.1 Discrepant growth of twins at birth. Percent difference in anthropometric and dual energy X-ray absorptiometry (DXA) measurements in 48 pairs of twins (From Koo et al. 2002)

	Mean ± SD	Range
Anthropometric measurements		
Head circumference	4.0 ± 3.5	0–16
Length	4.3 ± 3.5	0–15.9
Weight	14.3 ± 10.0	0.1–42.2
DXA measurements		
Lean body mass	13.4 ± 9.0	0.1–31.1
Fat body mass	26.0 ± 15.0	0.2–67.7
Bone mineral content	15.9 ± 11.6	0.4–45.0

Table 95.3 Body composition of twins and singletons at birth. Body composition components measured by dual energy X-ray absorptiometry, and expressed as percentage of total body weight in twins vs. singletons matched for birth weight or for gestational age (From Demarini et al. 2006)

	BMC (%)	Fat mass (%)	Lean mass (%)
AGA twin vs. AGA singleton (n = 76 per group)			
Twin	1.71 ± 0.18	10.4 ± 2.7	87.5 ± 2.9
Singleton	1.76 ± 0.18	10.4 ± 2.1	87.9 ± 2.2
SGA twin vs. AGA singleton (n = 20 per group)			
Twin	1.76 ± 0.23	10.6 ± 3.2	87.6 ± 3.4
Singleton matched for birth weight	1.71 ± 0.14	10.1 ± 2.5	88.2 ± 2.6
Singleton matched for gestation	1.78 ± 0.19	10.9 ± 1.8	87.3 ± 1.9

Values expressed as means ± SD. No significant difference in any comparisons between groups or within each body composition component
BMC bone mineral content; *AGA* appropriate for gestational age; *SGA* small for gestational age

was matched with two cohorts of appropriate-for-gestational-age infants: one with similar birth weight and another with similar gestational age. The aim of the study was to compare the body composition (bone mineral content, lean mass, and fat mass) of normally grown and growth-restricted twins to those of singletons. DXA scans were performed with a whole body scanner (Hologic QDR 1000/W), in the first few days of life. Between appropriate for gestational age twins and birth weight-matched singletons, there were no significant differences in bone mineral content, fat mass, and lean mass, either as absolute values or as percentage of weight.

With regard to small for gestational age infants, there was also no difference in body composition components when compared to singletons matched for birth weight. In contrast, small for gestational age twins, when compared to appropriate for gestational age singletons, matched for gestational age, showed significantly lower absolute amounts of lean mass and a tendency to lower fat mass and bone mineral content (Table 95.2). When body composition data was analyzed as a percentage of weight, small for gestational age twins had similar proportions of each body composition component to appropriate singletons, matched for gestational age (Table 95.3). The conclusion was that in

normally grown infants, body composition components are similar regardless of whether they are twins or singletons. In contrast, growth-restricted twins have lower lean mass, and possibly lower fat mass and bone mineral content, when compared to singletons matched for gestational age.

95.2.2 Growth in the First Decade of Life

Being born smaller than singletons, twins may be expected to grow more slowly than their singleton counterparts. Most singleton infants born small for gestational age show a catch-up growth during the first 2 years of life. A minority remain smaller and lighter than infants born appropriate for gestational age.

95.2.2.1 Growth from Birth to 2.5 years

Data from the Netherlands Twin registry were used to assess growth of twins vs. singletons in the first 2.5 years of life (Van Dommelen et al. 2008). Over 4,000 twin infants were enrolled into the registry. As expected, twins were growth-retarded when compared to singletons, at birth. Subsequently, twins showed a catch-up growth but could not reach the body size of singletons, at least over the study period. The authors estimated that about 50% of the growth retardation in the first 18 months of life could be attributed to the difference in gestational age. This difference decreased to about one third at 2.5 years of age. There was a statistically significant, but clinically irrelevant, difference in growth between monozygotic and dizygotic twins. As differences in growth between twins and singletons persist in the first 2.5 years of life, in spite of correction for gestational age, the authors recommended using specific growth charts for twins.

95.2.2.2 Growth Between 2 and 9 years

In a study of over 1,500 twins, Buckler and Green studied the effect of birth weight and parental height on somatic growth of twins up to the 9th year of age (Buckler and Green 2008). Height in twins resulted only slightly lower than singletons, whereas weight gain was considerably less (Fig. 95.2). Gender seemed to have some effect, as weight difference was higher in males than in females. Head circumference was also smaller in twins, with a different gender effect, as females had smaller heads than males. As expected, parental height did account for the height difference of twins, but only in part. With regard to zygosity, monozygotic twins remained both lighter and shorter than dizygotic twins. Additionally, monozygotic boys had decreased height and weight when compared to monozygotic girls. In conclusion, twins are smaller and thinner than singletons during the first decade of life. Birth weight, parental height, zygosity, and gender are the determinants of somatic growth of twins in the first 9 years of life.

95.2.3 Twins in Adulthood

In adulthood, twins seem to have a slightly lower weight than singletons (Andrew et al. 2001). With regard to body composition, there appears to be a significant correlation between birth weight and

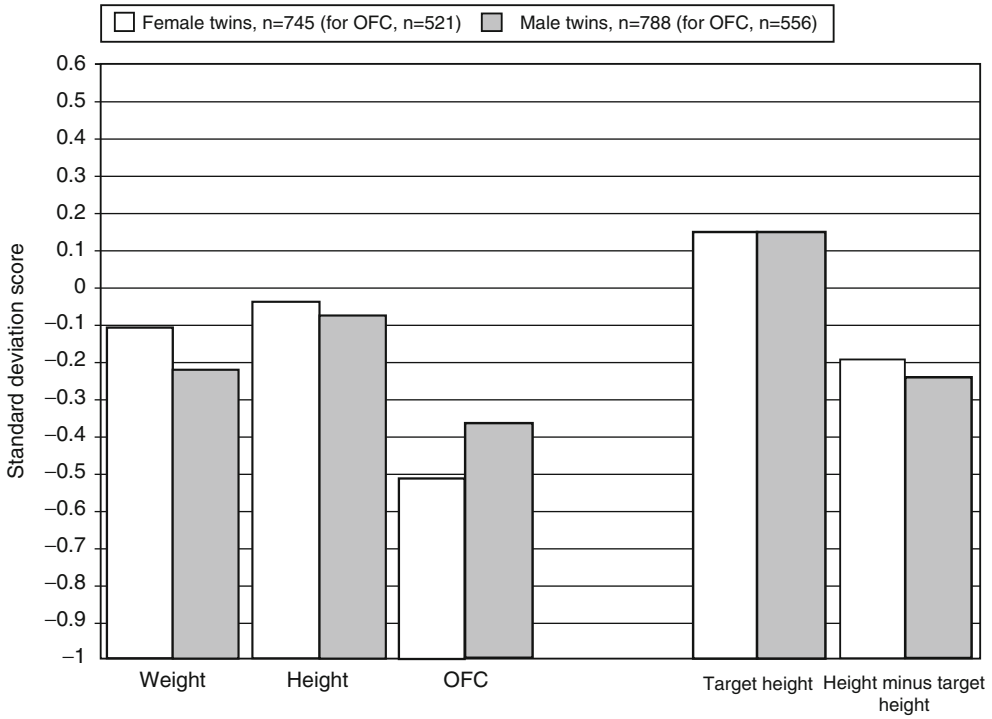

Fig. 95.2 Growth of twins between 2 and 9 years of age. Mean standard deviation scores are shown as histograms for twin boys and twin girls (From Buckler and Green 2008)

body composition components in twins aged between 18 and 80 years (Skidmore et al. 2009). Every 1.0 kg increase in birth weight was associated with: (1) a 1.7 kg increase in lean body mass, (2) a 0.25 kg increase in fat body mass, and (3) a 0.05 unit increase in lean:fat body mass ratio. Lean body mass was positively associated with birth weight both within and between twin pairs. Consequently, both individual intrauterine factors and shared environmental factors had an influence. In the correlation between body fat mass and birth weight, there were within-pair differences, possibly indicating individual intrauterine factors. With regard to lean: fat body mass ratio, the positive relation with birth weight was seen only between pairs, and thus believed to be mediated through the shared environment of the twin pairs. The authors concluded that, in twins, a greater birth weight is associated with a higher lean: fat body mass ratio in adults. Such effect appeared mediated through environmental factors common to twin pairs.

95.3 Applications to Other Areas of Health and Disease

The association between low birth weight and risk for cardiovascular disease and dysmetabolic syndrome is well described. The relative contribution of genetic and environmental factors (intra- and extrauterine) is less clear. Studies on twins may be helpful to clarify the relative influence of genetic and environmental factors on a given outcome.

Twins frequently show a difference in birth weight, in spite of sharing many factors during gestation. Consequently, discordance in birth weight cannot be explained by shared factors and must

Table 95.4 Studies of twins: hypothetical results of within-cohort vs. within-pair analyses on the association between birth weight and blood pressure (From Morley and Dwyer 2005)

	β within cohort	β within pairs	Inference
(a) In all twins	–2.0	–2.0	Shared factors *are not* involved in the association
	–2.0	–0.5	Shared factors *are* importantly involved in the association
(b) In MZ and DZ twins separately			
DZ	–2.0	–1.0	
MZ	–2.0	–1.0	Genes *are not* importantly involved in the association
DZ	–2.0	–1.5	
MZ	–2.0	–0.5	Genes *may be* importantly involved in the association (alternatively, the "healthy" MZ twin might be programmed for adult disease by the "compromised" twin by circulating factors, due to intraplacental vascular anastomoses)

Regression coefficient (β) for difference in systolic blood pressure (mmHg) per 1.0 kg increase in birth weight
MZ Monozygotic twins; *DZ* Dizygotic twins

depend on factors influencing the individual twin. If the correlation between a given factor and birth weight (or other variables) remains significant in analysis within pair, factors specific to individuals must play a role. If the correlation disappears, factors common to the twin pair must be involved. If the correlation diminishes but not disappear, both shared and individual factors may be involved. The role of genetic factors can be assessed studying monozygotic (MZ) and dizygotic (DZ) twins, both within cohort and within pairs. If a similar correlation is found between birth weight and a given outcome, in both MZ and DZ twins, genetic factors are unlikely to play a prominent role. If the correlation disappears within pairs in MZ twins, but not in DZ twins, then genetic factors are likely to play a role (Table 95.4).

A review of twin studies regarding the issue of origins of adult diseases is clearly beyond the scope of this chapter. However, a few significant examples of such studies are reported hereafter. (a) In twins, as in singletons, there appears to be a negative correlation between birth weight and systolic blood pressure, independent of factors such as length of gestation and catch-up growth (Morley and Dwyer 2005). (b) Although there are significant genetic influences on body mass index (BMI), physical activity appears to be a likely environmental contributor to BMI. As a matter of fact, the effect of vigorous exercise on BMI significantly affects BMI in both DZ and MZ twins (McCaffery et al. 2009). (c) Birth weight appears to be positively associated with adult height and fat mass. In turn, birth weight and fat mass are correlated to insulin sensitivity later in life. Such association appears to be mediated non-genetically and to possibly depend on the intrauterine environment (Monrad et al. 2009).

95.4 Practical Methods and Techniques

In infants, body composition has been assessed mainly by four methods: DXA, air displacement pletismography, skin fold thickness, and bioelectrical impedance.

95.4.1 Dual Energy X-Ray Absorptiometry (DXA)

DXA is an established method to study body composition in newborn infants. It is an X-ray-based method, using X-ray beams at two energies to scan the whole infant body. DXA represents the current standard for the detection of low bone mineral content in adults and children. Although designed to assess primarily bone mineral content, it provides values for both lean and fat body mass. Precision is generally considered excellent for bone assessment, good for lean mass, but only fair for fat mass. DXA was not designed for newborns and body scanners should be operated with software specific for newborn infants. Additionally, DXA is sensitive to motion artifacts and infants are usually scanned while asleep or tightly wrapped in a cotton blanket. Scan acquisition must be interrupted if significant movement artifacts are noted, as this significantly decreases the quality of the results. Reference ranges of body composition components (bone mineral content, lean mass, and fat mass) in infants are available (Koo et al. 2000).

95.4.2 Air Displacement Pletismography

Air displacement pletismography utilizes the principle of whole body densitometry to estimate the amount of body fat and lean mass. The method is based on the determination of body density by the measurement of body mass and body volume. Mass (weight) is measured by an electronic scale and volume is measured by air displacement pletismography in a test chamber, using the relationship between pressure and volume. Once body density is known, both the percentage and the absolute amounts of fat and lean mass are calculated using whole body densitometry principles. The instrument was initially created for adults, but has subsequently been adapted to study body composition in infants. The instrument has been validated against deuterium dilution method and a four-compartment body composition model, in healthy infants (Urlando et al. 2003; Ellis et al. 2007). Measurement precision appears to be good. The instrument is housed in a movable cart, and thus can be used in the ward, and is easy to operate. Measurements are obtained in approximately 2 min and the infant needs not be restrained during the procedure. Limitations of this instrument include: (a) lack of validation in preterm infants; (b) lack of data on ill newborns; (c) unsuitability for infants older than 6 months.

95.4.3 Skin Fold Thickness

Apart from measuring weight and length, skin fold thickness measurements are the simplest method to assess body composition and nutritional status. In general, two types of skin fold measurement techniques are utilized. The static skin fold thickness represents the reading obtained 60 s after the application of a caliper and is generally thought to be representative of subcutaneous fat. The dynamic skin fold thickness measures the difference between the caliper readings at 15 and 60 s and is thought to correlate with extracellular water content (Thornton et al. 1982). Dynamic skin fold thickness is calculated according to the formula: [(SFT at 15 s – SFT at 60 s)/SFT at 15 s] × 100 = % dynamic skin fold thickness. Standard measurement sites include midtriceps, subscapular area, and anterior abdominal wall. In infants, dynamic skin fold thickness measurements may be averaged to minimize the effect of gravity (body position) on body fluid distribution (Demarini and Pickens 1993).

95.4.4 Bioelectrical Impedance

Total body water is a major contributor to body weight and is also the main component of lean mass. Bioelectrical impedance is based on the electrical properties of hydrated tissues that is fat-free mass. It is based on the assumption that the resistance of human body to alternating electrical current is inversely proportional to the hydrated tissue mass. This technique has several advantages: (a) it is inexpensive, (b) it is compact and portable; (c) it is easy to measure, and the measurement can be repeated frequently. The instrument uses two electrodes, attached to hand and foot, to measure resistance to the current. Then, it converts resistance into an estimate of fat-free mass and calculates fat mass. Limitations are: (a) algorithms to calculate fat-free mass appear to be instrument specific and (b) measurements do not seem to offer important advantages over simple anthropometric measurements (Ellis 2007). Due to its simplicity, this technique has been used to assess body composition in newborns receiving intensive care (Tang et al. 1997).

Summary Points

- Twins are smaller than singletons at birth.
- Normally grown twins have a body composition similar to singletons.
- Growth-restricted twins have different body composition when compared to singletons.
- Twins, as a group, grow more slowly than singletons in the first decade of life.
- As adults, twins seem to remain slightly thinner than singletons
- A correlation between birth weight and body composition components persists well into adulthood.

Key Facts of Twin Anthropometry

- Twin deliveries have been rising considerably in recent years, due to assisted reproduction technology.
- Twins are smaller than singletons at birth and show intrapair discordance in birth weight.
- In twins, as in singletons, body weight and body composition vary with gestational age. In a given twin pair, a difference in weight is not proportional to differences in body composition components.
- In normally grown infants, body composition components are similar regardless of whether they are twins or singletons. In contrast, growth-restricted twins have lower lean mass, when compared to singletons matched for gestational age.
- In adults, both lean body mass and lean:fat body mass ratio appear to be related to birth weight.

Chapter 96
Anthropometry in Children with Cystic Fibrosis

Alexia J. Murphy and Peter S.W. Davies

Abstract Cystic fibrosis is the most common life shortening autosomal recessive disorder in Caucasians. The main symptoms are evident in the respiratory system, the gastrointestinal tract and the sweat glands. Anthropometric assessment of children and adolescents with cystic fibrosis is an obvious and worthwhile endeavour as there are many aspects of the disease that could directly or indirectly impact upon growth. The past stereotype of children with cystic fibrosis was that they had growth delay with relatively short stature and delayed puberty. There have been many improvements in the anthropometric status of children with cystic fibrosis over the recent decade in response to improved understanding of the disease, treatment and recognised need for nutritional support. Thus to ensure that all individuals with cystic fibrosis reach their anthropometric potential, the measurement of anthropometry is made all the more important. To measure and interpret anthropometry correctly and clinically worthwhile in this population, there are specific features of the disease that need to be considered such as reduced height, bone age and tissue hydration. The aim of this chapter is to introduce cystic fibrosis, discuss the anthropometric status of children with CF and detail some practical methods for measuring body composition in this population.

Abbreviations

ADP	Air displacement plethysmography
BCM	Body cell mass
BIA	Bioelectrical impedance analysis
BMI	Body mass index
CF	Cystic fibrosis
CFTR	Cystic fibrosis trans-membrane regulator
DXA	Dual energy X-ray absorptiometry
ECF	Extracellular fluid
FM	Fat mass
FFM	Fat free mass

96.1 About Cystic Fibrosis

Cystic fibrosis (CF) is a common serious genetic condition in children today, affecting about 70,000 people worldwide. CF is a recessive genetic disease that mainly affects Caucasians, being the most common life shortening autosomal recessive disorder in this population. The inheritance pattern is shown in Fig. 96.1.

Cystic fibrosis is caused by mutations in a single gene on the long arm of chromosome 7, named the cystic fibrosis trans-membrane regulator (CFTR), which was detected in 1989 (Riordan et al. 1989). The defect in the CF gene causes flawed ion transport as it acts on chloride channels in epithelial membranes, and results in the development of thickened mucus in all organs with mucus secreting glands. The principal effects are seen in the respiratory system, the gastrointestinal tract and the sweat glands. The clinical manifestations of CF include progressive lung disease and pancreatic insufficiency. The key features of CF are listed in Table 96.1.

96.1.1 Symptoms

For the typical CF patient the common symptoms are recurrent respiratory infections, coughing and wheezing, failure to thrive, fatigue, diarrhoea and male infertility. Other complications may include sinusitis, pancreatitis, nasal polyps, clubbing, liver disease, diabetes, gallstones and low bone density. As there are more than 1,000 mutations of the CF gene, symptoms of CF differ from person to person. The common component of CF is an abnormality in the function of the exocrine glands. The CFTR acts as a channel regulator and when the CFTR contains mutations and does not function, the movement of chloride across the membrane is affected and the epithelial secretions are more viscous. This increase in mucous thickness causes obstruction and lack of gland function. Cystic fibrosis leads to pathological changes in organs that express CFTR including the lungs, pancreas, liver and reproductive tract.

The lungs are structurally normal at birth, when in the first weeks of life sub-mucosal gland hypertrophy, duct obstruction and mucus cell hyperplasia occurs. Patients soon develop bacterial infections that are hard to destroy, specifically Staphylococcus aureus and Pseudomonas aeruginosa. The inflammatory response by the CF lungs to the bacterial pathogens causes progressive irreversible lung damage. The cellular response to bacteria combined with the excessive mucus production in the lungs causes difficulty with breathing and frequent infections. More than 90% of the mortality rate in CF can be attributed to chronic pulmonary disease (Rosenstein and Zeitlin 1998).

Pancreatic insufficiency is present in around 90% of patients with CF. Without sufficient fluid and low concentrations of bicarbonate, digestive pro-enzymes are retained in pancreatic ducts and are prematurely activated. This leads to the progressive loss of functioning tissue, replaced by fibrosis and fatty tissues. The fibrosis causes malabsorption of fat, protein and fat-soluble vitamins and contributes to the malnutrition seen in CF patients. CF can also cause problems in the liver and gallbladder with a third of CF patients having abnormal liver results and around 30% have a poorly functioning gallbladder.

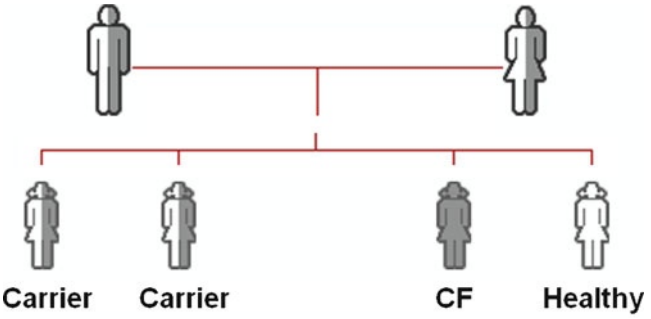

Fig. 96.1 Cystic fibrosis inheritance pattern. This figure shows the inheritance pattern for children born with cystic fibrosis. If both the mother and father are carriers of the gene then they have a one in four chances of having a child with cystic fibrosis

Table 96.1 Key features of cystic fibrosis

1. It is the most common life shortening autosomal recessive disorder.
2. It is caused by mutations in a single gene on the long arm of chromosome 7, the CFTR.
3. The principal effects from the defect in the CFTR are seen in the respiratory system, the gastrointestinal tract and the sweat glands.
4. Common symptoms are recurrent respiratory infections, coughing and wheezing, failure to thrive, fatigue and diarrhea.
5. Life expectancy for patients with CF has greatly improved due to neonatal screening, improved treatment regimes, lung transplantation and overall better understanding of the disease.

This table lists some key facts of cystic fibrosis
CFTR cystic fibrosis trans-membrane regulator

96.1.2 Management

The goal of CF management is to prevent infections, reduce the amount and thickness of lung secretion and maintain adequate nutritional status. Management of CF primarily involves pulmonary and dietetic treatment, but medication may also be needed to manage osteoporosis and liver problems. The purpose of pulmonary treatment is to keep the airway clear which reduces the severity of lung infections and improves lung function. Postural drainage and percussion combined with inhaled medication and antibiotics are the common components of a treatment program. Recent research has found several drugs which are improving the prognosis for patients with CF. Ibuprofen has been found to slow down the progression of lung disease in CF and Azithromycin, a common antibiotic, has shown to reduce the rate of decline in lung function.

The role of dietetic treatment for CF has increased in previous years due the recognised strong link between optimal nutritional status and improved pulmonary function, reduced hospitalizations and increased longevity. Most patients with CF will require enzyme supplements to treat pancreatic insufficiency and assist in nutrient absorption. Microspheres coated enzyme beads have been a treatment breakthrough for people with CF and significantly contribute to maintaining health and improving prognosis for patients with CF. Patients with CF will also require a high energy diet and may need fat-soluble vitamin supplements. Treatment may encompass behavioural interventions to increase calories, oral supplements, enteral feedings or parenteral nutrition.

Lung transplantation is an important option for patients with CF when they develop serious lung disease. A study which looked at the outcomes of transplant in a UK cohort noted survival figures of 82% at 1 year, 70% at 3 years, 62% at 5 years and 51% at 10 years (Meachery et al. 2008).

96.1.3 Prognosis

The prognosis for patients with CF has greatly improved over recent decades due to neonatal screening, improved treatment regimes, lung transplantation and overall better understanding of the disease. The earlier diagnosis of CF ensures that aggressive treatment can begin before the lung damage begins. When CF was first described in the 1930s, approximately 70% of the children died within their first year. The CF Foundation Patient Registry showed that the median age of survival was 31.6 years in 2002 (Cystic Fibrosis Foundation 2002) and in 2006 the CF Foundation reported the median survival age to have increased to 36.8 years (Cystic Fibrosis Foundation 2008).

Female patients with CF have shown to have a poorer prognosis than male patients, perhaps due to a more rapid decline in nutritional status in females and earlier acquirement of Pseudomonas aeruginosa in female patients. However, recent findings suggests that modern aggressive treatment regimens have removed any adverse female gender bias from lung function and that there is no intrinsic reason why females with CF should not have lung function and nutrition similar to their male counterparts.

96.2 Anthropometric Status in Children with CF

Anthropometric assessment of children and adolescents with CF is an obvious and potentially worthwhile endeavour as there are many aspects of the disease that could impact upon growth directly via alterations in endocrine status or indirectly via alterations in energy balance. Growth is impaired in children with CF due to nutritional deficiency caused by aspects of the disease. In CF, there are increased energy losses due to malabsorption of fat and nitrogen, impaired mucosal uptake, altered gut motility, increased energy cost of breathing due to altered pulmonary mechanics, hepatobiliary disease, reflux and CF-related diabetes. The increase in energy needs is further affected by the fact that children with CF have also been shown to have reduced energy intake which may be caused by feeding disorders, oesophagitis, iatrogenic fat restriction and cytokine release. Concentrations of insulin-like growth factor I and thyroid hormones are also lower in patients with CF and these hormones play an important role in increasing height. Loss of fat-free mass (FFM) and maintenance of fat mass (FM) in CF subjects may also be caused by the enhanced utilisation of protein for energy production in response to a negative energy balance and the pro-proteolytic effects of the catabolic intermediary metabolism. With aggressive nutritional support and adequate replacement therapy to combat these symptoms of the disease, normal growth in children with CF is possible.

The nutritional status and growth and development have often been studied in CF since the disease was described in the late 1930s and poor growth and development in children with CF was documented on many occasions since that time (Sproul and Huang 1964; Vaisman et al. 1987; Preece et al. 1986) through to the 1980s. Indeed, one of us was able to conclude in a publication not 25 years ago, that "…the pattern is growth delay with relatively short stature and delayed puberty. Weight is more severely affected than height so that these children are often extremely thin and further weight loss occurs during acute pulmonary complications" (Preece et al. 1986).

At that time in children with CF, height and weight were typically between one and two standard deviations below the mean and the longitudinal pattern of growth was consistent with retardation and delayed pubertal events. A basic endocrine disorder that would account for the reduction in stature and body weight had not been found in children suffering from CF. Levels of growth hormone were found to be normal in many studies, but a reduced somatomedin level was reported by some workers, although this was not a consistent finding. Despite these and other contradictory reports, a primary

This table shows the body composition of a group of 82 children with CF against the body composition of age and sex matched healthy peers. Groups were compared by independent *t* test: [1]$p < 0.05$; [2]$p < 0.005$; [3]$p < 0.0001$
SDS standard deviation scores

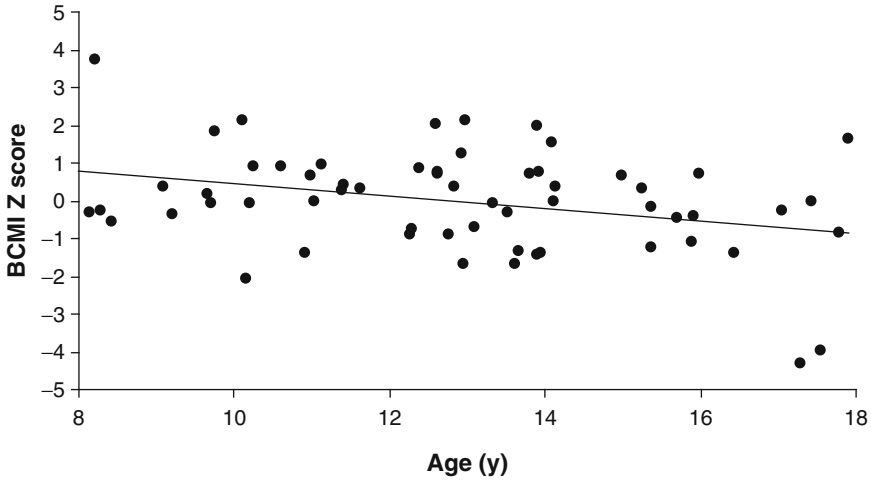

Fig. 96.2 The relationship between BCMI *Z* scores and age in children with CF. This figure shows the decline in age of the body cell mass index *Z* score with age in a group of children with cystic fibrosis. The regression line is BCM/Ht^p = -0.1642age + 2.0967

endocrine disorder resulting in poor growth and development in children with cystic fibrosis was not supported.

Clearly, there have been important changes in both nutritional and pharmaceutical interventions over recent years with a significant improvement in both morbidity and mortality in children, adolescents and young adults with CF. It would also seem that in parallel with these improvements, growth status and nutritional status have also changed for the better in many populations studied. Our own work, (Murphy et al. 2004a) reported mean SDS for weight and height of -0.36 (SEM ± 0.12) and -0.46 (SEM ± 0.14) in a population of 52 children with CF with a mean age of 10.8 years (SD 2.7). Moreover, the assessment of nutritional status in a slightly larger cohort of children from the same clinic (Murphy et al. 2006) revealed that only a small percentage were malnourished using Body Cell Mass adjusted for height (a technique discussed later) as the index of nutritional status (Table 96.2). The female CF patients were significantly shorter than the controls ($p = 0.01$); however, there was no significant difference in weight or BMI. The male CF subjects were found to be significantly shorter ($p = 0.02$) and lighter ($p = 0.003$) than their matched healthy controls, with resulting BMI also significantly lower ($p = 0.004$). A note of caution against complacent should be injected as this point, however, as these same data showed clearly that although children with CF appear better nourished, there was a small but statistically significant relationship between nutritional status and age in this group, suggesting that nutritional status may decline with age (Fig. 96.2). However, recent longitudinal

Table 96.3 Longitudinal measurements of body composition in children with cystic fibrosis

	CF (mean ± SD)		Control (mean ± SD)	
	T1	T2	T1	T2

BCMI SDS	0.81 ± 1.00	0.12 ± 1.14	0.14 ± 1.33	0.14 ± 1.51
Fat (%)	18.8 ± 10.4	24.4 ± 11.0	18.8 ± 5.2	24.0 ± 10.3

This table shows the body composition measurements of a group of 13 children with cystic fibrosis and age- and sex-matched healthy peers at 2 time points: T1 as the initial measurement and T2 as the follow-up measurement 6 years later. *SDS*, standard deviation scores

unpublished data in 13 CF children and controls shows that the small population of children with CF had similar BCM and percent fat to matched healthy controls over a 6 year period, concluding that the CF subjects were well nourished and that there is no evidence that nutritional status was affected by age (Table 96.3).

Much can be gained from appropriate anthropometric assessment in children and adolescents with cystic fibrosis. A minimal anthropometric set of analyses should include weight, height and some measure of body composition as described later. Equally important is that these data be evaluated and interpreted correctly so that interventions nutritional or otherwise might be appropriate.

96.3 Practical Methods and Considerations in Children with CF

96.3.1 Cystic Fibrosis and Body Composition Measurements

Research has shown that when the causes of malnutrition, that is, increased requirements, inadequate intake and inadequate absorptions are managed appropriately, then clinical outcomes are improved. Therefore, early detection of nutritional problems is essential to allow for intervention. Anthropometric measurements vary in their complexity, suitability and validity in children and the CF population; common methods will be addressed below.

96.3.1.1 Anthropometry

Anthropometry includes measurements of weight, height, circumferences and skinfolds. These methods are often used for assessing children with CF as they are simple, inexpensive, safe and portable; however, they are not recommended for individual clinical subject evaluations or for examining short-term changes in body fat. Anthropometric techniques usually demonstrate the largest standard error and lowest correlation coefficients when compared against other techniques for estimating total-body fat such as dual energy X-ray absorptiometry (DXA), bioelectrical impedance analysis (BIA), or in vivo neutron activation analysis. The standard anthropometric approaches of measuring weight and height can yield useful information and in conjunction with more appropriate estimates of body compositions as described later can offer insight into the clinical manifestations of the disease.

Interpretation of measurements of height, weight and BMI are clearly enhanced by the conversion of such measures to standard deviation score (SDS) using an appropriate reference data set. If there

is a suggestion that an inherent part of the natural history or progression of the disease is a delayed bone age then expressed weight, height or body mass index (BMI) as a SDS relative to estimated bone age may enhance further the analyses of growth data in this circumstance.

Indices of weight and height have been developed to provide a simple method of body composition. For years, percentage ideal body weight (%IBW) was recommended by the CF Foundation Consensus Report as the preferred measure of nutritional status. However, recent studies have found that this method underestimates the severity of malnutrition. A recent study compared %IBW to body mass index (BMI) percentiles in 4,577 children with CF (Wiedemann et al. 2007). They found that when using %IBW their population was reasonably nourished, but that BMI percentiles placed the population below the reference median. These findings were also supported by another study who reported that %IBW underestimated the prevalence of malnutrition in children with short stature and overestimated in children with tall stature (Zhang and Lai 2004).

These studies have led the CF Foundation to amend their recommendations and now advises that the BMI percentile method is used in weight for stature assessment for children and adolescents aged 2–20 years (Stallings et al. 2008). The use of BMI percentile only plays a role in determining whether weight is appropriate for stature. They should only be used in combination with other methods to detect malnutrition as BMI is not able to quantify fat mass or distinguish between fat and lean tissues, and subjects of the same BMI may differ widely in fatness. The normal relationship between height and weight is altered in CF and with the limited sensitivity of BMI percentiles to predict increased body fat in both a clinical and a healthy population; BMI is considered a poor measure of body fat in clinical situations. A study found that the number of CF patients diagnosed as malnourished depends on the assessment technique, with weight for height indices not performing well compared to total body potassium (TBK) measurements (McNaughton et al. 2000). Another study examined BMI values against skinfolds and BIA (Groeneweg et al. 2002). Their results indicated that BMI plots were within normal range despite a significant decrease in FFM in these children; thus proving that BMIs are not accurate reflections of body composition in children with CF.

Skinfold measurement is commonly used in children with CF because of their low cost, portability and simplicity. The measurement of skinfold thickness is taken by grasping the skin between thumb and forefinger and measuring this thickness with callipers. A number of measurements at different sites can be used in age- and gender-specific equations to determine body composition. Skinfold measurement is based upon two assumptions; that the thickness of subcutaneous fat represents a constant proportion of the total body fat, and that the measurement sites represent the thickness of the total body fat. Neither of these assumptions has been proven. The high variability of skinfold measurement may be due to the callipers used, the technique applied, the increased error with high fat content and the inappropriate application of equations.

A study examined the use of skinfolds in adults with CF (King et al. 2005). Compared to DXA, the authors found that FFM from the sum of skinfolds overestimated FFM on average by 2.2 kg compared to DXA. In children with CF, skinfolds have been compared to deuterium dilution measurements (de Meer et al. 1999). These results agreed with the adult findings, showing that skinfolds overestimate FFM in CF populations. The reason for skinfolds overestimating FFM may be because the prediction equations are validated in a healthy population and that skinfolds will be influenced by regional fat distribution.

Arm anthropometry is another simple method often used in CF patients. Arm anthropometry may include measures of triceps skinfolds, mid upper arm circumference and equations to estimate arm muscle area. When the use of arm anthropometry in children with CF has been compared to DXA and the four compartment model, it has been shown that this method was useful for predicting FM in a CF population (Chomtho et al. 2006).

Fig. 96.3 The Bod Pod®. This figure shows the Bod Pod® which uses air displacement plethysmography to measure body volume

96.3.1.2 Air Displacement Plethysmography

Air displacement plethysmography (ADP) is a relatively new method available to measure body composition and presents a preferred alternative to underwater weighing. The only available system for ADP is the Bod Pod® (Life Measurements Instruments, Inc., Concord, CA) (Fig. 96.3). The Bod Pod® measures body volume and body density is then calculated. Body density can be used to estimate body fat with a two-component body composition model or can be used in combination with other methods for a four-component model.

A publication compared FFM from the Bod Pod® to DXA in 52 children with CF and found it is an appropriate technique for use in children and adolescents with CF (Murphy et al. 2004a). Figure 96.4 shows the Bland-Altman Plot when the Bod Pod® is compared against DXA in a group of children with CF. The advantages of the Bod Pod® for children with CF are that it is quick, simple and non-invasive. The limitations of the Bod Pod® lie with the limitations of densitometry when used as a two-compartment technique; the Bod Pod® assumes the density of the FFM is similar in all ages and disease. However, assuming this constant in CF may lead to overestimation of fatness because altered fluid distribution and under mineralisation decreases the density of the FFM in children with CF depending on the extent that CF has affected the FFM density in the individual.

96.3.1.3 Bioelectrical Impedance Analysis

Bioelectrical impedance analysis measures the impedance of the body tissues to the flow of a low level alternating current. The principle of BIA is that when a current is passed through the body it will only pass through the water and electrolyte containing tissues which have low impedance, not the body fat

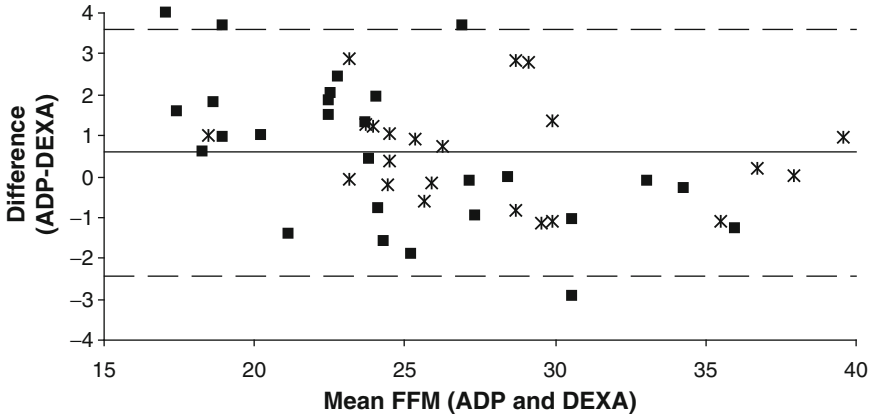

Fig. 96.4 A bland-Altman plot of the Bod Pod® versus dual energy X-ray absorptiometry (DXA). This figure shows the difference in FFM between ADP and DEXA against the mean FFM from the two methods. The squares represent females and crosses represent males. The correlation between the difference in FFM and the mean FFM from the two methods is $r = -0.26$, $p = 0.07$

or bone which have poor conduction properties. Impedance is therefore related to total body water, and by using this relationship in prediction equations, the clinically important value of FFM can be estimated from BIA. There are two assumptions involved in this measurement to determine body volume; the body is a collection of cylinders with their length proportional to their height, and the reactance contributing to impedance is small, with the resistance considered equivalent to impedance.

Recent studies suggest that BIA is not an accurate method in CF patients and that BIA equations will incorrectly estimate FFM in patients with CF. A study has shown that selected equations created to measure FFM from BIA in children are not optimal for use in the clinical population of CF (Murphy et al. 2004b). The problem with the prediction of FFM from BIA in CF patients is that the theory of BIA and the FFM prediction equations employ several assumptions that may not be applicable in children and adolescents with CF. It has been found that CF causes a disturbance in skin electrolyte composition, abnormal fluid distribution, sodium depletion and hydration levels, all of which could affect either the prediction of total body water or its use to calculate FFM.

96.3.1.4 Dual Energy X-Ray Absorptiometry

A DXA scan requires an X-ray source to produce a broad photon beam that is filtered, yielding two different energy peaks. The photons pass through the body's tissues and the resulting attenuation between the two energy peaks is characteristic for each tissue. The concept of DXA technology is that photon attenuation is a function of tissue composition, with bone, lean tissue and fat being distinguishable by their X-ray attenuation properties.

Although DXA studies are increasing in popularity in nutritional studies, such studies should be interpreted with caution as the technique does not represent a complete reference technique, especially in the CF population. Studies have shown that the bias of DXA is unreliable for monitoring body composition longitudinally or in case-controlled studies as results vary with gender, size, fatness and disease state, including CF (Williams et al. 2006). The findings indicate that caution is necessary when DXA is used to compare CF patients with healthy peers or used to longitudinally assess body composition if weight has changed significantly between measurements.

Issues such as hydration and tissue thickness have also been investigated for their effect on DXA measurements. Dual energy X-ray absorptiometry assumes that the lean tissue is normally hydrated.

Fig. 96.5 The total body potassium counter. This figure shows the total body potassium counter which uses sodium iodide detectors to measure the amount of potassium-40 in the body

In patients with CF, the addition of fluid is likely and may result in an underestimation of FM changes. It is suggested that a 5% change in the hydration of FFM will affect the estimate of body fat using DXA by 1–2.5% (Lohman et al. 2000). Dual energy X-ray absorptiometry also assumes a constant distribution of fat over bone tissue and bone-free tissue, which means that estimates of soft tissue may not be as accurate over regions with high bone content as the regions with low bone content (Genton et al. 2002). This also may lead to error in children with CF, who may have regional differences in bone content. There are also several technical factors that may affect DXA measurements of body composition. Results have been shown to differ with manufacturer, software version and beam mode (Kistorp et al. 2000).

Despite the limitations of DXA, the technology provides a body composition technique that with some further research will be useful in the CF setting, particularly as body composition and bone density measurements can be taken with the one test. The measurements are simple, quick and painless to perform, give immediate results, require minimal radiation dose and are available in many clinical settings.

96.3.2 Total Body Potassium Counting

An assessment method that is considered suitable for use in children with CF is TBK counting which provides a measure of body cell mass (BCM) (Fig. 96.5). BCM is the metabolically active component of FFM and is hence, the component of the FFM that is reduced most significantly in malnutrition.

Unlike measurements of FFM, measurements of BCM are a better reflection of nutritional status in children with CF because they are independent of extracellular fluid shifts that may occur as a result of disease state.

Typically, TBK measurements are reported as a raw value in grams or converted to BCM, or reported as a predicted TBK based on control values to represent nutritional status. The use of gender-specific BCMI *Z* scores to report TBK values has only been developed recently (Murphy and Davies 2008). The use of BCMI SDS allows adjustment for height and gender, and ensures that appropriate comparisons can be made within and between groups. This is especially important in children with CF who may be shorter than healthy peers.

96.4 Application to Other Areas of Disease

There are many chronic childhood illnesses that have as a component or consequence poor growth and development. The role of under nutrition or malnutrition in the aetiology of growth retardation in such illnesses has been actively investigated by a number of groups. For growth failure to be a consequence of under nutrition, an individual must be in negative energy balance for substantial periods of time. After the first few years of life, growth is not a major energy consuming process. The energy cost of synthesis and deposition of new tissue during the growth process accounts for between 1.5% and 2.0% of daily energy intakes in normal healthy children. Prolonged periods of negative energy balance could be produced in CF by a reduction in energy intake or an increase in energy expenditure or a combination of both of these factors. Indeed, it is not difficult to investigate both such scenarios in an affected child, and evidence has been produced that in CF this combination did occur frequently when the comments above relating to growth retardation, growth failure and pubertal delay were postulated.

An appropriate and efficient approach to the anthropometric monitoring of growth and development in children with CF can be applied to many chronic diseases of childhood and adolescence. A minimum requirement should be some assessment of linear growth, that is supine length, stature or in some cases limb lengths, some assessment of "body size", that is body weight and/or BMI and finally an estimate of body composition. Acceptable, reliable and accurate measures of body composition have been described in some detail in this chapter, and the method used will depend to some degree on practical issues such as availability and appropriateness.

As with all anthropometric assessments, interpretation is the key, and so the clinician, researcher or student should establish which are the best anthropometric references to use in any given situation. Variation in age and sex, for example, can be "adjusted for" by the use of SDS as previously mentioned and this approach makes statistical analysis and evaluation much easier. Often growth velocity ($cm/year^{-1}$) is an important factor in evaluating the effect of the disease or indeed the effect of an intervention. Growth velocity varies markedly throughout growth with significant changes occurring around puberty. Thus, again, physical maturity should be taken into account via bone age whenever possible. Unfortunately, there are scant data that allow the calculation of a height velocity SDS and it is perhaps better to consider the change (delta) SDS relative to bone age in this circumstance.

The choice of body composition technique is also an important consideration in children with CF and the logic that underpins that choice is equally valid in other circumstances. One notable important issue is the fact in many chronic diseases there is often an expansion of the extracellular fluid (ECF) compartment. Methods of body composition assessment that use a two-compartment model will likely overestimate the FFM in this situation as the model is unable to distinguish the expanded ECF as not being associated with FFM. This error might be especially important when attempting to evaluate changes in body composition either throughout disease progression or recovery.

Summary Points

- Cystic fibrosis (CF) is a common serious genetic condition in children. The principal effects are seen in the respiratory system, the gastrointestinal tract and the sweat glands. The goal of CF management is to prevent infections, reduce the amount and thickness of lung secretion and maintain adequate nutritional status.
- There have been improvements in anthropometric status of children with CF, paralleling improvements in treatment.
- Measurement and interpretation of anthropometric measurements in children with CF is vital. Basic measurements of growth need to be supported with body composition measurements. Delayed bone age should be considered by expressing weight, height or BMI as a SDS relative to estimated bone age.
- The choice of body composition technique is an important consideration in children with CF as in other diseases, considering the limitations of the technique for the population.
- Considerations of body composition interpretation in children with CF need to include height, bone age and hydration.

Key Features

- Cystic fibrosis is a common serious genetic disorder that affects children.
- Anthropometric assessment of children with cystic fibrosis is essential as the symptoms of the disease directly and indirectly impact upon growth and body composition.
- Height, weight and BMI need to be converted to standard deviation scores to understand their value in children with cystic fibrosis.
- Basic measurements of growth need to be supported with body composition measurements in children with cystic fibrosis.
- Bioelectrical Impedance Analysis, Total Body Potassium counting, Dual Energy X-ray Absorptiometry and the Bod Pod® are all suitable methods for use in children with CF.
- Height, bone age and hydration need to be considered when interpreting body composition in children with cystic fibrosis.

Chapter 97
Facial Anthropometry in Hypohidrotic Ectodermal Dysplasia (HED)

Claudia Dellavia, Francesca Catti, Michela Turci, Chiarella Sforza, and Virgilio F. Ferrario

Abstract Ectodermal dysplasias are a large and heterogeneous group of heritable disorders, with an estimate prevalence of 1/100,000 births. Hypohidrotic ectodermal dysplasia (HED) is the most frequent ED variant, and it is identified by the triad of hypotrichosis, hypohidrosis, and hypodontia. Patients with HED also have an abnormal craniofacial morphology.

Common phenotypic characteristic of patients suffering from HED is a generalized, but non-uniform, reduction of facial and head dimensions as compared to normal subjects. In particular, there is frontal bossing, reduced vertical facial height and cranial base width, maxillary and mandibular hypoplasia with small hard tissue palate, high-set orbits with increased biorbital and intercanthal widths, and prominent chin. Facial convexity in the horizontal plane (in all three facial thirds) is increased. The nose and ears are narrow and short, the mouth is narrow with protuberant and everted lips. The nasio-labial angle is acute, the supramental sulcus increased, and the vermilion area of the lips augmented.

The midface hypoplasia produces a skeletal Class III tendency (maxillary retrusion associated with mandibular protrusion) with flat or concave facial profile, and the reduction of the vertical dimension turns out an "aged" appearance. Overall, the largest deviations from the norm are found in facial height and anterior-posterior dimensions of facial lower two-thirds, while facial widths are more similar to reference values.

Patients with HED have extensive lack of both deciduous and permanent teeth and with hypoplasia of the alveolar processes. The severe facial and dental deficiencies induce alterations not only in masticatory function and in spoken communication, but also in esthetics, with subsequent psychological problems of self-confidence.

Overall, the facial soft-tissue of subjects with HED can be successfully measured and monitored with non-invasive computerized anthropometry. Diagnosis, treatment planning, and evaluation of results can be based on global, three-dimensional, quantitative assessment of the craniofacial characteristics of patients with HED. Both the hard- and the soft-tissue structures should be analyzed to provide a complete evaluation of any patient, and should be compared to those of healthy subjects of the same age, sex, race, and ethnic group.

HED	Hypohidrotic ectodermal dysplasia
SD	Standard deviation

97.1 Introduction

The overall form (size, shape, and reciprocal arrangement of the parts) of the human craniofacial skeleton and of its soft-tissue covering is dependent upon the coordinated pattern of development of separate cartilaginous, skeletal, dental, and soft-tissue elements. The complex harmony of the various developmental programs can be altered by genetic modifications.

Among the various genetic modifications affecting the craniofacial complex, the ectodermal dysplasias (ED) are characterized by anomalies in the embryonic development of ectodermal tissues and derivates (Ward and Bixler 1987; Saksena and Bixler 1990; Pinheiro and Freire-Maia 1994; Bondarets and McDonald 2000; Priolo and Laganà 2001; Ruhin et al. 2001; Bondarets et al. 2002; Johnson et al. 2002; Skrinjaric et al. 2003; Ferrario et al. 2004; Sforza et al. 2004). The ED are a large and heterogeneous group of heritable disorders, with an estimate prevalence of 1/100,000 births (Lamartine 2003). Patients with ED have altered epithelium-mesenchyme interactions, which produce modifications in the embryonic development of the ectodermal appendages (teeth, nails, hair, and sweat glands) (Priolo and Laganà 2001; Lamartine 2003).

According to the degree of sweat glands dysfunction, ED can be divided into the hidrotic and hypohidrotic variants. Hypohidrotic ectodermal dysplasia (HED), also called Christ-Siemens-Touraine syndrome, is the most frequent ED variant, and it is identified by the triad of hypotrichosis, hypohidrosis, and hypodontia (Ward and Bixler 1987; Pinheiro and Freire-Maia 1994; Pigno et al. 1996).

Genetic alterations in ED may involve the protein ectodysplasin-A (X-linked ED, ED1, MIM305100) (OMIM 2009), or the cellular receptor for its most important isoform (autosomal recessive ED, MIM224900; autosomal dominant ED, MIM606603) (OMIM 2009). Ectodysplasin-A is a collagenous trimeric transmembrane protein, a member of the tumor necrosis factor family. The proteins of this family regulate apoptosis and cell death, as well as cell adhesion (Priolo and Laganà 2001; Lamartine 2003). Activation of the ectodysplasin-A receptor starts a nuclear factor involved in the regulation of cellular fate, thus regulating cell survival, growth, and differentiation (Lamartine 2003).

Patients with HED have not only alterations of the teeth, nails, hair, and sweat glands, but also of the meso-ectodermal layer constituted by the neural crest, which results in an abnormal craniofacial morphology (Ward and Bixler 1987; Saksena and Bixler 1990; Pinheiro and Freire-Maia 1994; Montonen et al. 1998; Bondarets and McDonald 2000; Ruhin et al. 2001; Bondarets et al. 2002; Johnson et al. 2002).

Indeed, while the alterations in ectodermal derivates in patients with HED have been widely described in the literature, and are currently used for diagnosis, the effect of this group of genetic diseases on the craniofacial structures derived from the neural crest has received attention only more recently (Figs. 97.1 and 97.2). Considering that there are ED coupled with multiple congenital anomalies, always involving the skeleton, a relationship between epidermal alterations and modifications in the craniofacial skeleton might be hypothesized even in "pure" ED (those with abnormality in epidermal derivatives only). Accordingly, the gene defective in HED is also expressed in the neuroectoderm and developing bone (Montonen et al. 1998).

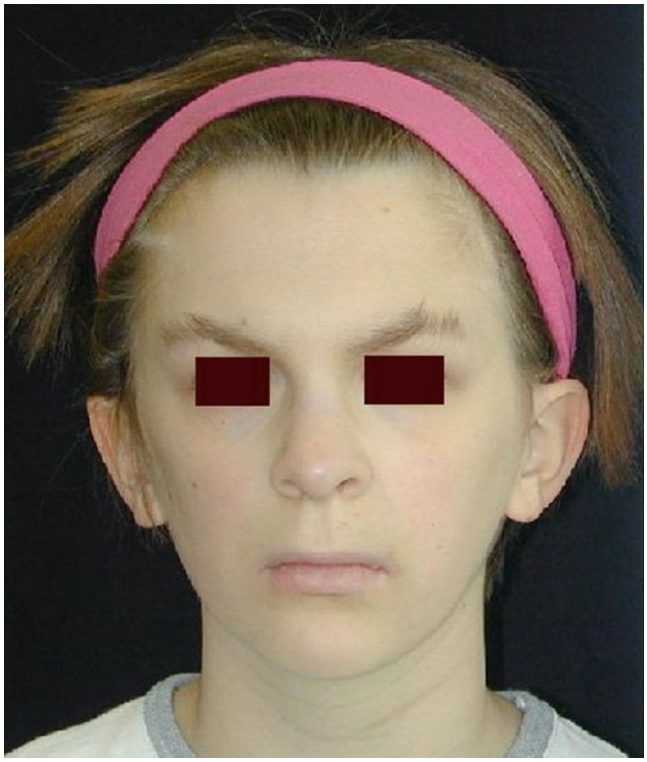

Fig. 97.1 A 10-year old girl with hypohidrotic ectodermal dysplasia. This girl has sparse hairs, with a facial phenotype typical of a mild expression of hypohidrotic ectodermal dysplasia

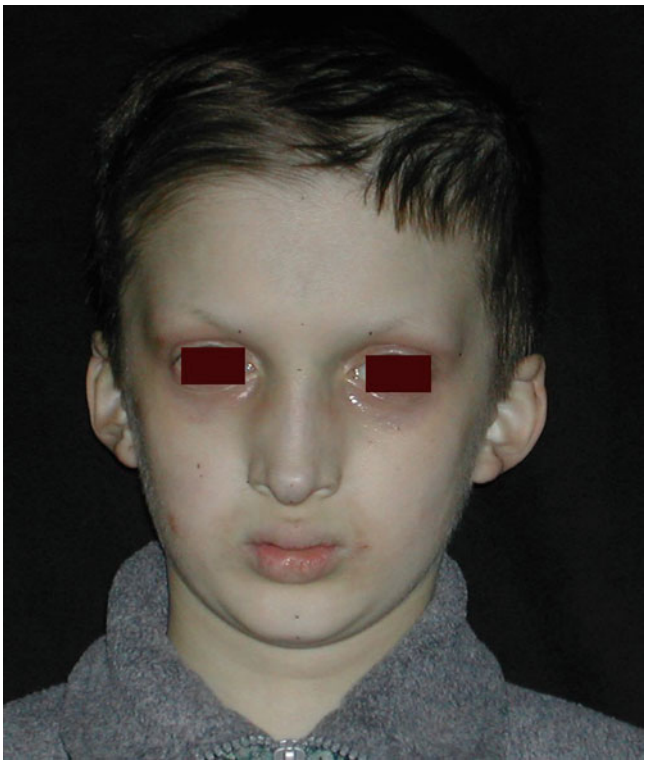

Fig. 97.2 A 7-year old boy with hypohidrotic ectodermal dysplasia. This boy has sparse hairs, narrow mouth, protuberant and everted lips, with a facial phenotype typical of a full expression of hypohidrotic ectodermal dysplasia

Craniofacial morphology in patients with HED has been investigated by lateral head radiographs, conventional anthropometry, and computerized anthropometry, and a set of alterations have been described both in children and in adults (Ward and Bixler 1987; Saksena and Bixler 1990; Bondarets and McDonald 2000; Bondarets et al. 2002; Johnson et al. 2002; Skrinjaric et al. 2003; Ferrario et al. 2004; Sforza et al. 2004, 2006; Dellavia et al. 2008).

In the current chapter, the methods used for the assessment of craniofacial phenotype in patients with HED will be briefly described, and the main results will be presented and discussed.

97.2 Phenotypic Assessment of the Craniofacial Complex in Patients with HED – Methods for Data Collection

Facial features in HED affected subjects have been analyzed using both qualitative and quantitative descriptors obtained by cephalometry and anthropometry.

Several quantitative investigations performed on patients with HED analyzed the hard tissue situation of the craniofacial skeleton, as depicted by lateral plane head radiographs (Bondarets and McDonald 2000; Bondarets et al. 2002; Johnson et al. 2002; Lexner et al. 2007). Head radiographs are currently part of the diagnostic procedures in almost all maxillo-facial, plastic, orthodontic, and dental clinical assessments, providing information about the morphology and reciprocal positions of the skeletal and dental structures. Unfortunately, they have several limitations. They use ionizing radiations, thus being potentially harmful to the subject; they provide a two-dimensional assessment of the skeletal configuration, neglecting most of the soft-tissues and projecting all structures on a single (usually mid-sagittal) plane.

On ethical grounds, radiographic analyses cannot be performed on healthy subjects without a medical indication, and even the longitudinal repetition of X-rays in patients should be limited. These limitations impede the use of radiographs for the construction of reference standards, and restrict their application for growth studies, and to assess the longitudinal effects of treatments.

The three-dimensional information of the entire craniofacial skeleton, together with the soft tissue structures, can currently be provided by computed tomography (a X-ray based technique) and magnetic resonance (a method that assess the behavior of living tissues introduced into magnetic fields). Novel computed tomograms (cone-beam, multislice) allow a detailed reconstruction of the hard- and soft-tissue components of the cranium and face with a significantly reduced exposure to ionizing radiations (Maal et al. 2008). Unfortunately, both methods are too expensive and have limited availability outside well-selected clinical settings. Also, it seems very difficult to obtain a database of normative values from healthy, non-patient subjects for both radioprotection concerns (computed tomography) and monetary considerations (magnetic resonance).

In contrast, anthropometry is non-invasive, three-dimensional, and it considers all the facial structures that contribute to the face of the single patient (Ward and Bixler 1987; Ward et al. 2000; Sforza and Ferrario 2006). Neither the collection of normative data, nor longitudinal examinations, infringe any current ethical consideration.

Conventional, direct anthropometry is currently considered the gold standard for patient assessments: the method is simple, low-cost, and it does not require complex instrumentation (Allanson and Newbury-Ecob 2003; Skrinjaric et al. 2003). A further advantage is the existence of normal databases for almost all craniofacial measurements, at least for white Caucasians, while norms for other ethnicities are scantier (Sforza and Ferrario 2006).

Several investigations assessed the facial characteristics of patients with HED using conventional direct anthropometry (Ward and Bixler 1987; Saksena and Bixler 1990; Skrinjaric et al. 2003; Lexner et al. 2007). Unfortunately, conventional anthropometry is time-consuming, very demanding on both the clinician and the patient, and needs very well trained and experienced examiners. Each measurement is taken individually, and the procedure does not leave permanent records of the facial morphology: missing values, miscalculations or reading errors cannot be corrected off-line. Additionally, no digital coordinate data are available, and new sets of features cannot be measured, nor more complex calculations be performed (surface and volume estimations, analyses of symmetry, form and shape quantification) (Douglas et al. 2003; Ferrario et al. 2004; Hammond et al. 2004).

In contrast, digital, computerized anthropometry currently allows a non-invasive, fast, and simple data collection (Douglas et al. 2003; Ferrario et al. 2004; Hammond et al. 2004; Sforza et al. 2004, 2006; Dellavia et al. 2008). Digital data allow the creation of computerized data bases, implementation of pattern recognition algorithms, and use of the computerized techniques of visualization and simulation of treatment (Sforza and Ferrario 2006).

Current instruments available for computerized, soft-tissue three-dimensional facial anthropometry can be divided into two main categories: optical, non-contact instruments (laser scanners, 3D range-cameras, optoelectronic instruments, stereophotogrammetry, Moiré topography), and contact instruments (electromagnetic and electromechanical digitizers, ultrasound probes). Both kind of instruments are non-invasive, not potentially harmful, and do not provoke pain in the subject (Douglas et al. 2003; Hammond et al. 2004; Sforza and Ferrario 2006; Maal et al. 2008).

The optical instruments allow a fast analysis of the facial surface, providing data on facial surface area and estimates of facial volume, and for indirect anthropometric assessments. The most used instruments are laser scanners and stereophotogrammetric systems. Laser scanners illuminate the face with a laser light source while digital cameras capture the images; triangulation geometry provides the depth information. In stereophotogrammetry a light source illuminates the face, and two or more coordinated cameras record the images from different points of view. A computerized stereoscopic reconstruction is then obtained (Sforza and Ferrario 2006).

Contact instruments digitize single selected facial landmarks (Fig. 97.3), thus reducing the information obtained from each face, but they provide the coordinates of facial features that directly correspond to anatomical and anthropometric structures (Ferrario et al. 2004; Sforza and Ferrario 2006; Sforza et al. 2004, 2006; Dellavia et al. 2008). Ultrasound probes, electromagnetic and electromechanic digitizers are currently in use, and collected data have been used for the characterization of normal individuals, and selected groups of patients. Data collection with these instruments is longer than with the optical devices, but they are less expensive, and can be moved with more ease to meet the patients even outside clinical settings. In particular, electromagnetic digitizers have been used for soft-tissue facial analysis of patients with HED (Ferrario et al. 2004; Sforza et al. 2004, 2006; Dellavia et al. 2008).

97.3 Phenotypic Assessment of the Craniofacial Complex in Patients with HED – Methods for Data Analysis

Craniofacial data collected from patients with HED have been analyzed using two principal approaches. Cephalometric and anthropometric measurements (distances, angles, ratios, but also areas and volumes) can be listed, and the distance of each from a reference assessed, thus providing a detailed, localized description of the altered morphology (Ward and Bixler 1987;

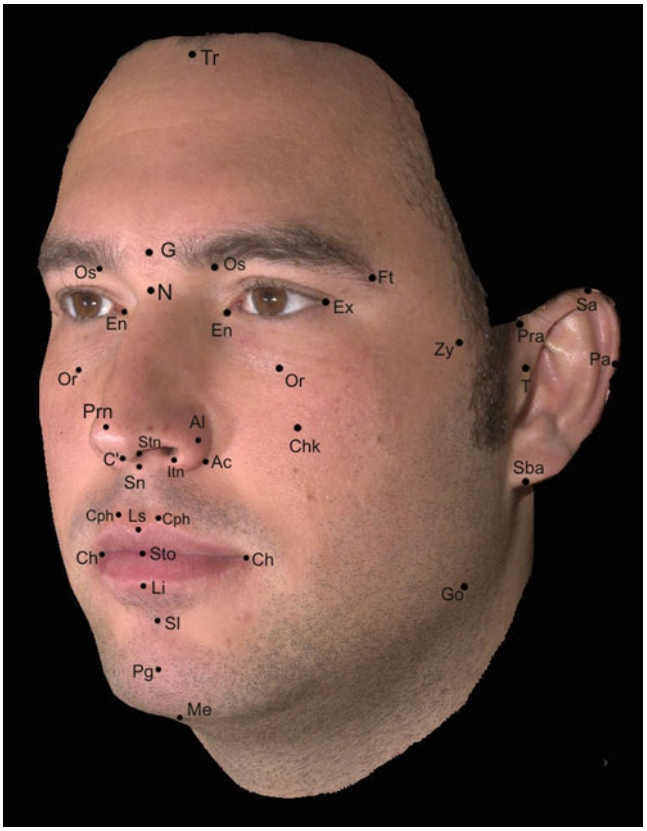

Fig. 97.3 Soft tissue facial landmarks digitized on all analyzed subjects. A detailed description of the method can be found in the chapter "Three-dimensional facial morphometry: from anthropometry to digital morphology" in this book. A set of 50 soft-tissue facial landmarks is marked on the face before data acquisition

Bondarets and McDonald 2000; Johnson et al. 2002). Data are transformed to *z*-scores by subtracting each from its sex and age reference mean value, and dividing by the relevant reference standard deviation (Garn et al. 1984; Skrinjaric et al. 2003; Ward and Bixler 1987; Ward et al. 2000). The *z*-scores are standardized measurements that quantify the distance of an individual from the reference population in terms of standard deviation; in other words, a *z*-score outside the ±2 interval means that the measurement is smaller (or larger) than the reference value of two standard deviations.

Furthermore, anatomic features can be combined, and global indices obtained (Saksena and Bixler 1990; Ward et al. 2000). Among the others, two summary anthropometric measurements have been used for quantifying craniofacial variations: the mean *z*-score (an index of overall facial size, compared to a reference population), and its standard deviation, called the craniofacial variability index (CVI) (Ward et al. 2000). CVI represents the amount of variability across the analyzed *z*-scores: it is low in subjects whose *z*-scores are all of analogous dimensions and in the same direction (increment or decrement) relative to the reference means. In contrast, CVI is high in subjects with disharmonious relationships between individual facial measurements.

For a global comparison of the craniofacial characteristics of two subjects or of two groups (for instance males and females, or subjects of different ages) a correlation analysis between the paired *z*-scores of the individuals of the two groups can be run: high correlation coefficients indicate very similar patterns (Garn et al. 1984).

97.4 Phenotypic Assessment of the Craniofacial Complex in Patients with HED – Main Results

Common phenotypic characteristics of patients suffering from HED is a generalized, but non-uniform, reduction of facial and head dimensions as compared to normal subjects (Ward and Bixler 1987; Saksena and Bixler 1990; Bondarets and McDonald 2000; Johnson et al. 2002; Sforza et al. 2004). In particular, there is frontal bossing, reduced vertical facial height and cranial base width, maxillary and mandibular hypoplasia with small hard tissue palate, high-set orbits and prominent chin. Facial convexity in the horizontal plane (in all three facial thirds) is increased. The nose and ears are narrow and short, the mouth is narrow with protuberant and everted lips. The nasio-labial angle is acute, the supramental sulcus increased, and the vermilion area of the lips augmented (Ward and Bixler 1987; Saksena and Bixler 1990; Bondarets and McDonald 2000; Ruhin et al. 2001; Johnson et al. 2002; Skrinjaric et al. 2003; Ferrario et al. 2004; Sforza et al. 2004, 2006; Suri et al. 2004; Dellavia et al. 2008).

The midface hypoplasia produces a skeletal Class III tendency (maxillary retrusion associated with mandibular protrusion) with flat or concave facial profile, and the reduction of the vertical dimension turns out an "aged" appearance (Sforza et al. 2006; Dellavia et al. 2008). Overall, the largest deviations from the norm are found in facial height and anterior-posterior dimensions of facial lower two-thirds, while facial widths are more similar to reference values (Ward and Bixler 1987; Skrinjaric et al. 2003).

The principal facial features of patients with HED are summarized in Table 97.1.

This kind of modification was further investigated using the mean *z*-score and the CVI, finding an averaged reduction in the mean *z*-score, and an increased CVI in comparison with the reference population (Sforza et al. 2004). In particular, 60% of the analyzed patients had a CVI larger than the normal interval, thus indicating a global disharmonious appearance, and 70% of patients fall outside of the quantitative definitions for normal facial size (*z*-score) and/ or harmony (CVI) (Sforza et al. 2004). A moderate relationship between the total number of maxillary and mandibular teeth present

Table 97.1 Key features of patients suffering from HED as compared to normal subjects

General	Generalized, but non-uniform, reduction of facial and head dimensions
	Increased facial convexity in the horizontal plane
	Reduced vertical facial height and cranial base width
	Narrow and short ears
	Flat or concave facial profile
Upper facial third	Frontal bossing
	High-set orbits
	Reduced orbital dimensions
	Increased biorbital and intercanthal widths
Middle facial third	Maxillary hypoplasia with small hard tissue palate
	Narrow and short nose
Lower facial third	Mandibular hypoplasia
	Narrow mouth
	Protuberant and everted lips
	Increased vermilion area of the lips
	More acute nasio-labial angle
	Increased supramental sulcus
	Prominent chin

This table lists the key facial features of patients with HED (hypohidrotic ectodermal dysplasia), divided into the three facial thirds

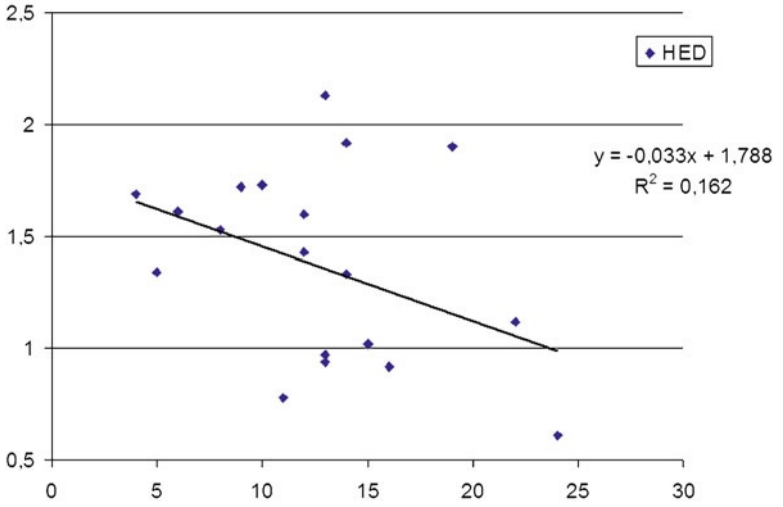

Fig. 97.4 Craniofacial variability index (CVI) as a function of the total number of teeth present in the mouth in 20 patients with hypohidrotic ectodermal dysplasia. Data were partly published by Sforza et al. (2006). The relevant regression line and its equation are also reported. The figure shows that the larger the number of teeth, the smaller is the deviation from the norm

in the mouth and the CVI was found: subjects with more teeth had a smaller CVI (that, a somewhat more harmonious phenotype) than subjects with fewer teeth (Fig. 97.4). Similarly, Sforza et al. (2006) reported that the facial soft tissues differed less from the norm in patients who had a larger number of mandibular teeth.

Indeed, patients with HED present with extensive lack of both deciduous and permanent teeth and with hypoplasia of the alveolar processes. Oligodontia (agenesis of more than six permanent teeth) is associated with growth disturbances of the maxillofacial skeleton leading to an atrophy and a reduced development of the stomatognatic system (Ward and Bixler 1987; Bondarets and McDonald 2000; Ferrario et al. 2004; Tarjan et al. 2005). The severe facial and dental deficiencies induce alterations not only in masticatory function and in spoken communication, but also in esthetics, with subsequent psychological problems of self-confidence.

For instance, the number of teeth was significantly related to the soft-tissue gonial angles: subjects with more teeth differed less from the norm (Sforza et al. 2006). This effect was tentatively explained hypothesizing a relationship between masticatory support (the teeth), chewing function (the masticatory muscles), and skeletal growth (all four masticatory muscles are inserted on the ramus and condylar process of the mandible) (Escobar and Epker 1998; Ruhin et al. 2001; Sforza et al. 2006). Additionally, significant relationships between the number of missing teeth, and mandibular plane inclination, gonial angle and mandibular prognatism have been reported for children and young adults with congenitally missing permanent teeth (but without ED) (Ben-Bassat and Brin 2003): the larger the number of missing teeth, the larger the deviation from the norm.

Nevertheless, the facial phenotype of patients with HED cannot be completely explained by hypodontia (Bondarets and McDonald 2000; Bondarets et al. 2002). While vertical growth seems to depend on the teeth in both HED patients (Bondarets and McDonald 2000; Ruhin et al. 2001) and in non-syndromic children with hypodontia (Ben-Bassat and Brin 2003), midfacial hypoplasia and a modification of the patterns of craniofacial growth appear to be peculiar to HED.

97.5 Phenotyptic Assessment of the Craniofacial Complex in Patients with HED – Ears and Orbital Region

Among the various parts of the face investigated in patients with HED, the eyes and the ears have not been analyzed in detail. For instance, Ward and Bixler (1987) reported a reduction in the dimensions of palpebral fissures, a finding substantiated by our previous study where we measured the soft tissue area of the orbital region (Ferrario et al. 2004). In contrast, the reduction in ear dimensions reported by Ward and Bixler (1987) and Skrinjaric et al. (2003) was not documented in the same subjects (Ferrario et al. 2004).

In our laboratory, ongoing investigations examining the soft-tissue facial characteristics of child and adult patients with HED, on both cross-sectional and longitudinal bases are being conducted. All patients with HED came from the Associazione Nazionale Displasie Ectodermiche (ANDE, Italy). Diagnosis was provided from clinical assessments of hypohidrosis, hypotrichosis, and hypodontia. None of the patients has clefting, syndactyly, or other alterations. Soft-tissue facial data were collected outside clinical settings, usually during meetings of the ANDE. Part of the data collected on these subjects have been previously reported (Ferrario et al. 2004; Sforza et al. 2004, 2006; Dellavia et al. 2008).

Data collected in patients with HED were compared to data collected in healthy persons of the same age, sex, and ethnic group.

In the present report, detailed quantitative data of ear and orbital morphology were reported in a group of 34 subjects with HED. A wide age range was covered, with children (seven boys aged 6–8 years, six girls aged 6–9.5 years), adolescents (six males, age range 11–14 years; four females, age range 10.9–12.6 years), and adults (four men, 21–31 years of age; seven women, 26–41 years of age). Mean age in females was 18.7 years, SD 12.1; in males, 13.6 years, SD 8.3; mean ages were not significantly different between sexes (unpaired Student's t test, $p > 0.05$).

A set of 50 soft-tissue facial landmarks was marked on the face of each subject (Fig. 97.3), and the digital, three-dimensional coordinates of the landmarks were obtained using an electromagnetic digitizer (Sforza and Ferrario 2006). Using custom software, linear distances, angles, and areas were automatically computed from the landmark coordinates (Ferrario et al. 2004; Sforza et al. 2004, 2006; Dellavia et al. 2008). A detailed description of the methods used in our laboratory can be found in the chapter "Three-dimensional facial morphometry: from anthropometry to digital morphology" in this book.

All data were converted into z-scores using our data bank of normal subjects of the same sex, age, and ethnic group. Some of the subjects were relatives (mother and two children of both sexes; two couples of mother and son; father and son; two sisters).

In the analyzed male subjects with HED, significant (Student's t tests for paired samples, 16 degrees of freedom) reductions in the right and left heights of the orbit (os-or), and external orbital surface areas were found (Table 97.2). Also the right and left lengths of the eye fissure (en-ex) were reduced, but the mean z-score was not significantly different from zero. In contrast, both the biorbital (ex_r-ex_l) and the intercanthal (en_r-en_l) widths were increased in the analyzed HED subjects when compared to the reference subjects, the second width also being significant at Student's t test.

The present findings contrast with the report by Skrinjaric et al. (2003), and only partly agree with that by Ward and Bixler (1987); in the present subjects with HED, transverse head dimensions in the orbital region were increased relative to a reference population, but their soft tissue orbital dimensions were smaller. Additionally, significant reductions of the right and left inclinations of the orbit (angle of the os-or line versus the true horizontal, head in natural head position) were found, with more vertical soft tissue orbits in male HED subjects than in the reference population.

Table 97.2 Three-dimensional soft-tissue orbital morphometry in subjects with hypohidrotic ectodermal dysplasia (HED) as compared to their reference groups matched for sex, age, and ethnicity. All values are *z*-scores [(HED subject value – reference mean)/reference standard deviation]

Ex-ex: biorbital width; en-en: intercanthal width; os-or: right and left height of the orbit; en-ex: right and left length of the eye fissure; H/L: right and left height of the orbit to length of the eye fissure ratio (os-or/en-ex × 100); area: right and left external orbital surface area (area of the quadrangle between ex, os, en and or); os-or vs. TH (true horizontal): right and left inclination of the eye fissure (angle of the en-ex line versus the true horizontal, head in natural head position); en-ex vs. TH: right and left inclination of the orbit (angle of the os-or line versus the true horizontal, head in natural head position); os-or vs. FH (Frankfurt plane): right and left inclination of the orbit relative to Frankfurt plane (angle between the os-or and t-or lines)

t-Paired: *p* value of Student's *t* tests for paired samples, 16 degrees of freedom for each sex; *NS*: not significant ($p > 0.05$)

Comparison males vs. females, Student's *t* test for independent samples, 52 degrees of freedom

On average, patients with HED have smaller eyes and orbital regions than reference subjects

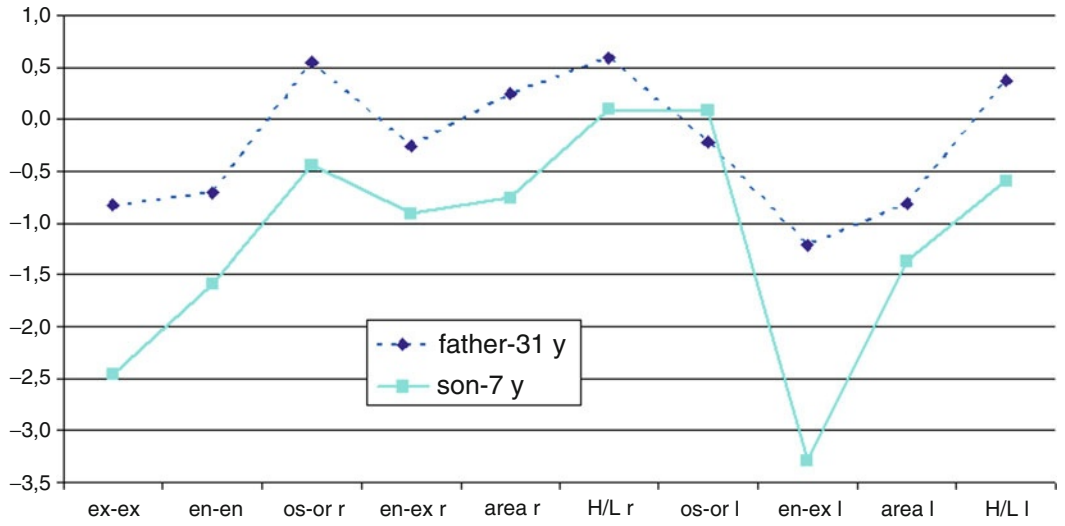

Fig. 97.5 Anthropometric pattern profile of the soft-tissue orbital measurements (linear distances, areas, ratios) made in a father and his son, both affected by hypohidrotic ectodermal dysplasia. Ex-ex: biorbital width; en-en: intercanthal width; os-or: right and left height of the orbit; en-ex: right and left length of the eye fissure; area: right and left external orbital surface area (area of the quadrangle between ex, os, en and or); H/L: right and left height of the orbit to length of the eye fissure ratio (os-or/en-ex × 100). Overall, father and son possess the same kind of deviation from the norm

No significant *z*-score values were found in the analyzed 17 females with HED (Table 97.2). Some sex-related differences were found in the mean *z*-scores, with significant *p* values (Student's *t* test for independent samples, 52 degrees of freedom) for the right and left inclinations of the eye fissure (angle of the en-ex line versus the true horizontal, head in natural head position): in males, the eye fissure was more vertical (angle to the true horizontal) relative to the norm than in females.

Previous reports on craniofacial morphology found no differences between male and female patients with either X-linked ED or autosomal HED (Saksena and Bixler 1990; Bondarets et al. 2002; Johnson et al. 2002; Ferrario et al. 2004; Sforza et al. 2004), in good agreement with current clinical reports (Priolo and Laganà 2001; OMIM 2009). The altered pathways in both the X-linked ED and the autosomally inherited EDs appear to converge in their final step on the same nuclear factor (Johnson et al. 2002; Lamartine 2003), thus producing a common phenotype from different genetic origins, a finding also reported for the murine model of ED (Priolo and Laganà 2001).

To assess the effect of family connections on soft-tissue orbital morphology, the subset of HED subjects who were relatives was analyzed in detail. Correlation analyses were run between the paired *z*-scores of 10 measurements of linear distances, areas, and ratios of the related subjects (Garn et al. 1984). The largest values $r = 0.841$ (correlation coefficient, $p < 0.01$) values were found between a father and his son (Fig. 97.5), and a 41-year-old mother and her 6-year-old son ($r = 0.744$, $p < 0.05$). More limited, non significant ($p > 0.05$), and even negative, correlations were found between a 32-year-old mother and her 7-year-old son ($r = 0.558$), two sisters (Fig. 97.6, $r = –0.108$), and a mother and her two children (Fig. 97.7, mother vs. son, $r = –0.49$; brother vs. sister, $r = –0.644$; mother vs. daughter, $r = 0.382$).

High correlation coefficients indicate very similar patterns of deviation of paired measurements from the norm (Garn et al. 1984). For instance, the father and his son had very similar patterns (Fig. 97.5), notwithstanding that the variations from the norm were more limited in the man than in the boy. In contrast, distinct patterns were observed in the two sisters, with the older sister being less

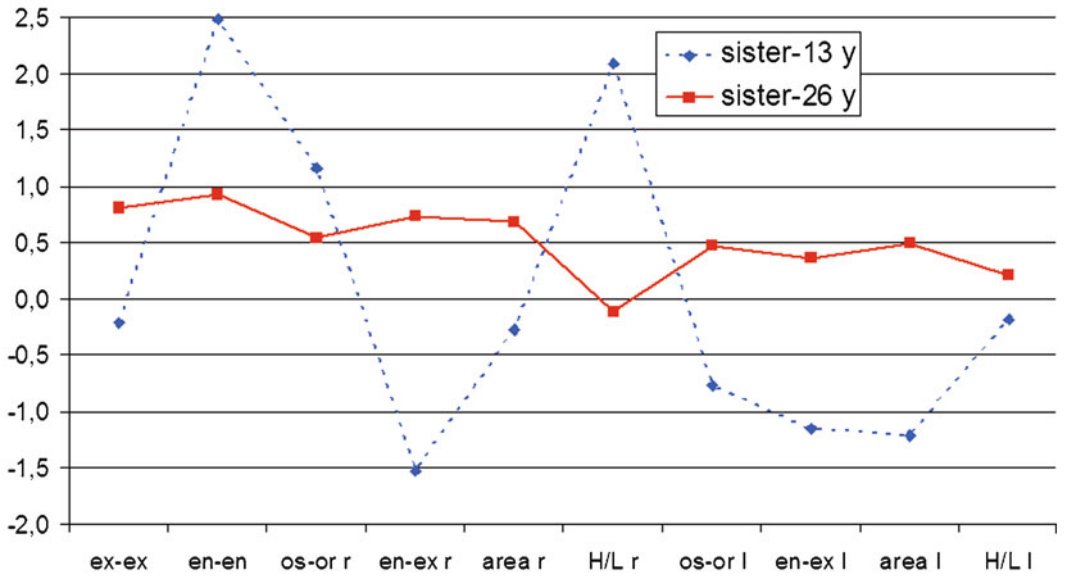

Fig. 97.6 Anthropometric pattern profile of the soft-tissue orbital measurements (linear distances, areas, ratios) made in two sisters, both affected by hypohidrotic ectodermal dysplasia. Ex-ex: biorbital width; en-en: intercanthal width; os-or: right and left height of the orbit; en-ex: right and left length of the eye fissure; area: right and left external orbital surface area (area of the quadrangle between ex, os, en and or); H/L: right and left height of the orbit to length of the eye fissure ratio (os-or/en-ex × 100). The younger sister deviates more from the norm than the older sister

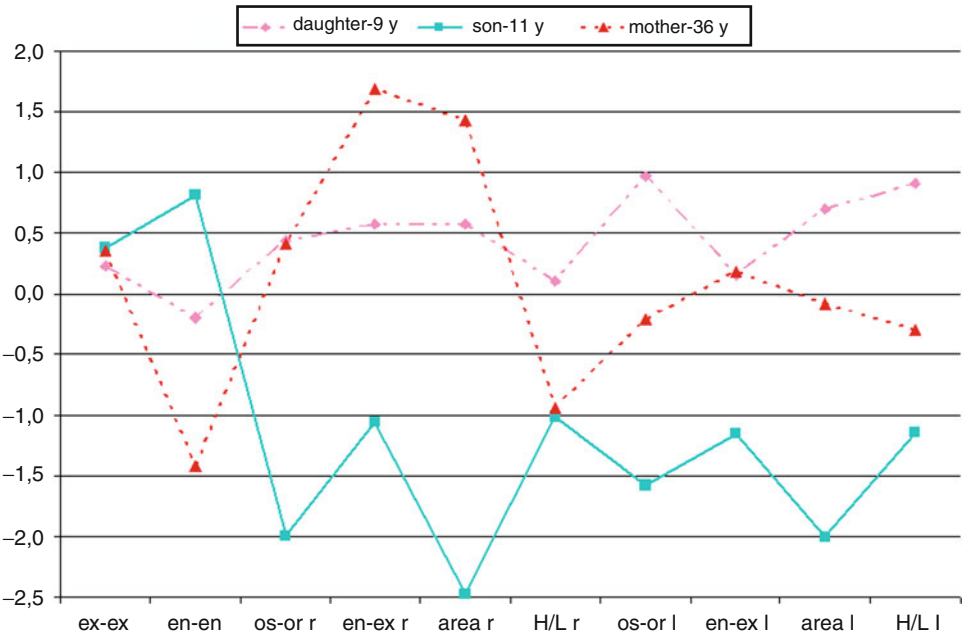

Fig. 97.7 Anthropometric pattern profile of the soft-tissue orbital measurements (linear distances, areas, ratios) made in a mother and her children, all affected by hypohidrotic ectodermal dysplasia. Ex-ex: biorbital width; en-en: intercanthal width; os-or: right and left height of the orbit; en-ex: right and left length of the eye fissure; area: right and left external orbital surface area (area of the quadrangle between ex, os, en and or); H/L: right and left height of the orbit to length of the eye fissure ratio (os-or/en-ex × 100). The brother and sister have contrasting patterns of deviation from the norm, while more similar patterns are observed between the mother and her daughter

Table 97.3 Three-dimensional ear morphometry in subjects with hypohidrotic ectodermal dysplasia (HED) as compared to their reference groups matched for sex, age, and ethnicity. All values are *z*-scores [(HED subject value – reference mean)/reference standard deviation]

Length: right and left ear length (sa-sba); width: right and left ear width (pra-pa); W/L: right and left ear width to ear length ratio (pra-pa/ sa-sba × 100); area: right and left ear area (area of the polygon between pra, sa, pa, sba, t); angle: right and left angle of the auricle versus the facial midplane, computed as the angle between the t-pa line and the sagittal midplane passing through nasion and perpendicular to the ex_r-ex_l line; index: three-dimensional symmetry index. For each ear, the spatial position of the centre of gravity was computed from the *x*, *y*, *z* coordinates of pra, sa, pa, sba, t, and the distances of the same five landmarks from the relevant center of gravity calculated. The ten distances were summed. The differences between the positions of each pair (right and left) of landmarks were also assessed, and the sum of the five absolute (signless) differences obtained. The index was computed as 100 minus the percentage ratio between the sum of the differences and the sum of the distances. This index ranges between 100% (perfect symmetry) and 0% (no symmetry)
t-Paired: *p* value of Student's *t* tests for paired samples, 16 degrees of freedom for each sex; *NS* not significant ($p > 0.05$)
Comparison males vs. females, Student's *t* test for independent samples, 52 degrees of freedom
On average, patients with HED have smaller ears than reference subjects

affected than the younger one (Fig. 97.6). The brother and sister also had contrasting patterns of deviation from the norm, as well as the mother and her son, while more similar patterns were observed between the mother and her daughter (Fig. 97.7).

Clinical reports often indicate very similar general facial phenotypes between HED subjects, even from different ethnic groups and races (Ward and Bixler 1987; Ruhin et al. 2001; Skrinjaric et al. 2003). Nonetheless, when quantitative analyses are performed, variable patterns can be discovered, underlying the usefulness of a global anthropometric assessment. Indeed, a detailed quantitative assessment of the characteristics of a single part of the face found some variability even within a single family. Different expression of the involved genes may explain the variable phenotype.

To the scope, several hypotheses have been proposed: a global alteration of the migration of the neural crest cells, a more severe expression of the ED genes in all parts of the craniofacial district, a reduction in masticatory function (Ward and Bixler 1987; Escobar and Epker 1998; Ruhin et al. 2001; Johnson et al. 2002). Also, lyonization (the random inactivation of one the two X chromosomes occurring in somatic cells) may explain the variable pattern found between the two sisters (Fig. 97.6). Variable expressions of the original pathological entity classically characterize HED: patients with a more severe expression of the HED genes may have a greater involvement of facial bones. Nevertheless, in bone morphogenesis, a functional redundancy of the proteins defective in HED has already been hypothesized (Montonen et al. 1998), thus explaining the variable pattern of deviation from the norm found in the present subjects coming from the same family.

On average, ear dimensions appeared somewhat reduced in the analyzed HED subjects (negative mean *z*-scores in Table 97.3), but the statistical significance was attained only sporadically. In the 17 males, ear length and width were significantly ($p < 0.05$, Student's *t* tests for paired samples, 16 degrees of freedom) reduced only in the left side of the face; in the 17 females, only the left side ear width was significantly reduced as compared to the norm. This produced a different shape in this same

ear (significant reduction in the width-to-length ratio). In males, variations were also observed in ear position, with a somewhat larger sagittal angle of the auricle (approximately half standard deviation larger than the norm, not significant), and a smaller three-dimensional symmetry ($p < 0.005$). This last measurement was the only one with a sexual dimorphism in its deviation from the norm.

The present results confirm the preliminary data reported by Ferrario et al. (2004): apparently, ear dimensions and three-dimensional position are only minimally affected by ectodermal dysplasia. The contrasting findings reported by Ward and Bixler (1987) and Skrinjaric et al. (2003) may be effects of sample size, different age range, and different method of the already discussed genotypic and phenotypic variation in HED subjects.

A further comment should be made on age: both Ferrario et al. (2004) and Dellavia et al. (2008) found that the deviation from the norm of the facial soft tissues of HED subjects tended to lessen with age. Unfortunately, no other study analyzed the age-related patterns of soft tissue structures.

97.6 Longitudinal Studies in HED Patients

Indeed, longitudinal information on global facial growth (hard and soft tissues) in patients with HED is scarce and arises from case reports with medium-short time follow-ups, as recently reviewed by Dellavia et al. (2008). In a longitudinal cephalometric study performed in untreated children, Bondarets et al. (2002) found trends of craniofacial growth toward a marked Class III sagittal relationship of the jaws and an anterior growth rotation with time. No quantitative data on the three-dimensional arrangement of the facial soft tissues were provided.

In non-treated patients with HED, skeletal craniofacial deviations from the norm increased with advancing age (Johnson et al. 2002). In contrast, prosthodontic treatment seemed to emphasize growth normalization, with a higher facial balance after treatment (Ruhin et al. 2001); implant treated adult subjects were more similar to the norm than non-treated adults (Johnson et al. 2002).

In previous studies, facial convexity was also related to age: older patients were less different from the controls than younger patients (Ferrario et al. 2004). It has to be considered that adolescent and adult patients were all provided with some kind of dental prostheses, while this support was lacking for the children; soft tissue facial morphology is obviously expected to be modified by the dental prostheses in situ.

To assess the facial growth patterns in young HED patients, Dellavia et al. (2008) non-invasively monitored the variations in soft-tissue facial structures during childhood and adolescence. Twelve children aged 7 years were annually assessed up to 14 years of age, and their growth patterns were compared to those of normal children.

In all children with HED, the nose had a reduced growth, in good accord with previous reports (Fig. 97.8, all mean differential normalized growths were lower than 100%) (Ward and Bixler 1987; Saksena and Bixler 1990; Lexner et al. 2007). The upper facial third (forehead) grew more in adolescents with HED than in reference subjects, a finding that could be partially explained by the tendency to develop frontal bossing (Saksena and Bixler 1990; Tarjan et al. 2005). The lower lip also grew more in HED subjects than in their reference peers, in accordance with the characteristic aspect of everted lip described in previous investigations (Ferrario et al. 2004; Sforza et al. 2006). In contrast, the upper lip growth pattern was similar to the norm.

Maxillary and mandibular volumes in the HED patients had time-delayed growth peaks in both sexes, and especially in girls. During childhood, growth was initially slower, but a large increment was detected during adolescence. The peak development was shifted about 2 years later than in normal subjects. A pivotal role in this adjustment may be played by the eruption of permanent teeth. The analyzed ED

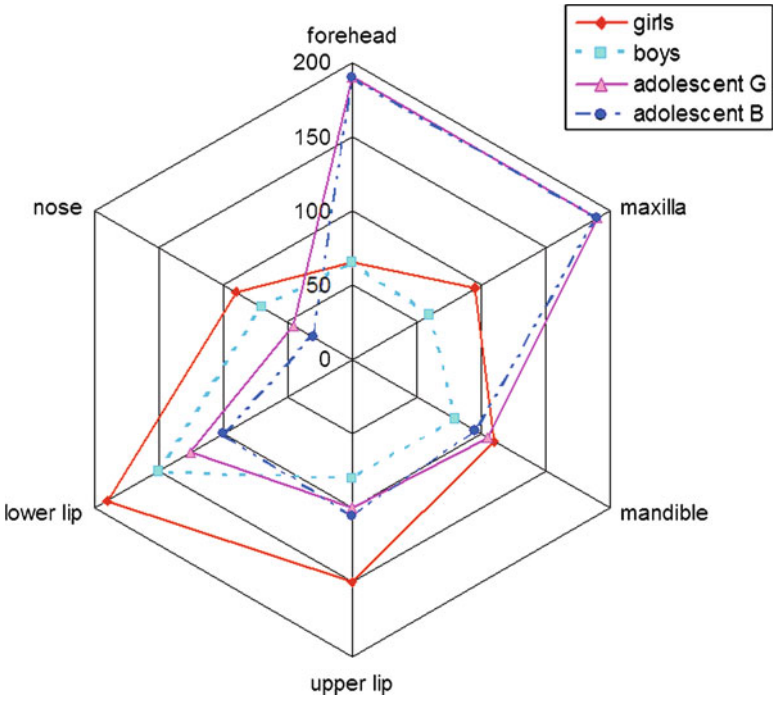

Fig. 97.8 Polar diagram showing the global differential normalized mean growth of soft-tissue facial volumes in hypohidrotic ectodermal dysplasia patients and in reference subjects of both sexes (males: continuous line; females: interrupted line) during childhood (computed between 7 and 10 years) and adolescence (computed between 11 and 14 years). 100% represents the normal mean growth of the reference children and adolescents; 50% represents a relatively reduced growth; 150% and 200% represent relatively larger growths. Origin of the axes (0%) represents a null growth. The various parts of the face have different growth potentials in children with hypohidrotic ectodermal dysplasia than in reference children

subjects presented with a variable number of missing teeth, and a significant correlation between number of maxillary missing permanent teeth and craniofacial dysmorphology has been suggested (Johnson et al. 2002; Ferrario et al. 2004). Reduced palatal dimensions were reported in boys with HED: the presence of teeth significantly influenced palatal characteristics (Dellavia et al. 2008).

The current results are only partially in accord with previous longitudinal studies (Bondarets et al. 2002), where a slightly retrognathic tendency of the maxilla, primarily related to the degree of hypodontia, was observed. The main difference between the two studies is that the children analyzed by Bondarets et al. (2002) did not receive orthodontic or prosthetic treatment, while almost all the HED subjects analyzed by Dellavia et al. (2008) wore removable prosthetic and orthodontic devices since 9 years of age. Subsequent stimuli to mandibular and maxillary growth can be hypothesized (Tarjan et al. 2005). Indeed, in children with HED prosthetic treatment has been recommended as early at 3 years of age to encourage a normal physiologic development and to improve masticatory efficiency (Tarjan et al. 2005).

Therefore, the modern perspectives of clinical management in patients suffering from ED are fully supported by the literature findings. In growing patients, an intermediate treatment with removable prostheses, orthopaedic devices, and temporary restorations will provide the best quality of life, and at the same time will prepare the skeletal and dental structures for the final therapy (Dellavia et al. 2008). Regular adjustments (approximately every year) and replacements of the prostheses should accomplish the growth of the jawbones (Suri et al. 2004). Removable appliances may also promote sagittal growth

of the mandible, thus bettering facial appearance and limiting subsequent major surgical interventions (Pigno et al. 1996; Tarjan et al. 2005). Speech therapy and physiotherapy of facial and masticatory muscles may also be recommended (Pigno et al. 1996; Kramer et al. 2007). At the end of skeletal growth, the final treatment may include orthognathic surgery, bone augmentation and dental implantology as necessary.

97.7 Conclusions

Diagnosis, treatment planning, and evaluation of results should all be based to a global, three-dimensional, quantitative assessment of the craniofacial characteristics of patients with HED. Both the hard- and the soft-tissue structures should be analyzed to provide a complete evaluation of any patient, and should be compared to those of healthy subjects of the same age, sex, race, and ethnic group (Ward and Bixler 1987; Saksena and Bixler 1990; Bondarets and McDonald 2000; Johnson et al. 2002).

Only further investigations, performed on larger numbers of subjects, may allow to better understand the complex phenomena that related genotype and phenotype in patients with HED. Additionally, longitudinal studies, performed with non-invasive data collections, may allow to follow the actual effects of oral rehabilitation in these patients, monitoring the various treatments and finding the best timing for each intervention.

97.8 Applications to Other Areas of Health and Disease

The quantitative assessment of those facial characteristics that differ the most from the norm serves not only for anthropometric and anatomical descriptions of a given disease or syndrome, but also for clinical applications. In a clinical approach, quantitative data support the qualitative description of facial alterations (Garn et al. 1984; Ward et al. 2000; Hammond et al. 2004), and may assist in the diagnosis of borderline patients or gene carriers (Saksena and Bixler 1990; Skrinjaric et al. 2003; Ward and Bixler 1987), especially for the less experienced clinical genetists.

In maxillo-facial, plastic, and reconstructive surgery, a quantitative approach is necessary to compare the outcome of different surgical procedures or intervention schedules, and it may also help in the identification of those facial areas susceptible to surgical intervention.

Quantitative assessments of suitable subjects can also offer unique possibilities to appraise the etiology of poorly understood clinical conditions, trying to isolate genetic from environmental factors.

For all these applications, the use of computerized image analyzers may allow to reduce time and costs, thus facilitating the screening of a larger number of persons even outside a clinical setting (Douglas et al. 2003).

Summary Points and Practical Methods

- The facial soft-tissue of subjects with HED can be successfully measured and monitored with non-invasive computerized anthropometry.
- Diagnosis, treatment planning, and evaluation of results should all be based on a global, three-dimensional, quantitative assessment of the craniofacial characteristics.
- Both the hard- and the soft-tissue structures should be analyzed to provide a complete evaluation

of any patient, and should be compared to those of healthy subjects of the same age, sex, race, and ethnic group.

- In children with HED, an early oral rehabilitation with suitable devices (removable prosthetic and orthopaedic appliances) seems to enhance the growth of structures of the middle and lower facial third.
- In growing patients with HED, a multidisciplinary intermediate treatment with removable prostheses, orthopaedic devices, and temporary restorations is mandatory.
- At the end of skeletal growth, the final treatment of HED patients may include orthognathic surgery, bone augmentation, and dental implantology as necessary.

Acknowledgments The precious and indispensable collaboration of all the analyzed subjects, their families, of the Associazione Nazionale Displasie Ectodermiche (ANDE, Italy). We are also deeply indebted to all the staff and students of our laboratory, who helped in data collection and analysis.

Chapter 98
Anthropometric Indices of Facial Features in Down's Syndrome Subjects

Chiarella Sforza, Claudia Dellavia, Cristina Allievi, Davide G. Tommasi, and Virgilio F. Ferrario

Abstract Down's Syndrome (DS) is the most frequent live-born autosomal aneuploidy in humans, and it is characterized by a distinctive craniofacial phenotype. Qualitative reports and quantitative investigations comparing subjects with DS to normal subjects found modifications in head size (overall reduction) and shape (brachycephaly with a flattened occipital bone). The faces of subjects with DS are narrower, less deep, and shorter than normal faces, with a global anomalous relationship between individual measurements. In the upper part of the face, the interorbital width is decreased, the palpebral fissures are reduced with slanted eyelids, and the forehead is prominent with a depressed nasal bridge. The middle part of the face (maxillary region) is hypoplasic, with reduced vertical, lateral, and anteroposterior dimensions. Overall, the nose is significantly smaller; its vertical and anteroposterior dimensions are reduced, but its horizontal dimensions are increased. In DS subjects the nose is shorter and less protruding, but with larger nostrils, a flatter angle of alar slope, and a more acute nasal tip angle. The mandible is small, with more acute gonial angles, and a more prominent position. Overall, there is a tendency toward a skeletal Class III pattern; the prominent forehead and mandible, associated with midfacial hypoplasia, may result in a concave sagittal plane facial profile. In the horizontal plane, the face is less prominent. Mouth width is reduced, with a smaller lower lip and a larger upper lip, with increased vermilion area and height. The lips are prominent, with reduced nasolabial, interlabial (soft tissues), and interincisal (teeth) angles. There are alterations in ear dimensions (global reduction), position and shape, with a significant larger asymmetry than in normal subjects. The ears are usually more prominent from head surface in DS subjects than in normal subjects. Persons with DS also possess several alterations in the hard- and soft-tissue structures of the oral cavity (teeth and dental arches, palate, tongue, oral mucosa), with reduced hard tissue palatal dimensions.

In conclusion, the facial soft-tissue of subjects with Down' syndrome can be successfully measured and monitored with noninvasive computerized anthropometry. A global, three-dimensional, quantitative assessment of the craniofacial characteristics may help in clinical diagnosis.

98.1 Introduction

In the human head and face, the skeleton, the muscles, the subcutaneous and cutaneous layers all combine together to form a complex structure. Its overall form (size, shape, and reciprocal arrangement of the parts) and function derive from a composite and coordinated pattern of development of separate cartilaginous, osseous, dental, and soft-tissue elements (Breitsprecher et al. 1999). Environmental stressors model and can even alter the genetically determined outline (Breitsprecher et al. 1999).

The correct assessment of this complex structure should be made with a comprehensive morphological and functional evaluation, aimed at a global assessment of all elements classically forming beauty: precision, symmetry, coordination and functional structure (Breitsprecher et al. 1999). The first elements to be considered are those describing the morphological structure that constitutes the base for function.

Facial phenotype can be modified in several genomic and chromosomal alterations, and often the specific phenotypic characteristics are used for clinical diagnosis. Down's syndrome (DS, MIM #190685; OMIM 2009) is the most frequent live-born autosomal aneuploidy in humans. The clinical entity is produced by the complete or partial trisomy of chromosome 21 (Desai 1997; Quintanilla et al. 2002; Roizen and Patternson 2003). The syndrome is characterized by morphological and functional abnormalities of body structures, from cellular organelles to multiorgan systems (Desai 1997; Roizen and Patternson 2003). Among the most constant features, there is a distinctive and immediately recognizable craniofacial phenotype (OMIM 2009) (Fig. 98.1).

In DS subjects, specific characteristics of the craniofacial phenotype can be identified even before birth, and the ultrasonographic assessment of their facial morphology is currently a useful diagnostic tool (Chitkara et al. 2002; Cicero et al. 2003; Minderer et al. 2003; Orlandi et al. 2003; Sonek 2003; Borenstein et al. 2008).

In contrast, the application of ultrasound for postnatal facial morphometrics is limited, and different instruments for three-dimensional (3D) imaging are in use, mainly divided into two categories: optical, noncontact instruments (laser scanners, 3D range-cameras, optoelectronic instruments, stereophotogrammetry, Moiré topography), and contact instruments (electromagnetic and electromechanical digitizers). Both kind of instruments are noninvasive, and can be safely used without any potential damage to the health of the subjects (Hammond et al. 2004; Sforza and Ferrario 2006; Maal et al. 2008). In particular, electromechanic digitizers have recently been used for the soft-tissue facial analysis of patients with DS (Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005a, b), thus partially substituting conventional methods like classic, manual anthropometry (Farkas et al. 2001a, b, 2002a, b; Bagic and Verzak 2003). Additionally, conventional X-rays (cephalometry) have been used for the detection and measurement of these skeletal characteristics (Quintanilla et al 2002).

In the current chapter, the principal pre- and postnatal craniofacial characteristics of patients with DS, as shown by 3D imaging, classic anthropometry, and cephalometry, will be presented and discussed. Additionally, a further set of anthropometric data collected in DS subjects living in the community will be shown.

Fig. 98.1 Soft-tissue landmarks identified on the face of a young woman with Down syndrome. The image shows the set of 50 landmarks identified on the face of a woman with Down's syndrome

98.2 Facial Features in Down's Syndrome Subjects: Prenatal Characteristics

In the western world, prenatal diagnosis is widely used to detect several anomalies. Both invasive (e.g., amniocentesis and fetal chromosomal analysis) and noninvasive techniques (ultrasonographic morphological evaluations) are currently used. Pregnant women and their clinicians would prefer the use of less invasive and less potentially dangerous examinations (so-called "soft" assessments), at least for a first screening.

In particular, ultrasonography is one of the noninvasive techniques that can currently be used for imaging and measuring the craniofacial area in human subjects before birth. Ultrasound probes use acoustic waves in the Megahertz frequency domain, and can image both the skeletal surface and its soft-tissue cover. The method has no (currently) known invasiveness and biological hazards (at least at the commonly used intensities, frequencies, and scan durations, which are usually limited to 15 min each). Ultrasounds are widely used for prenatal, intrauterine imaging and diagnosis, also providing 3D reconstructions of fetal face and allowing for the quantitative analysis of several craniofacial features (Chitkara et al. 2002; Cicero et al. 2003; Minderer et al. 2003; Orlandi et al. 2003; Sonek 2003; Borenstein et al. 2008). The 3D reconstructions provided by the most recent instruments allow more refined measurements, permitting corrections when the best measurement plane has not been perfectly imaged (Borenstein et al. 2008).

One of the first morphological ultrasonographic markers of DS was an altered fetal nuchal translucency, associated with an increased thickness of the nuchal skinfold; this first assessment

was introduced at the beginning of the 1990s. Subsequently, several craniofacial characteristics were progressively coupled with DS in both the first and the second trimesters of pregnancy.

The most quoted symptoms in the literature are nasal bone absence or hypoplasia, a flatter facial profile, and altered ear size and shape (Chitkara et al. 2002; Cicero et al. 2003; Minderer et al. 2003; Orlandi et al. 2003; Sonek 2003; Borenstein et al. 2008).

Fetuses with trisomy 21 have a significantly larger incidence of nasal bone absence (delayed ossification) or hypoplasia than fetuses with a normal karyotype (Cicero et al. 2003; Minderer et al. 2003; Orlandi et al. 2003; Sonek 2003). The ultrasonographic findings have also been coupled with pathomorphological analyses, and these show that hypoplasia vs. normal development seems more indicative of DS than absence vs. presence of a detectable nasal bone (Minderer et al. 2003).

Postnatally, alterations in ear size, shape, and position had been frequently reported in persons with DS (Sforza et al. 2005b); alterations have also been found before birth (Chitkara et al. 2002; Cicero et al. 2003). Indeed, the prenatal developmental period of the ear is relatively long, spanning from the embryonic to the fetal age; also, its complex shape makes it particularly prone to disturbances. On average, fetuses with DS have smaller ears than fetuses with normal karyotype, and ear length and area have been proposed as additional morphological markers for ultrasound-based prenatal screening of aneuploidy (Chang et al. 2000; Chitkara et al. 2002).

More recently, Borenstein et al. (2008) reported the intrauterine measurement of the frontomaxillary facial angle, calculated between the upper surface of the palate and a line connecting the anterior part of the maxilla with the external surface of the forehead. In the fetuses with normal karyotype, this angle decreased linearly with increased fetal dimensions. In trisomy 21 fetuses, the angle was significantly wider than in chromosomally normal fetuses. The authors concluded that measurement of the frontomaxillary facial angle improved the performance of first-trimester screening for DS.

98.3 Facial Features in Down's Syndrome Subjects: Postnatal Characteristics

Several radiographic and anthropometric investigations have analyzed the craniofacial morphology in human subjects with DS (Farkas et al. 2001a, b, 2002a, b; Quintanilla et al. 2002; Bagic and Verzak 2003; Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005a, b).

Qualitative reports and quantitative investigations comparing subjects with DS to normal subjects of the same sex, age and ethnic group found modifications in head size (overall reduction) and shape (brachycephaly with a flattened occipital bone). The faces of subjects with DS are narrower, less deep, and shorter than normal faces, with a global anomalous relationship between individual measurements (Sforza et al. 2005a). Indeed, the use of summary anthropometric indices (the mean *z*-score, that measures the average dimensional discrepancy between patients and a reference population; and its standard deviation, or craniofacial variability index) discriminates more than 89% of subjects with DS when compared to normal subjects (Sforza et al. 2005a).

In the upper part of the face, the interorbital width is decreased, the palpebral fissures are reduced with slanted eyelids and small skin folds at the inner corner of the eyes, and the forehead is prominent with a depressed nasal bridge.

The middle part of the face (maxillary region) is hypoplasic, with reduced vertical, lateral, and anteroposterior dimensions. In particular, considering the prenatal reports of nasal absence or hypoplasia in fetuses with DS, several researchers investigated the postnatal characteristics of the nose in detail. Overall, the nose is significantly smaller (volume, area) in subjects with DS than in the

reference subjects, and it has a different shape. The vertical (length of the nasal bridge, height of the nose) and anteroposterior (nasal tip protrusion, width of the nostrils) dimensions are reduced, but the horizontal dimensions (alar base width, superior and inferior widths of the nostrils) are increased (Farkas et al. 2001b; Tuxen et al. 2003; Ferrario et al. 2004a). Therefore, in DS subjects the nose is shorter and less protruding, but with larger nostrils, a flatter angle of alar slope, and a more acute nasal tip angle (Ferrario et al. 2004a). Also, the absence of nasal bones in adult subjects with DS has been reported (Tuxen et al. 2003).

The mandible is small, with more acute gonial angles, and a more prominent position. Overall, there is a tendency toward a skeletal Class III pattern; the prominent forehead and mandible, associated with midfacial hypoplasia, may result in a concave sagittal plane facial profile (Tuxen et al. 2003). In the horizontal plane, the face is less prominent (Ferrario et al. 2005).

Mouth width is reduced, with a smaller lower lip and a larger upper lip; the upper lip increment is particularly evident for the vermilion area and height. The lips are prominent, with reduced nasolabial, interlabial (soft tissues), and interincisal (teeth) angles (Farkas et al. 2001a, 2002b; Quintanilla et al. 2002; Tuxen et al. 2003; Ferrario et al. 2005).

There are alterations in ear dimensions (global reduction), position and shape, with a significant larger asymmetry than in normal subjects. In particular, ear length is reduced, ear width is often subnormal, and the ratio between ear length and face height is abnormal. Globally, ear area is reduced. Additionally, the ears are usually more prominent from head surface in DS subjects than in normal subjects (Desai 1997; Farkas et al. 2001a, b, 2002a, b; Quintanilla et al. 2002; Bagic and Verzak 2003; Roizen and Patterson 2003; Tuxen et al. 2003; Sforza et al. 2005b).

Nonpendulous ears (with a partially or totally adherent earlobe) are more frequent in DS subjects than in normal persons. DS subjects also can possess alterations in the ear cartilages, with a different morphology of the lateral surface of the auricle (Sforza et al. 2005b).

Some of the investigations on the facial phenotype of subjects with DS found some ethnic-related variation in the areas of major abnormalities, in particular as far as the nose and ears were concerned (Bagic and Verzak 2003; Farkas et al. 2001a, b; Cicero et al. 2003; Sonek 2003). By far, quantitative investigations on the facial morphology of Caucasian subjects with DS analyzed North American of European ancestry, Croatian, Spaniard and Italian people, but different methods were used (classic anthropometry, digital anthropometry and cephalometry), which makes comparisons difficult (Farkas et al. 2001a, b, 2002a, b; Quintanilla et al. 2002; Bagic and Verzak 2003; Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005a, b).

Additionally, some studies mainly analyzed persons living in residential institutions (Bagic and Verzak 2003), while other investigations measured persons living in the community (Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005a, b). Indeed, an increasing number of subjects with DS is living in the community (Roizen and Patterson 2003), and more detailed information on their facial characteristics may supply some information about the relationship between the global quality of life and craniofacial morphology. For instance, hypotonic facial muscles in subjects with DS (Desai 1997; Roizen and Patterson 2003) may modify soft tissue dimensions and positions in the lip area. Open mouth and everted lower lip are currently reported as a frequent feature for subjects with DS, but a better general muscular training and body fitness may result in improved orofacial conditions. Indeed, Sforza et al. (2004) measured a group of DS athletes who attended the "Special Olympics" games, and found less alterations in the mouth and lip area than expected: a better general muscular development (as it is expected in an athlete) may result in an improved orofacial health.

A further variation may derive from sex-related characteristics, even if most investigations did not find differences in the average deviation from the norm in DS men and women (Bagic and Verzak

2003; Ferrario et al. 2004a, 2005; Sforza et al. 2005a, b). Additionally, the effects of age on the deviation from the norm are still discussed. For instance, Ferrario et al. (2004a) and Sforza et al. (2005a) did not find age-related patterns in the facial structures; Quintanilla et al. (2002) and Bagic and Verzak (2003) reported age-related increments in the discrepancy in facial morphology; Farkas et al. (2002a, b) and Sforza et al. (2005b) found some improvements in facial morphology with advancing age. This aspect should be better clarified because the assessment of age-related variations in the altered craniofacial measurements can be used to monitor growth and development: subjects with DS often have altered postnatal growth rates (Farkas et al. 2002a b; Ferrario et al. 2005). A quantitative control of maturation may be used to find the best timing for reconstructive surgical intervention (Farkas et al. 2001a, 2002a).

98.4 Oral Features in Down's Syndrome Subjects

Together with a set of specific facial characteristics, persons with DS also posses several alterations in the hard- and soft-tissue structures of the oral cavity (teeth and dental arches, palate, tongue, oral mucosa) (Desai 1997; Quintanilla et al. 2002; Dellavia et al. 2007).

Persons with DS have xerostomia, with a reduction in salivary flow, which may result in alterations of the mucosal lining of the oral cavity, and an increased risk of periodontal disease (Desai 1997).

On average, hard tissue palatal dimensions are reduced in DS individuals than in control subjects (Desai 1997; Dellavia et al. 2007). The reduction in palatal size is in accord with the general reduction in craniofacial measurements, and it is often associated with a different shape: the hard- and soft-palate is narrower, shorter, but relatively higher (Dellavia et al. 2007).

The reduced dimensions of the oral cavity with dental crowding and posterior crossbite have often been cited as a cause of relative macroglossia in DS subjects, together with an actual enlargement of the tongue and muscular hypotonia (Desai 1997; Dellavia et al. 2007). Taken together, these conditions may lead to tongue and mandibular protrusion, and lastly to an open bite and a dental Class III malocclusion. A proinclination of the anterior mandibular teeth and a reduced interincisal angle are also common features in DS subjects (Quintanilla et al. 2002).

Patients with DS frequently have several dental morphological and numerical anomalies, with microdontia, crown variants, hypodontia and multiple congenitally missing teeth (Desai 1997). Eruption timing retardation of both the deciduous and the permanent dentitions have been reported (Dellavia et al. 2007; Quintanilla et al. 2002; Bagic and Verzak 2003), as well as hypoplasia and hypocalcification (Desai 1997). Also, short roots and unfavorable crown/ root ratio of incisor teeth may contribute to their mobility and subsequent tooth loss (Desai 1997).

Palatal dimensions are also related to the number of molar teeth: DS subjects with more molar teeth differ less from reference subjects, thus underlying the positive role of interdisciplinary dentofacial treatment (Dellavia et al. 2007). Indeed, early dental therapy, including arch expansion, tooth preservation, correction of impacted canines, may offer a significantly improved quality of life for aging DS patients (Desai 1997). Tooth preservation, and timely replacement of lost or congenitally absent teeth, would reduce the accelerated alveolar atrophy which makes dental prosthetic replacement more challenging (Dellavia et al. 2007). It is expected that subjects living with their families would receive a better oral care than institutionalized subjects, thus maintaining a better oral health and quality of life (Dellavia et al. 2009).

98.5 Selected Facial Features in DS Athletes ("Special Athletes")

The described facial phenotype of subjects with DS, both pre- and postnatally, pointed out that the ears and the nose are key parts of the specific characteristics of this syndrome. These two facial features were further analyzed in a group of 54 subjects (20 women, mean age 27.1 years, SD 7.2; 34 men, mean age 27.1 years, SD 9.1) with DS who were "special athletes" attending the Italian games of the Special Olympics in Fiuggi Frosinone (July 2003), and Rome (July 2004). Data were collected inside the "Special Smiles" program partly sponsored by Special Olympics. These "special athletes" were all living with their families, and had good health. Some facial measurements obtained on a subset of the present DS subjects were previously reported (Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005a, b).

All the analyzed individuals, and their parents or legal guardians, were previously informed about the procedures, and signed an informed-consent form approved by the local ethics committee.

A set of 50 soft-tissue facial landmarks was marked on the face of each subject (Fig. 98.1) and the digital, 3D coordinates of the landmarks were obtained using an electromechanic digitizer (Sforza and Ferrario 2006). Using custom software, linear distances, angles, and areas were automatically computed from landmark coordinates (Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005a, b). A detailed description of the methods used in our laboratory can be found in the chapter "Three-dimensional facial morphometry: from anthropometry to digital morphology" in this book.

Subjects covered a wide age range, and their facial data were converted into z-scores to allow an easier analysis and interpretation of results. Z-scores were obtained using data collected from a reference population (healthy subjects with normal karyotype and without craniofacial anomalies, previous trauma or surgery, matched for sex and age with the DS subjects). Each DS value was subtracted from its sex and age reference mean value, and divided by the relevant reference standard deviation. The z-scores are standardized measurements that quantify the distance of an individual from the reference population in terms of standard deviation; in other words, a z-score outside the ± 2 interval means that the measurement is smaller (or larger) than the reference value of two (or more) standard deviations.

98.5.1 Ear Morphometry in DS Athletes ("Special Athletes")

Several morphometric characteristics of the ears were measured: on each side, ear length and width, and the relevant ratio; ear area, ear angle versus the facial midplane, and ear 3D symmetry, as detailed by Sforza et al. (2005b).

In both sexes and for both sides of the face, all linear dimensions and areas measured on the ears were larger in the reference subjects than in the subjects with DS, with negative z-scores (Table 98.1). In men, size differences were associated with shape variations, with larger right and left ear width to ear length ratios in the subjects with DS than in the reference subjects. Variations were found also in the position of the auricle relative to the facial reference planes, with larger angles in both sexes and on both sides (positive z-scores, showing a more prominent auricle in DS subjects than in the reference subjects). The 3D symmetry index was larger in the reference subjects than in subjects with DS (larger asymmetry). All z-scores were not different between men and women (Student's t test for independent samples, $p > 0.05$ in all occasions), and pooled values were computed. Overall, all variations relative to the reference population were significant (Student's t test for

Table 98.1 3D ear morphometry in subjects with Down's syndrome as compared to their reference groups matched for sex, age and ethnicity

		Right-side ear					Left-side ear					3D symmetry

All values are *z*-scores [(DS subject value – reference mean)/reference standard deviation]

Length: right and left ear length (sa-sba); width: right and left ear width (pra-pa); W/L: right and left ear width to ear length ratio (pra-pa/sa-sba × 100); area: right and left ear area (area of the polygon between pra, sa, pa, sba, t); angle: right and left angle of the auricle versus the facial midplane, computed as the angle between the t-pa line and the sagittal midplane passing through nasion and perpendicular to the ex_r-ex_l line; index: 3D symmetry index. For each ear, the spatial position of the centre of gravity was computed from the *x*, *y*, *z* coordinates of pra, sa, pa, sba, t, and the distances of the same five landmarks from the relevant center of gravity calculated. The ten distances were summed up. The differences between the positions of each pair (right and left) of landmarks were also assessed, and the sum of the five absolute (signless) differences obtained. The index was computed as 100 minus the percentage ratio between the sum of the differences and the sum of the distances. This index ranges between 100% (perfect symmetry) and 0% (no symmetry)

Comparisons: males (M) vs. females (F), Student's t test for independent samples, 52 degrees of freedom; pooled: *p* value of Student's *t* tests for paired samples, 53 degrees of freedom; NS: not significant ($p > 0.05$)

Patients with Down's syndrome have smaller ears than reference people, with an increased asymmetry

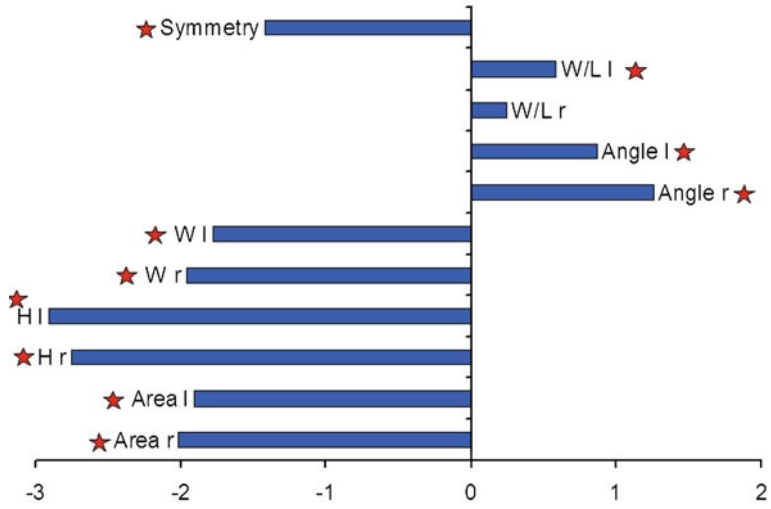

Fig. 98.2 Ear measurements smaller (lower than 0) or larger (larger than 0) in the analyzed Down's syndrome subjects than in the reference population. *X* axis shows the mean *z*-scores of the analyzed measurements. All *z*-scores are significantly different from zero (paired Student's *t*, $p < 0.05$, star) except the right side width-to-length ratio. The patients with Down's syndrome have smaller ears than reference people, with an increased asymmetry

paired samples), except the right side ear width to ear length ratio. Figure 98.2 shows the mean *z*-scores (men and women pooled) of the analyzed ear measurements that were smaller (lower than 0) or larger (larger than 0) in the analyzed DS subjects than in the reference population.

The present results confirm the reduction in ear size reported in the literature (Bagic and Verzak 2003; Chitkara et al. 2002; Farkas et al. 2002b; Sforza et al. 2005b), with mean values that were approximately 2 (ear width, ear area) or 3 SD (ear length) smaller than those found in the reference population (Fig. 98.2). A larger difference in ear length than in ear width was found also in our previous investigation (Sforza et al. 2005b) as well as by Farkas et al. (2002a). A contrasting finding was reported by Bagic and Verzak (2003). Indeed, in the subjects analyzed in the current chapter the *z*-score computed for the ear width to length ratio was not significantly different from 0 in the right side of the face. Differences in ethnicity (Bagic and Verzak 2003; Cicero et al. 2003; Farkas et al. 2001b, 2002a; Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005a, b; Sonek 2003), as well as the intrinsic genotypic and phenotypic variability of DS subjects may be factors in these variations (Tuxen et al. 2003).

98.5.2 Facial Volumes in DS Athletes ("Special Athletes")

As detailed before, another clinically useful marker for ultrasound-based prenatal screening seems to be nasal bone absence or hypoplasia (Cicero et al. 2003; Minderer et al. 2003; Orlandi et al. 2003; Sonek 2003). This characteristic underdevelopment of the nasal complex is found also postnatally (Tuxen et al. 2003), and it is associated with hypoplasia of the middle third of the facial form (Bagic and Verzak 2003; Desai 1997; Farkas et al. 2001a, b, 2002a, b; Ferrario et al. 2004a, b, 2005; Quintanilla et al. 2002; Roizen and Patterson 2003; Sforza et al. 2004; Tuxen et al. 2003). Indeed, all the faces in DS subjects are reduced, and to best appreciate their facial volumetric variations (both as

Table 98.2 Facial volumes in subjects with Down's syndrome as compared to their reference groups matched for sex, age, and ethnicity

		Total	Forehead	Maxilla	Mandible	Total lip	Upper lip	Lower lip	Nose

Patients with Down's syndrome have smaller facial volumes than reference people

absolute values and as percentages), several soft tissue facial volumes (total face; upper third/forehead; middle third/maxilla; lower third/mandible; total lip; upper and lower lip; nose) were computed and compared to data collected in reference subjects of the same sex, age, and ethnic group.

A general reduction of the volumes of all facial thirds was found in both sexes (almost all mean *z*-scores were negative, Table 98.2), with significant (Student's t for paired samples, $p < 0.02$) *z*-score values for all three facial thirds (forehead, maxilla, and mandible). The decrement was particularly evident in the maxillary region (Bagic and Verzak 2003; Desai 1997; Farkas et al. 2001a, b, 2002a, b; Ferrario et al. 2004a, b, 2005; Quintanilla et al. 2002; Roizen and Patterson 2003; Sforza et al. 2004; Tuxen et al. 2003), without sex-related differences (Student's t for independent samples, $p > 0.05$ for all facial volumes). In the same region, nose volume was significantly reduced, especially in males (Bagic and Verzak 2003; Farkas et al. 2001a; Ferrario et al. 2004b). In the lip and mouth region, some discrepancies were observed, with an opposite behavior of the volume of the upper (slightly – but not significantly – increased in men and unchanged in women) and lower (significantly decreased in both sexes, especially in women) lip. This finding parallels the modifications previously found for lip vermilion areas (Sforza et al. 2004), but partly contrast with investigations performed on Northern American DS subjects, where a reduction in the linear dimensions of the upper lip was found (Farkas et al. 2001a). Indeed, all the subjects analyzed in the present chapter had good anterior dental support, and modifications in the reciprocal positions of the upper and lower incisors were directly related to lip position (Dellavia et al. 2007, 2008, 2009; Quintanilla et al. 2002).

To better assess the differential variations in facial volumes in DS subjects, total lip and nose volumes were expressed as a fraction (1/1,000) of total facial volume (Fig. 98.3). In DS subjects, lip volume was approximately 7‰ of total facial volume (7‰ in DS women, 7.2‰ in DS men), a percentage slightly larger than in the reference population (6.4‰ in reference women, 6.3‰ in reference men). Within each sex, subjects with DS had also relatively larger nose volumes (in males, 7‰ in DS subjects, and 6.8‰ in reference subjects; in females, 6.4‰ in DS subjects, and 6.2‰ in reference subjects). Apparently, the general reduction in craniofacial configuration maintained relatively normal percentage dimensions for visceral structures of the digestive and respiratory systems (Roizen and Patterson 2003). Within these two structures, the volumetric distribution seemed to be a function of the genotype (Fig. 98.4), with relatively larger volumes for the upper lip in DS subjects (approx 33% of a total lip plus nose volume) than in reference subjects (approx 27–28%). In contrast, the percentage volume of the lower lip was larger in the reference subjects (21–23%) than in DS subjects (17–18%).

For both lips and nose, a sexual dimorphism was observed: noses were relatively larger in men than in women (both normal and DS men in Fig. 98.3, normal men in Fig. 98.4), lips were relatively

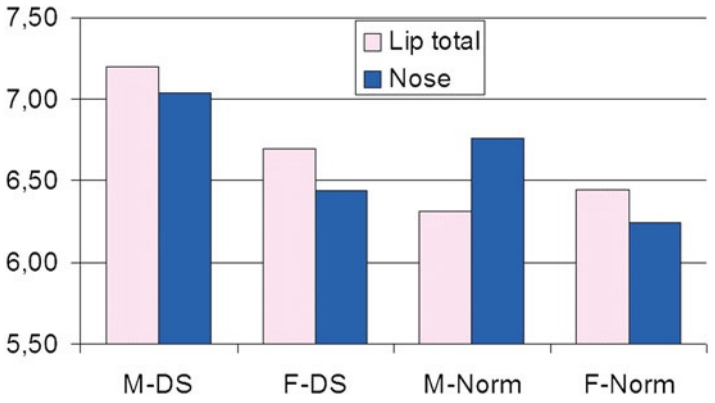

Fig. 98.3 Lip and nose volumes as a fraction (1/1,000) of total facial volume in the analyzed Down's syndrome (DS) subjects and in the reference population. In Down's syndrome subjects, lip and nose volumes as a percentage of facial volume are slightly larger than in the reference subjects

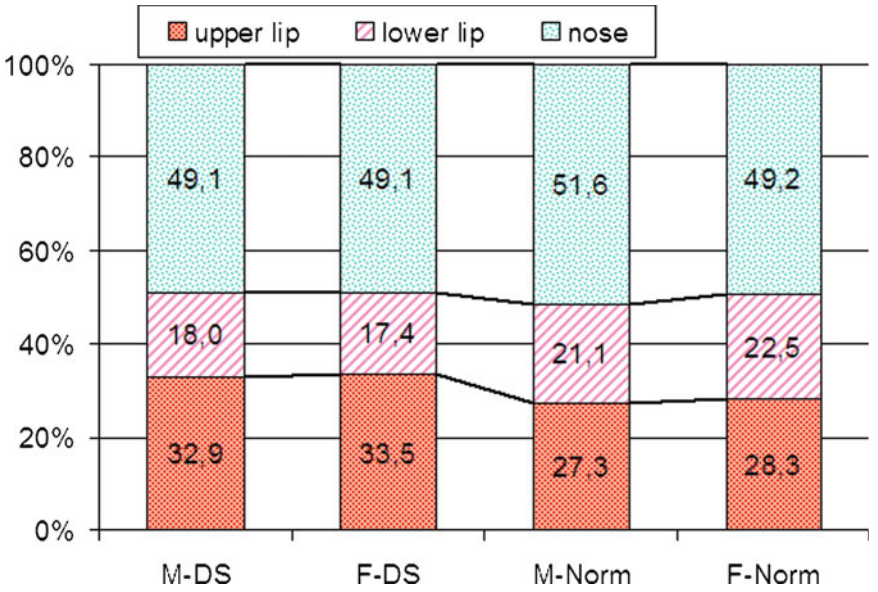

Fig. 98.4 Percentage upper and lower lip and nose volumes in the analyzed Down's syndrome (DS) subjects and in the reference population. All values are percentage of the total "lip plus nose" volume. Down's syndrome subjects have relatively larger volumes for the upper lip than reference subjects, while the reverse applies to the percentage volume of the lower lip

larger in women (total, upper and lower lip in normal women, Figs 98.3 and 98.4; upper lip in DS women, Fig. 98.4).

98.5.3 Global Facial Size and Harmony in DS Athletes ("Special Athletes")

To better investigate the global arrangement of facial features in DS subjects as compared to reference subjects, a set of facial measurements was selected, the relevant *z*-scores computed, and two summary

Table 98.3 Mean *z*-score and craniofacial variability index in subjects with Down's syndrome as compared to their reference groups matched for sex, age and ethnicity

	Mean *z*-score				CVI			
	Mean	SD	Min	Max	Mean	SD	Min	Max
Males	–1.25	0.65	–2.71	–0.11	1.61	0.31	1.08	2.30
Females	–1.61	0.76	–3.01	–0.64	1.69	0.42	1.01	2.89

Patients with Down's syndrome have smaller faces than reference people, with an increased variability in facial dimensions

No significant differences between male and female subject data (Student's *t* test for independent samples, 52 degrees of freedom, $p > 0.05$)

CVI craniofacial variability index

values assessed (Sforza et al. 2005a): the mean *z*-score and the standard deviation of the *z*-scores. This last value, also called craniofacial variability index (CVI), provides a single assessment of the variability across the analyzed *z*-scores. In the current group of subjects with DS, 16 soft-tissue measurements were selected: five widths (skull base width, t_r-t_l; interocular width, en_r-en_l; biorbital width, ex_r-ex_l; width of the mandible, go_r-go_l; mouth width, ch_r-ch_l); six heights (forehead height, tr-n; face height, n-pg; nose height, n-sn; lower face height, sn-pg; right and left ear length, sa-sba), and five depths (upper face depth, n-t_m; mid face depth, sn-t_m; lower face depth, pg-t_m; right and left ear width, pra-pa).

Table 98.3 reports the descriptive statistics of the mean *z*-score and CVI (over 16 measurements) of the analyzed subjects. In the reference population matched for sex, age and ethnicity, the mean *z*-scores were all zero, with standard deviations ranging between 0.471 and 0.663. All the subjects with DS had negative mean *z*-scores: they had, on average, a smaller facial size than the normal individuals. In both sexes, the average mean *z*-scores were significantly different from 0 (Student's t test for paired samples, $p < 0.001$ in both occasions). No sex-related differences were found (Student's t test for independent samples, $p > 0.05$): the deviation from the norm was not dependent from sex. The reduction in facial size was outside the normal interval (mean ± 2 SD) in approximately the same percentage of men (18 of 34, 53%) and women (12 of 20, 60%).

In the reference population, the mean CVI ranged between 0.74 and 0.88, with standard deviations up to 0.209. Twenty-nine male and 15 female subjects with DS had a CVI larger than the normal interval, thus indicating a global disharmonious relationship between individual measurements. No significant sex differences were found ($p > 0.05$). Overall, 33 males and 17 females (93% of the total group of 54) fall outside of the quantitative definitions for normal facial size (*z*-score) and/or harmony (CVI), and only one male and three females had both values inside the normal intervals (Fig. 98.5). Ten females and 14 males (44% of the total) had both values outside the relevant normal intervals.

The diminished facial dimensions (negative mean *z*-score) confirm the findings on the facial volumes and ear region (Tables 98.1 and 98.2), and are in good accord with data in the literature (Bagic and Verzak 2003; Desai 1997; Farkas et al. 2001a, b, 2002a, b; Ferrario et al. 2004a, b; Quintanilla et al. 2002; Roizen and Patterson 2003; Sforza et al. 2005b; Tuxen et al. 2003). The variations in facial proportions (CVI values outside the normal intervals) are in accord with previous reports: Bagic and Verzak (2003) found a nonuniform reduction in facial dimensions, Farkas et al. (2001a, b, 2002a, b) observed different percentages of normal and abnormal measurements in the various parts of the face. Also, the variations in lip volumes (Fig. 98.4) are in good accord with the present results. Overall, the present results confirm the findings reported by Sforza et al. (2004, 2005b) for a subsample of the current subjects: persons with DS possess a smaller face than reference subjects, but the reductions in the different facial areas and in the three spatial planes are not uniform.

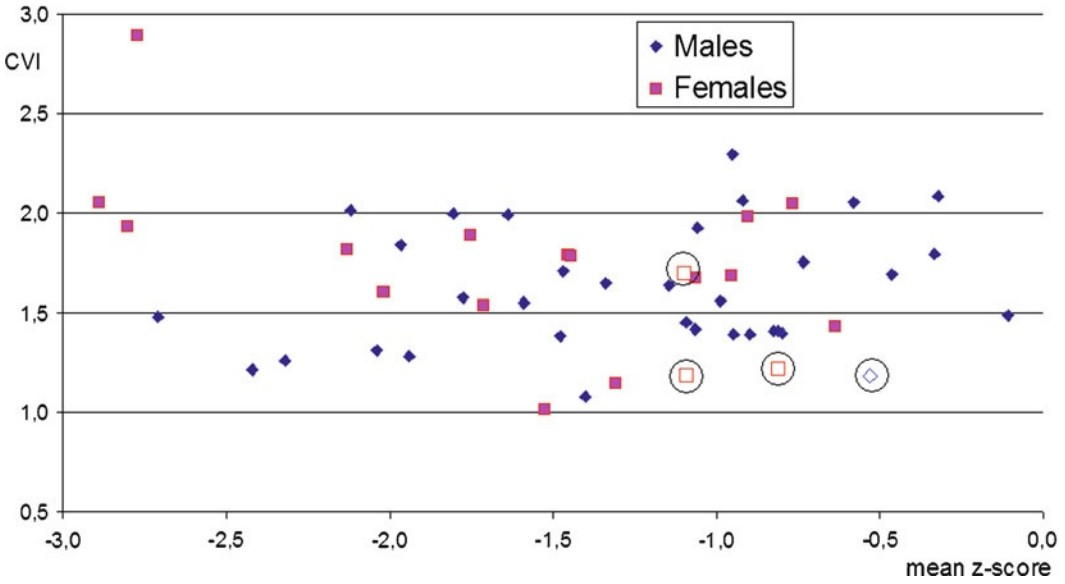

Fig. 98.5 Bivariate plot of mean *z*-score (*X* axis) and Craniofacial Variability Index (CVI, *Y* axis) in 54 subjects with Down's syndrome. Filled symbols: subjects with either *z*-score or CVI that exceed the normal range (mean ± 2SD) of individuals of the same age and sex; open symbols (also noted with an open circle): three women and one man with neither *z*-score or CVI that exceed the normal range (mean ± 2SD) of individuals of the same age and sex. Subjects with Down's syndrome possess a smaller face than reference subjects, but the reductions in the different facial areas and in the three spatial planes are not uniform. The mean *z*-score and Craniofacial Variability Index allow us to discriminate approximately 93% of subjects with Down syndrome when compared to normal subjects

These two indices (mean *z*-score and CVI) allowed discriminating approximately 93% of subjects with Down syndrome when compared to normal subjects (Fig. 98.5).

Current data confirm that the discrepancy of DS subjects from subjects with normal karyotype does not show a sexual dimorphism: the *z*-scores do not differ between male and females DS subjects (the only exception was lower lip volume in Table 98.2). As underlined before, this matter has not been analyzed in detail in previous studies, and only data from two laboratories were assessed separately for males and females: while Bagic and Verzak (2003) reported no sex-related differences, in our laboratory we found variations in some structures (Ferrario et al. 2004a; Sforza et al. 2004), and no differences in others (Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005b). In contrast, Farkas et al. (2001a, b, 2002a, b) reported only pooled values.

98.6 Conclusions

The assessment of the phenotype of DS patients should be based on a global, 3D, quantitative evaluation of all craniofacial characteristics (Table 98.4). Both the hard- (skeleton and teeth) and the soft-tissue structures should be analyzed to provide a complete evaluation of any patient, and should be compared to those of healthy subjects of the same age, sex, race and ethnic group.

Currently, more children and adults with DS are not being institutionalized and live in the community (Roizen and Patterson 2003), receiving more stimuli and sharing several aspects of life (like sport) with their coetaneous (Ferrario et al. 2004a, b, 2005; Sforza et al. 2004, 2005a, b). The effect of this improved quality of life of facial phenotype has not been investigated with sufficient detail.

Table 98.4 Features of patients with Down syndrome as compared to normal subjects

Prenatal	Nasal bone absence or hypoplasia
	Flat facial profile
	Reduced ear dimensions
Postnatal	
General	Reduction in head size
	Brachycephaly with a flattened occipital bone
	Concave sagittal plane facial profile
Upper facial third	Decreased interorbital width
	Reduced palpebral fissures with slanted eyelids
	Prominent forehead
	Depressed nasal bridge
Middle facial third	Maxillary hypoplasia
	Smaller, shorter and less protruding nose, but with larger nostrils
	Nearly normal nasal volume as a percentage of facial volume
Lower facial third	Reduced mandible with more acute gonial angles, and a more prominent position
	Tendency toward a skeletal Class III pattern
	Reduced mouth width, with prominent lips
Oral region	Xerostomia, reduced salivary flow
	Reduced hard tissue palatal dimensions
	Relative/absolute macroglossia
	Malocclusion (open bite, cross bite, incisal mandibular proinclination, Class III malocclusion)
	Dental morphological and numerical anomalies

The principal pre- and postnatal facial characteristics of patients with Down's Syndrome are listed

Preliminary studies indicate that DS subjects who live in their family and practice sports have better oral conditions than DS subjects living in institutions (Dellavia et al. 2007, 2009).

Additionally, longitudinal studies, performed with noninvasive data collections, are still lacking. For instance, the effects of better oral health care, teeth preservation and timely restoration of masticatory units, on soft tissue facial morphology should be quantified to monitor the treatment and find the best timing for each intervention.

98.7 Application to Other Areas of Health and Disease

Anthropometric and anatomical descriptions of a given disease or syndrome are always based on a combined qualitative and quantitative assessment of those facial characteristics that differ the most from the norm (Sforza and Ferrario 2006). The quantitative approach is particularly useful for clinical applications, allowing the direct comparison between different operators and clinical centers. In a clinical approach, quantitative data support the qualitative description of facial alterations (Hammond et al. 2004), and may assist in the diagnosis of borderline patients or gene carriers, especially for the less experienced clinical genetists.

Additionally, anthropometry may assist in the low-cost screening of neuro-developmental alterations that possess a specific facial morphology, like the fetal alcohol syndrome (Sforza and Ferrario 2006). A first discrimination among putative patients will reduce the costs for more complex examinations.

In those clinical and surgical specialties dealing with the face, a quantitative approach can more efficaciously compare the outcome of different medical, surgical, orthopedics, or orthodontic

procedures and intervention schedules (Dellavia et al. 2008, 2009), and it may also help in the identification of those facial areas susceptible of further improvement (Farkas et al. 2001a, b, 2002a, b).

For all these applications, the use of computerized image analyzers may allow us to reduce time and costs, thus facilitating the screening of a larger number of persons even outside a clinical setting.

Summary Points and Practical Methods

- The facial soft-tissue of subjects with Down's syndrome can be successfully measured and monitored with noninvasive computerized anthropometry.
- A global, 3D, quantitative assessment of the craniofacial characteristics may help in clinical diagnosis.
- Both the hard- and the soft-tissue structures should be analyzed to provide a complete evaluation of any patient, and should be compared to those of healthy subjects of the same age, sex, race and ethnic group.
- The principal facial prenatal markers of Down's syndrome, as assessed by intrauterine ultrasonography, are nasal bone absence or hypoplasia, a flat facial profile, and reduced ear size.
- The principal facial postnatal markers of Down's syndrome are overall reduction of head size, decreased interorbital width, reduced palpebral fissures with slanted eyelids, prominent forehead, depressed nasal bridge, hypoplasic maxillary and mandibular regions, and altered ear size and shape.
- In the oral region, subjects with Down's syndrome have a reduced mouth width, with prominent lips; reduced hard tissue palatal dimensions, with several dental anomalies.
- The effect of ethnic variations, as well as of sex and of physical activity, on the facial characteristics of subjects with Down's syndrome is still being debated. Overall, better general conditions seem to be related to lower alterations in the oral region.

Acknowledgements The precious and indispensable collaboration of all the analyzed subjects, their families, of the Italian Committee of the Special Olympics, is gratefully acknowledged. We are also deeply indebted to all the staff and students of our laboratory, who helped in data collection and analysis. Data collection in subjects with Down's syndrome was partly supported by Special Olympics Inc.

Chapter 99
Sex Chromosome Aneuploidy and Anthropometry

Lise Aksglaede, Niels Erik Skakkebæk, and Anders Juul

Abstract Human growth is a highly complicated process influenced by genetic, hormonal, environmental, dietary, metabolic and socioeconomic factors. Although the interaction between sex steroids and the growth hormone (GH)-IGF-axis is of major importance in regulating growth, multiple genetic factors, including genes located on the sex chromosomes play independent roles.

Sex chromosome aneuploidy is the most common chromosome disorder in humans, with an incidence of 1 in 400 newborns. The most frequent type of aneuploidy involve the addition or deletion of an X or Y chromosome resulting in a 47,XXX, 45,X, 47,XXY or 47,XYY karyotype. The clinical and behavioural characteristics of these conditions are relatively well described in the literature, whereas, the addition of more than one extra sex chromosome is rare and relevant clinical information is limited.

Sex chromosome aneuploidies have a high but varying impact on normal growth, and disorders of growth may be the first or only symptom of an underlying genetic disorder. Interestingly, the presence of supernumerary sex chromosomes affects growth in a dimorphic pattern indicating that genes on the X and the Y chromosome affect height in a different manner.

99.1 Introduction

Human growth is a highly complicated process influenced by genetic, hormonal, environmental, dietary, metabolic and socioeconomic factors. Although the interaction between sex steroids and the growth hormone (GH)–IGF axis is of major importance in regulating growth, multiple genetic factors, especially genes located on the sex chromosomes, play independent roles.

Sex chromosome aneuploidy is the most common chromosome disorder in humans, with an incidence of 1 in 400 newborns. Aneuploidies most often originate from non-disjunction during meiosis and result in individuals with either supernumerary or subnumary sex chromosomes. It may be either maternally or paternally derived, although, in cases with poly Y, the additional Y chromosome must be of paternal origin, either generated by a paternal non-disjunction at meiosis II or by a post-zygotic mitotic error (Robinson and Jacobs 1999). The most frequent types of aneuploidy involve the addition or deletion of an X or a Y chromosome, resulting in a 47,XXX; 45,X; 47,XXY; or 47,XYY chromosome constitution. The clinical and behavioural characteristics of these conditions are relatively well described in the literature, whereas, the clinical phenotypes of individuals with the rare karyotypes that include more than one extra sex chromosome are less well described.

Klinefelter syndrome (KS) affects 1 in 660 newborn males (Bojesen et al. 2003), and it is known that approximately 80% of the cases are caused by the numerical chromosome aberration 47,XXY; the remaining have higher grade chromosome aneuploidies (e.g. 48, XXXY; 48,XXYY; and 49,XXXXY) or mosaicisms (e.g. 46,XY/47,XXY). Another, less frequent sex chromosome aneuploidy, the *SRY*-positive 46,XX male (also called de la Chapelle's syndrome), occurs with a prevalence of 1 in 20,000–25,000 males. These patients have some Y-chromosomal material including the *SRY* (sex-determining region of the Y chromosome) gene translocated to one of the X chromosomes and are therefore phenotypically males. The double Y syndrome (47,XYY) affects 1 in 1,000 males, whereas XXYY syndrome occurs in approximately 1 in 18,000 to 1 in 50,000 males.

In females, trisomy X (47,XXX) is the most frequent aneuploidy affecting 1 in 1,000 newborns (Jones 1997). Most of these children present with a normal phenotype at birth (Linden et al. 1988). The deletion of one X chromosome in a female occurs in 1 in 2,500 newborn girls and results in Turner syndrome with the 45,X karyotype.

A sex-chromosome aneuploidy may affect the patient at multiple organ levels. Though many individuals with sex chromosome variations can live functionally normal lives, others may experience physical, developmental, psychosocial, behavioural, and learning impairments. The natural history of these consequences is not completely elucidated, but one hypothesis in KS is that multiple genes on the extra X chromosome escape inactivation and thereby exert dosage effects. It is known that the phenotype of Klinefelter males progressively deviates from the normal, with the increasing number of extra X chromosomes present, whereas the Klinefelter males with mosaicism most often are less severely affected (Lanfranco et al. 2004). By contrast, the phenotypic effects of extra Y chromosomes appear not as severe as those of supernumerary X chromosomes. However, few studies on individuals with sex-chromosome tetrasomy and pentasomy have been conducted, and these have mostly been limited to case reports, and relevant clinical information is therefore limited. Additionally, the majority of the original studies on sex-chromosome aneuploidies were carried out in institutionalised populations of mentally retarded or psychotic adults, and more recent studies on unselected patients have pointed out that these early studies may be subject to ascertainment bias due to the highly selected material. However, no consistent clinical features or specific abnormalities in patients with sex-chromosome aneuploidy exist, and the diagnosis can only be made by karyotyping.

With the discovery of the sex-chromosome-related *SHOX* (Short Stature Homeobox containing) gene, which is located in the pseudoautosomal region 1 (PAR1) (Rao et al. 1997), a new perspective was added to the understanding of the regulation of growth. *SHOX* escapes X-inactivation and is highly expressed in growth plates of long bones, where it plays a role in bone growth and maturation (Rao et al. 1997; Munns et al. 2004). Subsequently, it has been clarified that *SHOX* has a dosage effect on adult height and that, while haploinsufficiency may lead to short stature, *SHOX* overdosage is implicated in tall stature (Rao et al. 1997). Accordingly, it has been suggested that the tall stature of individuals with supernumerary sex chromosomes is related to an overexpression of *SHOX*. Gene-dosage effects of a potential growth-control gene on the Y chromosome (*GCY*) has also been proposed and may also be involved in the additional height in sex-chromosome aberrations with an extra Y.

99.2 Sex Chromosome Aneuploidy and Growth

Representative growth curves for children with the most common sex-chromosome aberrations are illustrated in Figs. 99.1 and 99.2, and a summary of the existing data on anthropometric measures in these conditions is presented in Table 99.1.

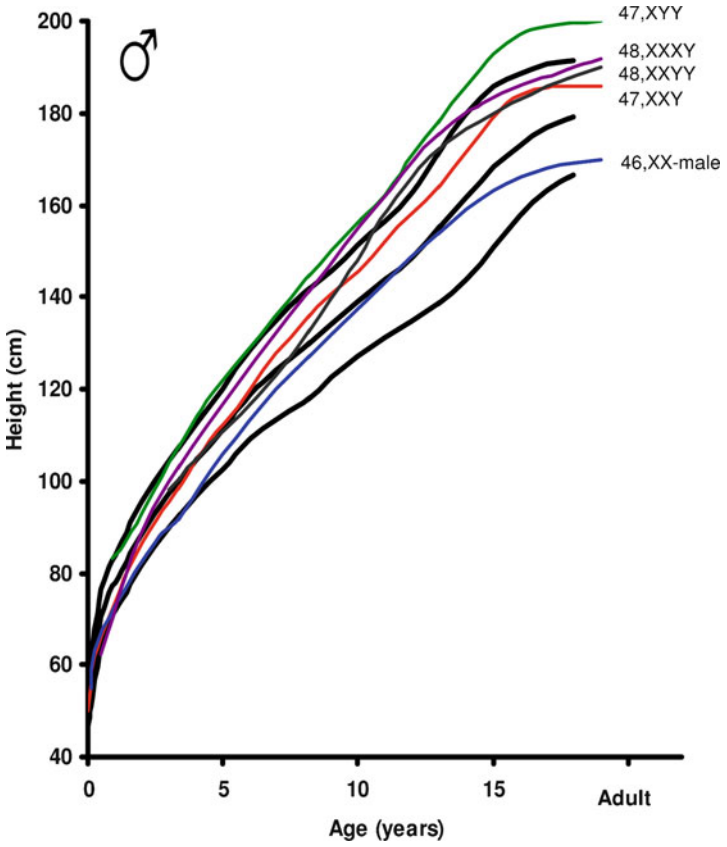

Fig. 99.1 Representative growth curves for boys with sex-chromosome aberrations. Wide lines represent mean +/-2SD in healthy Danish boys and adolescents.

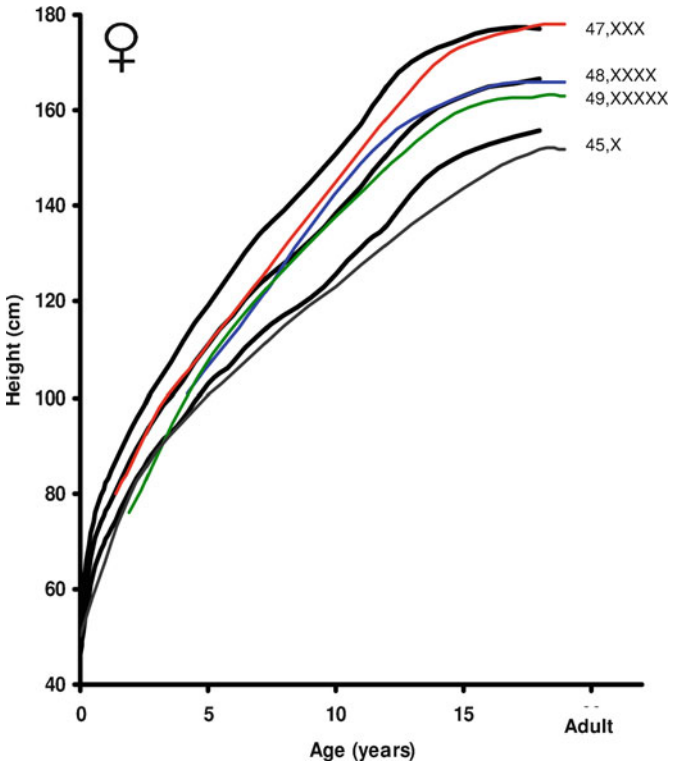

Fig. 99.2 Representative growth curves for girls with sex-chromosome aberrations. Wide lines represent mean +/-2SD in healthy Danish girls and adolescents.

99.3 47, XXY Klinefelter Syndrome

Patients with KS have been studied continuously since the syndrome was first characterised in 1942 by Harry F Klinefelter (Klinefelter 1942) and subsequently found to be caused by the presence of an extra X chromosome (Jacobs and Strong 1959). The 47,XXY male is characterised by small firm testes, gynaecomastia, eunuchoid body proportions, azoospermia, high levels of gonadotropins (FSH and LH) and low normal or subnormal levels of testosterone, learning disabilities and speech and language deficits (Paulsen et al. 1968). However, the phenotypic characteristics of KS are highly variable, and only approximately 25% of the cases are ever diagnosed (Bojesen et al. 2003).

99.3.1 Growth

Anthropometric studies in KS during infancy and childhood are somewhat inconsistent. Some studies find decreased birth length and weight and head circumference compared to controls, whereas others report normal stature at birth. Most studies find normal to increased growth during infancy and early childhood in these boys. Adult males with 47,XXY karyotype are taller than males with a normal karyotype, and their tallness is mainly caused by increased leg length.

In a study of 90 Klinefelter boys aged 2–17 years, height was becoming increasingly above normal with increasing age, whereas height velocity was above normal from 5 years of age. A significant tendency to disproportionately long legs during childhood was found. Head circumference was significantly reduced from birth and onwards, whereas bone age was on average 2SD below the normal until age eight, rising to near the mean by age 12 years (Stewart et al. 1982b).

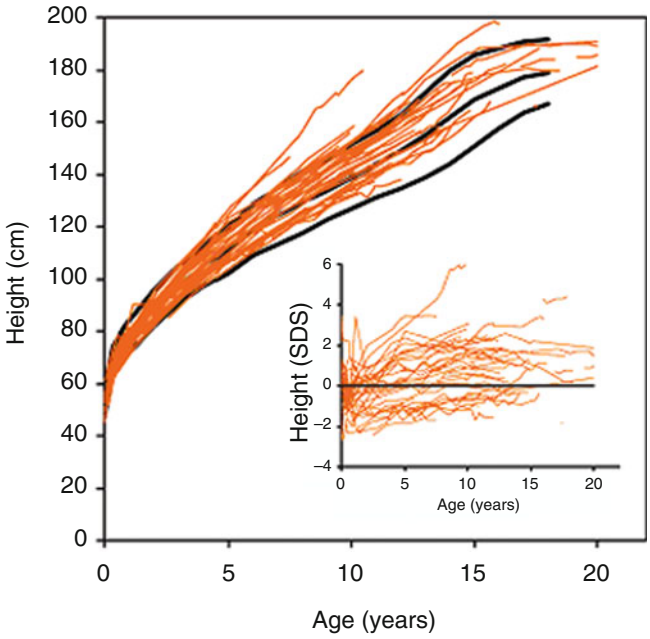

Fig. 99.3 Longitudinal growth curves in relation to chronological age in patients with 47,XXY Klinefelter syndrome. Inserted graph illustrates the height SDS in relation to age in these patients. *Lines* represent mean ±2 SD in healthy boys (Adapted from Aksglaede et al. 2008b. With permission. Copyright 2008, The Endocrine Society)

Robinson et al. reported unremarkable head circumference in 23 newborns with 47,XXY, whereas decreased head circumference was found in 40 boys above 4 years. The authors reported normal height in KS boys until the age of 3 years, whereas significantly fewer boys had a height percentile below 25 after the age of 3 years. These authors found low normal birth weight (Robinson et al. 1979).

Another 15 boys with 47,XXY were identified during the years 1964–1974 in The Denver Prospective Study, where 40,000 consecutive births at two Denver hospitals were screened by Barr-body analysis on the amniotic membranes obtained from their placentas (Robinson et al. 1990). Fourteen of these boys were followed until the age of 16–23 years. Mean height was at the 79th percentile, whereas mean weight was at the 50th percentile and head circumference at the 20th percentile at last follow-up.

A total of 23 47,XXY boys were followed from birth to adolescence in the Edinburgh Study of Growth and Development (Ratcliffe et al. 1990). These boys were diagnosed as part of a cytogenetics survey conducted during the years 1967 through 1979 where 34,380 consecutive infants were screened. At birth, the singleton XXY boys born at term were smaller than controls in weight, length and head circumference. During childhood, height velocity was significantly increased at all ages between 3 and 9 years. At 3 years of age, leg length was already proportionally increased and continued with a statistically significant increase present by age five. Standard deviation scores for head circumference were significantly reduced at all ages in this study (Ratcliffe et al. 1990).

Another study on growth in 87 males with Klinefelter syndrome found accelerated growth from early infancy through childhood and adolescence (Fig. 99.3). Height SDSs were higher than expected from the age of 6 years and onwards, and final height in adulthood was significantly increased as compared with healthy controls. Leg length was increased in these patients (Aksglaede et al. 2008b). Interestingly, these abnormal growth patterns were not reflected in the circulating levels of IGF-I (insulin-like growth factor) and IGFBP-3 (insulin-like growth factor binding protein), and the 47,XXY boys did not develop biochemical signs of hypogonadism until after puberty.

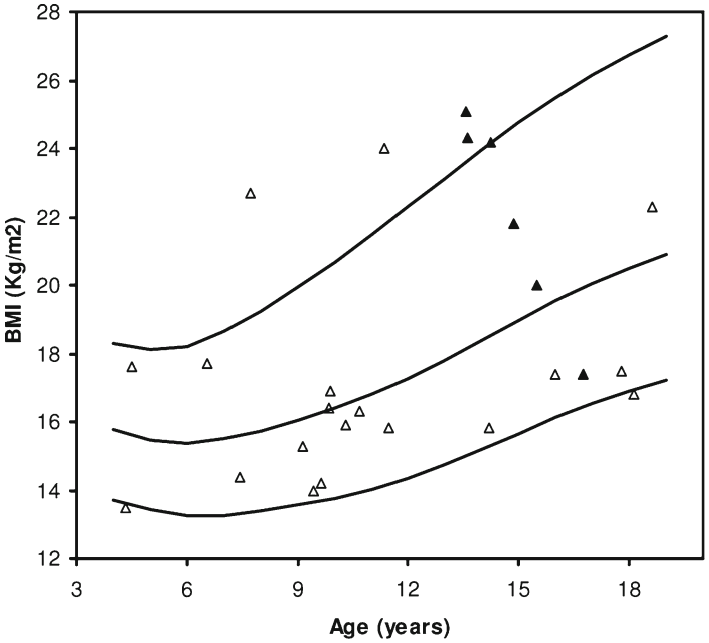

Fig. 99.4 BMI in relation to chronological age in boys with 47,XXY Klinefelter syndrome (*KS*). *Open triangles* indicate patients never treated with androgens and *solid triangles* indicate patients in androgen-substitution therapy. *Lines* represent mean and ±2 SD for healthy Danish boys and adolescents (Adapted by permission from BMJ Publishing Group Limited. Aksglaede et al. 2008a)

In the most recent multicentre study, median height SDS in 129 Klinefelter patients aged 27.7 (range 1.1–66.3 years) were +1.3 (range -1.8 to +4.9) (Ottesen et al. 2010). In this study, current height SDS was significantly ($p < 0.0001$) higher than target height SDS in 42 patients for whom parental heights were available.

In summary, patients with KS exhibit accelerated growth from early childhood, and, as a result, final height is significantly above normal. In addition, eunuchoid body proportions are a common feature in these patients. Head circumference is usually normal or slightly decreased at birth but below average in adulthood.

99.3.2 Body Composition

Increased deposits of body fat in KS patients from early childhood, evaluated by measuring subscapular and triceps skinfolds, have been reported (Ratcliffe 1982; Ratcliffe et al. 1990). Specifically, a tendency towards central obesity was observed in 75% of XXY boys from 6 years of age (Ratcliffe 1999).

In a study on whole-body DEXA scans in 24 children and adolescents with non-mosaic Klinefelter syndrome aged 4.3–18.6 years, a significantly increased body fat mass despite normal BMI and lean body mass was found, suggesting an unfavourable muscle/fat ratio to be present already in childhood (Figs. 99.4–99.6). This study included both androgen-substituted- and unsubstituted individuals, but there was no difference between treated and untreated patients (Aksglaede et al. 2008a).

In line with this, Bojesen et al. found significantly greater weight, BMI, waist circumference, total body fat and truncal fat in 71 adults (aged 35.0 years (range 19.0–66.2)) with KS compared with controls as evaluated by whole-body DEXA scan (Bojesen et al. 2006b).

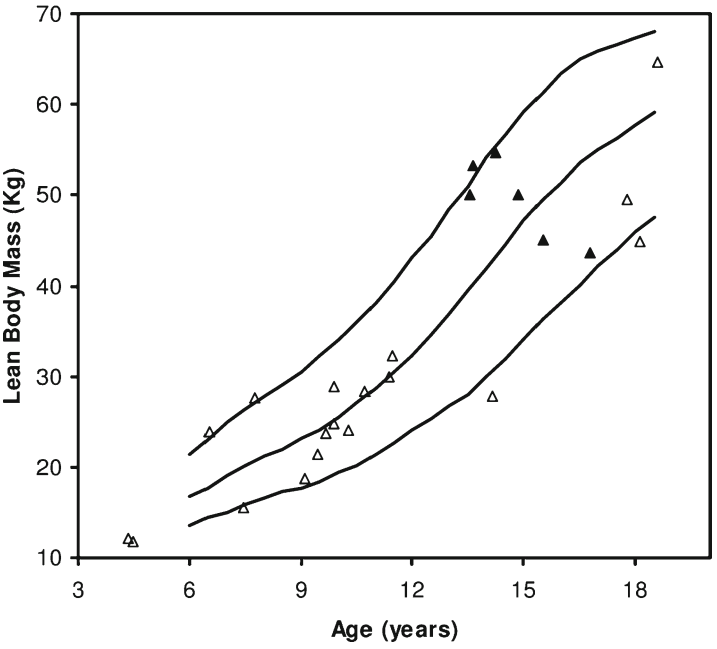

Fig. 99.5 Lean body mass in relation to chronological age in boys with 47,XXY Klinefelter syndrome (*KS*). *Open triangles* indicate patients never treated with androgens and *solid triangles* indicate patients in androgen-substitution therapy. *Lines* represent mean and ±2 SD for healthy Danish boys and adolescents (Adapted by permission from BMJ Publishing Group Limited. Aksglaede et al. 2008a)

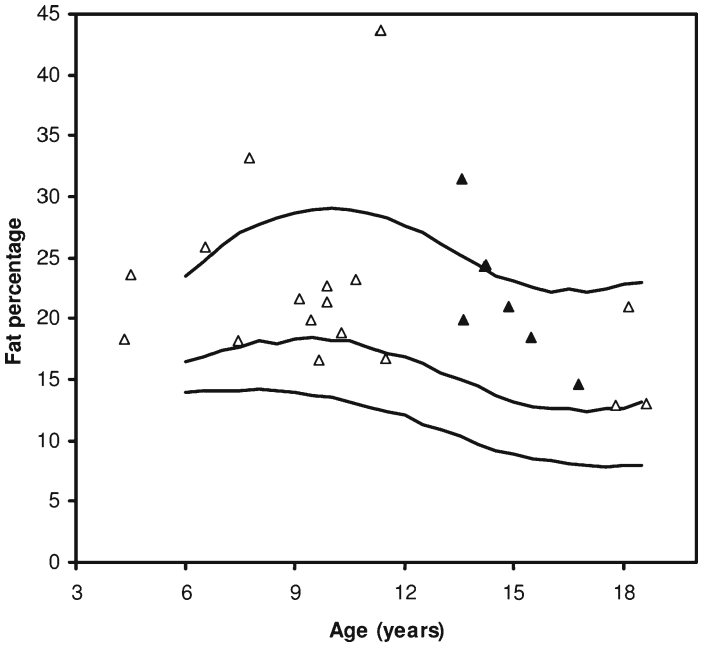

Fig. 99.6 Body fat percentage in relation to chronological age in boys with 47,XXY Klinefelter syndrome (*KS*). *Open triangles* indicate patients never treated with androgens and *solid triangles* indicate patients in androgen-substitution therapy. *Lines* represent mean and ±2 SD for healthy Danish boys and adolescents (Adapted by permission from BMJ Publishing Group Limited. Aksglaede et al. 2008a)

Thus, patients with KS present with increased body fat mass and an unfavourable muscle/fat ratio already from childhood and through adolescence.

99.4 48,XXYY

In addition to the characteristic physical features of Klinefelter syndrome (tall stature, hypogonadism and gynaecomastia), reports on patients with 48,XXYY have described hypertelorism, cubitus varus, pes planus, clubfoot, clinodactyly and scoliosis. Neurological problems, including seizures, intention tremor, hypotonia and tics have also been reported in multiple patients, along with occasional structural brain abnormalities including agenesis of the corpus callosum and frontoparietal cortical atrophy. Speech delays and motor delays with poor motor coordination are commonly described in the first 3 years of life. Although most cases reported in the literature describe some degree of cognitive disability or behavioural problems, a few reports describe adolescents with ''good social adjustment''.

99.4.1 Growth

In a study by Tartaglia et al. on 95 patients aged one to 55 years, who were diagnosed with a 48,XXYY karyotype, a significant increase in mean height SDS with age from +0.21 SDS in children less than 10 years of age (n = 25), to +1.06 SDS in the 11–19 age group (n = 35) and +2.18 SDS in the 20+ age group (n = 22) was found. Mean height of adult males was 192.4 cm (range 180.1–216 cm). Although mean BMI was stable across age groups in this study, there was considerable variation in body habitus within each age group, and individuals ranged from underweight to overweight. Thus, among the adults, 18.2% were underweight, while 31.8% were obese. Eighty-six percent (80/95) of the infants were born at term, with the average birth weight of term infants at 3,130 g (Tartaglia et al. 2008). In addition to tall stature, long leggedness and eunuchoid body proportions have been described (Sherman and Simpson 2003).

99.5 48,XXXY, 49,XXXXY

One study reported increased height with a height SDS of +1.8 (–2.0 to +3.2) in 48,XXXY (n = 9) but reduced height of –1.8 (–4.2 to – 0.1) in 49,XXXXY (n = 10) (Ottesen et al. 2010).

In summary, height deviates progressively from normal with increasing age in males with 48,XXYY karyotype, and final height is significantly above normal. By contrast, it seems that the presence of two extra X chromosomes affects height positively, whereas the addition of three extra X chromosomes affects height negatively. However, data on these latter patient categories are insufficient to draw firm conclusions.

99.6 *SRY*-Positive 46,XX Male

The *SRY*-positive 46,XX male has Y-chromosomal material including the *SRY* (sex-determining region of the Y) gene translocated to the distal tip of the short arm of the paternal X chromosome. Phenotypically, these patients are males and resemble the males with 47,XXY in many (hypogonadism, gynaecomastia and infertility), but not all, clinical aspects (growth).

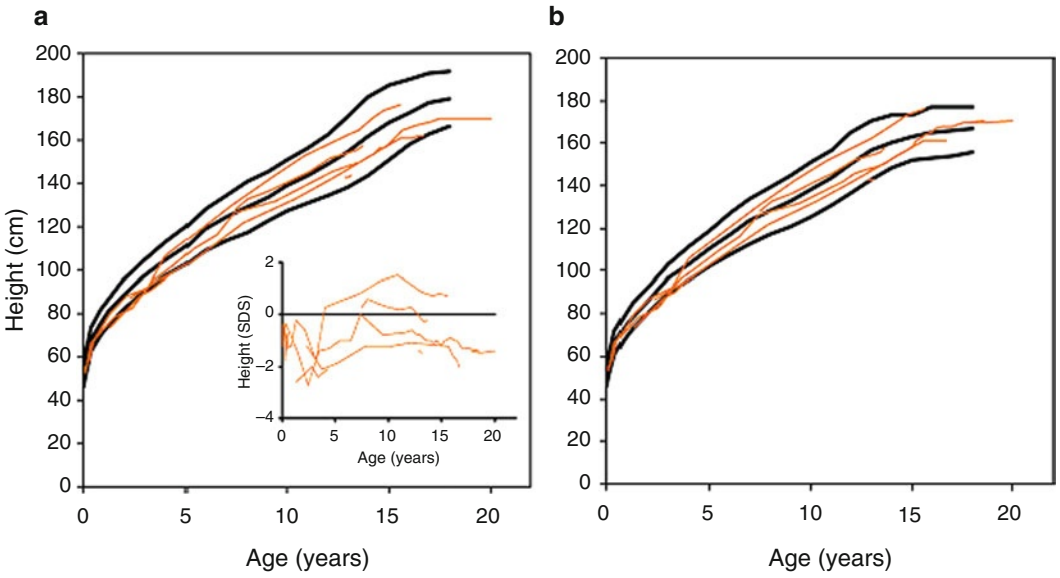

Fig. 99.7 Longitudinal growth curves in relation to chronological age in patients with *SRY*-positive 46,XX male syndrome. The *left panel* illustrates the growth curves in relation to growth in healthy boys, whereas, in the *right panel*, the growth curves are illustrated in relation to growth in healthy females. Inserted graph in A illustrates the height SDS in relation to age in these patients. *Wide Lines* represent mean ±2 SD in healthy boys (**a**) and in girls (**b**) (Adapted from Aksglaede et al. 2008b. With permission. Copyright 2008, The Endocrine Society)

99.6.1 Growth

Boys with *SRY*-positive 46,XX-male karyotypes are usually described as shorter than average. In a study of 14 46,XX males by Aksglaede et al., this was already evident in infancy where the height SDS were significantly reduced (Fig. 99.7a). Interestingly, when comparing these males with healthy females there was no difference (Fig. 99.7b). Final height of the adult males with *SRY*- positive 46,XX karyotype was decreased to a level equal to final height in females. These XX males had normal body proportions with normal sitting height/height ratios (Aksglaede et al. 2008b).

Vorona et al. studied 11 *SRY*-positive 46,XX males and found significantly reduced height and weight but no difference in BMI when comparing with 101 age-matched 47,XXY Klinefelter patients and 78 age-matched healthy males. In this study, the 46,XX males were also compared with a cohort of 157 age-matched healthy females, and no difference in height, weight or BMI was reported. The mean height of the *SRY*-positive 46,XX males was 170.6 cm, whereas mean height in patients with 47,XXY karyotype, healthy males and healthy females were 183.4, 180.7 and 168.9 cm, respectively (Vorona et al. 2007).

99.7 47,XYY

The karyotype 47,XYY is by far the most frequent and best characterised type of poly-Y complement, whereas trisomy and tetrasomy of the Y chromosome are much less frequent. The 47,XYY male has been described as tall, with an increased risk of learning difficulties but with a normal reproductive capacity except for the presence of Sertoli-cell-only syndrome, which has been described in 30% of boys with double-Y syndrome (Skakkebaek et al. 1973).

99.7.1 Growth

Birth weight and length and head circumference were normal in one study (Robinson et al. 1979), whereas these parameters were at or above the 97th percentile in another study (Geerts et al. 2003).

Stewart et al. found elevated growth velocity from early childhood (Stewart et al. 1982b), and, in line with this, several studies have reported increased height during childhood and through adolescence in 47,XYY males (Robinson et al. 1979; Stewart et al. 1982b; Varrela and Alvesalo 1985; Ratcliffe et al. 1990, 1992; Aksglaede et al. 2008b; Ottesen et al. 2010). One study found significantly ($p = 0.001$) higher final height than target height in 27 adults with 47,XYY (Ottesen et al. 2010).

Most studies on body proportions in 47,XYY have reported no difference as compared to normal males (Stewart et al. 1982b; Varrela and Alvesalo 1985; Ratcliffe et al. 1990). However, Stewart et al. found a slight, but non-significant increase in proportional leg length (Stewart et al. 1982b), and another longitudinal study reported slightly increased leg length around pubertal onset, but this difference was equalised in adolescence where the boys had normal sitting height/height ratios (Aksglaede et al. 2008b).

During childhood, head circumference and weight for height has been reported within normal limits (Stewart et al. 1982b).

In summary, *SRY*-positive 46,XX males present with impaired growth already in infancy, and final height is significantly below the height of healthy males but resembles the height of healthy females. By contrast, males with 47,XYY karyotype are significantly taller than healthy males, and final height in these patients usually exceeds final height of KS patients. In contrast to KS patients, the body proportions are within normal limits in both 46,XX males and 47,XYY males.

99.8 47,XXX

Girls with 47,XXX karyotype are usually normally developed at birth, and most cases have been discovered following a karyotype done as part of work-up of children with behavioural disorders. In accordance, learning disabilities and lower IQ scores are frequently seen (Otter et al. 2010). Most of the girls with 47,XXX karyotype have normal reproductive functions, including menstruation and fertility, although reports on delayed puberty and an increased incidence of premature ovarian failure exist (Otter et al. 2010).

99.8.1 Growth

Birth weight, length and head circumference in 47,XXX girls have been described as below average with respect to healthy girls (Robinson et al. 1979; Stewart et al. 1982a, b; Ratcliffe et al. 1990, 1994; Ratcliffe 1999). However, final height of triple-X girls usually exceeds that of controls, and their leg length in proportion to their overall height increases to a significant degree (Ratcliffe et al. 1994). Studies on skeletal maturation have revealed that bone age is about 1 SD below normal in early childhood (age 2–4 years) but well within normal limits by 7–10 years of age (Stewart et al. 1982b).

Sixteen 47,XXX girls were followed from birth to adolescence in the Edinburgh Study of Growth and Development (Ratcliffe et al. 1990). These girls were diagnosed as part of a cytogenetics survey conducted during the years 1967 through 1979, where 34,380 consecutive infants were screened. Twins and girls with a birth weight <2.5 kg were excluded from the data analyses. These girls had a birth weight,

length and head circumference significantly smaller than controls. During childhood, mean height velocity for the whole group did not differ from controls. However, looking at the individual growth curves, half the girls were below the 50th percentile, whereas the remaining were above that. The magnitude of the pubertal growth spurt in seven of these 16 girls did not differ from controls. However, age at onset of growth spurt and at peak height velocity was delayed in accordance with a 10-month delay in pubertal onset as assessed by Tanner stage B2. Sitting height/height ratio was reduced, indicating that the 47,XXX girls had proportionally long legs. The 47,XXX girls tended to be slim with a lower weight than height centile. Head circumference remained reduced throughout childhood and adolescence.

Another 11 girls with 47,XXX were identified during the years 1964–1974 in The Denver Prospective Study, where 40,000 consecutive births at two Denver hospitals were screened by Barr-body analysis on the amniotic membranes obtained from their placentas (Robinson et al. 1990). Ten of these girls were followed until early adulthood. At this time, height was at or above the 80th percentile in nine of ten and >95th percentile in five of these. Weights were within the normal range. Nine of ten had a head circumference at or below the 50th percentile, and five of these were at or below the 20th percentile.

Sixteen girls with 47,XXX karyotype were identified during the years 1967–1971 in seven Toronto Hospitals: The Toronto Study (Stewart et al. 1990). Six of these girls were followed annually until early adulthood. Height increased from the 55th percentile at age 2 years to the 85th percentile up to age nine. Height velocity was above the 50th percentile until age 12, and final height reached the 90th percentile, well above the midparental height, which was at the 48th percentile. In the early years, weight was below the 50th percentile, but rose above the 60th percentile later. Mean head circumference was consistently below the 50th percentile. Legs were significantly longer in comparison to sitting height. Arm span/height ratio was fairly constant between age 11 and 16 years.

Ottesen et al. found an increased median height SDS of +0.7 (–0.9 to +3.2) in 40 patients with 47,XXX. In a subgroup of 25 of these patients, where target height was available, current height SDS was significantly higher than target height SDS ($p = 0.009$) (Ottesen et al. 2010).

99.9 48, XXXX and 49,XXXXX

Very limited data on girls with 48,XXXX and 49,XXXXX karyotype exist. Ottesen et al. found slightly decreased height in 13 girls with 48,XXXX karyotype, whereas Jones et al. found normal to tall stature in these girls (Jones 1997; Ottesen et al. 2010). In line, median height SDS was –1.0 (–3.5 to –0.8) in 49,XXXXX, although only data from three girls were available (Ottesen et al. 2010).

In summary, girls with 47,XXX karyotype are usually small at birth, but end up with a final height above average for healthy females. In addition, these girls present with eunuchoid body proportions. By contrast, the presence of two or three extra X chromosomes may affect stature, but data on these patient categories are insufficient to draw any conclusions.

99.10 Applications to Other Areas of Health and Disease

The vast majority of studies on general health and disease in sex-chromosome aneuploidies have been conducted in patients with 47,XXY karyotype and 45,X Turner syndrome. Klinefelter syndrome has been associated with a significant 40–50% increase in mortality risk corresponding to a significantly reduced median survival of 2.1 years, in particular due to cardiovascular, infectious, neurological, pulmonary and urinary-tract diseases (Swerdlow et al. 2005; Bojesen et al. 2006a).

99.11 Metabolic Syndrome and Abdominal Fat

Truncal obesity has been related to the metabolic syndrome, which is defined as a clustering of insulin resistance and hyperinsulinaemia and is often associated with dyslipidaemia, hypertension, glucose intolerance or non-insulin-dependent diabetes mellitus and an increased risk of cardiovascular events. A fivefold increased risk of developing the metabolic syndrome in adults with KS compared to age-matched controls was found in a recent study where the strongest predictor for the metabolic syndrome was adiposity, especially truncal adiposity (Bojesen et al. 2006b). In this study on 71 adult patients with Klinefelter syndrome, Bojsen et al. found that all measures of insulin sensitivity and metabolic syndrome except blood pressure changed in a pathologic direction; fasting serum insulin and fasting plasma glucose were higher among the KS patients, whereas insulin sensitivity (HOMA2%S) was significantly reduced as compared with age-matched controls. Total cholesterol, LDL cholesterol and triglycerides were all significantly increased, and HDL cholesterol was significantly decreased in patients with KS. CRP and leptin levels were higher in Klinefelter syndrome patients, whereas levels of adiponectin and fructosamine were similar between the two groups. Using the NCEP/ATPIII criteria, significantly more Klinefelter syndrome patients (46%) than controls (9.9%) had metabolic syndrome. Furthermore, significantly more KS patients (9%) than controls (1.4%) had diabetic FPG levels, and significantly more patients (17%) than control subjects (3%) had impaired fasting glycaemia (Bojesen et al. 2006b).

99.12 Osteoporosis

Testosterone deficiency in otherwise healthy adult males is associated with a significant decrease in bone mineral density. Accordingly, it is well established that patients with KS have a high risk of developing ostopenia or even frank osteoporosis in young adulthood (Horowitz et al. 1992; Swerdlow et al. 2005; Bojesen et al. 2006a). It is, however, not clear whether the impaired bone density in these patients is a result of hypogonadism or a more complex genetic defect.

In a study on 24 children and adolescents with 47,XXY karyotype aged 11.0 years (range 4.3–18.6 years) bone mineralisation was examined. Eighteen of these patients (aged 10.1 years (range 4.3–18.6)) had never received sex-hormone therapy, whereas the remaining six (aged 14.6 years (range 13.6–16.8)) were treated with per oral testosterone undecanoate at the time of examination. Median lumbar BMD and BMC, whole-body BMC and BMD for age- as well as size-adjusted BMC were all within the normal ranges, indicating normal bone mineralisation in both treated and untreated subjects in this study (Fig. 99.8). Whole-body bone mineral content and lumbar mineral density were higher in the group of treated Klinefelter boys, although this did not reach statistical significance (Aksglaede et al. 2008a).

In adult Klinefelter patients, Kübler et al. found significantly lower bone mineral density in patients who had never received androgen replacement therapy or in whom treatment was instituted late (>the age of 20 years), whereas patients who started early androgen substitution (<20 years) had normal BMD (Kübler et al. 1992). In this study, patients never treated showed a significant positive correlation between BMD and serum T (Kübler et al. 1992). These data suggest that there is a critical time during development when adequate androgen levels are necessary for normal bone mineralisation. This may be due to an impaired androgen secretion at the critical stage of bone maturation during puberty so that subsequent therapy with androgen replacement may not be sufficient to restore normal bone mass.

In summary, bone mineralisation is normal in childhood and adolescence, whereas adult patients with KS have increased risk of developing osteopenia or osteoporosis.

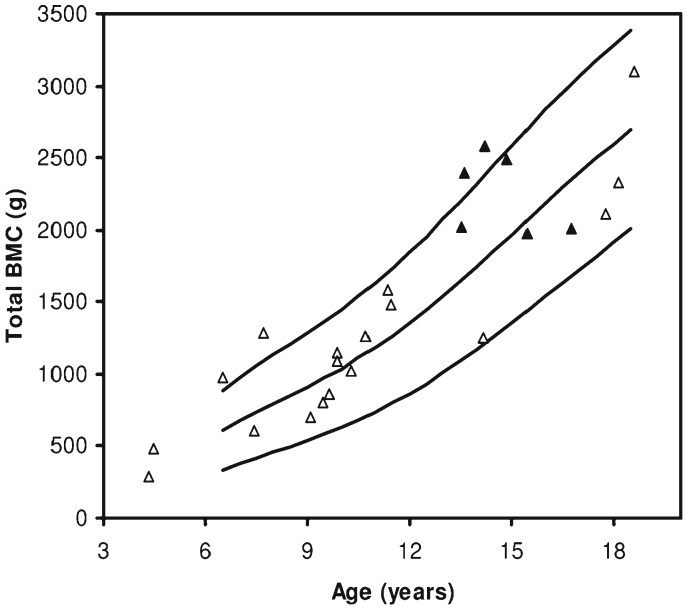

Fig. 99.8 Whole-body BMC in relation to chronological age in boys with 47,XXY Klinefelter syndrome. *Open triangles* indicate patients never treated with androgens and *solid triangles* indicate patients in androgen-substitution therapy. *Lines* represent mean and ±2 SD for healthy Danish boys and adolescents (Adapted by permission from BMJ Publishing Group Limited. Aksglaede et al. 2008a)

Summary Points

- Sex-chromosome aneuploidy is associated with physical, developmental, psychosocial, behavioural and learning impairments. However, the severity varies greatly.
- The phenotypic differences in sex-chromosome aberrations may result from gene-dosage effects of genes in the pseudoautosomal regions (PAR) of the X and Y chromosomes that escape X inactivation.
- Increased growth is a clinical hallmark in patients with polysomy X or Y.
- Patients with XYY and XXYY are taller than XXY.
- *SRY*-positive 46,XX males present with a growth pattern equal to female growth.
- The 47,XXY karyotype is associated with an increased risk of premature development of osteopenia or even frank osteoporosis.
- An unfavourable muscle/fat ratio is already present in patients with 47,XXY during childhood and adolescence.
- There is a five fold increased risk of developing the metabolic syndrome in adult 47,XXY, and the strongest predictor for the metabolic syndrome is adiposity, especially truncal adiposity.

Key Facts of Aneuploidy

- Sex-chromosome aneuploidy is defined as the addition or deletion of one or more X or Y chromosomes to a normal karyotype.
- It occurs during cell division and may be either paternally or maternally derived.
- It is the most common chromosome disorder in humans.
- The most frequent types of aneuploidies are 47,XXX; 45,X; 47,XXY; and 47,XYY.
- Some individuals with sex-chromosome variations can live functionally normal lives; others may experience physical, developmental, psychosocial, behavioural and learning impairments.

Key Facts of Klinefelter Syndrome

- Discovered in 1942 by Harry F Klinefelter.
- Defined by the presence of one or more extra X chromosomes (typically 47,XXY).
- Affects 1 in 660 newborn boys.
- Characterised by small testes, hypergonadotropic hypogonadism, infertility, tall stature and learning disabilities.

Chapter 100
Anthropometric Indices in Turner Syndrome

Anna M. Kucharska

Abstract Turner syndrome (TS) is defined as the complex of characteristic physical features in a phenotypic female, caused by complete or partial X monosomy in some or all cell lines. It is a relatively common chromosomal aberration, but the variability of phenotypes among the patients is very large. In a majority of patients with Turner syndrome, one can expect short stature and infertility. Many of the characteristic features are detectable by physical examination, and anthropometric measurements are a valuable tool in the diagnostics and therapy in TS. In this chapter, the symptoms of Turner syndrome are introduced and their anthropometric aspects are pointed out. The relevance of anthropometric examination in the diagnostics and monitoring of therapy in Turner syndrome is described. A natural development of body constitution and composition is characterized according to several studies performed on children and adults. The alterations of anthropometric parameters during hormonal therapy are depicted. Anthropometric indices are shown as valuable markers of the effectiveness of growth hormone treatment, as well as markers of metabolic effects of growth hormone, sex steroids, and insulin sensitivity. The conditions for the appropriate anthropometric examination of the patient with Turner syndrome and evaluation of the appropriate measurements are described.

Abbreviations

BMI	Body mass index
FM	Fat mass
GH	Growth hormone
HOMAindex	Homeostatic model assessment- index
IGF-1	Insulin-like growth factor-1
LBM	Lean body mass
SDS	Standard deviation score
SHBG	Sex hormone binding globulin
SHOX	Short stature homeobox-containing gene
TS	Turner syndrome

100.1 Introduction

Turner syndrome (Ullrich–Turner syndrome) is a relatively common chromosomal aberration causing characteristic physical features in girls, but the variability of phenotypes among the patients is very large. In the majority of patients with Turner syndrome, one can expect short stature and infertility. Other congenital anomalies are variable. Mental retardation is rare. Many of the characteristic features are detectable by a thorough physical examination. Anthropometric measurements are especially valuable in diagnostics, but anthropometric indices are also useful in monitoring of hormonal therapy and follow-up in patients with Turner syndrome.

100.1.1 Definition

Turner syndrome (TS) is defined as the complex of characteristic physical features in a phenotypic female caused by complete or partial X monosomy in some or all cell lines. Both criteria, a chromosomal aberration and physical symptoms are required for the diagnosis.

100.1.2 Frequency

The first definitive description of Turner syndrome was presented by O. Ullrich in 1930 and by H. Turner in 1938. It is a relatively common chromosomal disorder and its prevalence is approximately 1 in 2500 female live births (Saenger et al. 2001). This is much higher in early pregnancy. It has been estimated that as much as 1–2% conceptuses have a monosomy of X chromosome, but about 99% of them are spontaneously aborted (Gravholt et al. 1996).

100.1.3 Karyotypes

According to the available data from a classic karyotyping (a peripheral lymphocytes examination), approximately 50% of patients born with Turner syndrome have a monosomy of 45,X. Fifteen percent have a mosaicism for 45,X and one or more different cell lines. A majority of the rest (5–10% of TS patients) have an isochromosome Xq (a duplication of the long arm of one X chromosome, i(Xq)), or other structural disorders of a second X chromosome, for example a ring X chromosome (rX).

In the mosaicism, a percentage contribution of chromosomally different cell lines often varies in different tissues. Karyotypes of skin fibroblasts culture and of peripheral lymphocytes examination in the same individual often show different proportions of particular cell lines. Furthermore, mosaicism in patients with TS may be more frequent than was previously presumed. In the case of two different tissue examinations, approximately 80% of patients with monosomy 45, X in blood cells have mosaicism in skin fibroblasts (Held et al. 1992). In a small number of patients with TS material of Y chromosome may be present. Its presence can increase the risk of gonadoblastoma, which is recently estimated as approximately 7–10% (Gravholt et al. 2000).

100.1.4 Physical Features

The characteristics of Turner syndrome are dependent on the absence of some genes located on the second X chromosome. During a normal development, in 46,XX embryo, one X chromosome is inactivated shortly after a fertilization. Only the pseudoautosomal region of an X chromosome normally escapes this inactivation and two sets of genes are needed for its normal function. When only one set is present, the gene expression is impaired, and this phenomenon is known as the haploinsufficiency. The majority of genes involved in Turner syndrome are located on the short arm of the X chromosome, in the region Xp11.2–p22.1 (Zinn et al. 1998). In this region short stature homeobox-containing gene (SHOX) responsible for growth and genes responsible for normal development of lymphatic system are located.

Patients with Turner syndrome have variable manifestations of typical symptoms. The most common is short stature, in approximately 90% of patients. Webbed neck, cubitus valgus and lack of puberty are very characteristic for TS patients. These symptoms were described by H. Turner in his report on the syndrome. Many other features combined with this syndrome were found in the following years.

The most frequent manifestation of Turner syndrome, as mentioned above, is short stature and characteristic body proportions with a wide body, short legs, and relatively large hands and feet (Gravholt and Naeraa 1997). Gonadal failure occurs in approximately 90% of patients, and the majority of them has delayed or lack of spontaneous puberty. Nevertheless, 2–5% of patients have a chance of a normal pubertal development and fertility (Hovatta 1999). In a newborn or an infant, lymphatic edema of the hands and/or feet is very characteristic of Turner syndrome. Other typical features present in TS patients are: nuchal folds, low posterior hairline and nail abnormalities. Nails are hypoplastic, uplifted and hyperconvex. Multiple pigmented nevi are often present on the skin. Patients with TS have characteristic faces with epicanthal folds, hyperthelorism, low set ears, small mandible and high arched palate. Typical skeletal abnormalities for Turner syndrome are shortened fourth metacarpal bones (Fig. 100.1) and cubitus valgus. Scoliosis is more frequent than in normal population. A relatively common manifestation is recurrent, or chronic otitis media, and hearing disorders. Very characteristic are cardiac anomalies, especially left heart hypoplasia, coarctation of the aorta and bicuspid aortic valve. Cardiac manifestations occur in approximately 30% of patients with TS. Kidney anomalies are also more frequent in Turner syndrome girls than in the normal population. Typical malformations are horseshoe kidneys, malrotation of kidneys, other positional abnormalities, and aplasia or hypoplasia of the kidney. Most patients with TS have normal intelligence and only fewer than 10% of them have mild developmental delay. A detailed description of abnormalities characteristic of Turner syndrome is summarized in Table 100.1.

100.1.5 The Genotype–Phenotype Correlation

It has already been established that some symptoms are more characteristic for certain karyotypes in Turner syndrome. In the newborn with a pure monosomy of 45,X one can expect a congenital lymphedema of hands and/or feet. Mosaicism gives the patient a chance for a spontaneous puberty and fertility, especially in women with a mosaicism for 45,X/47,XXX (Sybert 2002). The isochromosome i(Xq) increases the risk for autoimmune diseases: hypothyroidism or bowel inflammatory disease (Elsheikh et al. 2002). A ring X chromosome (rX) is considered as associated with a mental retardation. Nevertheless the prediction of symptoms according to the classic karyotype in many cases is not completely reliable, because of a variable contribution of abnormal cell lines in different tissues and organs.

Fig. 100.1 Shortened fourth metacarpal bone in the patient with Turner syndrome

100.1.6 When Is Turner Syndrome Diagnosed?

Early diagnosis is made in 20–30% of patients soon after the birth, usually because of characteristic features: lymphedema of hands and/ or feet, or a webbed neck. The next 30% receive the diagnosis in midchildhood, due to the diagnostics of a short stature. The other 20–30% of patients are diagnosed as teenagers because of absent or delayed puberty. The remaining are diagnosed as adults -because of infertility, recurrent pregnancy loss, or secondary amenorrhea (Table 100.2).

100.1.7 Anthropometric Indices Useful in the Diagnosis of Turner Syndrome

Anthropometric indices may be very useful in the diagnosis of Turner syndrome, especially at midchildhood and adolescence. In any female with unexplained growth deficiency or delayed puberty the Turner syndrome should first be ruled out. The presence of other anthropometric features typical of TS, like obesity, shield-like chest, stocky build, relatively short legs, make the diagnosis very likely. Children with Turner syndrome have a characteristic pattern of body

Table 100.1 Abnormalities in patients with Turner syndrome

Growth and body building	Growth deficiency
	Short, webbed neck
	Broad chest
	Short legs
	Obesity
Skeletal manifestation	Cubitus valgus
	Shortened fourth metacarpals
	Scoliosis
Craniofacial manifestation	Flattened cranial base angle
	Marked reduction of posterior cranial base length
	Retrognathia
	Narrow maxilla
	High, arched palate
	Micrognathic mandible
	Crowded teeth
Sexual development disorders	Sexual infantilism
	Gonadal dysgenesis
	Hypoplastic nipples
Lymphatic system abnormalities	Lymphedema of hands and feet
Skin manifestation	Low posterior hairline
	Hyperconvex, uplifted nails
	Pigmented nevi
Ear abnormalities	Low set, dysplastic, rotated ears
	Otitis media
	Conductive/Sensorineural hearing impairment
Renal and urinary system abnormalities	Horseshoe kidney
	Malrotation of a kidney
	Duplication of collecting system
Cardiovascular anomalies	Left heart hypoplasia
	Coarctation of the aorta
	Bicuspid aortic valve
	Hypertension
Metabolic disorders	Glucose intolerance
Autoimmune and inflammatory disease	Hypothyroidism
	Celiac disease
	Iuvenile arthritis
	Inflammatory bowel disease
Mental development	Deficits in visuospatial organisation
	Nonverbal memory deficits
	Attention deficit hyperactivity disorder (ADHD)

proportions. The evaluation of the morphogram of the body is very helpful in the detection of typical changes. The standardization of measurement values should be calculated according to the data of a normal female population of the same ethnic origin. The evaluation of each parameter for chronological age and simultaneously for height age is very useful. The altered body proportions in TS girls seem to be more evident on morphograms calculated for height age (Table 100.3). (Compare the exemplary morphograms of the same, untreated girl, at the age of 8 years, standardized for chronological age (Fig. 100.2) and height age (Fig. 100.3)).

Reminder: a height age is the age for which the patient's height is on the 50th percentile.

Table 100.2 A typical causes of diagnosis of Turner syndrome at a different age

The age of diagnosis	Suspicious symptoms/the reason for karyotyping
Prenatal period	Fetus edema in USG
	Abnormal maternal triple screening/advanced maternal age
Newborn	Puffy hand and feet
	Webbed neck /redundant nuchal skin
	Hypoplastic left heart
	Coarctation of the aorta
Midchildhood	Short stature
Adolescence	Lack or delayed puberty
Adulthood	Secondary amenorrhea
	Infertility
	Recurrent miscarriages

Table 100.3 The comparison of anthropometric data standardized for chronological and height age in a patient with Turner syndrome. Additional data for Figs. 100.2 and 100.3

Antropometric parameters	SDS value normalized for chronological age	SDS value normalized for height age
Weight [SDS]	0.6	2.3
Height [SDS]	–1.9	0.0
Chest circumference [SDS]	1.5	3.0
Head circumference [SDS]	–0.4	0.1
Trunk length [SDS]	0.3	1.5
Leg length [SDS]	–3.0	–1.2
Biacromial diameter [SDS]	–1.1	0.3
Chest width [SDS]	1.0	2.3
Chest depth [SDS]	1.4	2.5
Biiliacal diameter [SDS]	–0.4	0.8
Upper arm circumference [SDS]	1.3	2.6
Arm length [SDS]	–2.4	1.1
Body mass index [SDS]	1.5	2.0

100.2 Natural Physical Development in Turner Syndrome

100.2.1 Height

Anthropometric data indicate that the final short stature in Turner syndrome is the result of the mild intrauterine retardation, slow growth during infancy and childhood, and lack of a pubertal spurt.

In a newborn with Turner syndrome the average birth size is lower by about 1 SDS (standard deviation score) (Ranke et al. 2002). During childhood the growth velocity is below 10th percentile for age. Approximately half of the patients with TS will have fallen below the fifth percentile even as soon as 2 years of age. The difference between TS children and healthy girls becomes greater at the age of puberty. Body height is the shortest measure in Turner girls, and the adult height deficiency in untreated patients is approximately 20 cm below the average for a normal female population, what corresponds with approximately –3.75 SDS. The final height values in TS women display distinct ethnic and geographic differences. For comparison, data from a multinational survey of adult height in Turner syndrome showed an average value of 144.3 ± 6.7 cm (Ranke et al. 1988), whereas in Scandinavian origin patients with TS the final height was 147.2 ± 7.1 cm (Karlberg Albertsson-Wikland 1995; Rongen Westerlaken et al. 1997), and in patients from Hungary was 140.8 ± 6.93 cm (Bösze et al. 1980). The differences according to karyotypes were not so strongly evident, but some studies suggest that patients with 46,X,delX(q) were significantly taller (Cohen et al. 1995).

100.2.2 Body Proportions

The body proportions in Turner girls, as well as in normal children, change with the age. This process is dependent on many factors. Among them, the most important seem to be hormonal factors: growth hormone, thyroid hormones, sex steroids secretion and function. The secretion of growth hormone in Turner syndrome is normal, but the production of gonadal steroids is impossible in the majority of patients. Furthermore, the sensitivity to growth hormone and sex steroids could be variable in Turner children. These factors lead to alterations of body constitution in TS patients.

Table 100.4 Key points of Anthropometric indices suggesting Turner syndrome

Height below 5th percentile for normal female population
Growth velocity below 10th percentile for the chronological age
Head circumference appropriate for a chronological age
Leg length [SDS] decreased more, than height [SDS]
A striking difference between height [SDS] and head circumference [SDS]

Data in several studies about the body proportions in Turner syndrome are not consistent. The first report considering adult patients showed that TS women without any growth- promoting treatment had reduced height with short extremities (Park 1977), but Varrela and coworkers did not find any significant alteration in body proportions (Varrela and Vinkka 1984). The next studies revealed that females with TS have growth deficiency along the longitudinal axis, and horizontal measurements are comparable to healthy female population. The body proportions were variable, but in shorter women the sitting height was taller. The same correlation was found in menstruating women (Gravholt and Naeraa 1997).

In conclusion: in adult women with Turner syndrome the height, sitting height, and arm-span may be reduced by 3–4 SDS. Size of hands and feet is usually reduced to a lesser extent. Biacromial and biiliacal diameter are comparable to the values in healthy women. Head circumference is equal to that in a reference population (Table 100.4).

According to anthropometric data, the significant difference between height SDS and head circumference SDS was proposed as an auxiliary marker diagnostic for Turner syndrome. Its usefulness was confirmed in children (Eggert et al. 1990) and also in adult patients with TS (Gravholt and Naeraa 1997). But it was not clearly established what amount of difference should be considered as significant.

The changes in body proportions in a TS patient before a final height achievement were investigated by the Dutch Growth Hormone Working Group (Rongen Westerlaken et al. 1993). According to their data, in early midchildhood the mean sitting height in TS children may be normal, but thereafter the trunk growth becomes slower, and at the age of 16 years is deviated from the normal mean value by –3.4 SDS. In the adulthood it achieves approximately –2.4 SDS. Similar changes were observed in leg length. It also decreased for the period between 3 and 12 years of life and from approximately –2.7 SDS at the age of 3 years down to –3.6 SDS and next increased to –2.5 SDS in adulthood. The ratio of the sitting height to the leg length was 3.2 SD above the normal mean value at the age of 3 years. Thereafter the ratio systematically rises to normal percentiles and reaches at the age of 15–18 years 0.6 SD, and again increases to 1.7 in adult patients with Turner syndrome. Similar results were reported by Gravholt and coworkers. Their study showed that the sitting height was approximately 10 cm below the averages, which corresponds to –3.69 SDS. The size of hands and feet was slightly smaller (to approximately –1.5 SDS). Arm-span was reduced almost exactly as much as height, to –2.9 SDS (Gravholt Gravholt and Naeraa 1997).

100.2.3 Body Composition in Turner Syndrome

Patients with Turner syndrome have a predisposition to obesity. Glucose metabolism is often altered in TS, and type 2 diabetes is seen frequently in adults, but insulin resistance has been reported as early as childhood (Caprio et al. 1991). Body mass index (BMI) and fat mass (FM) have been found to be higher in adult TS patients in comparison to age matched controls, total lean body mass (LBM) is inappropriately low. The body composition is altered in TS patients and displays characteristic

Table 100.5 Key points of body composition in Turner syndrome

BMI tends to be increased in Turner syndrome
Visceral FM is increased
Trunk and appendicular LBM is decreased
TS patients have higher content of body water (%) and lower resistance (Ω)
In adults visceral fat and hepatic adipose tissue is increased
FM correlates positively with HOMA-index, insulin and leptin
In adult TS women BMI below 25 kg/m^2 and a waist/hip ratio less, than 0.80 are recommended

regional differences: increased visceral fat mass (FM) and decreased trunk and appendicular lean body mass (LBM) (Ostberg et al. 2005; Gravholt et al. 2006) (Table 100.5).

In young TS girls BMI is close to normal, but after the 9th year of age, mean BMI SDS progressively increase in relation to unaffected age matched girls. After 12 years it remains greater than in normal population, but the next BMI gain becomes slower (Blackett et al. 2000; Gravholt et al. 2005).

Girls with Turner syndrome have a reduced amount of subcutaneous fat on limbs, and a normal amount of subcutaneous fat on the trunk (Hanaki et al. 1993). TS patients have higher content of body water (%) and lower resistance (Ω), measured by bioelectrical impedance (Gravholt and Naeraa 1997). No statistically significant difference in the body composition dependent on karyotypes was found.

100.3 Anthropometric Indices in Evaluation of the Therapy of Turner Syndrome

100.3.1 Anthropometric Markers of the Effectiveness of Growth Hormone Treatment

In the clinical picture of Turner syndrome the growth hormone (GH) deficiency does not exist, but there is a kind of tissue hyposensitivity to GH. Since 1980 it is well established that growth hormone treatment improves the final height in Turner patients and it became a standard of care for girls with TS in many countries worldwide. Initiation of GH therapy is recommended in girls with Turner syndrome, when the height drops below the fifth percentile of the normal female growth charts. If necessary the GH therapy should be started as early as 2 years of age. Below this age the effectiveness of GH treatment is limited. The effect of GH therapy is dependent on the dose and age at the start of therapy. Higher doses and earlier start of therapy are correlated with a better effect and a higher final height (Ranke et al. 2000). A final height after GH therapy in most patients is now 150 cm and more (The Canadian Growth Hormone Advisory Committee 2005).

Anthropometric examinations should be performed at intervals of 3–6 months during GH therapy. It is a good tool for the evaluation of the effectiveness of GH treatment and individualization of dosing. On the other hand the safety of GH therapy is controlled by insulin-like growth factor-1 (IGF-1) levels, which should be within the normal range. The prolonged exposure to elevated IGF-1 levels theoretically may cause potential long-term adverse effects. Growth hormone therapy should be continued until a satisfactory height has been achieved, or until the bone age is above 14 years and the patient's height has increased less than 2 cm for last 12 months (Bondy 2007).

The highly variable effectiveness of GH treatment in TS is not fully understood and the individualization of therapy allows to optimize the balance of costs and potential risk of therapy.

Table 100.6 Key points of Anthropometric predictors of a good effect of a GH treatment

The distance between the patient's present height [SDS] and mean parental height SDS
Body weight at the start of GH therapy
Height velocity during the first year of therapy
Leg length SDS increase similar or more than height SDS during GH therapy
Proportion upper to lower part of the body (the smaller the better)

Prediction models rise by analyzing data from the Kabi International Growth Study (KIGS; Pharmacia & Upjohn, Inc, International Growth Database) (Ranke et al. 2000). It revealed, that the strongest predictors, which positively correlate with the height velocity in the first year of GH treatment are: the weekly dose of GH and injections frequency, the difference between the patient's present height [SDS] and mean parental height in SDS, body weight, and additional oxandrolone therapy. Chronological age was negatively correlated with the height velocity (Ranke et al. 2000).

According to the authors own experience, the best predicting anthropometric marker of GH effectiveness is the reduction of leg length deficiency equal or higher, than the reduction of height deficiency during GH treatment (Kucharska et al. 2007). This observation is in agreement with the results of other authors. In the study of Gravholt and coworkers, shorter patients had relatively taller sitting height (Gravholt and Naeraa 1997). Similar results were reported by Rongen Westerlaken (Rongen Westerlaken et al. 1993). Their study showed that in Turner syndrome the ratio of sitting height and leg length was negatively correlated with statural height. In taller girls the ratio was lower, though one may also conclude that the proportion upper to lower part of the body is a valuable anthropometric marker of GH sensitivity.

100.3.2 Anthropometric Markers of Insulin Resistance

Total and regional FM correlates positively with homeostatic model assessment- index (HOMA-index), and levels of insulin and leptin. Other measures of body composition did not correlate with biochemical markers of insulin sensitivity.

100.3.3 Alterations of the Body Composition in Turner Syndrome During Hormonal Therapy

Among many factors that influence the low LBM and increased FM in Turner syndrome the most important are hormonal changes (GH/IGF-1 axis, insulin, estrogens and androgens). In patients with Turner syndrome the alterations of body composition with regional differences are due to resistance to the anabolic effect of GH and IGF-1, as well as insulin, testosterone and estradiol sensitivity. The fact that the effect of growth hormone is augmented by sex steroids is well known for years. Measurement of fat mass and lean body mass is much better in the precise evaluation of the alterations during hormonal treatment than BMI. BMI changes were found to be unaffected by GH treatment (Blackett et al. 2000). However the increase of LBM and decrease of FM are valuable markers of the metabolic effect of GH (Table 100.6).

Oxandrolone and estrogens also influence the body composition. In patients treated with oxandrolone, sex hormone binding globulin (SHBG) increases and correlates negatively with measures of adiposity (Gravholt et al. 2006).

Gonadal failure is one of the most common clinical features of Turner syndrome. The estrogen therapy should be introduced at the normal age of puberty, or as closely as possible. Recent data suggests that the replacement therapy started at the age of 12 does not disturb the positive effect of GH treatment on a final height in girls with Turner syndrome (van Pareren et al. 2003, Bondy 2007; Gravholt et al. 2005) and decreases fat accumulation in the liver (Ostberg et al. 2005).

100.4 Practical Methods and Techniques

100.4.1 Anthropometric Measures in Turner Syndrome

100.4.1.1 The Conditions of Appropriate Anthropometric Examination in Patients with Turner Syndrome

Patients should be measured in the morning, in underwear, and obviously barefoot by the Harpenden stadiometer. Three height measurements should be obtained, and the average value should be calculated. Sitting height measurement should be also obtained and leg length should be calculated by subtracting sitting height from standing height (Table 100.7).

Biacromial and biiliac diameters, head, hip, waist and upper arm circumferences characterize the body constitution in patients well. Skin folds measurements are useful in the evaluation of the body composition.

100.4.1.2 The Measurements Evaluation

Weight, height, BMI and other parameters, if possible, should be calculated in standard deviation score (SDS) on the basis of the local references of contemporary normal female population.

The growth charts specific for Turner syndrome of contemporary population are not available.

The best known growth curve for TS was prepared by Lyon approximately 30 years ago (Lyon 1985). The use of this historical data may not be valid for contemporary populations, because of growth acceleration. Nevertheless this growth chart can be useful in making a decision about the necessity of growth hormone testing in Turner girls, whose growth is not consistent with the expected for TS pattern.

Table 100.7 Key points of the anthropometric examination in Turner syndrome

Anthropometric parameters of TS individual should be evaluated according to the data of contemporary normal female population of the same ethnic origin
Morphograms are a valuable tool for the evaluation of a body constitution
Parameters of body proportions should be calculated for chronological age and height age
A reminder:
Height age = the age, for which the patient's present height is on the 50th percentile

A good practice is the preparation of morphograms in examined patients (see Figs. 100.2 and 100.3). The SDS values should be calculated according the references of normal female population of the same ethnic origin and prepared for chronological age and height age. It allows comparison between all parameters and characteristic alterations are easily detectable.

Chapter 101
Polymorphisms in the Serotonin (5-Hydroxytryptamine (5-HT)) Type 2A Receptor (5-HTR2A) Gene, Other Related Genes and Anthropometry

Dolores Corella and Mercedes Sotos-Prieto

Abstract Serotonin or 5-hydroxytryptamine (5-HT) is a monoamine neurotransmitter, which helps to regulate many physiological processes such as sleep, appetite, eating disorders, thermoregulation, hormone secretion, mood, anxiety, etc. The serotonin and related genes, such as the 5-HT2A receptor gene (HTR2A), the 5-HT transporter gene (SLC6A4), the 5-HT2C receptor gene (HTR2C), or the 5-HT1A receptor (HTR1A) gene, are re-emerging as powerful candidates for studying the association between food intake and anthropometry. Variations in all of these genes need to be studied to better understand the effects of serotonin and its receptors on anthropometry. The most widely studied polymorphism is the −1438G>A (rs6311) in the regulatory region of the HTR2A. Despite the controversy in functional studies, it is suggested that the A allele is associated with decreased HTR2A expression. In epidemiologic studies, it has been reported that the A allele is associated with lower energy and macronutrient intake and, in association studies, with lower body mass index in obese subjects. Furthermore, a 44-bp insertion/deletion promoter region polymorphism (alleles L and S) in the serotonin transporter gene (SLC6A4) has been associated with greater body weight and obesity in those SS subjects. More controversy arises, however, regarding eating disorders. The −759C/T SNP in the HTR2C gene has been associated with weight changes after antipsychotic treatments. Patients with the −759T variant allele showed significantly less weight gain than those without the allele. These results, however, do not allow any definite conclusion to be drawn about the impact of genetic variation in the 5-HT-related genes on anthropometric variables and further studies are needed to gather more evidence on these associations.

Abbreviations

5-HT	5-hydroxytryptamine
5-HTTP	5-hydroxytryptophan
SLC6A4	Carrier family 6 neurotransmitter transporter, serotonin
HTTLPR	5-HTT gene–linked polymorphic region
VNTR	Variable number of tandem repeats
FTO	Fat mass and obesity associated
BMI	Body mass index

101.1 Introduction

Both increased energy intake and reduced physical activity have been major drivers of the current obesity epidemic. It has been estimated that, to return to the average weights of past decades in industrialized countries, the increased food intake would have to be reversed to about 500 cal a day for adults, or alternatively, similar results could be achieved by increasing physical activity by about 100 min (Swinburn et al. 2009). Although there are several ways to promote and increase physical activity (see the corresponding book chapters) with winning results, successful changes in food intake are more difficult to achieve. One of the reasons for this is the still incomplete knowledge that we have on the factors that determine food intake. Thus, one of the main lines of current research is the study of both genetic and environmental factors that influence food intake. This field is extremely complex because there are many processes involved, some of which are almost completely unknown, as is the case of the recently discovered fat mass and obesity-associated (FTO) gene that has now become the first gene to be regarded as a thoroughly replicated risk factor for obesity in dozens of epidemiological studies on different populations. Despite the fact that it has been consistently found in population studies that common variants in the first intron of the FTO gene define a risk allele predisposed to obesity, with homozygous subjects for this allele weighing approximately 3 kg more than homozygotes for the low-risk allele, the functional role of FTO in energy homeostasis remains elusive. Some studies have reported that the risk allele that confers a predisposition to obesity may play a role in the control of food intake and food choice, suggesting a link to a hyperphagic phenotype or a preference for energy-rich foods. However, the mechanisms behind this observation remain largely unknown.

Consistent results on the association between polymorphisms in the FTO gene and obesity-related measures in dozens of populations around the world have rekindled interest in investigating genes related to food intake. Among them, serotonin (5-hydroxytryptamine (5-HT))–related genes are re-emerging as powerful candidates. 5-HT is a monoamine neurotransmitter found in both the central and peripheral nervous systems, which contributes to the regulation of many physiological processes such as sleep, appetite, eating disorders, thermoregulation, pain perception, hormone secretion, mood, anxiety, and sexual behaviour. It is synthesized in the serotonergic neurons of the central nervous system and the enterochromaffin cells of the gastrointestinal tract (80–90% of the human body's total 5-HT), where it is used to regulate intestinal movements. Rapport et al discovered serotonin in 1948 while searching for vasoconstrictors causing hypertension and aptly named it for its presence in serum (sero) and its vasoactive properties (tonin). 5-HT is released into the synaptic junction and exerts its effect on specific receptors on the postsynaptic membranes. More details about biochemistry and physiology of 5-HT can be found in recent reviews (Jonnakuty and Grangnoli 2008; Garfield and Heisler 2009).

There are multiple genes related to the actions of 5-HT. The most important are the genes that codify for the different types of 5-HT receptors as well as the gene of the serotonin transporter. In this chapter, we will review the general functions of 5-HT related directly or indirectly with anthropometric measures, focusing on studies analyzing variations in the most important 5-HT-related genes. Taking into account the large number of variations reported, we will focus on the 5-HT receptor 2A (*HTR2A*) gene although some relevant variants in other genes will also be analyzed. To better understand the genetic concepts and association studies we also include a section on practical methods and techniques.

101.2 Biochemistry and Physiology of 5-HT and Its Receptors

Over 95% of 5-HT synthesis occurs in the enterochromaffin cells of the intestine and only a small fraction of total body serotonin is produced in the brain-stem neurons of the raphe nuclei. The precursor of 5-HT is the essential amino acid tryptophan (taken with the diet) that is converted into serotonin via a series of reactions (Fig. 101.1). First, the tryptophan is converted by tryptophan hydroxylase, which transfers the hydroxyl group to the benzyl ring of tryptophan, to 5-HTP (5-hydroxytryptophan). This reaction constitutes the rate-limiting step in serotonin synthesis. For this reaction, the cofactors oxygen and tetrahydropteridine are needed. The 5-HTP is converted into 5-HT by decarboxylation via the enzyme L-amino acid decarboxylase, together with the cofactors vitamin B6, B3, and magnesium. Serotonin synthesis in the central nervous system is influenced by the amount of plasma free tryptophan, which crosses the blood–brain barrier and competes with other neutral amino acids (aromatic amino acids) that have the same carrier. Serotonin degradation occurs in the intersynaptic space through the action of monoamino oxidase enzyme to form 5-hydroxyindole acetic acid (5-HIAA). Serotonin in the central nervous system is stored in secretory granules and released into a synapse. The removal of the neurotransmitter from the synaptic space occurs by re-uptake. The serotonin transporter (5-HTT, SERT, or SLC6A4) diminishes the function of 5-HT at its extracellular cognate receptor by removing 5-HT from outside the cell and bringing it back into a cell for metabolism via monoamino oxidase or vesicular repackaging.

Table 101.1 Families of the 5-HT receptors and main characteristics

Family	Main characteristics of the receptors
5-HT1	The 5-HT1 subfamily consists of 5 G-protein-coupled receptors (GPCRs), which are coupled to Gi/Go and mediate inhibitory neurotransmission. They include: 5-HT1A, 5-HT1B, 5-HT1D, 5-HT1E, and 5-HT1F. The 5-HT1A receptors are located at the presynaptic serotonergic neurons and postsynaptic nonserotonergic neurons and are the most widespread of all the 5-HT receptors. Studies carried out in mice showed a relation with increased anxiety and stress responses. Furthermore, the 5-HT1A receptors are associated with the opening of K^+ channels through a G-protein in the central nervous system and it is associated with the stimulation and inhibition of adenylcyclase.
5-HT2	The 5-HT2 subfamily consists of 3 GPCRs, which are coupled to Gq/G11 and mediate excitatory neurotransmission, including 5-HT2A, 5-HT2B, and 5-HT2C. The 5-HT2A is the main excitatory receptor subtype among the GPCRs. It was widely studied because it was the target of classic hallucinogens. Currently, the study of variations in the gene that codifies for this receptor has allowed its function to be linked to numerous disorders related with anthropometric variables. These associations will be detailed in the corresponding section. The 5-HT2B receptor has an important role in the regulation of cardiac structure and functions. The 5-HT2C receptor is rapidly regulated by 5-HT and it is important in the expression of anxiety, depression, and compulsive behaviours. Variations in its gene have also been widely studied and related to anthropometric variables.
5-HT3	This receptor is a member of the superfamily of ligand-gated ion channels. It consists of five subunits arranged around a central ion conducting pore. Its antagonists are used in the treatment of nausea and diarrhoea.
5-HT4	These receptors are GPCRs that stimulate cAMP production. They are located in the gastrointestinal tract, urinary bladder, heart, adrenal gland as well as the central nervous system and are involved in memory, cognition, feeding, respiratory control, and gastrointestinal motility.
5-HT5,5-HT6, 5-HT7	These receptors have been cloned in the last decade and more research is needed. 5-HT6 receptor could play a role in appetite and cognition as well as 5-HT5 in anxiety and motor control

At least seven different major families of receptors in the serotonin that mediate some of the effects of the serotonin (5-HT1-5-HT7) have been described. They are located both in the nervous system and peripheral organs. Furthermore, there are different subtypes in many of the major families of receptors. These have been divided into different families depending on their characteristics, such as, amino acid sequence, gene organization, and the system of signal transduction coupled to them (Hoyer et al. 1994). The main characteristics of each one are summarized in Table 101.1:

101.3 Serotonin Functions

5-HT has a wide range of physiological roles in the human body, involving various tissues (Jonnakuty and Grangnoli 2008; Garfield and Heisler 2009). The most directly related to anthropometry are the following:

- *Brain*: Serotonin is localized in the raphe nuclei of the brain stem where it is synthesized. As a central neurotransmitter, serotonin carries out an important role in the regulation of mood, sleep, body temperature, appetite and it is involved in numerous disturbances (anxiety, depression, headache, bipolar disturbance, etc). In terms of psychiatric disorders, there is compelling evidence on the implication of 5-HT in major depression, borderline depression (dysthymia) anxiety, obsessive–compulsive disorders, agoraphobia, etc. (Lowry et al. 2008). In general, too little brain 5-HT is linked to depression, anxiety, bulimia, bingeing, alcoholism, uncontrolled aggression, etc.

However, too much 5-HT may also be detrimental. 5-HT also controls appetite. The smell, sight, or expectation of food stimulates 5-HT release in the hypothalamus. As eating begins, 5-HT continues to increase until it registers in the hypothalamus as the experience of satiety. In comparison with other compounds that regulate food intake, 5-HT has been reported as more influential than other compounds. Generally, it has been demonstrated in animal models that the increase in 5-HT activity or availability will tend to reduce food intake, whereas decreasing 5-HT activity will tend to increase food intake. These changes are closely associated with changes in the concentrations of dopamine, another hypothalamic monoamine closely involved in the regulation of food intake. The pivotal role of central serotonin appetite is also strengthened by the evidence that drugs licensed to interfere with food intake in obese patients involve the serotonergic system.

- *Gastrointestinal tract*: Over 90–95% of peripheral serotonin is located in the enterochomaffin cells. By acting directly and via modulation of the enteric nervous system, 5-HT has numerous effects on the gastrointestinal tract. It is released in response to acetylcholine and increases internal motility. It also stimulates fluid secretion and provokes nausea and vomit by means of stimulating the sensory nerves in the stomach. Under normal conditions, 5-HT regulates the regular waves of gastrointestinal contractions that move food through the gastrointestinal tract. Underactivity or overactivity of the gut 5-HT system can produce symptoms of irritable bowel syndrome. The main gut disturbances in which 5-HT is involved are acute chemotherapy-induced nausea and vomiting. 5-HT also plays a role in the liver. In a diseased liver, 5-HT is involved in the progression of hepatic fibrosis and the pathogenesis of steatohepatitis.
- *Cardiovascular system*: Serotonin plays a role in vasoconstriction, vasodilatation, and vascular tone. Activation of the 5-HT1A receptor mediates central sympathoinhibition and bradycardia. In contrast, the 5-HT2A receptor mediates sympathoexcitation, which leads to a rise in blood pressure and tachycardia. In addition, 5-HT1B, 5-HT2A, 5-HT2B, 5-HT4, and 5-HT7 are present in vascular smooth muscle cells and modulate contraction and relaxation of blood vessels. 5-HT4 receptor is also present in cardiac myocytes, through which serotonin mediates chronotropic and inotropic effects. Cardiovascular dysfunction is observed when serotonin signalling is altered or when a variation in serotonin concentration occurs. Recent studies have provided evidence that, in the absence of peripheral serotonin synthesis, blood serotonin (which is almost exclusively stored in platelets) is markedly reduced, and that this drop leads to heart failure.
- *Glucose metabolism*: There are some controversial results on how 5-HT participates in glucose metabolism. In some studies it has been found that serotonergic agents, used for reducing appetite and body weight, have unexpected effects on peripheral glucose homeostasis regardless of food intake and body weight. Some evidence suggests that 5-HT may increase blood glucose. However, there are other studies that suggest a hypoglycaemic effect, but the mechanisms are not well understood. It has been suggested in rat and human skeletal muscle studies that the 5-HT2A receptor may mediate the effect through which serotonin leads to rapid glucose uptake. A recent study involving polymorphisms in the 5-HT2A and 5-HT2C lends further support to the involvement of serotonin in glucose homeostasis and the risk of type 2 diabetes (Kring et al. 2009).

101.4 Practical Methods and Techniques

Research into 5-HT biochemistry and its functions has been greatly improved by studying the genetic variability in the main related genes. In humans, genetic analysis has evolved from the unmeasured genotype approach, carried out in affected families, to the direct assessment of DNA-sequence variability in unrelated or related individuals. The simplest type of polymorphism, known as

single-nucleotide polymorphism (SNP), results from a single base mutation that substitutes one base for another. Other types of genetic polymorphisms result from the insertion or deletion of a section of DNA, which include microsatellite repeat sequences and gross genetic losses and rearrangement. SNPs are scattered throughout the genome and are found in both coding and noncoding regions. Nucleotide substitutions occurring in protein-coding regions can also be classified as synonymous and non-synonymous according to their effect on the resulting protein. A substitution is synonymous if it causes no amino acid change, while a non-synonymous substitution results in alteration in the encoded amino acid. The latter type can be further classified into missense and nonsense mutations. A missense mutation results in amino acid changes due to the change of codon used, whereas a nonsense mutation results in a termination codon. SNPs occur with a very high frequency, with estimates ranging from about 1 in 1,000 bases to 1 in 100–300 bases. The candidate gene strategy, based on well-established biochemical studies, has facilitated the discovery of scores of single-nucleotide polymorphisms (SNP) that can be easily determined at low cost, providing the opportunity to study a large set of SNP combinations. Although the majority of genetic studies have focused on SNPs, variation in the human genome is not only present in the form of SNPs. Recently, large-scale copy-number variations that involve gains or losses of several kilobases of DNA have been reported to be common in the general population. The association of these genetic variations with the 5-HT functions and anthropometry remains to be investigated. Moreover, genomic technology is moving toward genome-wide association studies (GWAs) where various thousands of SNPs are measured at the same time. This approach has allowed the discovery of new genes related to several diseases, among them the above-mentioned FTO, and will also help to reveal new genes involved in the 5-HT biochemistry and functions.

The SNP or SNPs in the candidate gene are analyzed by different methods, which include the classic restriction fragment length polymorphism (RFLP) technique, or the more high-throughput techniques, based on fluorescent probes. Later, statistical analyses are carried out to assess the association between the measured anthropometric phenotype (height, weight, body mass index, obesity, waist circumference, total body fat, etc.) and the SNP. Codominant, dominant, or recessive models of inheritance are tested to establish the effects. In some studies, associated polymorphisms (in linkage disequilibrium) are analyzed together by haplotype analysis. Statistically significant associations between the SNPs and the anthropometric trait are obtained through these statistical analyses. However, a statistically significant association does not imply a causal association and several complementary methods are required. Replication of the observed associations in other independent populations is a common practice to increase the validity of associations. However, it is also important to distinguish between functional variants (i.e., altering an amino sequence or a transcription factor-binding element, etc) and nonfunctional SNPs. It has been suggested that before inclusion in an epidemiological study, every SNP used should undergo a thorough functional study (mainly in *in vitro* gene expression transcriptomic assays). However, as these *in vitro* data may be difficult to obtain, some researchers have proposed several bioinformatic tools to infer functionality. Recently, several simulation programs have been designed to predict whether a non-synonymous SNP is likely to have a functional effect on the phenotype or not. However, caution about these *in silico* predictions has also been advised. One of the problems with the results obtained from association studies using nonfunctional SNPs (that in some cases act as markers of the unknown functional variant) is their different degree of linkage disequilibrium with the true functional SNP among different populations. Thus, a nonfunctional variant may have a different impact on association studies depending on the linkage disequilibrium with the functional polymorphism, so contributing to the lack of replication.

Although in the recent decades, the vast majority of studies on the genetic effects of 5-HT-related genes variations have focused only on one or on a very few number of SNPs, currently the simultaneous determination of several of these SNPs has allowed us to discover some so-called gene–gene

interactions. In such situations, the effect of an SNP on an anthropometric phenotype is not independent but is modulated by the other SNP studied. These gene–gene interactions contribute to increasing the explained variability of the genotypic effect.

Nevertheless, when studying anthropometric traits, it should be borne in mind that these traits are very complex and that environmental (nongenetic) factors also play a crucial role. Although for many years diseases have been classified as either genetic or environmental, currently it is widely accepted that even the so-called single-gene disorders develop from the interaction of both genetic and environmental factors. Thus, new studies taking place in the field should incorporate this gene–environment interaction approach. For example, when studying the effect of an SNP on 5-HT effects, it should be of great interest to obtain information about the dietary intake of the individuals, as it is known that low-fat diets cause hormonal swings that can disrupt the balance of 5-HT in the brain. Without enough dietary fat, levels of 5-HT could be low and can result in several alterations. Thus, the combined effects of different amounts of dietary fat intake and SNPs in candidate genes should be studied to obtain more complete information. Further details about how to integrate genes and environment into the study of specific traits can be found in this review (Corella and Ordovas 2005).

Taking into account the vast number of SNPs described in the various 5-HT-related genes, we will focus more closely on the 5-HT2A receptor gene, which has been the gene most frequently linked to anthropometric variables. However, considering the importance of other SNPs in other 5-HT-related genes, we also included a brief review of the effects of these genes in order to obtain a more complete picture.

101.5 Description of the 5-HT2A Receptor Gene

The 5-HT2A receptor gene (*HTR2A*, formerly *HTR2*) was one of the first human 5-HT receptor genes to be cloned. It is located in chromosome 13q14–q21 and contains three exons separated by two introns spanning 20 kilobases (kb) (Chen et al. 1992). It seems to have two alternative promoters, with a silencer element just downstream of the second promoter element. Four transcription initiation sites have been described, with similar initiation sites found in mouse and rat homologues (Chen et al. 1992). The structure of this gene, including the promoter region, introns and exons, as well as the main SNPs is shown in Fig. 101.2. The 5-HT2A gene is involved in important brain functions and is implicated in the cause and treatment of psychiatric disorder. Thus, disruption of *Htr2a* signalling in mice reduced inhibition in conflict anxiety paradigms without affecting fear-conditioned and depression-related behaviour, which could indicate that the 5-HTR2A has a specific role in modulating conflict anxiety. Moreover, *HTR2A* has been a candidate gene for studying eating disorders because of its influence on food intake. Thus, pharmacological studies have demonstrated lower activity of the 5-HTR2A in individuals with bulimia nervosa.

Dozens of polymorphisms in the *HTR2A* gene have been described. Among them the -1438G>A, T25N, I197V, A447V, H452Y, 102T>C, and S421F coding and noncoding SNPs are the most analyzed. Table 101.2 shows SNPs in this gene as well as their minor allele frequency in different populations. The SNPs that have been most often studied in this gene are the non-synonymous or missense polymorphisms because of the high likelihood of a deleterious effect on protein structure and function. However, their impact in the HTR2A function has not been widely studied. Of particular interest are two common SNPs that are in almost complete linkage disequilibrium with each other: a variant close to the promoter region (–1438A>G) and a silent variant in exon 1 (102T>C). The –1438A>G SNP lies upstream of the promoter region of *HTR2A* and might affect expression by

altering promoter function. The functionality of this SNP has been investigated in various studies with conflicting results. Spurlock et al. (1998) carried out a functional analysis using a luciferase assay. Although basal promoter activity in both the A and G variants in the *HTR2A* was found, no significant differences in basal activity between those variants were noted in HeLa cells (epithelial cells derived from adenocarcinoma). Moreover, when promoter activity was induced by cAMP acid protein kinase C–dependent mechanisms, no differences were found. Five years later, Parsons et al. (2004) pointed out that one of the limitations of these assays carried out by Spurlock et al. (1998) to test the functionality of the –1438A>G SNP was that the constructs used did not take into consideration the more downstream promoter and employed only a single reporter gene vector. Taking into account the limitations of the work of Spurlock et al. (1998), Parsons et al. (2004) aimed to test the functionality of the –1438A>G SNP by employing an adequately designed expression system.

They tested the influence of a downstream enhancer in the construct design and employed three human cell lines (SH-SY5Y cells, epithelial cells derived from neuroblastoma; HeLa cells; and IMR-32 cells, fibroblast cells derived from neuroblastoma), using two reporter gene assays. They obtained very interesting results: the differences in expression of the A and G alleles were small in absence of the downstream enhancing element, while in the presence of the downstream enhancer large differences in expression between both variants were detected. Thus, the authors concluded that the *HTR2A* –1438A/G SNP might be a functional SNP in which the presence of the A allele significantly increases promoter activity in comparison with the G allele. However, this difference may be masked by some conditions related to the presence of transcription factors. Three years later, Myers et al. (2007) investigated several SNPs in the *HTR2A* gene promoter including the -1438A/G, -1420C/T, and -783A/G and carried out functional analyses using a luciferase reporter assay, as well as quantitative real-time polymerase chain reaction in a set of human fibroblast cell lines. Given that -783A/G and -1420C/T were in linkage disequilibrium with -1438A/G, they examined the promoter activity of putative haplotypes. In vitro reporter assays, using full promoter construct showed that the -1438A/G polymorphism, when expressed with the major allele at -1420 and -783 loci, did not significantly alter promoter activity. When the minor allele at -783 was expressed with the -1438A/G polymorphism, however, promoter activity was significantly altered. These results suggested possible gene–gene (epistasis) interactions between both variants and indicated the importance of determining the -783A/G SNP in epidemiological studies aimed at assessing the association between the -1438A/G polymorphism and phenotypical traits. Taken together, the G allele of the -1438 A>G polymorphism is supposed to reduce 5-HT2A receptor density or functional availability in the brain. This reduction seems more evident under certain genetic or epigenetic conditions.

101.6 Description of the 5-HT Transporter Gene

The serotonin transporter, also called *SCL6A4* (solute carrier family 6 neurotransmitter transporter, serotonin) (*5-HTT* or *SERT*), a sodium-dependent transporter located in presynaptic neuronal membranes, is a key determinant of brain 5-HT function as it controls 5-HT availability at postsynaptic receptors through high-affinity reuptake of released 5-HT into presynaptic terminals for metabolism via MAOA or vesicle repackaging. It allows neurons, platelets, and other cells to accumulate the chemical neurotransmitter serotonin. Some studies have shown that changes in serotonin transporter metabolism appear to be associated with many different phenomena, including alcoholism, obsessive–compulsive disorder, clinical depression, hypertension, and other diseases. The *SLC6A4* is found on chromosome 17 at location 17q11.1–q12 with 15 exons separated by 14 introns. Several genetics variations in this gene have been described. Table 101.3 shows several SNPs in this gene as well as their allelic frequencies in different populations. One that has been widely studied is the 44 bp insertion/deletion mutation in a region of the *SLC6A4* promoter (known as the 5-HTT gene–linked polymorphic region or 5-HTTLPR). Researchers commonly report it as having two functional alleles, a short (S) and a long (L) one, that correspond to the presence of 14- or 16-repeat units of a 20–23 bp incomplete repeats, but it can be subdivided further. Associated with this region are two SNPs, rs25531 and rs25532. Some *in vitro* studies have found that the long allele (LL) results in higher serotonin transporter mRNA transcription and increased 5-HT uptake in the brain compared to the SS or SL. Other SNPs that have been described in this gene are the STin2 (a variable number of tandem repeats (VNTR)) in the functional intron 2, which involves two major alleles (termed STin2.10 and STin2.12) that correspond to 10- or 12-repeat units of the 17bp VNTR, the G56A on the second exon and the I425V on the tenth exon.

101.7 Description of the 5-HT2C Receptor Gene

The 5-HT2C receptor gene (*HT2RC*, formerly *HTR1C*) is located in Xq24. Its location makes haplotypic analysis difficult because of genetic heterogeneity between males and females. It was previously thought that it belonged to the '5-HT1-like' family; however, it exhibits considerable sequence homology with the 5-HT2A binding site and is coupled to the same second messenger system. It has six exons and five introns and spans approximately 1.4 kb. The *HT2RC* is a key contributor in controlling central dopamine functions and may play an important role in the aetiology of mental disorders. Yuan et al. (2000) screened the upstream region of the *HT2RC* gene and identified 3 SNPs (G>A at -995, C>T at -759, and C>T at -697) and a (GT)n dinucleotide repeat polymorphism at -1,027. They also carried out a luciferase reporter assay to test functionality and found significant differences between haplotypes. The haplotypes containing the minor alleles could be associated with higher transcription levels of the gene. Another widely studied SNP (rs6318) involves an amino acid change Cys23Ser. Table 101.3 summarizes some SNPs in the *HT2RC* indicating the minor allele frequency in different populations. Evidence shows that the antagonism of 5-HT2C receptor can result in higher food consumption while the 5-HT2C agonist could lead to

anorexic behaviour. The most relevant SNP regarding anthropometric studies is the -759C/T (rs3813929), which is associated with increased transcriptional levels of the *HT2RC* and may confer resistance to obesity and Type II diabetes.

101.7.1 Description of the 5-HT1A Receptor Gene

The 5-HT1A receptor is codified by the *HTR1A* gene. It is located at 5q11.2-q13. It is intronless and only has one exon. The HTR1A receptor plays a key role in regulating the activity of the serotonin system and mediates serotonin actions on mood and emotion. Presynaptic 5-HTR1A receptors are especially important as key effectors of a negative autoregulatory loop that inhibits the activity of serotonergic neurons. Studies carried out on receptor-deficient animal models showed behaviours related to increased anxiety and stress response. There are several human polymorphisms in this gene with different frequency depending on the population (Table 101.3). The most widely investigated SNPs are C-1019G (rs6295), C-1018G, Ile28Val (rs1799921), Arg219Leu (rs1800044), and Gly22Ser (rs1799920). Some of the other SNPs are Pro16Leu, Gly272Asp, and the synonymous polymorphism G294A (rs6294). These gene variants have been studied in relation to psychiatric disorders with no definitive results.

101.8 Associations Between the *HTR2A* Gene Variation and Phenotypes Related with Anthropometry

The most widely studied polymorphism in association studies is the -1438G>A (rs6311) in the regulatory region. This SNP is in complete linkage disequilibrium with the 102T>C SNP and occurs within the European population at a frequency of about 50%; this frequency, however, is lower in the Sub-Saharan African population (Table 101.2). Although several studies have examined the potential association between the -1438 A allele and a greater risk of anorexia, a few studies have also shown an association with direct anthropometric measures (such as weight, height, body mass index, obesity, waist to hip ratio, etc). As pointed out before, investigation on the functional effects of -1438 A/G showed that this SNP has the potential to modulate HTR2A promoter activity. However, results have been controversial and context dependent (gene–gene interactions of other modulations). In general, it has been shown that promoter activity was greater with the A allele than in the G allele (Parsons et al. 2004). In the following sections, we show the main associations of this SNP and others related with the above-described genes. We have grouped studies together depending on whether the examined phenotype involves anorexia or bulimia nervosa or other phenotypes such as body-mass index, obesity, etc.

101.8.1 Associations Between the -1438 G>A SNP in the HTR2A Gene and Eating Disorders (Anorexia Nervosa and Bulimia Nervosa)

Genetic research into eating disorders is of great importance in evaluating possible relationships between genetics and different eating disorder phenotypes. Serotonin reduces food intake and it could be involved in the aetiology of anorexia nervosa and weight regulation. In addition, drugs that

increase serotonergic transmission exert anorectic activity. Furthermore, 5-HT genes have been targeted in the study of bulimia nervosa, as it has been shown that 5-HT functioning is disrupted in patients with bulimia nervosa. This gene is, therefore, a candidate for studying the genetics involved in eating disorders, weight, and other anthropometries measures.

Anorexia nervosa, a psychiatric illness and eating disorder, is characterized by extremely low body weight (18.5–19% of BMI is considered low weight) and body image distortion accompanied by an obsessive fear of gaining weight, while bulimia nervosa is characterized by recurrent binge eating, followed by compensatory behaviours. The criteria for diagnosing anorexia nervosa and bulimia nervosa are established by the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) and the World Health Organization's International Statistical Classification of Diseases and Related Health Problems (ICD). Anorexia nervosa is characterized by a refusal to maintain body weight at or above a minimally normal weight for age and height (e.g. weight loss leading to maintenance of body weight less than 85% of that expected). Furthermore, the DSM-IV-TR specifies two subtypes of anorexia nervosa: restricting type and binge-eating type or purging type; similarly, there are two types for bulimia nervosa: purging type and non-purging type. Although it is very difficult to establish general and specific anthropometric measures for these diseases, several studies have characterized their own samples mostly in women where the prevalence is higher. For instance, Vaz et al. 2003 showed different anthropometric measures between different subtypes of anorexia nervosa and bulimia nervosa, to investigate whether there could be changes in the nutritional status of the patients depending on the type of disease (Table 101.4).

The -1438G>A polymorphism has been implicated in many diseases such as schizophrenia, alcohol dependence, obesity, and seasonal affective disorder but also with anorexia nervosa and bulimia nervosa. Although there are some studies that have found an association between the A allele of the -1438 G>A polymorphism and this disorder, additional studies did not confirm such associations. Possible explanations for the inconsistency of these findings may include ethnic admixture, inadequate statistical power, and genetic and clinical heterogeneity. In Table 101.5, we summarize the main characteristics of the studies, analyzing the association of the polymorphism in the promoter region of the 5-HT2A receptor with anorexia nervosa and bulimia nervosa. It is suggested that the A allele of the -1438G>A polymorphism could be associated with restrictive behaviour and may be involved in lower caloric intake and body weight. Furthermore, different studies have shown that the A allele of this SNP is more frequent in anorexic patients than in controls and also in individuals with

bulimia compared to controls. Rybakowski et al. (2007) found that A allele was associated with personality traits, which are more typical of patients with restrictive anorexia. That may point to the A allele as a greater vulnerability factor in restrictive-type anorexia nervosa than in other subgroups of patients with anorexia. In addition, the A allele could be related to high levels of weight and shape concern, as well as greater general eating disorders (Ricca et al. 2004). A study that investigated whether the *5-HT2A* polymorphism could influence energy and nutrient intakes in adolescents showed that the A allele was significantly associated with lower energy and with total monounsaturated and saturated fat intakes (Herbeth et al. 2005). Also, this group had previously reported that this polymorphism could influence food and alcohol intakes in overweight adults. That could explain the serotoninergic action in food intake as well as in eating disorders. On the other hand, in bulimia nervosa a significant association between bulimia nervosa and the G allele has also been reported. Bruce et al. (2005) found that GG homozygotes in women with bulimia are characterized by increasing impulsiveness. Consistent with that, it is speculated that within individuals with active bulimia, the GG genotype may act as a phenotype modifier (increasing susceptibility to impulsiveness and dysregulation of serotonin when is activated by bulimia symptoms. Furthermore, functional activity of the *5-HT2A* promoter and 5-HT2A receptor activation appears lower for the G allele and higher for A allele. However, there are also studies that have found no association between bulimia and the -1438G>A polymorphism, probably due to the sample size of the studies.

101.8.2 Associations Between the -1438G>A SNP in the HTR2A Gene and Body Mass Index and Obesity

Although multiples studies have examined the potential association between the -1438 A allele and anorexia or bulimia, its association with body mass index and obesity risk has not been studied to the same extent.

Aubert et al. (2000), in unrelated overweight subjects (180 women, 96 men; BMI = 33.3 ± 4.8 kg/m^2) from Paris and from the Stanislas Family Study (31 women, 49 men; BMI = 29.6 ± 3.1 kg/m^2), found that in the whole overweight population, the A allele was associated with lower energy intake, and that this specific allele was more significant in the patient sample from Paris, which had a higher body mass index. These results were further supported by the findings of Herbeth et al. (2005) in 370 children and adolescents drawn from the Stanislas Family Study showing that the A allele was significantly associated with lower energy (GG (BMI: 19.2 ± 2.7 kg/m^2): 9.35 ± 2.70 MJ/day; GA (BMI: 19.5 ± 3.1 kg/m^2): 9.02 ± 2.17 MJ/d; AA (BMI: 19.1 ± 3.1 kg/m^2): 8.61 ± 2.17 MJ/d) and with total monounsaturated, and saturated fat intakes (expressed in g/d). Rosmond et al. (2002) examined the association between the -1438G/A SNP and obesity-related variables in 84 unrelated Swedish men. Homozygotes for the -1438G allele had, in comparison with -1438A/A subjects, higher body mass index (26.9 ± 4.3 vs. 25.1 ± 3.5 kg/m^2, $p = 0.017$ respectively), waist-to-hip ratio (0.96 ± 0.06 vs. 0.92 ± 0.06, $p = 0.015$ respectively), and abdominal sagittal diameter (23.6 ± 3.2 vs. 21.9 ± 3.4 cm, $p = 0.039$) (Table 101.6). Serum leptin, fasting insulin, fasting glucose, and serum lipids did not differ among genotypes. The authors suggested that an abnormal production rate of the *HTR2A* gene product might lead to the development of abdominal obesity.

We carried out a case–control study including 303 obesity cases and 606 controls paired by gender and age (Sorlí et al. 2008) (Table 101.6). In this sample of Spanish subjects, we did not find a significant association between the -1438G/A SNP and obesity (BMI ≥ 30 kg/m^2). However, as previous works suggested an increase in the effect of -1438G/A SNP in subjects with higher overweight, we carried out a subgroup analysis in obese and nonobese subjects. We found that in the obese group, AA subjects had a lower body mass index than G allele carriers (35.2 ± 5.3 kg/m^2 vs. 37.5 ± 7.8 kg/m^2;

Table 101.6 Antropometric values in different studies according to 5-HT2A-1438 G/A genotypes

	AA	AG	GG

Hip (cm)	115 ± 12	120 ± 17		0.066
Ying et al. (2009)	**AA**	**AG**	**GG**	***P***
	(mean ± S.D)	**(mean ± S.D)**	**(mean ± S.D)**	
Age (overweight group, *n* = 210; vales expressed only for men) 43 ± 7.31 years				
BMI (kg/m^2)	26.2 ± 2.0	29.1 ± 2.4	31.5 ± 3.2	0.043
Waist (cm)	93.9 ± 6.4	100.7 ± 8.5	105.3 ± 8.0	0.038
Hip (cm)	102.6 ± 5.9	102.3 ± 8.0	106.2 ± 6	0.102
Waist to hip ratio	0.93 ± 0.06	0.95 ± 0.06	0.98 ± 0.06	0.045

P = 0.039; Fig. 101.3). Likewise, significant differences were also obtained in waist perimeter, this being lower in AA subjects compared to G allele carriers (105 ± 11 cm vs. 112 ± 17 cm; *P* = 0.011; Fig. 101.4). These associations remained statistically significant even after multivariate adjustment for gender, age, origin, education, alcohol consumption, tobacco smoking, and physical activity (*P* = 0.029 and 0.01 for body-mass index and waist perimeter, respectively). Conversely, these associations were not observed in the nonobese control group (Figs. 101.3 and 101.4). In another study carried out on Spanish children, the authors did not find any significant association between the -1438G/A SNP and anthropometric variables. Our results supported the hypothesis of a greater influence of the -1438G>A polymorphism in the serotonergic system and anthropometric measurements in cases of greater BMI. Moreover, results from animal models demonstrate that obesity increases hypothalamic 5-HT2A receptor gene expression, and pharmacologic inactivation of 5-HT2A receptors inhibits overfeeding and obesity in mice (Nonogaki et al. 2006).

Ying et al. (2009) partially agreed with our findings. They studied 210 patients with overweight/obesity (27.9 ± 2.4 kg/m^2) and 216 unrelated healthy subjects (BMI: 22.6 ± 1.4 kg/m^2) and found that in overweight/obese men (BMI: 27.9 ± 2.4 kg/m^2), carriers of the G allele had statistically significant increased body mass index, waist circumference, waist-to-hip ratio, in comparison with patients carrying the A allele. However, the authors did not find significant difference between the -1438A>G genotype groups in overweight/obese women (Table 101.6).

Conversely, Kring et al. (2009), in a study carried out in obese men (*n* = 726) (BMI ≥ 30 kg/m^2) and in a randomly selected group of the same cohort of young men from Denmark, did not find any association between the 1438A>G SNP in the *HTR2A* gene and anthropometric variables (-1438G/A: BMI (kg/m^2): OR (95% CI) 1.01 [0.97–1.04], *p* = 0.70; Waist (cm): OR (95%CI):1.00[0.97–1.04], *p* = 0.81).

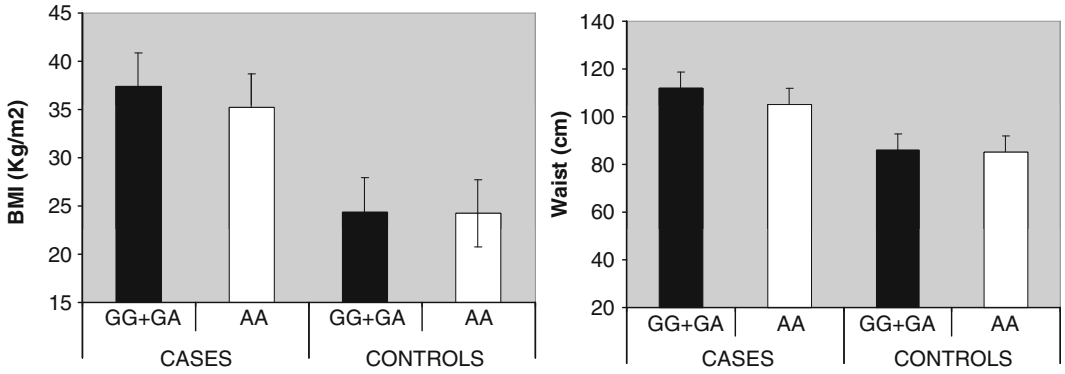

Fig. 101.3 Differences between case and controls BMI (kg/m^2) depending on the -1438G>A polymorphism in the serotonin 2A receptor gene. $^{*}P$ value for comparison between GG + AG and AA genotype for BMI (kg/m^2) in case subjects. $^{**}P$ value for comparison between GG + AG and AA genotype for BMI (kg/m^2) in control subjects

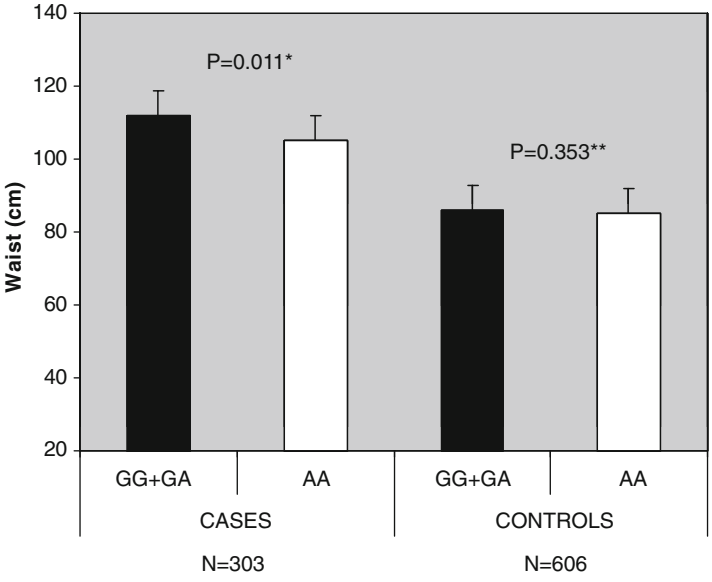

Fig. 101.4 Differences between case and controls waist circumference (cm) depending on the -1438G>A polymorphism in the serotonin 2A receptor gene. $^{*}P$ value for comparison between GG + AG and AA genotype for waist (cm) in case subjects. $^{**}P$ value for comparison between GG + AG and AA genotype for waist (cm) in control subjects

In general, association studies that have examined the effect of the 1438A>G SNP in the *HTR2A* gene on anthropometric measures have reported different results. The most replicated data suggest that the A variant allele is associated with a lower food intake (mainly in a recessive model) as well as with lower mean body mass index and waist circumference, but this association is only seen in subjects with higher BMI. These results could be supported by gene expression studies showing that the A allele was associated with lower receptor expression. However, these results do not allow us to draw any definite conclusion about the impact of the 1438A>G SNP in the *HTR2A* on obesity. Further studies are needed to provide more evidence on these associations.

101.9 Associations Between the SLC6A4 Gene Variation and Phenotypes Related with Anthropometry

The *SLC6A4* gene has also been studied in relation to eating disorders; however, the findings are still inconsistent. The variant that has been most studied is the functional length variation polymorphism (5-HTTLPR), which has functional implications. However, there is controversy over its association with bulimia nervosa. One study found that one or two copies of the short allele increased the risk sevenfold for bulimia, while subsequent studies did not find any association or even a higher frequency of long allele in women with bulimia and binge eating disorder. On the other hand, the short allele has been implicated in lowered dietary intake and decreased body mass index. Regarding anorexia nervosa, controversy over its association with this polymorphism in the promoter region is also expressed in different papers. In a study carried out by Matsushita et al. (2004), the short allele was related to lower dietary intake among subjects observed over 3 years or more, and the short allele frequency was significantly higher in those diagnosed with anorexia nervosa at eating disorder onset than in those diagnosed as anorexic later on, suggesting that the short allele might play some role in the development of anorexia among those with a prior eating disorder. However, Rybakowski et al. (2006) did not find a significant difference in the allelic frequency between anorexia nervosa patients and controls or personality dimension traits. This controversy could be due to the low samples size but also to uncertain diagnosis. Furthermore, a recent meta-analysis suggests the possibility that the L allele may be associated with obsessive–compulsive disorder in specific obsessive–compulsive disorder subgroups such as childhood-onset obsessive–compulsive disorder and in Caucasians (Bloch et al. 2008). Therefore, future research should continue to explore interaction effects in this SNP or other related ones by examining larger samples and also evaluating environmental factors that could be related to eating disorders.

Regarding the associations between the *SLC6A4* gene variation and obesity, recent results from animal studies have reported that depression-prone 5-HT transporter knockout (SERT(-/-)) rats had a strong increase (54%) in abdominal fat, in a sex-dependent way (observed in females but not in males), suggesting that SNPs associated with a decrease in the expression of the *SLC6A4* gene could confer a higher risk of increased abdominal fat formation in humans (Homberg et al. 2010). Some epidemiological studies analyzing the association between *SLC6A4* gene variation and anthropometric variables have reported results consistent with this hypothesis. Thus, one of the polymorphisms described in that gene consists of a 44-bp insertion/deletion in the promoter region yielding the so-called long (L) and short (S) alleles. In 1996, it was published that the short variant (S allele) reduces the transcriptional efficiency of the gene resulting in decreased 5-HT transporter expression in the neuron, a similar situation as that found in knockout (SERT(-/-)) rats. Sookoian et al. (2008) examined this polymorphism in a large sample of 1,329 adult men of European ancestry included in a population-based study in Argentina. They observed that the S allele was significantly associated with higher body mass index with codominant effects (LL: 25.4 ± 0.2, LS: 26.0 ± 0.1 and SS: 26.7 ± 0.2, $p < 0.0002$), and obtained a statistically significant odds ratio (OR) for obesity in SS carriers in comparison with LL carriers (OR and 95% confidence interval (CI): 1.32 and 1.01–1.85). These results, supporting the role of the LL genotype as a higher risk allele for obesity, were in agreement with a previous study undertaken by the same group in adolescents. These results are also in agreement with more than five studies in different populations showing a consistent association between the SS genotype and increased risk for depression. However, more studies and meta-analyses are needed to increase the evidence level.

101.10 Associations Between HTR2C Gene Variation and Phenotypes Related with Anthropometry

In 1995, Tecott et al observed that knockout mice for the *HTR2C* gene developed obesity. This gene has also been implicated in the regulation of feeding behaviour in animal models. However, the main role attributed to this gene is the modulation of weight gain in antipsychotic medications. The importance of the 5-HT system in psychiatric symptomatology and several side effects of antipsychotic drugs are well established. Weight gain is a frequently observed side effect of many antipsychotic treatments. Reynolds et al. (2003) investigated the influence of the –759C/T SNP in the *HTR2C* gene in weight changes in Chinese Han patients with first-episode schizophrenia after 6 weeks of clozapine treatment. The authors found that the patients with the –759T variant allele showed significantly less weight gain than those without (–759T allele (mean = 0.32 kg/m^2, SD = 0.68, vs. mean = 1.12 kg/m^2, SD = 0.88, $p < 0.05$). However, this study was undertaken in a small sample of patients and requires replication and further functional evidence. In this regard, gene-expression studies have reported controversial results. One of the most recent and complete studies assessed the activity of four promoter haplotypes expressed as luciferase constructs (Hill and Reynolds 2007). The presence of either -759T or -697C alleles reduced promoter activity, suggesting that resistance to weight gain in -759T patients may be mediated by reduced *HTR2C* gene expression. De Luca et al. (2007) carried out a meta-analysis of epidemiological studies investigating the influence of the -759C/T SNP in the *HTR2C* gene on weight gain after antipsychotic treatment. The authors identified 10 studies published between 2002 and 2005. The combined estimation showed a statistically significantly lower risk of weight gain associated with the -759T allele. However, there was evidence of significant heterogeneity among studies. Some further studies also supported this lower risk associated with the 759T allele, adding more evidence to this effect. More controversial is the association between this SNP and obesity in the absence of pharmacological treatment. Kring et al. (2009) studied the association between the -759C>T SNP and anthropometric and biochemical traits in Danish men. The authors did not find any association between this SNP and anthropometric variables. However, a significant association between the -759 T allele and impaired glucose tolerance and higher type 2 diabetes was found.

101.11 Associations Between *HTR1A* Gene Variation and Phenotypes Related with Anthropometry

Studies analyzing variations in the *HTR1A* have focused on major depressive disorder and other disorders (Savitz et al. 2009). The nexus between these disorders (including anxiety) and food intake and further obesity risk remains to be studied in well-powered and unbiased studies.

Summary Points

- Serotonin or 5-hydroxytryptamine (5-HT) is a monoamine neurotransmitter, which contributes to the regulation of many physiological processes such as sleep, appetite, eating disorders, thermoregulation, hormone secretion, mood, anxiety, etc., all of these processes being directly or indirectly associated with anthropometric measures.

- There are several genes related to 5-HT effects, among which the most important are: the 5-HT2A receptor gene (*HTR2A*) located at 13q14–q21, the 5-HT transporter gene (*SLC6A4*) located at 17q11.1–q12, the 5-HT2C receptor gene (*HTR2C*) located at Xq24, and the 5-HT1A receptor (*HTR1A*) gene, located at 5q11.2-q13.
- Several gene variations consisting of single-nucleotide polymorphisms (SNPs), insertion/deletion or tandem repeat variants have been described in all of these genes. The study of the association between genetic variations may help to better understand the effects of serotonin and its receptors on anthropometry.
- The most widely studied phenotypes related with anthropometry have been complex eating-related disorders including anorexia nervosa and bulimia, as well as direct anthropometric measurement such as body weight, waist circumference, height, body mass index, obesity, and percent of body fat.
- The most studied polymorphism is the -1438G>A (rs6311) in the regulatory region of the *HTR2A* that is in complete linkage disequilibrium with the 102T>C SNP. In epidemiologic studies, it has been reported that the A allele is associated with lower energy and macronutrient intake as well as with lower body mass index in obese subjects.
- Results from animal studies described that depression-prone 5-HT transporter knockout (SERT(-/-)) rats had a strong increase in abdominal fat, suggesting that SNPs, associated with a decrease in the expression of the *SLC6A4* gene, could confer a higher risk of increased abdominal fat formation in humans.
- In gene expression studies, a 44-bp insertion/deletion promoter region polymorphism (alleles L and S) was demonstrated to be functional with reduced expression in the S allele. Epidemiological studies have reported statistically significant body weight and higher obesity risk in SS subjects.
- The –759C/T SNP in the *HTR2C* gene has been associated with weight changes after antipsychotic treatments. It has been reported that patients with the –759T variant allele showed significantly less weight gain than those without the allele.
- However, these results do not allow us to draw any definite conclusion about the impact of genetic variation in the 5-HT-related genes on anthropometric variables and further studies are needed to provide more evidence on these associations.

Key Features

Table 101.7 Key points

– Genetic variation may play an important role in determining anthropometry. However, the identification of the candidate genes involved is still a work in progress. Among these, the serotonin (5-hydroxytryptamine (*5-HT*)) type 2A receptor (*5-HTR2A*) gene, and other serotoninergic genes have emerged as important candidates.
– Variations in the serotoninergic genes have been widely related to complex behavioral phenotypes such as anorexia and bulimia nervosa in addition to other psychiatric disorders. However, the evidence level is still low.
– Although some studies have found an association between the -1438G>A polymorphism in the regulatory region of the *HTR2A* gene and lower body mass index in obese subjects, more studies are needed to increase the consistency.
– To firmly establish the contribution of genetic variation in the serotoninergic genes to anthropometry, new studies including thousands of individuals and dozens of well selected functional genetic markers should be carried out. In addition, environmental modulations should be analyzed.

Part XVI
Anthropometry in Cancer

Chapter 102
Anthropometry and Thyroid Cancer Risk

Cari Meinhold Kitahara and Amy Berrington de González

Abstract Thyroid cancer is a relatively rare malignancy, accounting for less than two percent of all cancer diagnoses, but the incidence of thyroid cancer has risen dramatically over the past thirty years in many parts of the world. This increase in thyroid cancer incidence has paralleled the shift in the distribution of body weight over the same period. However, the only established environmental risk factor for thyroid cancer is ionizing radiation, particularly in childhood and adolescence. Until recently, there were relatively few epidemiologic studies of the association between body size and thyroid cancer. Evidence from early case–control studies suggested that greater body mass index (BMI) may increase the risk of thyroid cancer in women, and recent case–control and prospective studies suggest a similar positive association for men. Several epidemiologic studies have also suggested that height is associated with an increased risk of thyroid cancer. Although little is understood about the potential underlying mechanisms for the associations of anthropometric factors with thyroid cancer risk, thyroid-stimulating hormones and iodine status may play a role. Future studies with information on central adiposity, obesity-related biomarkers, and weight at different ages may provide greater insight into the etiology of this malignancy.

Abbreviations

BMI	Body mass index
HR	Hazards ratio
OR	Odds ratio
RR	Relative risk
T_3	Triiodothyronine
T_4	Thyroxine
TSH	Thyroid-stimulating hormone

102.1 Introduction

Thyroid cancer accounts for 1.3% of cancer diagnoses (approximately 141,000 incident cases) and 0.5% of cancer deaths (approximately 35,000 deaths) worldwide each year and is approximately three times more common in women compared to men (Parkin et al. 2005) (Table 102.1). Thyroid cancer is diagnosed at a relatively young age compared to other cancer types; for women the incidence peaks around age 50–54 and declines thereafter, while for men the incidence peaks much later, between ages 65 and 69 (SEER 2009). The main histological types are papillary, follicular, medullary, and anaplastic cancers, and each differ in terms of microscopic characteristics, incidence, prognosis, and, possibly, etiology. Of the cancers deriving from the follicular epithelium, papillary and follicular cancers are the most common, accounting for approximately 70% and 20% of all thyroid cancers, respectively, are well-differentiated, and have a very good prognosis, whereas anaplastic cancers account for less than 5% of all thyroid cancers, are non-differentiated, and have a much higher fatality rate; medullary cancers arise from the parafollicular cells of the epithelium (Ron and Schneider 2006). Although over 97% of thyroid cancer patients survive beyond 5 years after diagnosis (SEER 2009), the rapidly increasing number of incident cancers diagnosed worldwide over the past three decades has been cause for concern (Kilfoy et al. 2009). In the United States, particularly, the incidence has increased at a more rapid rate than any other cancer site, and thyroid cancer is now the seventh most common cancer in women (Enewold et al. 2009; Jemal et al. 2008).

One common explanation for these patterns is the more widespread use of sensitive diagnostic tools, which may detect very small papillary tumors of limited clinical significance (Parkin et al. 2005; Jemal et al. 2008). If improvements in detection were the sole explanation for the trends in thyroid cancer incidence, then a subsequent decrease in the incidence of larger tumors would be expected. However, larger and more advanced tumors have also increased in incidence during this time period, suggesting that environmental factors may also play a role in the rising number of thyroid cancer diagnoses over the past 30 years (Enewold et al. 2009).

Currently the only established environmental risk factor for thyroid cancer is exposure to ionizing radiation, particularly during childhood or adolescence (Ron and Schneider 2006). Consequences of the Chernobyl accident, for instance, included a steep increase in the number of papillary thyroid cancers diagnosed in Belarus and parts of Northeast Ukraine and Southwest Russia (Ron 2007). Greater knowledge on the health consequences of radiation has led to decrease in the use of radiation treatment for minor illnesses or conditions. Increases in medical radiation exposure including CT scans are unlikely to account for much of the increase in thyroid cancer risk, however (Berrington and Darby 2004).

Paralleling the rise in thyroid cancer incidence, an international 'epidemic' of obesity has been observed. In the United States, for instance, the proportion of obese adults increased from 15% to over 30% between 1980s and 2000s (Ogden et al. 2007). An adoption of 'western' behaviors, such as low physical activity and diets high in saturated fat and sugar, has certainly contributed to a shift in the distribution of body weight in less developed countries (Ogden et al. 2007). As the prevalence of obesity has increased worldwide, so has the importance of understanding its potential public health consequences and to identify individuals most at risk for obesity-related conditions.

In 2007, the World Cancer Research Fund/American Institute for Cancer Research published a review of the literature on obesity and cancer and concluded that there was convincing evidence of a causal association between obesity and cancers of the pancreas, colorectum, breast (postmenopausal), endometrium, and kidney, while "probable" and "limited" evidence existed in support of a causal relationship with gallbladder and liver cancers, respectively. The panel did not formally assess

Table 102.1 Key facts about thyroid cancer

1. Worldwide, there are approximately 141,000 new diagnoses and 35,000 deaths annually from thyroid cancer
2. The incidence of thyroid cancer, particularly papillary carcinoma, has increased in many countries worldwide since the 1970s. Recent studies suggest that this increase is not due entirely to improvements in detection or changes in diagnostic criteria
3. The prognosis for thyroid cancer is generally favorable. The 5-year survival is approximately 97%, and thyroid cancer incidence is approximately four-fold higher than thyroid cancer mortality
4. The female:male incidence ratio is typically 3:1. In the United States, thyroid cancer is now the seventh most common cancer in women and fifteenth most common cancer in men
5. The four main histological types (papillary, follicular, anaplastic, and medullary) differ in terms of microscopic characteristics, incidence, prognosis, and, possibly, etiology
6. The only established environmental risk factor for thyroid cancer is exposure to ionizing radiation, but iodine deficiency and a medical history of benign thyroid conditions, particularly goiter and thyroid nodules, are also consistently associated with thyroid cancer incidence

These key facts are based on the descriptive epidemiology and current information on the etiology of thyroid cancer

the level of evidence linking obesity with thyroid cancer risk, most likely due to the lack of prospective studies and a greater focus on more common cancer outcomes.

However, there is increasing evidence from epidemiologic studies in support of a role for anthropometric factors in thyroid carcinogenesis, particularly overall adiposity and height.

102.2 Observational Studies of Adiposity, Weight Gain, and Thyroid Cancer Risk

102.2.1 Case–Control Studies

Much of the evidence on the association between adiposity and thyroid cancer is based on results from case–control studies (Table 102.2). Some of these studies have also examined BMI or weight at different ages or periods in life (i.e., menarche), by age at diagnosis, and by sex, and all of these studies ascertained height and weight by self-report. However, if thyroid cancer patients experience disease-related weight loss or weight gain, or they tend to over- or under-report their height and weight compared to control participants, then the results from case–control studies may be biased estimates of the true relationship. Also, earlier case–control studies may have had limited power due to the lower prevalence of obesity.

In general, case–control studies have shown fairly consistent, though modest, positive associations between BMI and thyroid cancer risk (Fig. 102.1). An international pooled analysis, combining original data from 12 thyroid case–control studies, including 2,056 female and 417 male cases, showed an overall modest effect of BMI in women (highest versus lowest tertile, OR = 1.2, 95% CI: 1.10, 1.50, P-trend = 0.04) but no association in men (OR = 1.0, 95% CI: 0.80, 1.40, P-trend = 0.71) (Dal Maso et al. 2000). The results for women did not differ substantially by age at diagnosis or menopausal status. However, no association was observed with BMI in young adulthood (Dal Maso et al. 2000). A pooled case–control analysis restricted to medullary cancers ($n = 67$) showed a non-significant inverse association for BMI (highest vs. lowest tertile, OR = 0.65, 95% CI: 0.33, 1.28, P-trend = 0.23). More recently, a case–control study in New Caledonia found a positive association

Table 102.2 Case–control studies with information on anthropometric factors in relation to thyroid cancer risk, from the years 2000 through 2009

First author, year	Study period	Geographic location	No. cases/controls	Data collection (height/weight)	Adjustment factors
Dal Maso et al. (2000)*	Before 1998	USA, Japan, China, Sweden, Norway, Italy, Switzerland, Greece	M:417/965 F:2,056/3,358	Self-reported height and weight at age 17–20 and at diagnosis/pseudo-diagnosis	Age†, sex†, study†, A-bomb exposure and radiation dose (Japanese study)†, ethnicity (Hawaiin study)†, history of radiation
Guignard et al. (2007)	1993–1999	New Caledonia	M:39/58 F:293/354	Self-reported height and weight at diagnosis	Age†, sex†, year of diagnosis/reference, ethnic group, number of full-term pregnancies, miscarriages, irregular menstruations
Suzuki et al. (2008)	2001–2005	Japan	M:42/210 F:131/655	Self-reported height and weight at age 20 and at diagnosis	Age†, sex†, smoking, alcohol, family history of thyroid cancer, past history of thyroid diseases, total non-alcohol energy intake, hospital referral pattern, menopausal status, age at menarche, parity, hormonal replacement therapy
Brindel et al. 2009	1979–2004	French Polynesia	M:24/44 F:195/315	Self-reported height at interview and weight at age 18, 30, 40, 50, and at interview	Age†, sex†, height, ethnicity, education level, smoking, interviewer, radiation to head or neck for diagnosis before 15 years old, number of full-term pregnancies,

The case-control studies included in the table are the pooled analysis of 12 case-control studies Dal Maso et al. (2000), as indicated by the symbol *, which includes most case-control studies of anthropometric factors and thyroid cancer published prior to 2000, and three recent case-control studies not included in the pooled analysis. All studies collected height and weight information through self-report. As shown, these studies differed in terms of study period, geographical location, number of incident thyroid cancers, size of the study population, information available on body size, and covariates included in the analysis. The symbol † represents a matching factor

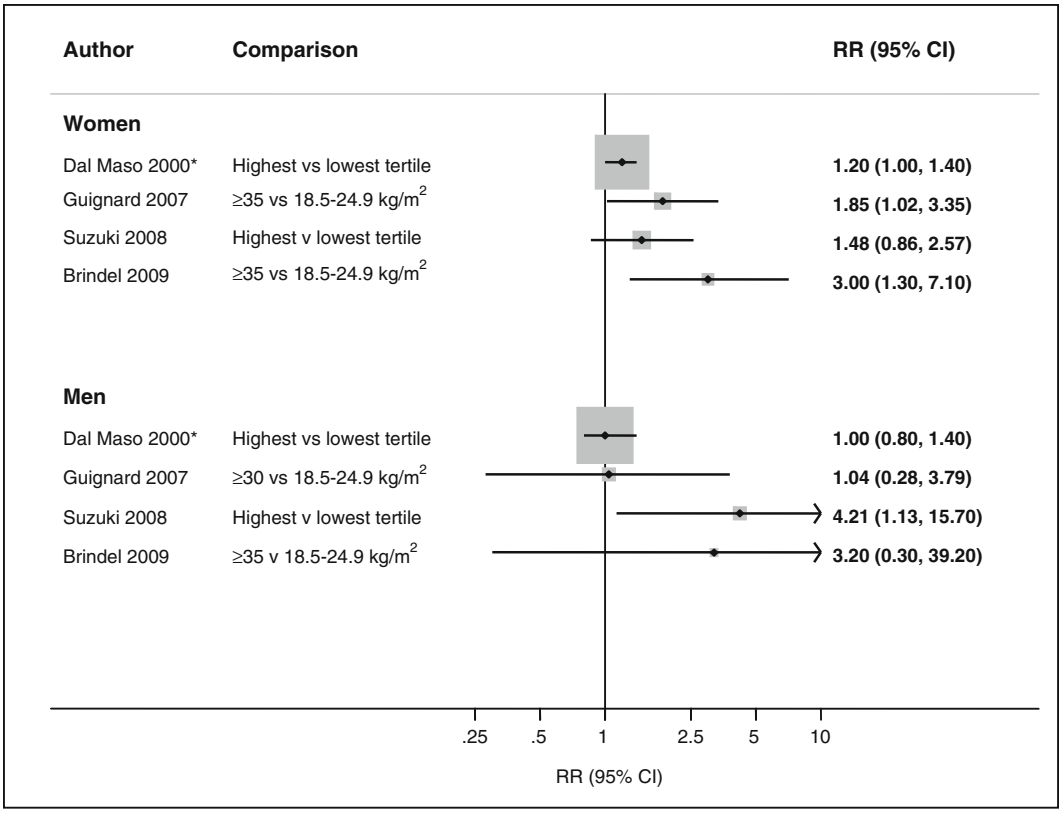

Fig. 102.1 Relative risks (RRs) of thyroid cancer according to highest versus lowest categories of body mass index (BMI) based on published data from case-control studies. The results are presented separately for women and men. In general, case–control studies have shown fairly consistent positive associations between BMI and thyroid cancer risk. While earlier studies showed stronger associations for women compared to men, more recent studies have also suggested a positive association in men. The * indicates the pooled case-control analysis (Dal Maso et al. 2009)

between BMI and thyroid cancer in women, particularly in women diagnosed over the age of 50 (≥35 vs. 18.5–24.99 kg/m^2, OR = 5.51, 95% CI: 1.49, 20.30); no clear associations were observed in men (Guignard et al. 2007).

Other recent case–control studies have suggested that the association may not be restricted to women (Suzuki et al. 2008; Brindel et al. 2009; Fig. 102.1). A Japanese case–control study found that BMI was positively associated with thyroid cancer risk in men only, particularly at younger ages, and greater weight both at age 20 and at diagnosis was associated with increasing risk in both men and women (Suzuki et al. 2008). Body surface area (calculated as (weight in kilograms)$^{0.425}$ × (height in meters)$^{0.725}$ × 0.7007184) was more strongly related to thyroid cancer risk in both men and women in this study, which suggests that BMI may not be the most appropriate measure of body fat in a Japanese population. A case–control study in French Polynesia showed clear associations between thyroid cancer risk and greater weight and BMI at age 18, 30, 40, and currently, both for men and women (Brindel et al. 2009). When the analysis was stratified by size of the tumor, it appeared that current weight and BMI were more strongly related to risk of smaller tumors, whereas weight and BMI at younger ages increased the risk of larger tumors. One possible explanation for this is that greater body size in young adulthood has a promotional effect on thyroid tumors, while thyroid cancers related to greater body size at older ages may result from greater surveillance and

detection. Although the number of thyroid cancers in these studies was small, particularly for men (Table 102.2), the latter two studies suggest that body size in both men and women and in early life and later adulthood may contribute to an increased risk of cancer.

102.2.2 Prospective Studies

Until recently, there have been few prospective studies on the association between obesity and thyroid cancer risk due to the relatively low incidence of thyroid cancer in the general population. These studies differ greatly in terms of size, geographic location, demographic characteristics, data collection, and information on important covariates (Table 102.3).

Although there are some inconsistencies, overall, the evidence is in support of a positive association between obesity and risk of thyroid cancer (Fig. 102.2). In a very large cohort of over two million Norwegian men and women, a positive association between obesity and thyroid cancer incidence was observed (BMI ≥ 30.0 vs. 18.5–24.9 kg/m^2: RR for women = 1.29, 95% CI: 1.13, 1.46; RR for men = 1.14, 95% CI: 0.82, 1.56) (Engeland et al. 2006). Positive dose–response associations were observed for well-differentiated thyroid cancers in women (RR for papillary cancer = 1.9, 95% CI: 1.01, 1.41, P-trend = 0.008; RR for follicular cancer = 1.63, 95% CI: 1.24, 2.15, P-trend = 0.002), but these associations were less clear in men (RR =1.11, 95% CI: 0.73, 1.69, P-trend = 0.05; RR = 1.66, 95% CI: 0.82, 3.37, P-trend = 0.05). The risk of anaplastic thyroid cancer increased with greater BMI, particularly in men (RR = 2.33, 95% CI: 0.88, 6.20, P-trend = 0.03). In contrast, an inverse association was observed in relation to medullary cancer, with the dose–response association being more evident in women (RR = 0.35, 95% CI: 0.16, 2.32, P-trend = 0.004). The Norwegian study had several strengths, including a large number of incident thyroid cancers in men and women (2,268 female and 778 male cases), nearly complete follow-up in the study area, and standardized measurements of height and weight. However, information on potential confounding factors, such as cigarette smoking and medical history of benign thyroid conditions, was not ascertained, potentially biasing these associations. A medical history of benign thyroid conditions, particularly of goiter or thyroid nodules, has been strongly related to the risk of thyroid cancer (Dal Maso et al. 2009). Also, weight gain is a common symptom of hypothyroidism, while weight loss is often observed in patients with hyperthyroidism (Fox et al. 2008). Current cigarette smoking is generally inversely related to both body weight and possibly also thyroid cancer risk (Mack et al. 2003), so inadequate control of smoking may bias the association between BMI and thyroid cancer risk in a positive direction.

A large prospective study of over 780,000 Korean men examined the relationship between obesity and risk of multiple cancers (Oh et al. 2005). In this study, BMI was associated with greater thyroid cancer risk (BMI 27.0–29.9 vs. 18.5–22.9 kg/m^2: RR = 2.23, 95% CI: 1.40, 3.55, P-trend <0.001). The magnitude of the association was the same after restricting the outcome to papillary thyroid carcinomas (RR = 2.23, 95% CI: 1.25, 3.99, P-trend <0.001). Based on these results and the prevalence of obesity in this cohort (defined as the standard cutoff in Asian populations, BMI ≥25 kg/m^2 (WHO 2000)), the population-attributable fractions of thyroid cancer from obesity were estimated to be 18% in the total population and 23% among never smokers alone.

Two large prospective studies, with 360,000 male Swedish construction workers (Samanic et al. 2006) and 204,964 men and women from San Francisco (Iribarren et al. 2001), showed no overall association between BMI and thyroid cancer risk. Considering that the Swedish cohort was relatively homogeneous in terms of socioeconomic status, it is unlikely that residual confounding by some poorly measured or unmeasured factor could account for the null results. The men were younger, on average, than men included in the Korean and Norwegian studies, but currently it is not

Table 102.3 Prospective cohort studies with information on anthropometric factors in relation to thyroid cancer risk, from the years 1997 to 2009

First author, year	Study period	Geographic location	Cohort	No. cases/study population	Data collection (height/weight)	Adjustment factors
Tulinius et al. (1997)	1968–1995	Iceland	Reykjavík Study	M:37/11,366 F:46/11,580	Measured height and weight at baseline	Age
Iribarren et al. (2001)	1964–1997	U.S. (San Francisco)	Kaiser Permanente Medical Care Program of Northern California (San Francisco or Oakland)	M: 73/94,549 F: 123/110,415	Measured height and weight at baseline and self-reported weight at age 20	Age, sex, race, education, smoking status, alcohol intake, self-reported personal history of hyperthyroidism, hypothyroidism, goiter, treatment of tonsils or neck region with X-rays, family history of thyroid disease, body mass index, weight gain, height, occupational exposures
Samanic et al. (2004)	1969–1996	U.S.	Veteran Affairs hospitals	M: 1,044/4,500,700	Discharge diagnosis of obesity (ICD8 = 277, ICD9 = 278.0)	Age, calendar year
Rapp et al. (2005)	1985–2002	Austria	Vorarlberg Health Monitoring and Promotion Program	M: unknown/67,447 F: 61/74,484	Measured height and weight at baseline	Age, smoking status, occupational group
Oh et al. (2005)	1992–2001	Korea	Korea National Health Insurance Corporation	M: 226/781,283	Measured height and weight at baseline	Age, smoking status, alcohol intake, regular exercise, family history of cancer, residence
Engeland et al. (2006)	1963–2003	Norway	Norwegian health surveys (linkage study)	M: 778/963,523 F: 2,268/1,037,424	Measured height and weight at baseline	Year of birth, age at measurement
Samanic et al. (2006)	1971–1999	Sweden	Swedish Foundation for Occupational Safety and Health of the Construction Industry	M: 171/362,552	Measured height and weight at baseline and follow-up examinations	Attained age, calendar year, smoking status
Sung et al. (2009)	1994–2003	Korea	Korea Medical Insurance Corporation (part of Korean National Health Insurance Corporation)	M: 43/449,214 F: 1,550/339,575	Measured height at baseline	Age, sex, body mass index, smoking, alcohol intake, regular exercise, monthly salary, occupation, area of residence, age at menarche, duration of breastfeeding, age at first child-birth, menopausal status, estrogen replacement, oral contraceptive use
Meinhold et al. (2010)	1983–2006	U.S.	U.S. Radiologic Technologists Study	M: 40/21,207 F: 242/69,506	Self-reported height and weight at baseline and during follow-up	Age, sex, birth year, smoking status, occupational and personal radiation exposure, history of benign thyroid conditions

The prospective studies included in the table had information on weight or height at entry into the study or hospital discharge records for obesity. As shown, these studies differed in terms of study period, geographical location, number of incident thyroid cancers, size of the study population, anthropometric information, and covariates included in the analysis

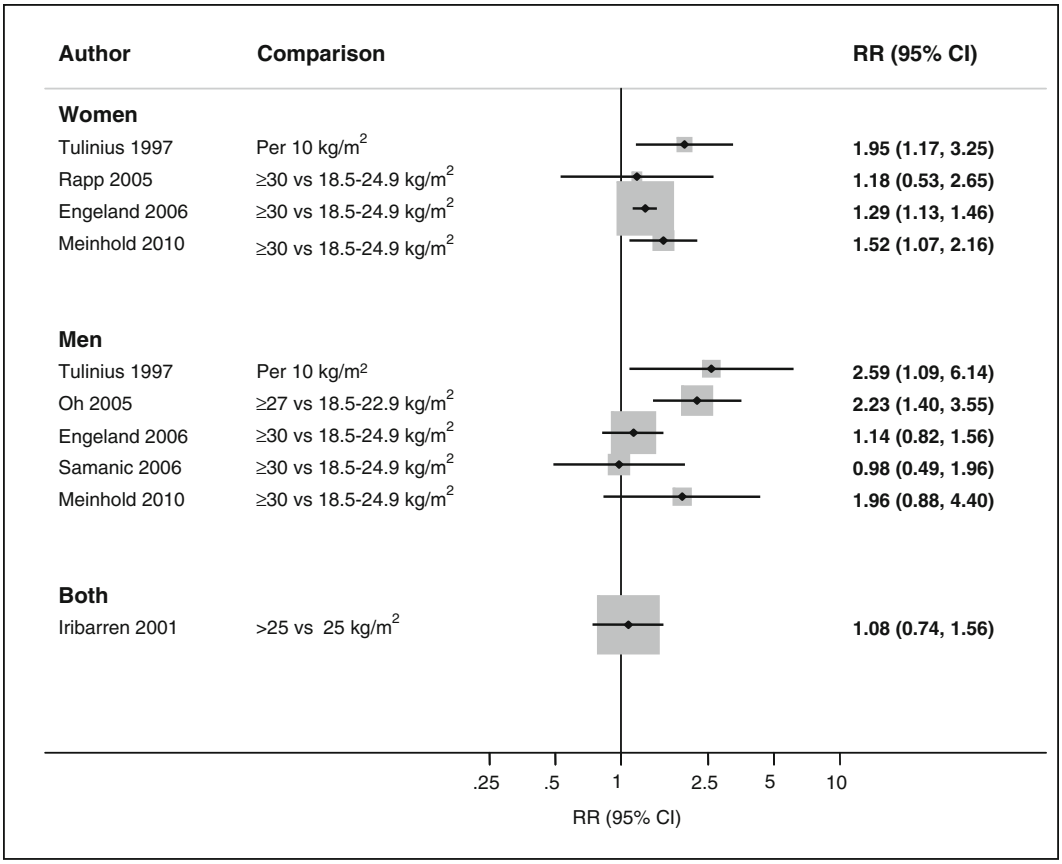

Fig. 102.2 Relative risks (RRs) of thyroid cancer according to highest versus lowest categories of body mass index (BMI) based on published data from prospective studies. The results are presented separately for women and men, where available. Although there are some inconsistencies, overall, the evidence is suggestive of a positive association between obesity and risk of thyroid cancer in both women and men

clear whether age modifies the association between body fat and thyroid cancer risk in men. The San Francisco study only compared participants with a BMI above or below 25 kg/m^2 and did not present results separately for each sex (Iribarren et al. 2001).

Two prospective studies had fewer than 100 incident thyroid cancer cases, limiting the interpretability of the results. One Icelandic study observed a relative risk of 1.1 (95% CI: 1.01, 1.20) for every 1-unit increase in BMI in men and 1.07 (95% CI: 1.02, 1.13) in women, but these results were only adjusted for age (Tulinius et al. 1997). Another small cohort did not show overall association between BMI and thyroid cancer in women, based on 61 incident cases; the number of male cases and the results for men were not presented (Rapp et al. 2005).

In a more recent prospective study of over 90,000 radiologic technologists in the United States, a positive association between BMI and thyroid cancer risk was observed for women (BMI ≥35.0 vs 18.5–24.9 kg/m^2: HR = 1.74, 95% CI: 1.03, 2.94, P-trend = 0.04) (Meinhold et al. 2010). The dose–response association was less clear in men (HR = 2.14, 95% CI: 0.60, 7.67, P-trend = 0.11); however, the number of thyroid cancers in the male participants was small (40 male vs. 242 female cases). Participants in this study were relatively young, with a mean age at entry of 43 for men and 39 for women. This study had information on established or potential thyroid cancer risk factors, including

personal and occupational exposure to ionizing radiation, medical history of benign thyroid conditions, cigarette smoking, and alcohol consumption. However, as this was an occupational group, the generalizability of these results may be limited.

One large prospective study used information from hospital discharge records to classify participants as being obese or nonobese (Samanic et al. 2004). Having a hospital discharge record for obesity was positively associated with thyroid cancer in a cohort of US veterans (RR for white men = 1.40, 95% CI: 1.09, 1.81; RR for black men = 1.92, 95% CI: 1.09, 3.40) (Samanic et al. 2004). However, some major limitations of this study included the potential for underestimation of obesity, as height and weight measurements were not available. Also, cancer diagnoses in this study were based only on inpatient records, and cancers diagnosed outside of the VA hospital system were not identified as cases. Additionally, obese patients may be under greater surveillance for other medical conditions than non-obese patients, which may have led to a greater detection of subclinical thyroid cancer in these individuals.

A recent systematic review and meta-analysis included five prospective observational studies of BMI and risk of thyroid cancer, not including the study using obesity discharge data from US veterans (Samanic et al. 2004) or the cohort in northern California (Iribarren et al. 2001). The pooled relative risk per 5 kg/m^2 increase in BMI was 1.33 (95% CI: 1.04, 1.69) for men and 1.14 (95% CI: 1.05, 1.22) for women (Renehan et al. 2008). The results from prospective studies suggest that the positive association is not restricted to women, as was observed in the pooled case–control study (Dal Maso et al. 2000).

102.3 Observational Studies of Other Anthropometric Measurements and Thyroid Cancer Risk

102.3.1 Weight Change and Thyroid Cancer

Several epidemiologic studies have examined the association of weight gain between young adulthood and middle-to-late ages with the risk of thyroid cancer. Weight gain was not associated with greater risk of thyroid cancer in the Japanese case–control study (Suzuki et al. 2008), the pooled case–control study (Dal Maso et al. 2000), or the large prospective study in San Francisco (>10 vs. ≤5 kg, RR = 0.88, 95% CI: 0.57, 1.38) (Iribarren et al. 2001). However, weight gain (highest attained weight except during pregnancy minus weight at menarche) was positively associated with thyroid cancer in a case–control study of Shanghai women under the age of 55 (≥19 vs. ≤9 kg, OR = 2.0, 95% CI: 1.1, 3.7) (Preston-Martin et al. 1993). Currently, it is not clear whether there is a relevant period in one's lifetime where weight change may have an important effect on thyroid cancer development. Studies with detailed information on weight at different ages and reproductive events (i.e., menarche, pregnancy, menopause, etc.) would be useful in investigating this relationship.

102.3.2 Body Fat Composition and Distribution

Body fat and lean body mass were examined in relation to thyroid cancer in the small Icelandic cohort, using information on height, weight, and femur condyl and radio ulnar measurements (Tulinius et al. 1997). A 1-unit increase in body fat was associated with a 2% increased risk of thyroid

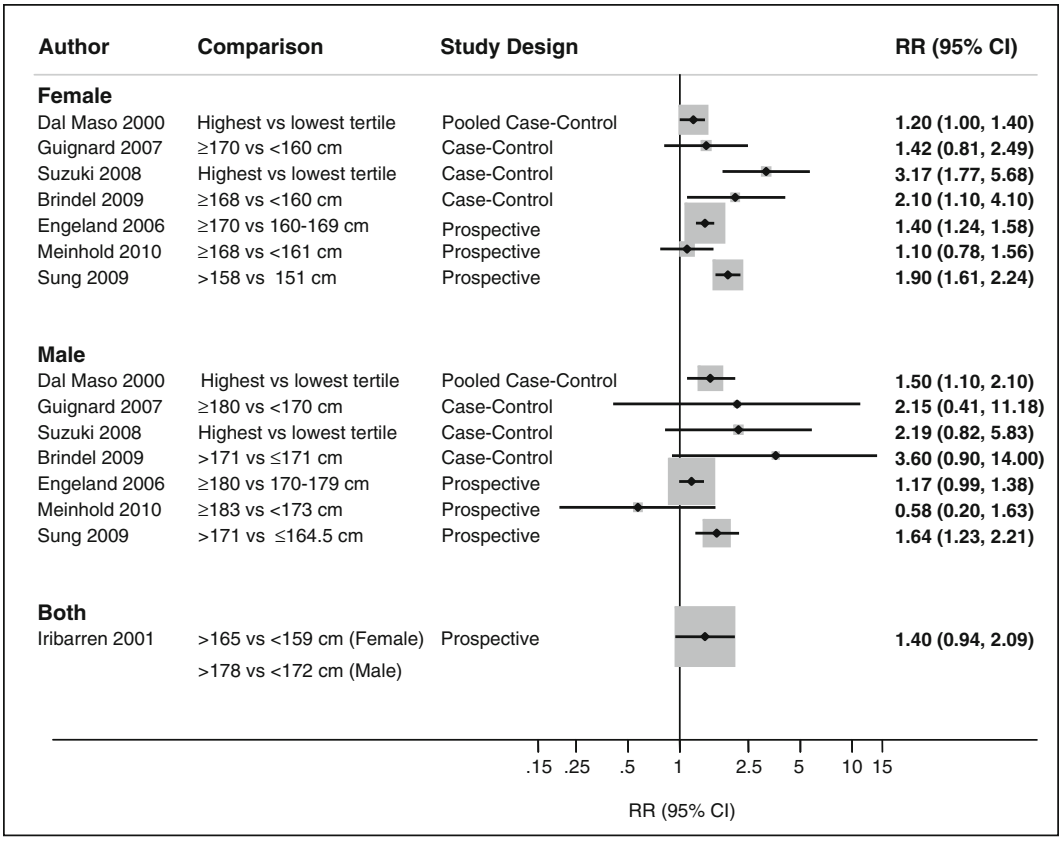

Fig. 102.3 Relative risks (RRs) of thyroid cancer according to highest versus lowest categories of height. The results are presented separately for women and men, where available. Evidence from epidemiologic studies suggests that greater height may increase the risk of thyroid cancer in both women and men, independently of body mass index

cancer in women (95% CI: 0.5–3.6%), but the results in men and for lean body mass in women were not presented, presumably due to lack of an association. As mentioned previously, the interpretation of these results is limited due to the small number of cases and the lack of adjustment for potential confounders other than age.

Currently, there is no evidence from published studies on the relationship between central adiposity and thyroid cancer risk. Epidemiologic studies with measurements for waist circumference or waist-to-hip ratio may provide some insight into potential biologic mechanisms underlying the associations for BMI, or overall adiposity, and thyroid cancer.

102.3.3 Height

Some evidence from these epidemiologic studies (Tables 102.2 and 102.3) suggests that greater height may increase the risk of thyroid cancer, independent of BMI (Fig. 102.3). In the international case–control pooling study, a positive association between height and total thyroid cancer was observed for both men (highest vs. lowest tertile, RR = 1.5, 95% CI: 1.1, 2.1) and women (highest vs. lowest tertile, RR = 1.2, 95% CI: 1.0, 1.4) (Dal Maso et al. 2000). Positive associations between

height and thyroid cancer were observed in two subsequent case–control studies (Suzuki et al. 2008; Brindel et al. 2009). A large study of Norwegian men and women showed a positive association between height and weight in both men (≥180 vs. 170–179 cm, RR = 1.2, 95% CI: 1.0, 1.4) and women (≥170 vs. 160–169 cm, RR = 1.4, 95% CI: 1.2, 1.6) (Engeland et al. 2006). In a large prospective study of Korean adults, every 5-cm increase in height was associated with an increased risk of thyroid cancer in men (HR = 1.16, 95% CI: 1.06, 1.28) and women (HR = 1.24, 95% CI: 1.18, 1.31) (Sung et al. 2009). A positive, but not significant, association was observed in the prospective study from San Francisco (Iribarren et al. 2001). However, no clear association was observed in a recent prospective study (Meinhold et al. 2010).

Positive associations between height and the risk of several other cancer sites, including colon, prostate, and breast have been consistently observed (Sung et al. 2009). The biological mechanisms whereby height may lead to cancer development have not been completely clarified, but it is possible that genes, growth factors, hormones, or other early environmental exposures in childhood and adolescence which contribute to skeletal growth may also have long-term health consequences (Sung et al. 2009); however the role of these factors in thyroid carcinogenesis is not well-understood (Dal Maso et al. 2009).

102.4 Strengths and Limitations of the Available Evidence

In contrast to nearly all of the prospective studies, which had direct measurements of height and weight, information on height and weight in the case–control studies were ascertained through self-report (Table 102.2). In addition to random variation, the results from these case–control studies may be influenced by systematic errors in self-reported height (often overestimated) or weight (often underestimated). Additionally, the same categories of BMI and other anthropometric factors were not always used across the case–control and prospective studies, making comparisons across studies slightly difficult.

The epidemiologic studies described above may not be representative of all the available evidence on the relationship between anthropometric factors and thyroid cancer risk. The strength of the results often influences whether or not researchers submit their work for publication (Olson et al. 2002). Evidence from published studies, therefore, may falsely support a positive association between these anthropometric factors and thyroid cancer risk. Publication bias may become less important in studies combining primary data from small, individual studies using meta-analytic or pooling techniques.

102.5 Biologic Mechanisms

Despite increasing evidence from epidemiologic studies that obesity increases the risk of thyroid cancer, potential biological mechanisms have not been well-described.

Thyroid stimulating hormone (TSH) is secreted from the pituitary gland to compensate for low levels of thyroid hormone, triiodothyronine (T_3) and thyroxine (T_4), and TSH levels are considered a more sensitive measure of thyroid function than thyroid hormones. TSH is a known thyroid growth factor which has been shown to regulate the growth and differentiation of thyroid cells in rodents (Hard 1998), and higher concentrations have been found in thyroid surgery patients with differentiated thyroid cancer compared to patients with benign thyroid disease (Haymart et al. 2008).

It is possible that these hormones are etiologically involved in human thyroid carcinogenesis, although epidemiologic studies directly examining the relationship between thyroid hormone or TSH levels and thyroid cancer are lacking.

Prospective studies examining TSH and its relation to potential thyroid cancer risk factors, particularly obesity, are needed to elucidate whether TSH is a cause or a consequence of these conditions. Thyroid hormones play a role in regulating resting energy expenditure, and may in turn influence the regulation of body weight (Kim 2008). Weight gain is a well-recognized symptom of hypothyroidism, a condition in which the levels of thyroid hormones are deficient, TSH levels are elevated, and the ability of the body to regulate metabolism and resting energy expenditure is impaired. The relationship between weight and thyroid function within a range of TSH considered to be normal, or euthyroid, is more controversial. For instance, it is unknown whether variation in thyroid function within normal range may result in weight change (i.e., through an influence on resting energy expenditure), or whether changes in weight lead to imbalances in thyroid hormones. Some cross-sectional and longitudinal studies show a positive dose–response association between BMI and TSH (Iacobellis et al. 2005; Fox et al. 2008). Increasing evidence from weight-loss intervention studies suggests that moderate-to-extreme weight loss may lead to normalization of TSH levels, and this association may be mediated by adipokines, such as leptin, which directly influence the hypothalamic-pituitary-thyroid axis (Kok et al. 2005).

Alternatively, adiposity may increase the risk of thyroid cancer through an influence on adult iodine requirements (Dal Maso et al. 2009). Given that excess or deficient iodine status may increase the risk of papillary and follicular thyroid cancer, respectively, iodine status could confound an association between BMI and thyroid cancer risk (Dal Maso et al. 2009). However, iodine intake is difficult to measure at the individual level, as iodine-containing foods, such as dairy, bread, and fish vary widely in iodine content depending on geographic region and processing and handling, and self-reported dietary intake is known to be captured with a great amount of variability.

102.6 Applications to Other Areas of Health and Disease

Thyroid cancer is just one of several diseases that may be more common in obese compared to normal-weight individuals. As the prevalence of obesity has risen dramatically over the past few decades in the United States and across the world, it has become increasingly important to study the potential public health consequences of this phenomenon. Gaps in the literature still remain, however. The incorporation of obesity-related biomarkers or more valid measurements of body fat, such as waist circumference or percent body fat, in epidemiologic studies may provide a more accurate picture about the health impact of obesity in the population.

102.7 Conclusion

Although thyroid cancer is a relatively uncommon malignancy, the incidence has been increasing for the past 30 years worldwide. Evidence from epidemiologic and experimental studies suggests that obesity may play a role. In early case-control studies, greater body size was associated with a higher risk of thyroid cancer in women but not men. However, more recent evidence from case–control and prospective studies indicates that overweight or obese men may also be at higher risk compared to normal-weight men. Several epidemiologic studies have observed a positive association between

height and risk of thyroid cancer. Little is understood about the biological pathways underlying the associations between anthropometric factors and thyroid cancer risk, though thyroid stimulating hormone and iodine status may play a role. Large prospective studies, particularly those with measurements of central adiposity or obesity-related biomarkers, may provide greater insight into thyroid cancer etiology. Additionally, data on tumor size would be useful to assess the possibility of over-detection of very small tumors in overweight or obese adults.

Summary Points

- There are few established risk factors for thyroid cancer, and most of these are non-modifiable.
- It has been hypothesized that obesity may be partly responsible for the increase in thyroid cancer incidence over the past three decades.
- Early case–control studies suggested that greater body size may increase the risk of thyroid cancer in women, but recent epidemiologic evidence indicates that overweight or obese men may also be at increased risk.
- Several epidemiologic studies have observed a positive association between height and risk of thyroid cancer.
- The biologic pathways underlying the associations between anthropometric factors and thyroid cancer risk are not well-understood.
- Epidemiologic studies with biomarkers related to obesity of more valid measures of body fat may provide greater insight into the etiology of this malignancy.

Chapter 103
Anthropometry and Ovarian Cancer: The Inflammation Connection

Julia B. Greer

Abstract Ovarian cancer affects over 200,000 women worldwide each year and has one of the highest case-fatality rates of any of the major cancers. Overweight and obesity have been associated with an increased risk of a variety of different illnesses and some types of cancer, in part, due to hormonal and metabolic factors that may drive tumorigenesis. Recent studies have demonstrated that obesity may play a role in ovarian carcinogenesis. Individuals who carry excess adipose tissue have been shown to have a characteristic state of systemic, low-grade inflammation. Many of the risk factors for ovarian cancer, including endometriosis, polycystic ovarian syndromes (PCOS), talc and asbestos exposure, and pelvic inflammatory disease (PID), have a recognized inflammatory component. Evidence linking obesity with an elevated risk of ovarian cancer, to date, has been conflicting; however, many prospective studies have shown that excess adiposity in young adulthood is related to both premenopausal and postmenopausal ovarian cancer risk. Other risk factors for ovarian cancer often affect women in their earlier, reproductive years; thus, the association between obesity in a woman's younger years and ovarian cancer is plausible. Moderate physical activity may be protective against ovarian cancer by decreasing estrogen levels, while vigorous activity may promote ovarian carcinogenesis via aberrations in androgen and progesterone levels. This chapter will review the traditional hypotheses of ovarian cancer—including incessant ovulation, gonadotropin stimulation, and the inflammatory hypothesis—and discuss the most relevant research on adiposity, diet and physical activity, and ovarian cancer risk. A brief overview of obesity and ovarian cancer survival is also included.

Abbreviations

BRCA	Breast cancer antigen gene
SEER	Surveillance Epidemiology End Results
PCOS	Polycystic ovarian syndrome
LH	Luteinizing hormone
FSH	Follicle-stimulating hormone
PID	Pelvic inflammatory disease
NSAIDS	Non-steroidal anti-inflammatory medications

103.1 Introduction

Ovarian cancer is the leading cause of death due to gynecological malignancies among women (Clarke-Pearson 2009). Approximately 140,000 women die of ovarian cancer in any given year and ovarian cancer is the seventh most common female cancer worldwide. Two thirds of women are over the age of 55 years, when they are diagnosed with ovarian cancer and more than two-thirds of cases, are diagnosed when the disease is advanced, either in state III or stage IV, and has progressed to involve the peritoneal cavity or other organs (Heintz et al. 2006). Figure 103.1 and Tables 103.1 and 103.2 display the staging of ovarian cancer as well as 5-year survival rates by stage and surgical outcomes. Epithelial ovarian cancer is the most common form of ovarian cancer and accounts for about 80–90% of all ovarian cancers, in comparison to germ cell or sex cord stromal tumors, which will not be covered in this chapter (Ness and Cottreau 1999). Invasive and noninvasive epithelial ovarian tumors have the same risk factors.

Ovarian cancer has been called "the silent killer" because it often lacks symptoms until it is in an advanced stage. Some women may experience characteristic symptoms prior to their diagnosis; however, these symptoms are rarely gynecological in nature and may be misleading (see Table 103.3). A large body of research has been devoted to trying to elucidate the etiology of this highly fatal cancer. Table 103.4 displays variables which have been recognized as positively or negatively influencing the likelihood of developing ovarian cancer. The factors which have been shown to be protective against developing ovarian cancer include parity (childbearing), oral contraceptive use, tubal ligation, hysterectomy, and prolonged breast feeding—especially if breastfeeding occurs frequently and without bottle supplementation (Clarke-Pearson 2009; Ness and Cottreau 1999). Risk factors for ovarian cancer include a lack of childbearing (nulliparity), family history of ovarian and/or breast cancer, inheritance of BRCA1 and BRCA2 mutations, infertility, endometriosis, talc use (i.e. talcum powder), asbestos exposure, polycystic ovarian syndrome, and hormone replacement therapy—particularly estrogen-only types of hormone replacement (Clarke-Pearson 2009; Ness and Cottreau 1999).

Evidence also suggests that obesity may contribute to ovarian carcinogenesis (Greer et al. 2006). A sizeable body of research has demonstrated that excess adiposity is associated with risk of cancer at several organ sites, including the colon, breast, pancreas, endometrium, esophagus, and kidney (Calle et al. 2003). The associations observed with the risk of these cancers may, in part, be explained by metabolic dysregulation of various hormones and growth factors that have potentially mitogenic effects (Bianchini et al. 2002). Mounting recent initiatives have also found that obesity and overweight are pro-inflammatory conditions, which may impact the risk of developing a variety of different illnesses, including some forms of cancer. This chapter will review the theories of ovarian carcinogenesis and focus on the interrelationship between obesity and the inflammatory hypothesis of ovarian cancer.

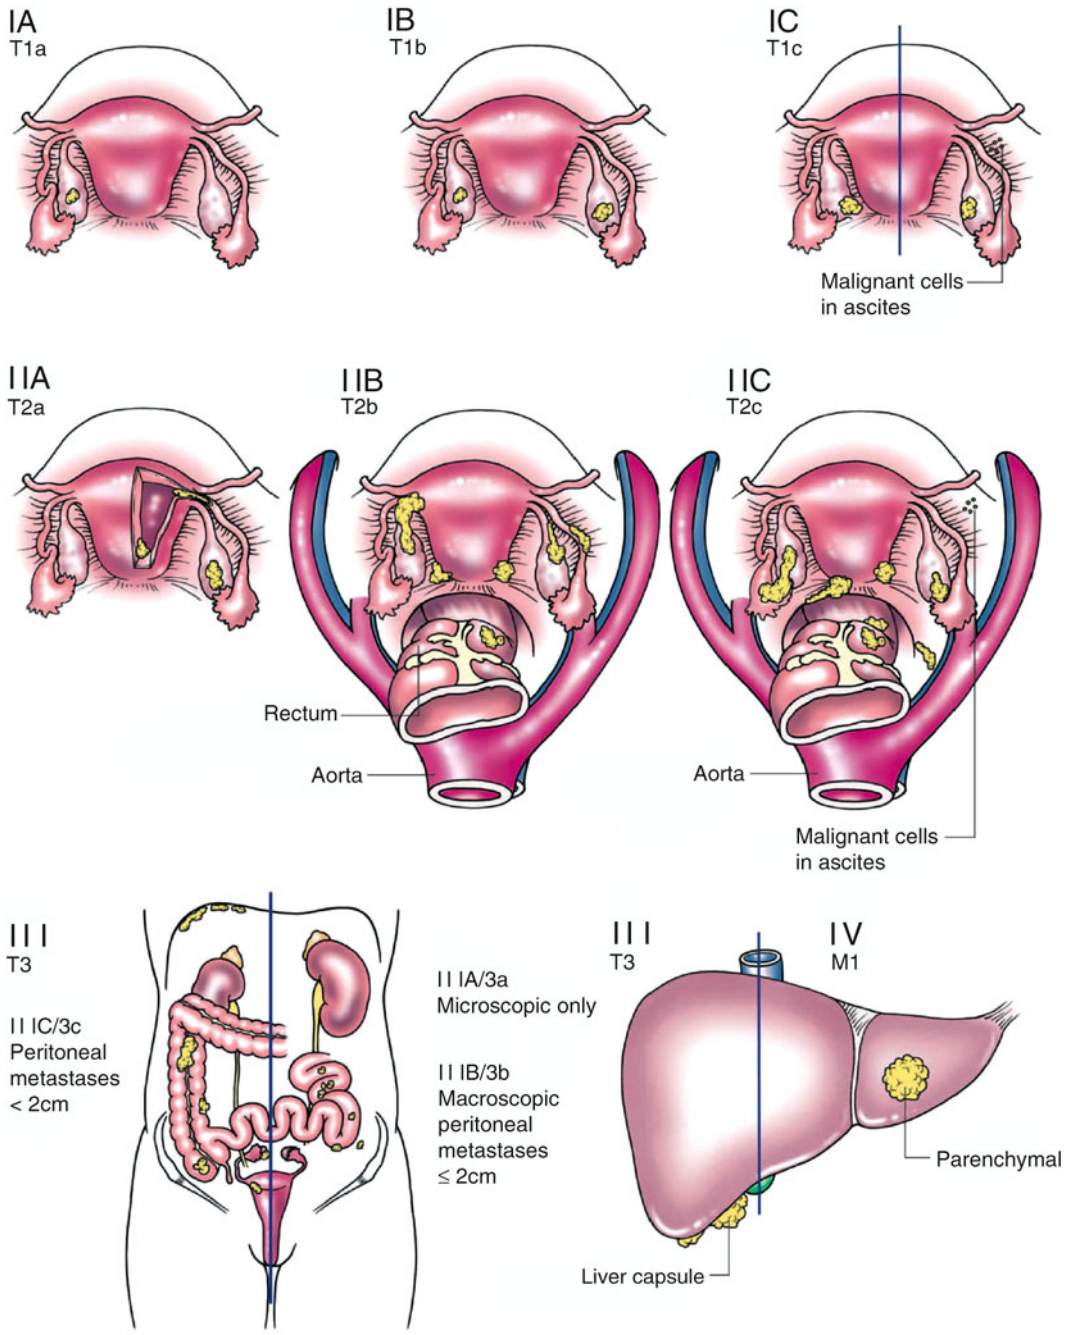

Fig. 103.1 Illustrated staging of ovarian cancer, reprinted with permission from (Heintz et al. 2006)

Table 103.1 Staging of ovarian cancer

Stage	Affected areas
Stage I	Cancer is confined to one or both ovaries. Tumor may be found on the surface of the ovary
IA	Tumor limited to one ovary
IB	Tumor in both ovaries
IC	Tumor limited to one or both ovaries with any of the following present: capsule ruptured, tumor on ovarian surface, malignant cells in ascites, or peritoneal washings
Stage II	Cancer involves one or both ovaries with extension into the pelvic region—it may be found in the uterus, fallopian tubes, bladder, sigmoid colon, or rectum. Few women are diagnosed at this stage
IIA	Tumor involves one or both ovaries with pelvic extension to uterus and/or fallopian tube(s)
IIB	Tumor involves one or both ovaries with pelvic extension to other pelvic tissues
IIC	Tumor involves one or both ovaries with pelvic extension (IIA or IIB) with malignant cells in ascites or peritoneal washings
Stage III	Cancer has spread beyond the pelvis to the abdominal wall or abdomen, small bowel, lymph nodes, or liver surface
IIIA	Tumor involves one or both ovaries with microscopically confirmed peritoneal spread beyond the pelvis
IIIB	Tumor involves one or both ovaries with macroscopic peritoneal spread beyond the pelvis 2 cm or fewer in greatest dimension
IIIC	Tumor involves one or both ovaries with a macroscopic peritoneal spread beyond the pelvis 2 cm or greater in greatest dimension and/or regional lymph node spread
Stage IV	Cancer has spread to distant organs including the liver, spleen, bones or lung

Table 103.2 Stage of ovarian cancer at diagnosis and 5-year survival rates, in percentages (Reprinted with permission from Clarke-Pearson 2009)

Stage	Patients with tumor stage at diagnosis	5-year survival rate (international)
Stage I	37	83–90
Stage II	8	65–71
Stage III	44	
IIIA	3	47
IIIB	5	42
IIIC	35	33
Outcome of initial surgery		
No residual tumor	NA	63
Residual disease		
Optimal debulking (<2 cm nodules)	NA	33
Suboptimal debulking (≥2 cm nodules)	NA	25
Stage IV	11	19

NA not applicable

Table 103.3 Frequent symptoms of ovarian cancer

Fatigue
Back pain
Urinary symptoms, such as urgency and frequency
Bloating, increasing abdominal girth
Abdominal or pelvic pain
Constipation

Table 103.4 Variables associated with increased or decreased risk of developing ovarian cancer

Increased risk	Decreased risk
Family history of breast, ovarian cancer	Childbearing (parity)
Known BRCA1 or BRCA2 germline mutation	Oral contraceptive use
Lack of childbearing (nulliparity)	Breastfeeding (of significant duration)
Endometriosis	Tubal ligation
Talc use/asbestos exposure	Hysterectomy
Polycystic ovarian syndrome (PCOS)	
Pelvic inflammatory disease (PID)	
Obesity, especially in youth	
Infertility	
Cigarette smoking (mucinous tumors)	

103.2 Hypotheses Concerning Ovarian Cancer Etiology

103.2.1 Incessant Ovulation

In 1971, Fathalla first suggested that consistent ovulation without pregnancy-induced rest periods contribute to neoplasia of the ovarian epithelium (Fathalla 1971). The incessant ovulation hypothesis of ovarian cancer posits that stromal epithelial clefts and inclusion cysts form following ovulation and undergo rapid proliferation during the 24 h that follow each ovulatory episode. This hypothesis hinges on the idea that repeated cell damage on the ovarian epithelium due to the effects of ovulation translates into an enhanced potential for ineffective DNA repair and/or inactivation of tumor suppressor genes and, subsequently drives mutagenesis (Ness and Cottreau 1999). Oral contraceptive use, parity, and breastfeeding decrease the risk of ovarian cancer by interrupting the long-standing and consistent ovarian ovulation process. However, weighted evidence of the actual quantitative decrease in risk due to interrupted ovulation is in greater magnitude than what would be inferred due only to the number of anovulatory months that a woman experiences with pregnancy or from taking oral contraceptives.

As Risch noted, ovulations typically occur over a period of at least 20 years (Risch 1998). On average, any given full-term pregnancy suppresses ovulation for perhaps a year, which amounts to, at most, 5% of the total number of ovulations. Even including a latency effect, this would correspond to only a 6% risk reduction, using SEER data. Epidemiologic studies demonstrate that among parous women, the reduction in risk for each pregnancy subsequent to the first is about 14–16%, an amount statistically inconsistent with the 5% for the number of suppressed ovulation. Each year of oral contraceptive use also suppresses ovulation at most for a year but the risk reduction for an additional year of use among ever users is only about 9%, which also is inconsistent with the reduction in risk that has been noted with pregnancy. Additional conflicting evidence for this hypothesis of ovarian cancer risk is seen in conditions such as polycystic ovarian syndrome (PCOS) and infertility (Ness and Cottreau 1999). Each of these conditions is associated with an *increased* risk of ovarian cancer although anovulation is a frequent characteristic of both; obese women are also more likely to be diagnosed with PCOS and often suffer fertility issue.

103.2.2 Gonadotropin Stimulation

The gonadotropins include luteinizing hormone (LH) and follicle-stimulating hormone (FSH). FSH stimulates ovarian granulosa cells and incites follicular growth, while LH stimulates the theca cells

of the ovaries and its surge triggers ovulation. The gonadotropin hypothesis asserts that hormonal stimulation of ovarian epithelial cells, either on the surface of the ovary or within ovarian inclusion cysts, and possibly mediated through excessive gonadotropin secretion, contributes etiologically to ovarian carcinogenesis (Ness and Cottreau 1999). In 1983, Cramer and Welch published an important paper in which they noted that the ovarian epithelium repeatedly invaginates during a woman's life to form clefts and inclusion cysts (Cramer and Welch 1983). The authors suggested that under significant gonadotropin stimulation of the ovarian stromal cells and consequent activation by estrogen and/or estrogen precursors, the epithelium may proliferate and undergo malignant transformation. Cramer and Welch conclude that factors which influence systemic estrogen level regulation would also affect gonadotropin stimulation and, tangentially, the paracrine estrogenic milieu of the ovarian epithelium. The gonadotropin hypothesis is reflective of why pregnancy/parity and oral contraceptive use have been shown to be protective against ovarian cancer, since both may lower basal and peak gonadotropin stimulation and also suppress ovulation.

An extrapolation of this hypothesis is the theory that excess estrogenic stimulation increases ovarian cancer risk (Risch 1998). Estrogen is derived primarily from the ovaries, and to a lesser extent, from adipose tissue during a woman's premenopausal years; postmenopausally, estrogen is derived primarily from the aromatization of androgens to estrogen from visceral adipose tissue. Under this principle, obesity should contribute to postmenopausal ovarian cancer more than to premenopausal ovarian cancer because overweight and obese older women should create excess, endogenous estrogen via the aromatization of testosterone and other androgens to estrogen from their increased adiposity. In a meticulous review of hormonal factors and ovarian cancer, Risch describes the current research on hormonal theories of ovarian cancer and provides conclusive evidence for the role of androgens in promoting and progesterone in attenuating ovarian cancer risk (Risch 1998). As evidence, he notes that higher levels of androstenedione and dehydroepiandrosterone have been observed among women with ovarian cancer than controls, and that PCOS—which is characterized by elevated androstenedione and testosterone levels among women—is a well established risk factor for ovarian cancer. Additionally, he notes that pregnancy and childbearing have been shown to be associated with decreased risk of ovarian cancer, although pregnancy is a state in which women have greatly elevated levels of estrogen and progesterone; if estrogen is a risk factor for ovarian cancer, then pregnancy would be associated with increased, rather than decreased risk. He provides evidence of the apoptotic effects of progesterone, which attenuate and counteract estrogen's mitogenic effects. Although reiterating the body of Risch's research goes beyond the scope of this chapter, readers particularly interested in the hormonal etiology of ovarian cancer are referred to his article and encouraged to read it in depth (Risch 1998). Regardless of the myriad theories relating to hormonal risks of ovarian tumorigenesis, there have been limited numbers of studies of endogenous hormone levels and ovarian cancer. To date, no consistent evidence implicates steroid hormone levels in ovarian carcinogenesis.

103.2.3 Inflammation

The inflammatory hypothesis asserts that conditions involving local inflammation to the ovarian epithelium trigger cellular turnover and rapid proliferation, as well as a change in the cellular environment in which a chronic inflammatory response predominates (Ness and Cottreau 1999). States of chronic inflammation result in a concurrent shift in cytokine and chemokine balance that may foster an environment of genomic instability in addition to cellular regeneration, thereby potentiating the carcinogenic process. Asbestosis, talc exposure, endometriosis, and pelvic inflammatory disease

(PID) are all conditions in which a consistent and long standing state of local inflammation encompasses the ovarian epithelium; each of these conditions has been associated with a significantly elevated risk of developing ovarian cancer (Ness and Cottreau 1999; Brinton et al. 1997). Parallel findings are that tubal ligation and hysterectomy, each of which interrupts the pathway of inflammants to the ovaries, decrease the risk of developing ovarian cancer. Many studies have examined inflammatory variables and their relationship with ovarian cancer. For instance, the records of 20,686 women hospitalized with endometriosis during the period 1969–1983 were evaluated in a Swedish study by Brinton and colleagues (Brinton et al. 1997). The risk of ovarian cancer was found to be 4.2 times as high among subjects with a long standing history of ovarian endometriosis compared to age and period-specific incidence rates of the Swedish population.

Additional evidence supporting a role for inflammation in ovarian cancer risk was noted in a Canadian study conducted between 1989 and 1992 of 450 histologically verified new primary epithelial ovarian cancer cases in women ages 35–79 years and 564 randomly selected population controls (Risch and Howe 1995). In this study, cases were more likely than controls to report having had one or more episodes of PID. After making adjustments for age, parity, duration of oral contraceptive use, and other factors, the odds ratio (OR) was 1.53 [95% confidence interval (CI) = 1.10–2.13; $P = 0.012$] for women who reported having an episode of PID. Higher risk was present for women with recurrent PID (OR 1.88; 95% CI = 1.13–3.12; $P = 0.014$). The elevated risk associated with PID was observed particularly among women <60 years of age at interview (OR 1.60; 95% CI = 1.09–2.35; $P = 0.016$), for nulliparous women who had given birth to only one child (OR 2.40; 95% CI = 1.39–4.15; $P = 0.0017$), and for the small number of women who reported having an episode of PID prior to the age of 20 (OR 3.08; 95% CI = 1.17–8.13; $P = 0.023$).

103.3 Obesity, Inflammation, and Cancer

103.3.1 What Is Inflammation and How Might It Contribute to Carcinogenesis?

Inflammation is the multi-step, immune, and vascular response to tissue injury due to the effects of pathogens, irritants, and a variety of other noxious stimuli (Coussens and Werb 2002). Inflammation incites a synergistic network of chemical messengers, which establish and maintain a host response that is specifically designed to heal damaged tissue. Mobilized leukocytes and a family of modulating chemotactic cytokines activate downstream effector cells, establishing the natural evolution of the inflammatory response. Acute inflammatory responses are the primary systems by which wounds heal. Numerous mechanisms involved in the inflammatory response may contribute to neoplasia. In fact, each of the three hallmark steps involved in carcinogenesis—initiation, promotion, and progression—may be significantly influenced by the inflammatory process.

The cellular environment that characterizes inflammatory states supports the development of genomic aberrations and may help to initiate carcinogenesis. Free radicals are highly reactive atoms or groups of atoms with an unpaired electron that are generated by normal physiological processes including both the acute and chronic inflammatory states and are ubiquitous in the human body. Free radicals' effects may contribute to cancer initiation. Some free radicals can induce genetic alterations and posttranslational modifications of key, regulatory cancer-related proteins. Reactive oxygen and nitrogen intermediates, for instance, are capable of causing oxidative damage and nitration of DNA bases, which potentiate the frequency of the occurrence of DNA damage (Macarthur et al. 2004).

Table 103.5 Various types of cancers associated with inflammation

Malignancy	Inflammatory agent(s)
Bladder	Chronic urinary bladder catheterization, Schistosomiasis
Bronchial	Asthma, cigarette smoke, silica
Cervical, anogenital	Human papillomavirus
Cholangiocarcinoma	Chinese liver fluke
Colorectal	Inflammatory bowel disease (Crohn's, ulcerative colitis)
Esophageal	Barrett's metaplasia, gastroesophageal reflux
Gastric adenocarcinoma/MALT (mucosa-associated lymphoid tissue)	*Helicobacter pylori*-associated gastritis/ulcers
Hepatocellular	Hepatitis B and/or C
Kaposi's sarcoma	Human herpes virus type B, human immunodeficiency virus (HIV)
Mesothelioma	Asbestos
Nasopharyngeal	Epstein-Barr virus
Ovarian (epithelial)	Asbestos, talc, PID (pelvic inflammatory disease)
Pancreas	Chronic pancreatitis, hereditary pancreatitis
Prostate	Prostatitis
Vulvar	Lichen sclerosus

The inflammatory response also contributes to the growth of tumors. When tissues are injured, cells that have been depleted will expand and repopulate to achieve the numbers necessary for proper tissue or organ function. By extension of their role in tissue repair and replacement, inflammatory mediators may send survival and proliferative signals to normal as well as initiated cells, leading to the growth promotion of healthy tissues as well as dysplastic or neoplastic tissues (Coussens and Werb 2002).

In the majority of cases, the inflammatory response is a self-limiting event that resolves without complications. However, chronic inflammation is characterized by a shift in the cell types at the site of inflammation which can lead to lasting and deleterious health effects. Considerable evidence demonstrates that chronic inflammatory states may positively influence the development of cancer (Coussens and Werb 2002; Macarthur et al. 2004). Some of the known medical conditions and infectious agents with a recognized inflammatory component that are associated with increased cancer risks include *H. pylori* infection and gastric cancer, hepatitis B and hepatocellular cancer, chronic pancreatitis and pancreatic cancer, inflammatory bowel disease and colon cancer, and many others (as displayed in Table 103.5). Various types of tumors have been shown to over express cyclooxygenase-2 (COX-2), a modulatory molecule in inflammation and carcinogenesis which has been implicated in the positive regulation of growth and tumorigenesis. Some studies have also noted a protective effect of nonsteroidal anti-inflammatory medications (NSAIDs) on the risk of developing some forms of cancer (reviewed in Coussens and Werb 2002).

Epidemiologic evidence from both *in vivo* and *in vitro* studies has demonstrated that inflammation is an important component in the etiology of various cancers, including ovarian cancer. Although the incessant ovulation hypothesis often focuses on the interplay of hormonal factors and ovulation in carcinogenesis, the potentially mutagenic effect of ovulation may, in fact, be inflammation mediated. At the level of the ovarian follicle(s), ovulation may be characterized by a remarkable inflammatory process. A number of inflammatory mediators, including prostaglandins, leukotrienes, and vasoactive substances such as bradykinin are locally elevated during ovulation (Ness and Cottreau 1999). The rupture of follicles likely also involves a stage of tissue remodeling in which cell division and turnover rates are heightened, just as during inflammatory states.

103.3.2 Obesity: A Growing, Global Issue

Being overweight has become a public health issue of huge proportions. Obesity is defined as a body mass index (BMI) of ≥30 kg/m squared. Rates of both childhood and adult obesity in developed countries have been rising at an alarming rate. In February of 2001, the International Agency for Research on Cancer of the World Health Organization concluded that limiting weight gain during adult life, thereby avoiding overweight and obesity, reduces the risk of postmenopausal breast cancer and cancers of the colon, endometrium, kidney (renal cell), and adenocarcinoma of the esophagus (Vainio et al. 2002). In a 16-year prospective study of over 900,000 U.S. adults (404,576 men and 495,477 women) who were free of cancer at enrollment, members of this cohort who had a BMI of at least 40 had death rates from all cancers combined that were 52% higher (for men) and 62% higher (for women) than the rates in men and women of normal weight (Calle et al. 2003). In both men and women, BMI was also significantly associated with higher rates of death due to cancer of the esophagus, colon and rectum, liver, gallbladder, pancreas, and kidney; the same was true for death due to non-Hodgkin's lymphoma and multiple myeloma. Significant trends of increasing risk with higher BMI values were observed for death from cancers of the stomach and prostate in men and for death from cancers of the breast, uterus, cervix, and ovary in women. Avoidance of weight gain thus seems to be an important factor for cancer prevention.

103.3.3 Obesity and Insulin Resistance: The Inflammation Connection

In part, associations of excess adiposity with cancer risk are explained by alterations in the metabolism of endogenous hormones—including sex steroids, insulin, and insulin-like growth factors—which can lead to distortion of the normal balance between cell proliferation, differentiation, and apoptosis (Bianchini et al. 2002). Although visceral adipose tissue was once viewed simply as a depot of fatty tissue and energy, recent research shows that it may also act as an active endocrine organ capable of undergoing hyperplastic changes (Hajer et al. 2008). Adipose tissue plays a central role in lipid and glucose metabolism, blood pressure maintenance, coagulation, as well as feeding behavior and satiety. Visceral adiposity also produces a variety of hormones and cytokines that are the main participants in the inflammatory process, including tumor necrosis factor-alpha, interleukin-6, adiponectin, leptin, resistin, and plasminogen activator inhibitor-1. A clustering of vascular risk factors including dyslipidemia, hypertension, and hyperglycemia, that has been observed among individuals who have an elevated proportion of visceral obesity is often referred to as metabolic syndrome (Baranova 2008). The most critical after-effect of the metabolic syndrome is low-level systemic inflammation supported by adipose-specific synthesis of active proinflammatory molecules. The factors secreted by adipocytes and stromal cells mediate increased peripheral insulin resistance and contribute to the development of the metabolic syndrome and a prediabetic state.

Obesity is associated with reduced glucose oxidation, increased lipid oxidation, hyperinsulinemia, and the development of clinical diabetes. Some studies have found that diabetes may increase the risk of neoplasia. Notably, a 16-year, prospective study that included over 1 million individuals (467,922 men and 588,321 women) who were free of cancer at baseline observed that diabetes was an independent predictor of mortality from cancer of the colon, pancreas, female breast, and, in men, of the liver and bladder (Coughlin et al. 2004). In the past decade, research on type II diabetes has found that inflammatory mediators may play a role in disease etiology. Some studies have shown that elevated levels of the inflammatory markers C-reactive protein and interleukin-6 are able to predict the development of type II diabetes in prospective cohort investigations (Pradhan et al. 2001). Most studies of diabetes and ovarian cancer risk have been inconclusive or have failed to show a significant association.

Risch's androgen hypothesis may come to play in ovarian cancer risk and obesity. Elevated BMI has been noted to be associated with increased free serum testosterone and decreased sex hormone binding globulin. Even without signs of androgenization among women, such as hirsutism or menstrual abnormalities, moderate levels of obesity have been correlated with women having increased quantities of both free and total serum testosterone (Risch 1998). In addition, due to the existence of low-grade, systemic inflammation, obese individuals have been observed to have higher circulating levels of the proinflammatory adipokines resistin and leptin, both of which have been correlated to increased insulin resistance (Baranova 2008). In general, obese individuals also have lower circulating levels of the anti-inflammatory adipokine, adiponectin (Baranova 2008); this adipokine profile favors sustained systemic inflammation, and creates an environment that supports the development of type II diabetes, fatty liver disease, atherosclerosis, and the promotion of some types of neoplasia. Increased levels of angiogenic factors such as vascular growth factors have also been noted in overweight and obese individuals (Silha et al. 2005), which may explain why obese individuals diagnosed with a number of different cancer types have decreased disease-free survival following initial treatment, worse prognosis, and greater risk of metastatic disease than lean individuals.

103.4 Obesity and Ovarian Cancer

103.4.1 Anthropometric Variables and Ovarian Cancer Risk

While the evidence has been conflicting, some studies support the relationship of anthropometric variables with ovarian cancer risk. Case-control studies of anthropometric variables and ovarian cancer risk suffer a number of limitations. Studies of current or recent weight and ovarian cancer risk may be biased by weight loss due to disease; studies of recalled, former weight may also be biased by underreporting. Additionally, among all studies, self-reported height and weight are more common than measured height and weight, which may further dilute findings. Nonetheless, each of these biases may steer results more towards the null. A 2005 study by Zhang and colleagues attempted to address the effects of disease on ovarian cancer risk (Zhang et al. 2005a). The study sample included 254 cases with histologically confirmed epithelial ovarian cancer and 652 controls. Information of adult height and weight at diagnosis, at 5 years before diagnosis and at age 21 years was recorded. Ovarian cancer risk was significantly increased with higher body weight and BMI at 5 years before diagnosis, but not at diagnosis. The adjusted ORs were 1.67 (95% CI = 1.04–2.67) for body weight >60 kg versus < or =50 kg and 1.75 (95% CI = 1.13–2.72) for BMI > or = 25.0 versus 18.5–21.9 at 5 years before diagnosis.

Due to the relative rarity of ovarian cancer, prospective studies may not be adequately powered to detect valid associations. Among prospective studies, some studies have found that a woman's risk of ovarian cancer might be more affected by her weight in youth rather than during adulthood. One large-scale, prospective study recruited a Norwegian cohort of approximately 1.1 million women, aged 14–74 years, who were measured and evaluated between 1963 and 1999 (Engeland et al. 2003). The cohort was followed for an average of 25 years through linkage to population-based cancer and death registries. Results indicated that women who were overweight or obese in adolescence or young adulthood had an increased risk of ovarian cancer; women with a very high BMI in adolescence had a relative risk of 1.56 (95% CI = 1.04 - 2.32) compared with women with average BMI. No such association was seen in older women (see Tables 103.6 and 103.7). This finding is especially valuable in light of the growing epidemic of obesity among children and adolescents in developed countries.

Other studies have found that obesity is only related to ovarian cancer in selected situations or among particular cohorts of women. For instance, Table 103.8 shows the results of a prospective

Table 103.6 Relative risk of ovarian cancer with 95% confidence intervals (95% CI) by age at measurement from Cox regression analysis by body mass index (BMI), adjusted for birth cohort (Engeland et al. 2003)

[a] BMI and height, respectively, were included as continuous variables

[b] Defined by percentiles in a U.S. reference population: low (<25th), medium (25th–74th), high (75th–84th), and very high (≥85th)

study of 94,525 U.S. women who were followed for 7 years demonstrated that there was an elevated risk of ovarian cancer among obese compared to normal weight women, but only among those women who never used hormone replacement therapy (multivariable relative risk 1.83, 95% CI = 1.18–2.84) (Leitzmann et al. 2009). A recent meta-analysis by Schouten and colleagues was composed only of prospective studies and evaluated anthropometric variables and ovarian cancer risk (Schouten et al. 2008). Results of this study demonstrate that, while height was associated positively with risk of ovarian cancer, the only pooled finding concerning adiposity was that elevated BMI was associated with an increased risk of premenopausal ovarian cancer. A shown in Tables 103.9 and 103.10, in our own work evaluating a population-based study of 763 ovarian cancer cases and 1348 healthy controls in the U.S., we found that high weight and BMI in early adulthood, as well as weight gain since adolescence, were associated with an elevated risk of ovarian cancer, but particularly among nulliparous women (Greer et al. 2006)

103.4.2 Physical Activity and Ovarian Cancer Risk

There is a strong correlation between lack of physical activity and obesity. Physical activity has been shown to decrease adiposity, increase lean muscle mass, and improve glucose and lipid profiles. Physical activity decreases postmenopausal endogenous estrogen levels, which have been correlated to the relationship of increasing physical activity levels and diminished risks of breast and endometrial cancers among older women. The association between physical activity and ovarian cancer is

[a]Adjusted for age, race (white/other), family history of ovarian cancer, tubal ligation, and oral contraceptive use (ever/never)

less well defined. For example, in a population-based case-control study (767 histologically-verified cases and 1367 healthy controls) of women 20–69 years of age, leisure-time physical activity was significantly associated with reduced occurrence of ovarian cancer ($P = .01$) (Cottreau et al. 2000). After adjusting for age, parity, oral contraceptive use, tubal ligation, family history of ovarian cancer, race, and BMI, women who reported the highest level of activity had an OR of 0.73 (95% CI = 0.56–0.94) for ovarian cancer compared with women who reported the lowest level s of physical activity. When the authors analyzed the relationship by various recalled time periods during life, the odds ratios for the highest versus the lowest category of activity at ages 14–17, 18–21, 22–29, 30–39, 40–49, and >50 years ranged from 0.64 to 0.78.

However, other studies have noted that frequent and vigorous physical activity may actually *increase* the risk of ovarian cancer. For instance, during a 16-year follow-up (from 1980 to 1996), 1.2 million person-years were accrued by 92,825 cohort members 377 cases of epithelial ovarian cancer were confirmed in a prospective study known as the Nurses' Health Study (Bertone et al. 2001). Recreational physical activity was quantified in hours of duration, as well as intensity level. Compared with inactive women, participants reporting higher activity in terms of metabolic equivalent task hours (MET hours) were at greater risk of ovarian cancer (Relative Risk [RR] for 20 to <30 MET hours/week = 1.84 [95% CI = 1.12–3.02]; RR for >30 MET hours/week = 1.27 [95% CI = 0.75–2.14]). These findings are plausible, because known hormone and ovulatory function changes are a frequent consequence of vigorous athletic training. Running may increase levels of androgens, prolactin, and gonadotropins and levels of some androgens remain elevated even hours after a long race (Mathur et al. 1986). Even moderate amounts of aerobic exercise may have effects on female reproductive function, such as altered luteal progesterone levels, which would not be suspected from menstrual patterns alone (Risch 1998).

103.4.3 Dietary Variables and Ovarian Cancer

An unhealthy diet can contribute to the risk of cancer, either directly by ingesting known carcinogens (such as high-heat cooked meats that contain heterocyclic amines and polyaromatic hydrocarbons) or indirectly, by the promotion of overweight and obesity. Among the Women's Health Initiative Dietary Modification Randomized Controlled Trial of over 48,000 post-menopausal women, a lowfat diet was shown to be protective against ovarian cancer and decreased risk by about 40% (Prentice et al. 2007). Other studies, both prospective and case-control in design, have found increased risk of ovarian cancer to be correlated with eggs, cholesterol, saturated fat, and other dietary nutrients. Decreased risks have been noted in some studies to be related most consistently to intake of various types of fruits, whole grains and vegetables, particularly leafy greens and cruciferous vegetables. In all, however, too few consistent findings have been made to establish any clear guidelines for dietary intake and ovarian cancer risk other than those that have been established for general health and well being; in other words, eat a variety of foods, but limit intake of calorie-dense foods and increase intake of fiber and nutrient-rich foods, such as fruits and vegetables.

103.4.4 Obesity and Ovarian Cancer Prognosis: Outcomes and Survival

Obesity is known to be a negative prognostic factor for a number of cancers, including breast and endometrial cancer. Shortened overall and disease-free survival have been found in obese cancer patients when compared to normal weight cancer patients, especially among patients with advanced disease (i.e. Stage III or IV) (Pavelka et al. 2006). To date, findings relating to obesity and survival in ovarian cancer patients have been limited and contradictory. One recent study of 214 patients with histopathologically confirmed invasive epithelial ovarian cancer who were recruited in 1999–2000 observed reduced survival among patients with BMI > or = 25 kg/m(2) at 5 years before diagnosis (P = 0.001) (Zhang et al. 2005b). Compared to nonobese individuals, obese individuals have longer operative times, greater likelihood of wound breakdown and elevated intraoperative blood loss (Matthews et al. 2009). Obese individuals also tend to be more difficult to manage in terms of

anesthesia; their greater number of common medical comorbidities may also contribute to notably elevated rates of perioperative and/or morbidity and mortality among obese individuals (Matthews et al. 2009). Nonetheless, many studies have not shown a significant difference in survival rates for obese versus nonobese women with ovarian cancer, given similar rates of optimal surgical debulking. Another issue to contend with in evaluating the research conducted on survival relates to chemotherapy dosage. In some instances, the calculation of chemotherapy dosing might be based on ideal body weight, rather than actual body weight, which may result in less-than-therapeutic dosing among women of greater weight or BMI.

103.5 Conclusions

103.5.1 Applications to Other Areas of Health and Disease

In studying many types of cancer, relevant risk factors, including anthropometric variables, such as height, weight, and BMI, should be evaluated at early life stages to accurately assess cancer risk, not just in the years closest to cancer diagnosis. Individuals who are predisposed to certain types of cancers, such as those with germline mutations that are known to cause recognized cancer syndromes, should especially be counseled on diet, exercise, and weight loss and/or maintenance. For breast and ovarian cancers, it would be especially valuable to examine the risk of being obese in young women who carry BRCA mutations, as this is the cohort with the greatest known relative lifetime cancer risk. Data collected on study participants should accurately assess known inflammatory conditions, including pathogens, as well as noninfectious causes of chronic inflammation, in order to discern whether obesity is additive or multiplicative in terms of specific cancer risks. Prospective studies that examine obesity and other lifestyle-related risk factors, including cigarette smoking, alcohol consumption and, for women, reproductive choices, are warranted to accurately evaluate the impact of obesity on the etiology and risk of various types of cancer. Many of the previously performed studies may not be adequately powered to detect weak associations or interactive effects.

Summary Points

(Key points that relate anthropometric variables with ovarian cancer risk are provided in Table 103.11).

- There is an increasing awareness that obesity plays a contributory role in numerous pathologies, including ovarian carcinogenesis.
- Obese individuals have been found to experience a constant, low-grade state of systemic inflammation which may contribute to tumorigenesis.
- The initiation, promotion, and expansion of tumors may be influenced by numerous components that function in the inflammatory response—and these effects are accentuated for individuals carrying excess adiposity.
- High BMI in early adulthood may be particularly associated with an increased risk of developing ovarian cancer.
- Ideally, large-scale, prospective studies that recruit and evaluate young women who can be followed into late adulthood would be most valuable in studying the effects of anthropometric, lifestyle and reproductive variables on the risk of developing cancers with a recognized hormonal influence, such as ovarian cancer.

Table 103.11 Key points that relate anthropometric variables to ovarian cancer risk

Some, but not all, studies have noted that obesity may increase the risk of ovarian cancer
Much of the evidence indicates that obesity in young adulthood is especially associated with elevated ovarian cancer risk
• Having an elevated BMI at age 18 has been shown to increase the risk of either/both premenopausal and postmenopausal ovarian cancer
• This relationship is plausible, because other risk or protective factors appear to have the greatest influence in women's younger years
• Excess adiposity may influence the development of ovarian cancer due the systemic effects of low grade, constant inflammation, as well as by its effects on hormonal levels, especially the excess of estrogens and androgens and the deficits in progesterone levels
The effects of physical activity on the risk of ovarian cancer are as yet undetermined
• Some studies have shown that moderate to vigorous physical activity may decrease risk
• Other studies have demonstrated that activity, particularly vigorous physical activity, is associated with elevated risk of ovarian cancer
• Either relationship makes sense, given that physical activity lowers estrogen levels while increasing levels of androgens; even moderate activity may alter luteal progesterone levels

Chapter 104
Anthropometry and Breast Cancer Risk

Amanda I. Phipps

Abstract Anthropometric factors are among the few risk factors for breast cancer that are potentially modifiable. As such, many studies have attempted to characterize the relationship between body size and breast cancer risk. Although there is much variability between studies with regard to the nature and the magnitude of such risk factor relationships, most studies indicate some association between body size and breast cancer risk. In particular, there is evidence of an increased breast cancer risk in postmenopausal women who are overweight or obese, particularly among nonusers of menopausal hormone therapy. Conversely, studies in premenopausal women suggest a weak inverse association between adult weight and breast cancer risk. Risk factor relationships have also been noted with measures of fat distribution and weight change in adulthood, with similar distinctions in associations by menopausal status. While most studies have focused on measures of body size in adulthood, a growing literature suggests that body size in early life is also relevant to breast cancer risk. Regardless of the anthropometric measure of interest, there are several methodological issues to consider in assessing these relationships, which can impact study findings and comparisons across studies. In particular, using self-reported anthropometric measures is problematic if women are biased in reporting their body size or have problems with recall, however, it may not always be possible or preferable to collect physical measurements of body size. Variability in population characteristics, study design, protocols for data collection, and the way anthropometric data are handled in analyses all contribute to variability in study findings.

Abbreviations

BMI	Body mass index
cm	Centimeters
ER	Estrogen receptor
HRT	Menopausal hormone replacement therapy
kg	Kilograms
m	Meters
PR	Progesterone receptor
WHR	Waist-to-hip ratio

104.1 Introduction

Breast cancer is the most commonly diagnosed malignancy among women worldwide, with more than one million cases diagnosed each year (Bray et al. 2004). While mortality rates from breast cancer have declined in recent decades and survival rates have improved in most countries, breast cancer remains a leading cause of cancer death in women (Bray et al. 2004) (Table 104.1). Consistent with the high burden of breast cancer, particularly in more developed countries, an extensive literature has been devoted to exploring the etiology of this disease. Still, it is estimated that established breast cancer risk factors explain less than 50% of all incident disease (Madigan et al. 1995).

Epidemiologic studies implicate a role of genetics, reproductive history, and environmental and lifestyle factors in the development of breast cancer. Given that few established risk factors for breast cancer are potentially modifiable, the role of anthropometric factors in breast cancer etiology is of particular public health importance. A large number of prior studies have noted associations between weight, weight change, body mass index, height, and abdominal adiposity and breast cancer risk. Most studies have focused on measures of adult body size and shape, although evidence also exists to suggest associations between measures of body size and shape from childhood or adolescence and risk of breast cancer in adulthood. Regardless of the timing or measure of interest, there are substantial methodological complexities that studies must account for in exploring anthropometric risk factors for breast cancer, and many potential sources of bias.

Here we broadly summarize what is known about anthropometric factors in relation to breast cancer risk, as well as some of the methodological issues that complicate the study of anthropometric risk factors in breast cancer studies.

104.2 Adult Body Size

Studies of anthropometric risk factors for breast cancer have focused primarily on measures of body size in adulthood. Adult weight, body mass index (BMI), abdominal adiposity, weight change, and height have all been implicated as risk factors for the development of breast cancer. The magnitude and

Table 104.1 Key facts about breast cancer

1. Breast cancer is the most commonly diagnosed cancer among women worldwide, with greater than one million women diagnosed each year.
2. Breast cancer can be diagnosed in men and women and at almost any age, but greater than 95% of all breast cancers are diagnosed in women aged 40 years and older.
3. Incidence rates for breast cancer vary geographically and, within countries, between racial/ethnic groups. Rates are highest in developed countries among non-Hispanic white women.
4. Through screening mammography, it is possible to detect breast cancer at an early stage before the tumor has spread and before the onset of disease symptoms.
5. Breast cancer is the second leading cause of cancer death among women, contributing to almost half a million deaths each year.
6. Survival from breast cancer is generally favorable, especially when diagnosed at an early stage: in developed countries, 5-year survival is close to 90%.
7. Inherited genetic mutations are thought to be responsible for 5–10% of all breast cancers.
8. In addition to genetic factors, many other risk factors for breast cancer are things that women cannot easily change; the age at which a woman starts and stops her menstrual periods, her pregnancy history, and the density of her breasts all impact breast cancer risk.

This table lists key facts about breast cancer including the global burden of breast cancer, the populations most impacted, information about detection and survival, and nonmodifiable risk factors for disease

directionality of associations between these measures and breast cancer risk, however, vary considerably between studies. Much of this variability is likely attributable to differences in methodology and study population characteristics. Still, the lack of consistency in observed associations does contribute to some uncertainty about the true association between adult body size and breast cancer risk.

104.2.1 Weight and Body Mass Index (BMI)

Adult weight, typically adjusted for adult height (i.e., BMI) has long been considered a risk factor for breast cancer. Repeated studies have noted that this relationship between weight in adulthood and breast cancer risk is a complex one, likely involving multiple biological pathways. In particular, the majority of studies assessing this risk factor relationship have demonstrated important differences in associations by menopausal status: a weak inverse association in premenopausal women has been demonstrated by several studies, while studies in postmenopausal women suggest an increased breast cancer risk in overweight and obese women (Table 104.2).

In a pooled analysis of seven large prospective studies, van den Brandt et al. (2000) found that a 10 kilogram (kg) increase in weight was associated with a 10% reduction in risk of premenopausal breast cancer and a 6% increase in risk of postmenopausal breast cancer. Similarly, an increase in BMI of 4 kg/meters $(m)^2$ was associated with an 11% reduction in risk and a 7% increase in risk among premenopausal and postmenopausal women, respectively (van den Brandt et al. 2000). However, associations between weight and breast cancer risk may not follow a linear trend. For example, the previously mentioned pooled analysis noted that the reduced risk of premenopausal breast cancer associated with elevated BMI was limited primarily to women with a BMI of at least 31 kg/m^2 and the increased risk of postmenopausal breast cancer did not increase further past a BMI of 28 kg/m^2 (van den Brandt et al. 2000).

Studies that are able to stratify analyses in postmenopausal women according to the use of menopausal hormone replacement therapy (HRT) suggest that the positive association between BMI and postmenopausal breast cancer risk is limited to women who are not users of HRT (van den Brandt et al. 2000; Morimoto et al. 2002; Lahmann et al. 2004). In postmenopausal users of HRT, the association between BMI and breast cancer risk more closely resembles the weak inverse association observed in premenopausal women. This marked contrast in associations with BMI across menopausal status and HRT use is consistent with the theory that BMI or weight influences breast cancer risk through an effect on hormone levels. Briefly, given that adipose tissue is the primary source of endogenous estrogens in postmenopausal women, elevated BMI or weight contributes to elevated levels of endogenous estrogens, which, in turn, contribute to an increased risk of breast cancer (Lorincz and Sukumar 2006). In HRT users, however, circulating hormone levels are driven primarily by exogenous estrogens from HRT, masking the effect of increased endogenous estrogen from adipose tissue. Mechanisms behind the inverse association between BMI or weight and premenopausal breast cancer have not been well described (Lorincz and Sukumar 2006).

In the context of most breast cancer studies, weight and BMI are ascertained either through self-report or physical measurements. Some concerns about validity arise when using self-reported weight given the tendency for women, particularly overweight and obese women, to underreport their weight (Elgar and Stewart 2008). Somewhat less pronounced is the tendency for overestimation in self-report of adult height (Elgar and Stewart 2008). When considered in combination, bias in self-reported weight and height can lead to considerable bias in the estimation of BMI: one nationally representative survey conducted in Canada estimated that measures of BMI calculated from self-reported height and weight were, on average, 1.31 kg/m^2 units lower than BMI calculated

Table 104.2 Summary of cited studies on adult BMI (kg/m^2) and breast cancer risk

Author (year)	Study design (location)	Study period	Breast cancer cases	Method of data ascertainment	Comparison categories	Relative risk estimate (95% confidence interval)
Premenopausal women						
Huang et al. (1997)	Prospective cohort (USA)	1976–1992	1,000	Self-report (collected biennially during follow-up)	Whole number cut-points: >31.0 vs. ≤20.0	0.62 (0.45–0.86)
Coates et al. (1999)	Case-control (USA)	1990–1992	1,590	Physical measurement	Quintiles: ≥30.4 vs. <21.6	0.69 (0.54–0.88)
van den Brandt et al. (2000)	Pooled prospective studies (USA, Europe, Canada)	1976–1993	703	Self-report (3 studies); physical measurements (1 study)	Whole number cut-points: ≥33 vs. <21	0.58 (0.34–1.00)
Lahmann et al. (2004)	Prospective cohort (Europe)	1992–2000	474	Physical measurement (baseline interview)	Quintiles: ≥28.8 vs. <21.6	0.82 (0.59–1.14)
Weiderpass et al. (2004)	Prospective cohort (Europe)	1991–1999	716	Self-report (collected at baseline)	WHO cut-points: ≥30.0 vs. 20.0–24.9	0.66 (0.40–1.07)
Postmenopausal women (overall)						
Huang et al. (1997)	Prospective cohort (USA)	1976–1992	1,517	Self-report (collected biennially during follow-up)	Whole number cut-points: >31.0 vs. ≤20.0	1.13 (0.87–1.46)
Magnusson et al. (1998)	Case-control (Sweden)	1993–1995	2,904	Self-report (1 year prior to data collection)	Quintiles: ≥28.3 vs. <22.2	1.65 (1.40–1.95)
van den Brandt et al. (2000)	Pooled prospective studies (USA, Europe, Canada)	1976–1993	3,208	Self-report (6 studies); physical measurement (1 study)	Whole number cut-points: ≥33 vs. <21	1.27 (1.03–1.55)
Postmenopausal women (no HRT use)						
Huang et al. (1997)	Prospective cohort (USA)	1976–1992	N/A	Self-report (collected biennially during follow-up)	Whole number cut-points: >31.0 vs. ≤20.0	1.59 (1.09–2.32)
van den Brandt et al. (2000)	Pooled prospective studies (USA, Europe, Canada)	1976–1993	N/A	Self-report (5 studies); physical measurement (1 study)	Continuous: per 4 kg/m^2 increase	1.09 (1.04–1.14)

Morimoto et al. (2002)	Prospective cohort (USA)	1993–2000	315	Physical measurement (baseline interview)	Quintiles: >31.1 vs. ≤22.6	2.52 (1.62–3.93)
Lahmann et al. (2004)	Prospective cohort (Europe)	1992–2000	911	Physical measurement (baseline interview)	Quintiles: ≥28.8 vs. <21.6	1.36 (1.06–1.75)
Postmenopausal women (HRT users)						
van den Brandt et al. (2000)	Pooled prospective studies (USA, Europe, Canada)	1976–1993	N/A	Self-report (5 studies); physical measurement (1 study)	Continuous: per 4 kg/m^2 increase	1.04 (0.92–1.18)
Morimoto et al. (2002)	Prospective cohort (USA)	1993–2000	704	Physical measurement (baseline interview)	Quintiles: >31.1 vs. ≤22.6	0.96 (0.73–1.27)
Lahmann et al. (2004)	Prospective cohort (Europe)	1992–2000	494	Physical measurement (baseline interview)	Quintiles: ≥28.8 vs. <21.6	0.71 (0.50–1.01)

This table summarizes key studies cited in the text examining the association between adult weight and breast cancer risk in premenopausal and postmenopausal women. Postmenopausal women who are obese or overweight are at an increased risk of developing breast cancer, particularly if they are not users of HRT, while studies in premenopausal women suggest a slightly reduced risk of breast cancer associated with overweight and obesity

BMI body mass index, *HRT* hormone replacement therapy, *kg* kilograms, *m* meters, *WHO* World Health Organization

from measured height and weight (Elgar and Stewart 2008). For this reason, the use of physical measurements for weight may be preferable in some settings. However, in retrospective studies where measurements must be taken subsequent to breast cancer diagnosis, measured weight is likely to have been influenced by the progression of disease and by breast cancer treatment; in such settings, self-report of weight prior to breast cancer diagnosis may be more appropriate even if it is associated with some degree of bias.

Studies assessing the association between weight or BMI and breast cancer risk must also consider the influence of body size on the performance of breast cancer screening. Prior studies have reported that women who are overweight or obese are less likely to seek out routine breast cancer screening and, among those who do receive screening, the performance of screening may be influenced by the fattiness of the breast (Kerlikowske et al. 2008). As a result, overweight and obese women may be underrepresented in case populations, especially populations of early stage disease, in breast cancer studies.

104.2.2 Abdominal Adiposity

The distribution of adipose tissue, not just the amount, has also been implicated as a risk factor for the development of breast cancer. Specifically, evidence suggests that increased abdominal fat deposition is associated with an increased breast cancer risk. Studies assessing the association between abdominal adiposity and breast cancer risk have focused primarily on three measures: waist circumference, hip circumference, and the ratio of waist-to-hip circumference (WHR) (Table 104.3).

With respect to the relationship between WHR and breast cancer risk, evidence is most consistent in indicating a positive association among postmenopausal women (Huang et al. 1999; Friedenreich 2001; Connolly et al. 2002; Morimoto et al. 2002). Positive associations have also been noted among premenopausal women, but with less consistency (Friedenreich 2001; Connolly et al. 2002). In a meta-analysis of studies on the relationship between WHR and breast cancer risk, 9 of 11 studies reported an increased risk among women in the highest versus lowest category of WHR, with relative risk estimates ranging from a 1.1-fold to 8.2-fold increased risk in postmenopausal women and a 1.2-fold to 7.8-fold increased risk in premenopausal women in the highest versus lowest WHR category (Connolly et al. 2002). As with BMI, some studies have suggested that the association between WHR and postmenopausal breast cancer risk is limited to women who are not users of HRT (Huang et al. 1999; Morimoto et al. 2002), which could imply an underlying hormonal mechanism of action.

Fewer studies have reported on associations between breast cancer risk and the two component measures of WHR (i.e., waist circumference and hip circumference). However, studies assessing associations between these component measures and breast cancer risk suggest that waist circumference (Huang et al. 1999; Morimoto et al. 2002) and hip circumference (Morimoto et al. 2002; Lahmann et al. 2004) may be stronger predictors of breast cancer risk when considered individually than when considered in combination as WHR.

Although waist circumference, hip circumference, and WHR are all highly correlated with BMI (Huang et al. 1999), associations between these measures and breast cancer risk appear to persist after adjusting for BMI and certain dietary measures (Huang et al. 1999; Connolly et al. 2002; Morimoto et al. 2002). This suggests that associations between these body size measures and breast cancer risk are not simply reflections of an association between overall obesity and breast cancer risk. Central adiposity, measured most directly by waist circumference, may be particularly relevant

Table 104.3 Summary of cited studies on abdominal adiposity and breast cancer risk

Author (year)	Study design (location)	Study period	Breast cancer cases	Measure of interest	Comparison categories	Relative risk estimate (95% confidence interval)
Premenopausal women

				Waist-to-hip ratio	≥0.847 vs. <0.736	0.85 (0.60–1.20)

This table summarizes key studies cited in the text examining the association between measures of abdominal adiposity and breast cancer risk in premenopausal and postmenopausal women. Evidence suggests that increased abdominal fat deposition is associated with an increased breast cancer risk
HRT hormone replacement therapy, *cm* centimeters, *in* inches

to breast cancer risk given that upper abdominal (i.e., visceral) fat has a higher production rate of free estradiol and a lower concentration of sex hormone binding globulin than peripheral fat (Huang et al. 1999; Friedenreich 2001).

Certain methodological issues should be considered when interpreting the results of epidemiologic studies assessing the relationship between central adiposity and breast cancer risk. While the majority of studies obtain physical measurements for waist and hip circumference as part of an in-person interview protocol, there is considerable variability in the protocols used for collecting these measurements (Connolly et al. 2002). For example, some studies measure waist circumference at the narrowest part of the trunk while others take measurements at the umbilicus or at some specified distance above the umbilicus. Although any measurement error is not likely vary with disease status, the possible effect of measurement error should be considered in any interpretation of these measures. Measures of WHR are particularly subject to measurement error given that this variable incorporates two sources of measurement error (i.e., from waist circumference and from hip circumference). Additionally, given that there are no clinically relevant cut-points for categorizing waist circumference, hip circumference, or WHR, measures classified as "high" or "low" in one study may not be so-classified in another study. This lack of consistency in category cut-points complicates the comparison of findings across studies.

104.2.3 Weight Change

In a review published by the International Agency for Research on Cancer, adult weight gain was cited as the measure of body size most consistently associated with breast cancer risk in postmenopausal women (Vainio and Bianchini 2002). Several studies have suggested that weight change is more strongly associated with breast cancer risk than recent weight or BMI, and several have noted associations with weight change even in the absence of any association between weight or BMI and breast cancer risk (Friedenreich 2001) (Table 104.4).

As with weight and BMI, associations between weight change and breast cancer risk differ according to menopausal status and, among postmenopausal women, according to the use of HRT (Morimoto et al. 2002; Lahmann et al. 2005; Eliassen et al. 2006). In one prospective analysis using data from the Nurses' Health Study in the United States, postmenopausal women who had gained at least 25 kg since age 18 years experienced a 1.4-fold increased risk of breast cancer relative to women whose recent weight was within 2 kg of their weight at age 18; when stratifying estimates according to HRT use, a 25 kg weight gain since age 18 was associated with a 1.9-fold increased risk in women who had never used HRT compared to a 1.2-fold increased risk in current or former users of HRT (Eliassen et al. 2006). Weight gain after the onset of menopause was not significantly associated with an increased breast cancer risk in this study population, regardless of HRT use status, although other studies have observed an increased risk with an increase in BMI late in adulthood (Morimoto et al. 2002). Some, but not all studies have reported an opposite effect of weight loss on postmenopausal breast cancer risk (Friedenreich 2001; Lahmann et al. 2005; Eliassen et al. 2006). Evidence of an association between weight change and breast cancer risk in premenopausal women is more limited. The majority of studies in premenopausal women report a null or nonsignificant inverse association between weight gain and breast cancer risk (Coates et al. 1999; Weiderpass et al. 2004; Lahmann et al. 2005). A relationship between weight loss or BMI reduction since early adulthood and breast cancer risk has not been observed in premenopausal women (Coates et al. 1999; Weiderpass et al. 2004; Lahmann et al. 2005).

While the literature is relatively consistent in reporting associations between weight change and breast cancer risk, there is substantial heterogeneity across studies in terms of how weight change is

Table 104.4 Summary of cited studies on adult weight gain and breast cancer risk

Author (year)	Study design (location)	Study period	Breast cancer cases	Weight/BMI change time period	Method of data ascertainment	Comparison categories	Relative risk estimate (95% confidence interval)
Premenopausal women							
Huang et al. (1997)	Prospective cohort (USA)	1976–1992	1,000	Age 18–present	Self-report	Weight loss/gain ≤2 kg vs. gain >25 kg	0.74 (0.54–1.03)
Coates et al. (1999)	Case-control (USA)	1990–1992	1,590	Age 20–present	Self-report (age 20)/ physical measurement (present)	Weight loss/gain ≤2 kg vs. gain ≥21 kg	0.72 (0.54–0.95)
Lahmann et al. (2005)	Prospective cohort (Europe)	1992–2000	254	Age 20–present	Self-report (age 20)/ physical measurement (baseline)	Weight loss/gain ≤2 kg vs. gain >20 kg	0.87 (0.51–1.49)
Weiderpass et al. (2004)	Prospective cohort (Europe)	1991–1999	680	Age 18–present	Self-report	BMI gain 0–1.4 kg/m^2 vs. gain >4.0 kg/m^2	0.95 (0.72–1.25)
Postmenopausal women (overall)							
Magnusson et al. (1998)	Case-control (Sweden)	1993–1995	2,331	Age 18–present	Self-report	Weight gain 0–9.5 kg vs. gain ≥30 kg	1.45 (1.13–1.86)
Eliassen et al. (2006)	Prospective cohort (USA)	1976–2002	4,393	Age 18–present	Self-report	Weight loss/gain ≤2 kg vs. gain ≥25 kg	1.45 (1.27–1.66)
			2,376	Menopause–present	Self-report	Weight loss/gain ≤2 kg vs. gain ≥10 kg	1.18 (1.03–1.35)
Postmenopausal women (no HRT use)							
Morimoto et al. (2002)	Prospective cohort (USA)	1993–2000	311	Age 18–present	Self-report (age 18)/ physical measurement (baseline)	BMI change ≤0 kg/m^2 vs. gain >9.7 kg/m^2	1.92 (1.07–3.43)
			314	Age 50–present	Self-report (age 50)/ physical measurement (baseline)	BMI change ≤0 kg/m^2 vs. gain >4.0 kg/m^2	1.45 (0.98–2.15)
Lahmann et al. (2005)	Prospective cohort (Europe)	1992–2000	626	Age 20–present	Self-report (age 20)/ physical measurement (baseline)	Weight loss/gain ≤2 kg vs. gain >20 kg	1.52 (1.08–2.13)
Eliassen et al. (2006)	Prospective cohort (USA)	1976–2002	1,394	Age 18–present	Self-report	Weight loss/gain ≤2 kg vs. gain ≥25 kg	1.98 (1.55–2.53)
			876	Menopause–present	Self-report	Weight loss/gain ≤2 kg vs. gain ≥10 kg	1.19 (0.94–1.50)

Postmenopausal women (HRT users)							
Morimoto et al. (2002)	Prospective cohort (USA)	1993–2000	692	Age 18–present	Self-report (age 18)/ physical measurement (baseline)	BMI change ≤0 kg/m^2 vs. gain >9.7 kg/m^2	1.36 (0.94–1.97)
			699	Age 50–present	Self-report (age 50)/ physical measurement (baseline)	BMI change ≤0 kg/m^2 vs. gain >4.0 kg/m^2	0.90 (0.68–1.17)
Lahmann et al. (2005)	Prospective cohort (Europe)	1992–2000	456	Age 20–present	Self-report (age 20)/ physical measurement (baseline)	Weight loss/gain ≤2 kg vs. gain >20 kg	0.95 (0.32–1.38)
Eliassen et al. (2006)	Prospective cohort (USA)	1976–2002	2,687	Age 18–present	Self-report	Weight loss/gain ≤2 kg vs. gain ≥25 kg	1.20 (1.01–1.43)
			1,379	Menopause–present	Self-report	Weight loss/gain ≤2 kg vs. gain ≥10 kg	1.15 (0.96–1.38)

This table summarizes key studies cited in the text examining the association between adult weight gain and breast cancer risk in premenopausal and postmenopausal women. Adult weight gain is consistently associated with breast cancer risk in postmenopausal women, but no real relationship between weight change and breast cancer risk has been observed in premenopausal women

BMI body mass index; *HRT* hormone replacement therapy; *kg* kilograms

defined. Some studies consider changes in weight while others measure changes in BMI. The ages between which these changes are measured also vary: some studies consider the difference between weight or BMI at age 18 or 20 and recent weight, while other focus on weight or BMI change within a more recent time period (e.g., since age 50, since menopause, or since age 30). Differences in the time frame over which weight or BMI changes are defined are particularly important to consider when comparing results across studies, since changes over different time periods may influence breast cancer risk through different biological mechanisms. It is possible that weight changes during periods of hormonal transition, such as pregnancy or menopause, may be particularly relevant given that the breast is more susceptible to carcinogenic insult during these time periods (Friedenreich 2001). Recent weight gain could function as a promoter of breast cancer growth; however, studies assessing the relationship between recent weight changes and breast cancer risk must consider the possibility that the disease itself could have an impact on body weight and BMI rather than vice versa.

As in studies of adult weight and BMI, studies measuring weight change must consider the potential for bias and measurement error when collecting measures of recent and historical weight. In addition to these complexities, there are important limitations inherent to breast cancer studies that define weight change as the difference between two weight or BMI measures at two points in time. Calculating weight change in this manner may not capture the full range of change during adulthood if weight or BMI fluctuates within this time period. Such measurements also fail to capture information on the rate or trajectory of weight change (e.g., whether the weight change occurred gradually beginning at age 18 or occurred rapidly within recent years). Few studies have assessed the possible relationship between weight cycling and breast cancer risk, but it is possible that patterns of weight change and not just the magnitude of change may be important.

104.2.4 Height

Existing studies indicate that women who are tall in stature experience a slightly increased risk of breast cancer relative to shorter women. This modest positive association between adult height and breast cancer risk has been noted by repeated studies in diverse study populations, although not all studies support an association (Table 104.5). While the biological basis for an influence of height on breast cancer risk is not well understood, it has been suggested that adult height is a reflection of childhood energy intake and the number of ductal stem cells in the breast that develop *in utero* (Friedenreich 2001). Thus, an association between breast cancer risk and the height a woman attains in adulthood may actually implicate a role of early life exposures in breast cancer development.

Most epidemiologic studies assessing the association between height and breast cancer risk have separately assessed associations in premenopausal and postmenopausal women. Although studies are relatively consistent in noting an association between height and breast cancer risk among postmenopausal women, evidence is weaker and less consistent in premenopausal women. In a pooled analysis of seven large prospective studies, a 5-cm increase in height was associated with a 2% nonsignificant increase in risk of premenopausal breast cancer (van den Brandt et al. 2000). The same increase in height was associated with a statistically significant 7% increase in breast cancer risk among postmenopausal women (van den Brandt et al. 2000). Studies examining adult height as a categorical rather than a continuous variable, however, suggest that height may not be linearly associated with breast cancer risk (van den Brandt et al. 2000; Lahmann et al. 2004). For example, one large prospective study noted a 1.3-fold increased risk of premenopausal breast cancer and a 1.4-fold increased risk of postmenopausal disease among women in the highest versus lowest quartile of height, but found no evidence of a trend (Lahmann et al. 2004).

Table 104.5 Summary of cited studies on adult height and breast cancer risk

Author (year)	Study design (location)	Study period	Breast cancer cases	Method of data ascertainment	Comparison categories	Relative risk estimate (95% confidence interval)
Premenopausal women						
van den Brandt et al. (2000)	Pooled prospective studies (USA, Europe, Canada)	1976–1993	703	Self-report (3 studies); physical measurements (1 study)	A priori cut-points:	
					≥175 cm vs. <160 cm	1.42 (0.95–2.12)
					Linear (5-cm increase):	1.02 (0.96–1.10)
Lahmann et al. (2004)	Prospective cohort (Europe)	1992–2000	474	Physical measurement (baseline interview)	Quintiles:	
					≥167.7 cm vs. <156.0 cm	1.33 (0.96–1.84)
					Linear (1-cm increase):	1.01 (1.00–1.03)
Weiderpass et al. (2004)	Prospective cohort (Europe)	1991–1999	716	Self-report (collected at baseline)	A priori cut-points:	
					≥175 cm vs. 165–169 cm	0.91 (0.67–1.23)
					Linear (1-cm increase):	1.02 (1.00–1.03)
Postmenopausal women						
Magnusson et al. (1998)	Case-control (Sweden)	1993–1995	2,803	Self-report (1 year prior to data collection)	A priori cut-points:	
					≥175 cm vs. <160 cm	1.08 (0.79–1.49)
van den Brandt et al. (2000)	Pooled prospective studies (USA, Europe, Canada)	1976–1993	3,208	Self-report (6 studies); physical measurement (1 study)	Whole number cut-points :	
					≥175 cm vs. <160 cm	1.28 (0.94–1.76)
					Linear (5-cm increase):	1.07 (1.03–1.12)
Morimoto et al. (2002)	Prospective cohort (USA)	1993–2000	1,024	Physical measurement (baseline interview)	Quintiles:	
					>167.0 cm vs. ≤156.4 cm	1.27 (1.00–1.62)
Lahmann et al. (2004)	Prospective cohort (Europe)	1992–2000	1,402	Physical measurement (baseline interview)	Quintiles:	
					≥167.7 cm vs. <156.0 cm	1.40 (1.16–1.69)
					Linear (1-cm increase):	1.02 (1.01–1.03)

This table summarizes key studies cited in the text examining the association between adult height and breast cancer risk, indicating a weakly positive association in premenopausal and postmenopausal women

cm centimeters

A small but increasing literature suggests that the age at which a woman first reaches her adult height could also be associated with breast cancer risk. Initial reports indicated as much as a 30% reduced risk of breast cancer in young women who reached their adult height at age 18 years or older relative to women who reached their adult height at age 13 or younger (Li et al. 1997). Subsequent studies have reported similar associations in older women, but indicate that the role of this factor may be restricted to certain subtypes of disease (Beaber et al. 2008). While a woman's age at maximum height is not itself an anthropometric measure, evidence of an association between this factor and breast cancer risk highlights the importance of considering patterns of growth and the timing of growth in the context of breast cancer risk.

As with weight and BMI, information on adult height in epidemiologic studies of breast cancer is typically collected in the form of either physical measurements or self-report. Studies assessing the validity of self-reported height indicate a high level of concordance with measured values overall; however, there is a tendency for women to slightly overestimate their height (Elgar and Stewart 2008). Any such bias in the reporting of height is not likely to differ between breast cancer cases and women without breast cancer, still the potential for misclassification must be considered in interpreting associations between height and breast cancer risk in studies relying on self-report. The use of physical measurements for height avoids the potential for bias in self-report, but it is not always feasible to directly measure the height of study participants. Finally, as with previously discussed measures, comparisons across studies of the relationship between height and breast cancer risk must take into consideration the fact that categorical cut-points (e.g., quartiles of height) tend to differ in different study populations and settings.

104.3 Body Size in Early Life

The process through which breast cancer develops from a single cancerous cell to a detectable tumor is thought to occur over a period of several years. Therefore, exposures measured at the time of breast cancer diagnosis may not reflect the environment under which that cancer first began to develop. The most etiologically relevant time period may instead be many years prior to breast cancer diagnosis. Thus, with respect to anthropometry, it is plausible that body size in early adulthood and childhood could be relevant to a woman's breast cancer risk. There are considerable methodological complexities to studying the association between early life body size and breast cancer risk. Still, existing epidemiologic studies of these potential associations suggest an important role of body size prior to adulthood.

104.3.1 Birth Weight and Birth Size

Motivated by the hypothesis that *in utero* exposures to circulating estrogens and other hormones could influence a woman's risk of developing breast cancer in adulthood, birth size has been examined in relation to breast cancer risk (dos Santos Silva et al. 2008). Birth weight and, to a lesser extent, birth length, head circumference, and ponderal index (i.e., weight in kg/height in m^3) have now been examined as breast cancer risk factors in a number of studies.

Modest positive associations between adult breast cancer risk and birth weight, birth length, and head circumference at birth were noted in a large meta-analysis of published and unpublished data (dos Santos Silva et al. 2008). Based on measurements taken from birth records, a 500 g increase in birth

weight was associated with a 6% increase in breast cancer risk, however, this association disappeared after adjusting for birth length and head circumference. The strongest independent association was noted with respect to birth length: women who were at least 51 cm in length at birth had a 17% increased risk of breast cancer relative to women who were 49 cm in length. After adjusting for birth weight and head circumference, a 2-cm increase in birth length was associated with a 9% increase in breast cancer risk. As with birth weight, a positive association between head circumference at birth and breast cancer risk was noted but did not persist after adjusting for other measures of birth size. Associations did not differ substantially with age and were only slightly attenuated after adjusting for maternal height, adult height, and adult BMI.

Studies examining associations between birth weight, birth length, head circumference at birth, and breast cancer risk typically rely on measurements abstracted from birth records. The use of birth records is generally preferable over self-report given that women may have considerable difficulty recalling these measurements with accuracy. Still, some reports have noted considerable interobserver variability in measurements from birth records, particularly birth length (Johnson et al. 1997). In studies that do rely on self-report, problems with recall are not likely to differ between women with and without breast cancer, but are still likely to impact study findings. In the previously mentioned meta-analysis, a positive association between birth weight and adult breast cancer risk was noted when based on data taken directly from the birth record, but no association was noted when relying on self-report or maternal report; statistical heterogeneity between studies was largely accounted for by differences in the source of birth weight data (dos Santos Silva et al. 2008). Therefore, the source of birth size data must be considered when interpreting and comparing findings across studies.

104.3.2 Body Size in Childhood and Adolescence

As with adult body size, the possible relationship between overweight and obesity in childhood and adolescence and breast cancer risk is of growing public health significance. Still, relatively few studies have explored associations between breast cancer risk and body size in childhood or adolescence. Studies that have examined such anthropometric risk factors have varied, not only in their findings but also in their methodologies. While some studies rely on self-report for obtaining height and weight measures at specific ages, others rely on measurements abstracted from medical records or school records, and still others use comparative measures and visual aides to help women approximate their past body shape or fatness.

Overall, studies in premenopausal women suggest a modest inverse association between body size during childhood or adolescence and subsequent breast cancer risk (Huang et al. 1997; Berkey et al. 1999; Weiderpass et al. 2004). A lower risk of postmenopausal breast cancer in women who were obese during adolescence has also been noted by some, but not all studies (Huang et al. 1997; Magnusson et al. 1998; Berkey et al. 1999). In an analysis of data from the Nurses' Health Study, women who reported a BMI greater than 25 kg/m^2 at age 18 years had a 0.6-fold lower risk of breast cancer prior to menopause and a 0.7-fold lower risk of breast cancer after menopause as compared to women with a BMI of 18.2 kg/m^2 or lower at age 18 (Huang et al. 1997). Information on body size at ages 5 and 10 years was also collected from this study population using a 9-level silhouette scale (Stunkard et al. 1983) (Figure 104.1): women were asked to identify the body silhouette (i.e., somatotype) that most closely corresponded with their recalled shape at these ages. Using this methodology, women who identified with the largest somatotype at age 10 had a reduced risk of breast cancer relative to women who identified with the thinnest somatotype, regardless of menopausal status

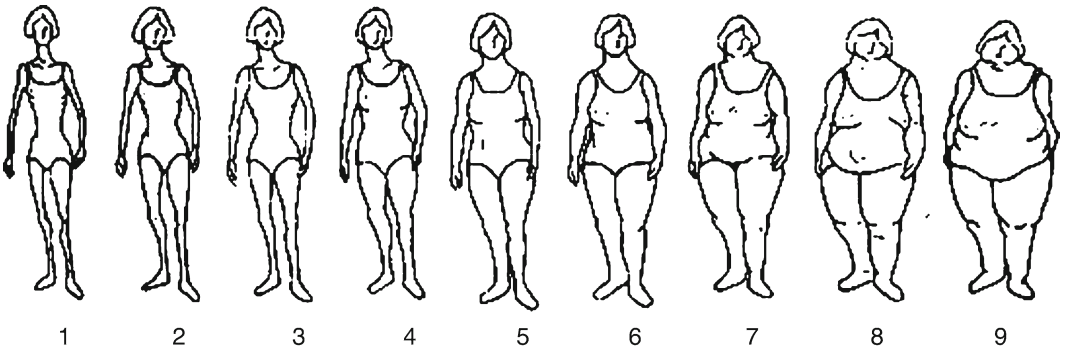

Fig. 104.1 Female body somatotype scale (Reprinted from Stunkard et al. (1983) with permission). Female body somatotype scales such as this, reprinted from Stunkard et al. (1983) with permission, are frequently used as visual aides in recalling past body size

(Berkey et al. 1999), however, a woman's somatotype at age 5 years was not associated with breast cancer risk. Consistent with these findings, other studies have reported a 30% lower breast cancer risk in premenopausal women who perceived themselves to have been fatter than other girls at age 7 years (as compared to women with an average body size at that age) (Weiderpass et al. 2004), and a significant trend of decreasing postmenopausal breast cancer risk with increasing somatotype size at age 7 (Magnusson et al. 1998). In another analysis using data on height and weight from school records, women in the lowest quintile of BMI at age 7 and at age 15 had a significantly higher breast cancer risk than women in the highest BMI quintile at these ages (Hilakivi-Clarke et al. 2001).

More so than with other anthropometric measures, there are considerable complexities in obtaining body size measurements from childhood and adolescence. Prospective collection of physical measurements for height and weight at young ages is unrealistic since any breast cancer study collecting such measurements would require a prohibitively long study follow-up. While a small number of studies have been able to use historical measurements of height and weight from medical and/or school records, such data sources are rare. The majority of studies instead rely on self-reported measures for past height and weight, although this approach is associated with considerable measurement error. Validation studies have suggested that using somatotype drawings to help women approximate their past body shape allows for a reasonably accurate assessment of body fatness at young ages (Must et al. 1993). Other studies approximate gradients of adolescent body size by asking women to recall how their body size at certain ages compared to that of their peers at that age. Each of these approaches to ascertaining body size carry advantages and limitations, and the choice of methodology should be considered when evaluating study results or comparing results across studies. Similarly, the timing of body size measures is important given that measures prior to the onset of puberty (e.g., age 5) could influence breast cancer risk in a manner different from measures during or after the onset of puberty (e.g., age 15).

104.4 Sources of Heterogeneity

As can be inferred from the literature cited throughout this chapter, there is substantial heterogeneity among studies of anthropometry and breast cancer risk. Some differences between studies result from differences in methodologies, but it is also plausible that the role of anthropometric risk factors may differ between populations. Specifically, associations between anthropometric factors and breast

cancer risk may differ with population characteristics (e.g., menopausal status, race/ethnicity), as well as certain tumor characteristics (e.g., hormone receptor status, histology). Studies that stratify analyses according to these characteristics provide the most sensitive estimation of risk factor associations. It is important to keep in mind potential sources of heterogeneity when interpreting the results of any given study.

104.4.1 Population Characteristics

As previously detailed, most studies of anthropometric risk factors for breast cancer assess associations separately for premenopausal and postmenopausal women and, among postmenopausal women, according to use of HRT. Given considerable evidence that the role of anthropometric risk factors varies with menopausal status and HRT use, it is plausible that the biological mechanisms through which anthropometric factors influence breast cancer risk differ with respect to these characteristics. Assessing associations in premenopausal women separately from postmenopausal women also allows for the likely possibility that the relative impact of anthropometric factors on breast cancer risk varies with menopausal status. Similarly, the role and impact of body size on breast cancer risk may vary with race/ethnicity. Fewer studies have addressed this potential source of heterogeneity, but those that have suggest considerable variability in associations with anthropometric factors. In a recent analysis of Hispanic white and non-Hispanic white women conducted in the southwestern United States, adult height and BMI were associated with premenopausal and postmenopausal breast cancer risk, but only among non-Hispanic women (Slattery et al. 2007). Thus, the racial/ethnic composition and age distribution of the study population can have an impact on observed associations between body size and breast cancer risk.

104.4.2 Tumor Characteristics

In light of increasing evidence that breast cancer is a biologically heterogeneous disease, the relationship between anthropometric factors and disease risk is likely to differ for distinct biological subtypes of breast tumors. That is, because different kinds of breast tumors are thought to arise through different pathways, anthropometric factors may differentially influence a woman's risk of developing certain kinds of breast tumors. Studies that are able to separate breast cancer cases into biologically distinct case groups provide some evidence that adult body size is most strongly associated with risk of hormone receptor-positive breast cancer. In a recent meta-analysis, women in the highest category of BMI had a significantly lower risk of premenopausal estrogen receptor (ER) positive/progesterone receptor (PR) positive breast cancer (odds ratio = 0.80), and a significantly higher risk of postmenopausal ER-positive/PR-positive breast cancer (odds ratio = 1.89); however, no such associations were noted with respect to risk of ER-negative/PR-negative breast cancer (odds ratio = 1.03 and 1.17 for premenopausal and postmenopausal women, respectively) (Suzuki et al. 2009). On a related note, studies evaluating risk factor relationships for different molecular subtypes of breast cancer have suggested that body size, particularly in postmenopausal women, is most strongly associated with risk of basal-like and luminal A subtypes of breast cancer (Millikan et al. 2008). Although less pronounced, differences have also been noted by studies stratifying case groups according to tumor histology (Li et al. 2006).

104.5 Summary of Methodological Considerations

Many methodological considerations impact the study design, data collection, and data analysis phases of epidemiologic studies investigating anthropometric risk factors for breast cancer. Considerations include the choice of different measures of body size (e.g., waist circumference versus WHR for characterizing central adiposity), different methods for measuring body size (e.g., self-reported versus measured weight), and the choice of analytic approach (e.g., linear versus quartile categorization of continuous measures). Several of these issues have been described above in relation to specific measures, but most relate more generally to the study of anthropometry and breast cancer risk.

As previously described, a wide variety of anthropometric measures have been studied as possible risk factors for the development of breast cancer – from measures of adult body size and fat distribution, to changes in body size, and body size early in life. Given that these different measures could plausibly impact a woman's risk of breast cancer through different mechanisms, the choice of which measure(s) to ascertain and over which time period should be largely determined by the scientific hypothesis of interest. However, even though the biological mechanisms through which the measures discussed here influence breast cancer risk may be distinct, most of these measures are highly correlated. For example, in an analysis using data from the Women's Health Initiative Observational Study (WHI-OS,) a woman's recent BMI was highly correlated with her reported change in BMI since age 18, her waist circumference, and her hip circumference (Pearson correlation coefficients = 0.9, 0.8, and 0.8, respectively) (Morimoto et al. 2002). Therefore, in order to assess the independent effects of any given measure of body size it is typically necessary to collect information on a variety of related measures.

For any given measure of body size, there may be multiple possible methods for data collection. Different methods carry different advantages and limitations, which must be weighed in the context of a study's design and objectives. With respect to measures of recent body size, the choice between using self-report versus physical measurements generally depends on the timing of data collection (i.e., prior to breast cancer diagnosis or at some interval following diagnosis) and the study interview protocol (i.e., in-person interview, telephone interview, or self-completed survey). Studies that rely on self-reported measurements of body size must consider the potential for bias in reporting, while studies that rely on physical measurements must consider that body weight and central adiposity are likely to be influenced by breast cancer progression and treatment. Studies examining the role of body size in the more distant past must typically rely on self-report and, as such, face considerable problems with recall. Although any bias or errors in recall are not likely to differ between women with breast cancer and women without, such bias may have an appreciable impact on study findings. The use of somatotype drawings is one approach to aiding recall of body size in the distant past, but reporting of body size under this approach is more subjective. While measurement error is almost guaranteed in any study of anthropometric risk factors for breast cancer, the source, nature, and magnitude of that measurement error is largely dependent on the manner in which anthropometric data are collected.

Once anthropometric data have been collected, the way in which those data are analyzed also presents an important methodological consideration. Given evidence that the relationships between measures of body size and breast cancer risk may not be linear, most studies assess anthropometric risk factors for breast cancer as categorical variables. However, with the exception of adult BMI category cut-points recommended by the World Health Organization (i.e., underweight: <18.5 kg/m^2, normal weight: 18.5–24.9 kg/m^2, overweight: ≥25 kg/m^2, obese: ≥30 kg/m^2), there are no standard

categorical cut-points for analyzing anthropometric measures. In the absence of standardized category cut-points, continuous measures, such as height, weight, and waist circumference are typically analyzed in tertiles, quartiles, or quintiles. While convenient, categorizing variables in this manner makes it difficult to draw comparisons across studies: since the range and distribution of body size measures varies between study populations, the tertile, quartile, and quintile distributions also vary. For example, in comparing two large prospective studies with data on breast cancer incidence and recent BMI, the European Prospective Investigation into Cancer and Nutrition (EPIC) and the Women's Health Initiative Observational Study (WHI-OS), both analyzed BMI as a categorical variable using the quintile distribution of BMI to generate category cut-points: in the EPIC study, women with a BMI less than 21.6 kg/m^2 and women with a BMI of at least 28.8 kg/m^2 were grouped into the lowest and highest quintiles, respectively (Lahmann et al. 2004), while in the WHI-OS the cut-points for the lowest and highest quintiles were equal to 22.6 and 31.1 kg/m^2, respectively (Morimoto et al. 2002). Thus, comparisons of breast cancer risk in the highest versus lowest category of an anthropometric measure may not be entirely comparable across studies. Additionally, because there is no biological basis for categorizing continuous anthropometric measures according to tertiles, quartiles, or quintiles, the use of such cut-points may obscure true patterns of increasing or decreasing breast cancer risk with body size, especially if the true relationship involves some threshold effect. In the absence of biological evidence to inform category cut-points for analyzing measures of body size and standardized cut-points, there is substantial variability between studies in terms of how measures of body size are handled in data analysis.

In spite of considerable methodological complexities, epidemiologic studies have now clearly demonstrated a link between anthropometry and breast cancer risk. However, such complexities do contribute to uncertainty about the exact nature of the relationship between anthropometric factors and breast cancer risk.

Summary Points

- Postmenopausal women who are obese or overweight are at an increased risk of developing breast cancer, particularly if they are not users of HRT. Studies in premenopausal women suggest a slightly reduced risk of breast cancer associated with overweight and obesity.
- The distribution of fatty tissue, not just the amount, may also be a risk factor for breast cancer. Evidence suggests that increased abdominal fat deposition is associated with an increased breast cancer risk.
- Adult weight gain is the anthropometric measure most consistently associated with breast cancer risk in postmenopausal women, although no consistent relationship between weight change and breast cancer risk has been observed in premenopausal women.
- Women who are tall in stature experience a slightly increased risk of breast cancer relative to shorter women.
- Increasing evidence suggests that body size in early life is associated with breast cancer risk. While there is considerable variability between studies, women with a short birth length and women with larger than average body size in adolescence may have a slightly lower risk of breast cancer.
- Most epidemiologic studies of breast cancer rely on participant self-report for ascertaining body size. Using self-reported measures can lead to bias if women are biased in reporting their body size or have problems with recall. However, it is not always possible or even preferable to collect physical measurements.

- Associations between many measures of body size and breast cancer risk differ greatly by menopausal status and HRT use. The relationship between anthropometric factors and breast cancer risk may also differ for different subtypes of breast cancer.
- Studies assessing the relationship between anthropometric factors and breast cancer risk vary widely in their study design, protocols for data collection, and the way anthropometric data are handled in analyses. All of these differences contribute to variability in study findings.

Chapter 105
Anthropometric Parameters in Hospitalized Elderly Patients with Cancer

E. Paillaud, B. Campillo, E. Alonso, and P.N. Bories

Abstract The prevalence of malnutrition in hospitalized elderly patients >70 years is estimated to be between 50% and 70% and is considered as one of the criteria of frailty in this population. On the other hand, malnutrition is common in patients with advanced cancer and is a poor prognostic factor; as such it should be detected as soon as possible. Therefore, the assessment of nutritional status is an essential element of therapeutic strategy in geriatric oncology and includes the determination of anthropometric parameters, biological data and measure of food intake. The most widely used anthropometrics measures in cancer are body mass index (BMI) and weight loss, with a prevalence of malnutrition varying between 20% and 70%, depending on threshold values reported (BMI<20 or 21, weight loss <5 or 10%). In elderly patients as in other adults, the impairment of these parameters is mainly determined by the localization of the tumor and the stage of the disease, with a higher prevalence of malnutrition occurring in digestive tract tumors and in advanced cancers. Aging per se does not represent a risk factor for malnutrition. However, elderly patients are at high risk of altering their nutritional status in terms of muscular mass as well as fat mass during the course of hospitalization. This calls for a specific nutritional intervention in geriatric oncology.

Abbreviations

BMI	Body mass index
CC	Calf circumference
HAS	High authority of health
MAC	Mid-arm circumference
MAMC	Mid-arm muscle circumference
MNA	Mini nutritional assessment
TST	Triceps skinfold thickness
10th perc	10th percentile

105.1 Introduction

The terms "older persons," "elderly people," and similar words generally refer, in the international literature, to the age group ≥65 years (Yancik 1997). This age break, somewhat arbitrary, is associated with the retirement age. There is an increasing tendency to use age 70+ or 80+ years in reference to the elderly in geriatric medicine. In France, the age threshold of 70 years has been proposed by the French institution HAS, High Authority for Health, to define the elderly population. The number of elderly people over 65 years in the industrialized world is steadily increasing and, at that time in France, represented 16.2% of the population (Beaumel and Vatan 2008). Approximately 25% of individuals aged 80 years will become centenarians. With the increase of the aged population, there is an increase in prevalence of health problems (Fried et al. 1999). The prevalence of malnutrition in hospitalized elderly patients over 70 years of age is high and may vary from 30% to 70%, according to several surveys conducted in Europe (Constans et al. 1992; Paillaud et al. 2000; Mowe and Bohmer 1991; Kyle et al. 2002; Potter et al. 1995; Persson et al. 2002). Malnutrition is considered as one of the criteria of frailty in older patients (Xue et al. 2008). The nutritional status of older persons is influenced by many factors including underlying diseases. Cancer is one of the diseases that frequently alters nutritional status; in addition, its incidence increases with age. Epidemiological data indicate that, in France, 30% of cancers and 48% of deaths attributable to cancer occurred after the age of 75 years (Belot et al. 2008). In advanced stages of the disease, malnutrition can progress to cachexia, characterized by the loss of adipose tissue and skeletal muscle mass. The causes of cancer cachexia include hypercatabolic activity related to interactions between host- and tumor-derived factors including pro-inflammatory cytokines, anorexia, and intake inability (Tisdale 2004). Malnutrition in cancer patients reduces the body's defense against infectious diseases. It is associated with a poorer response to treatment, shorter survival, and a reduced quality of life (Andreyev et al. 1998; Dewys et al. 1980). For these reasons, malnutrition should be prevented or detected as early as possible and clinical practice in geriatric oncology includes routine nutritional screening of elderly patients at risk of malnutrition and assessment of nutrition status at the time of hospitalization (Balducci and Extermann 2000). The assessment of nutritional status includes several markers: anthropometric measures, dietary intake, and serum protein profile. Two anthropometric parameters are often used to identify a cancer patient at risk of malnutrition: weight loss and body mass index. Other anthropometric variables can be used to make a complete assessment of nutritional status, which may highlight more discrete changes during hospitalization. Two questions arise regularly in geriatric oncology:

1. Is age a risk factor for malnutrition in cancer patients?
2. Is cancer associated with more extensive changes in nutritional status than other diseases occurring in the elderly?

105.2 Practical Methods and Techniques of Nutritional Assessment in Geriatric Oncology

Anthropometric parameters include weight, weight changes expressed as percent of initial body mass, body mass index (weight[kg]/height^2[m^2]), skinfold thicknesses, and mid-arm circumference (Table 105.1). The most widely used anthropometric parameter is body mass index (BMI). The World Health Organization categorizes underweight as BMI <18.5 and normal weight as 18.5–24.9. In elderly patients, the cutoff used to define malnutrition differs among studies and varies from 20 to 22. The threshold value usually used corresponds to the 10th percentile of data

Table 105.1 Anthropometric parameters usually used in elderly patients for malnutrition diagnosis

Anthropometric parameters	Threshold value for malnutrition diagnosis in elderly	Threshold value for severe malnutrition diagnosis
Weight loss (%)		
HAS criteria*	≥5% within 1 month ≥10% within 6 months	≥10% within 1 month ≥15% within 6 months
BMI (kg/m^2)	<10th perc	
70–74 years (F/M)**	<21.7/<21.8	
75–79 years (F/M)**	<21.9/<21.2	
>80 years (F/M)**	<19.7/<21.8	
HAS criteria*	<21	<18
Arm circumference (cm)	<10th perc	
75–79 years (F/M)**	<25.3/<26.9	
>80 years (F/M)**	<23.1/<24.9	
Triceps Skinfold (mm)	<10th perc	
75–79 years (F/M)**	<12/<6.9	
>80 years (F/M)**	<10.2/<6.1	
Muscle arm circumference (cm)	<10th perc	
75–79 years (F/M)**	<20.5/<23.7	
>80 years (F/M)**	<19.7/<22.0	
Mini Nutritional Assessment	<17 points	

This table lists the parameters measured to diagnose moderate or severe malnutrition. The threshold values given are those defined by the French National Authority for Health* and the 10th percentiles of anthropometric measures** assessed in a French healthy elderly population (Delarue et al. 1994). The Mini Nutritional Assessment is a global score including anthropometric parameters, which are body mass index (BMI), weight loss over the last 3 months, mid-arm muscle circumference, and calf circumference (Vellas et al. 2006).
10th perc 10th percentile of a nationally specific anthropometric reference data, *HAS criteria* French National Authority for Health criteria for undernutrition diagnosis in the elderly, *BMI* body mass index

assessed in a population of healthy elderly. However, such anthropometric reference values in the elderly are scarce and only a few national anthropometric reference percentiles for elderly populations have been published (Delarue et al. 1994). The use of these tables derived from a healthy population can be controversial because the definition of healthy in the elderly is not consensual. Moreover, BMI may be unreliable in the presence of overt fluid retention (edema or ascitis) and may not identify significant unintentional weight loss, if used as a single assessment. Nevertheless, BMI correlates strongly with mid-arm muscle circumference and tricipital skinfold thickness in elderly cancer patients and shows the highest sensitivity for detecting severe malnutrition (Table 105.2) (Campillo et al. 2004). Reliable measurement of height can be difficult in the elderly hospitalized patients because of postural changes and unsteadiness. Furthermore, cumulative height loss between 30 and 80 years averages about 5 cm for men and 8 cm for women. This height loss would account for an artifactual increase in body mass index of approximately 1.4 kg/m^2 for men and 2.6 kg/m^2 for women (Sorkin et al. 1999). For these reasons, it could be of interest to use the self-reported height or use Chumlea's formulae to estimate height from the heel–knee height (Chumlea and Guo 1992).

A loss of more than 10% of the usual body weight suggests malnutrition. Ideally, the reference weight should be obtained from an earlier medical record. If this is not available, the usual self-reported body weight may be used. In case of acute illness, the body weight must have been measured before the onset of the disorder. Factors that may influence the interpretation of the result, such as dehydration or edema, should be taken into account. Nevertheless, weight loss can be difficult to determine in elderly people with cognitive disorders because the self-reported weight often cannot

Table 105.2 Value of BMI in the detection of malnutrition (Campillo et al. 2004)

	Diagnosis of malnutrition (%) according to:	Sensitivity (%) of BMI <20 to detect	Specificity (%) of BMI <20 to detect
BMI < 20	38.6		
MAMC < 5th or 10th perc	44.7	65.8	81.8
TST < 5th or 10th perc	20.0	64.7	66.2
MAMC and TST < 5th or 10th perc	11.8	62.2	86.5
MAMC or TST < 5th or 10th perc	52.9	80.0	65.3

This table shows the sensitivity and specificity of BMI<20 to detect malnutrition in comparison to other anthropometric parameters. Anthropometric parameters were measured within 48 h of admission in 91 patients (mean age ± SD = 66.7 ± 12.7 years) with advanced cancer of various organs. The prevalence of malnutrition was assessed by low BMI, low MAMC, low TST, and the association of low MAMC or TST, whereas severe malnutrition was diagnosed on the basis of low MAMC and TST. The sensitivity and specificity of BMI < 20 to detect moderate or severe malnutrition varied between 62% and 86%. This parameter showed a high specificity for the detection of severe malnutrition in cancer patients.

BMI body mass index, *MAMC* mid-arm muscle circumference, *TST* triceps skinfold thickness, *5th or 10th perc* 10th percentile of a nationally specific anthropometric reference data

be used. Skinfold thickness can be measured with standardized calipers, but this requires technical skill. Several different sites can be used: subscapular, suprailiac, biceps, triceps, thigh, and calf. Finally, all these anthropometric indicators are simple and inexpensive to obtain, but have to be interpreted in the light of age, gender, and ethnicity.

To improve the assessment of malnutrition in elderly, the Mini Nutritional Assessment (MNA) was developed in home-care programs, nursing homes, and hospitals (Vellas et al. 2006). The MNA is a multidimensional tool, which combines anthropometric measurements, global assessment, dietary assessment, and subjective assessment. The anthropometric variables used in MNA are weight loss over the last 3 months, BMI, mid-arm muscle circumference (MAMC), and calf circumference (CC).

According to the recommendations of the High Authority for Health in France (HAS) (HAS 2007), the diagnosis of malnutrition is based on the presence of one or more of the following criteria: weight loss ≥5% in 1 month or ≥10% in 6 months, body mass index <21, serum albumin concentrations <35 g/l, and global MNA score <17.

105.3 Prevalence of Malnutrition in Hospitalized Elderly Patients with Cancer

Modification of the nutritional status is a frequent complication in patients with cancer. The nutritional status can be affected either directly by the malignant process, by side effects of treatment (surgery, chemotherapy, and radiotherapy), or by psychological factors. There are very few studies concerning exclusively elderly cancer patients. Table 105.3 reports the nutritional studies of hospitalized cancer patients with mean age of 60 years or more. The most widely used anthropometrics measures in cancer are body mass index (BMI) and weight loss, with a prevalence of malnutrition varying between 20% and 70%, depending on threshold values reported (BMI<20 or 21, weight loss <5 or 10%). The body weight or BMI, measured once, can have a limited capacity to effectively detect patients at nutritional risk in breast and prostate cancer (Toliusiene and Lesauskaite 2004) because preexisting overweight may mask the beginning of the deterioration of the nutritional status. In order to tackle nutritional deterioration, it is important to gather objective data on nutritional status and its evolution throughout the course of the cancer. Other anthropometrics measures, such as

Table 105.3 Prevalence of malnutrition in elderly patients with cancer

References	Age (year) Number of patients	Cancer	Anthropometric parameters used for diagnosis	Prevalence of malnutrition (%)

This table lists the nutritional studies of cancer elderly in-patients published in peer review journals. We reported mean age, number of patients, cancer localization, nutritional parameters used, and prevalence of malnutrition. The most widely used anthropometrics measures in cancer are body mass index (BMI) and weight loss, with a prevalence of malnutrition varying between 20% and 70%, depending on threshold values reported.
BMI Body mass index, *TST* Triceps skinfold thickness, *MAMC* Mid-arm muscle circumference, *MNA* Mini Nutritional Assessment

MAMC or TST, reflect the body composition changes that may occur during the disease. It is the loss of the fat-free mass that is responsible for the reduced functional status, increased mortality, and other negative outcomes associated with malnutrition (Tchekmedyian et al. 1992). The prevalence of malnutrition also varied according to the tumor site, disease stage, and the type of treatment used. One factor which most heavily influenced the nutritional status is the tumor site (Table 105.4). Patients with pancreatic, gastric, or esophagus cancer appear to have highest prevalence of weight loss, whereas those with breast or prostate cancer have the lowest ones.

105.4 Influence of Age

At admission, nutritional status is similarly altered in elderly and in other adults: aging per se does not represent a risk factor for malnutrition in cancer (Table 105.5) (Paillaud et al. 2006). However, during the course of hospitalization, elderly patients suffer from a greater loss of both fat and muscular mass

Table 105.4 Influence of the tumor type on the prevalence of malnutrition

	Dewys WD* 1998 *n* = 3,047	Nourissat et al.** 2007 *n* = 477
Type of tumor: *n* (%)		
Gastric	52 (38%)	8 (89%)
Esophagus		7 (78%)
Pancreas	29 (26%)	4 (58%)
Lung	154 (15%)	21 (31%)
Colon	46 (14%)	37 (36%)
Ovary		5 (25%)
Prostate	8 (10%)	4 (17%)
Lymphoma	29 (10%)	
Sarcoma	13 (7%)	
Breast	17 (6%)	13 (10%)
Acute Leukemia	5 (4%)	

This table lists the two international studies showing the prevalence of malnutrition according to tumor type. Malnutrition was assessed on the basis of weight loss >* or ≥** 10% in the previous 6 months. The prevalence of malnutrition was higher in patients with digestive tract cancer

Table 105.5 Comparison of nutritional status in cancer patients according to age (Paillaud et al. 2006)

	>70 years (*n* = 45)	<70 years (*n* = 43)	Statistical significance
Age (year)	77 ± 0.7	55.3 ± 1.2	
Gender (M/F)	20/25	24/19	$P < 0.0001$
Tumor type:			
Digest/hemato/solid	7/24/14	10/7/26	
Weight (kg)	56.6 ± 1.8	58.1 ± 1.8	
Weight loss (%)	16.1 ± 1.4	17.0 ± 1.4	
BMI (kg/m²)	21.4 ± 0.6	20.7 ± 0.6	
MAC (cm)	25.8 ± 0.7	25.7 ± 0.7	
TST (mm)	12.6 ± 0.9	13.3 ± 1.0	
MAMC (cm)	21.8 ± 0.6	21.5 ± 0.5	

This table shows the comparison of nutritional status in cancer patients according to age. Two groups of hospitalized patients with advanced cancer were defined according to age: an elderly group (>70 years) and a younger group (<70 years). Their nutritional status was assessed by different anthropometric parameters. Data are given as mean ± SEM. Means between groups were compared using the unpaired Student's *t* test. Anthropometric values did not differ between the two groups.
BMI body mass index, *MAC* mid-arm circumference, *TST* triceps skinfold thickness, *MAMC* mid-arm muscle circumference

(Table 105.6). This is partly explained by: (1) a lower spontaneous oral intake, compared with younger patients and (2) an intake below the recommended value for healthy, sedentary, elderly people. This higher risk for elderly patients calls for a specific nutritional strategy during hospitalization.

105.5 Comparison With Other Types of Disease

Cancer is associated with a more extensive modification of nutritional status than other diseases occurring in the elderly. Table 105.7 (personal data) compares anthropometric data in elderly cancer patients with those operated on for osteoarthritis, or those hospitalized for neurological or cardiac

Table 105.6 Changes in anthropometric parameters after a 2-month hospitalization in cancer patients, according to age (Paillaud et al. 2006)

	>70 years (n = 13)			<70 years (n = 9)		
	Day 0	Day 60	p	Day 0	Day 60	p*
BMI (kg/m²)	20.5 ± 1.5	20.3 ± 1.5		20.0 ± 1.7	19.9 ± 1.5	
MAC (cm)	25.7 ± 1.4	24.2 ± 1.0	< 0.03	27.0 ± 2.0	27.4 ± 1.7	
TST (mm)	11.5 ± 1.3	9.9 ± 1.0	< 0.03	15.2 ± 2.9	16.4 ± 2.8	
MAMC (cm)	22.1 ± 1.1	21.1 ± 0.8	0.085	22.2 ± 1.3	22.2 ± 0.9	
Fat mass (%)	25.4 ± 1.7	23.6 ± 1.4	< 0.05	28.5 ± 2.5	30.0 ± 2.6	

*not available, not significant

This table shows the changes in anthropometric parameters during the course of hospitalization in cancer patients according to age. Two groups of hospitalized patients with advanced cancer were defined according to age and were nutritionally assessed upon admission (day 0) and 2 months after (day 60) by measurement of anthropometric parameters. Data are given as mean ± SEM. Comparison of means between Day 0 and Day 60 using the paired Student's t test. MAC, TST, and fat mass decreased in the elderly patients after a 2-month hospitalization.
BMI body mass index, *MAC* mid-arm circumference, *TST* triceps skinfold thickness, *MAMC* mid-arm muscle circumference

Table 105.7 Comparison of anthropometric parameters between elderly hospitalized patients with cancer and those operated on for hip fracture or osteoarthritis or hospitalized for medical disorders (personal data)

Groups	Surgical (prosthesis for osteoarthrosis) n = 33	Medicine n = 44	Hip fracture n = 51	Cancer n = 47	p
Age (years)	74.7 ± 5.1	82.9 ± 8.2	83.0 ± 8.2	77.7 ± 5.4	$<10^{-4}$
Gender (H/F) (n)	15/18	9/35	10/41	10/27	0.009
MNA-sf	10.3 ± 3.1	5.7 ± 2.1	5.7 ± 2.4	5.1 ± 2.0	$<10^{-4}$
Weight (kg)	75.0 ± 17.9	60.0 ± 15.2	55.8 ± 11.3	56.3 ± 12.0	$<10^{-4}$
BMI (kg/m²)	28.1 ± 6.2	24.0 ± 5.6	21.8 ± 4.2	21.4 ± 4.2	$<10^{-4}$
MAC (cm)	31.0 ± 4.1	27.5 ± 4.8	25.6 ± 3.3	25.8 ± 4.7	$<10^{-4}$
TST (mm)	16.3 ± 8.0	11.1 ± 6.1	9.9 ± 3.8	12.5 ± 5.8	$<10^{-4}$
BST (mm)	7.2 ± 4.4	5.2 ± 4.1	3.9 ± 2.6	4.8 ± 4.6	0.003
Dietary intake (kcal/day)	1884 ± 326	1599 ± 422	1507 ± 461	1117 ± 657	$<10^{-4}$
Dietary intake (kcal/kg/day)	26.3 ± 6.8	27.9 ± 9.8	27.7 ± 8.3	22.8 ± 13.4	0.054

Four groups of hospitalized patients over 70 years were defined according to the cause of hospitalization. They were nutritionally assessed by measurement of anthropometric parameters and dietary intake. Data are given as mean ± SEM. Means between groups were compared using the ANOVA test. All data differed significantly among the four groups, with the most impaired values observed in patients with cancer and hip fracture.
MNA-sf mini-nutritional assessment-short form, *BMI* body mass index, *MAC* mid-arm circumference, *TST* triceps skinfold thickness, *BST* biceps skinfold thickness

diseases, or those operated on for hip fracture. Nutritional status is similarly compromised in the cancer and hip-fracture groups. These two geriatric populations are at particular risk of malnutrition and should be nutritionally evaluated upon admission and during hospitalization, and if necessary, should benefit from nutritional support.

Summary Points

- Clinical practice in geriatric oncology includes routine nutritional screening of elderly patients at risk of malnutrition and assessment of nutrition status at the time of hospitalization (Table 105.8).
- The most widely used anthropometric parameters are BMI and weight loss.

- The prevalence of malnutrition assessed by weight loss or BMI on hospital admission is not higher in elderly patients with cancer than in younger ones.
- During the course of hospitalization, anthropometric parameters decrease in elderly persons with advanced cancer resulting in a more impaired nutritional status in comparison with that of younger persons.
- Two elderly hospitalized populations are at particular risk of malnutrition: patients operated for hip fracture and cancer patients. These groups require increased surveillance.

Key Points

Table 105.8 Key points of malnutrition in hospitalized elderly patients with cancer

Key points
The number of elderly people in the industrialized world is steadily increasing and is associated with an increased prevalence of health problems.
The prevalence of malnutrition in hospitalized patients >70 years is between 30% and 70%.
More than 30% of cancers occur in patients aged >70 years.
Malnutrition is a poor prognostic factor and should be detected in cancer patients.
Elderly cancer patients are usually nutritionally assessed by means of BMI and percent weight loss.
The prevalence of malnutrition is similarly high in hospitalized elderly and in other adult patients with advanced cancer on admission (≥50%).
Elderly patients are at high risk of altering their nutritional status during the course of hospitalization.

This table lists the key facts of malnutrition in elderly patients with cancer including the tools to measure it

Chapter 106
Body Weight and Body Surface Area in Chemotherapy

Dominique Levêque

Abstract In oncology, dosing of anticancer drugs in adult patients is mostly adjusted to estimated body surface area or more rarely to body weight. When compared with a fixed (or flat) dose which is the rule in other therapeutic areas, this approach is a complication necessitating calculations that can lead to prescription and administration errors. Dosing according to body surface area or to body weight is based on the intuitive belief that the variability in drug exposure (ie, the capacities of the organism to clear a drug) is related to body size in adults. Dose normalization to body size is assumed to decrease the interindividual pharmacokinetic and pharmacodynamic variability and in turn, to optimize clinical outcomes. Unfortunately, this approach is mostly empirical and is rarely validated before approval of the anticancer drug. Theoritically, body size-based dosing should only be used if it has been demonstrated that it constitutes a significant factor affecting clinical variability. Numerous studies have shown that dosing according to body surface area or body weight did not significantly affect drug exposure variability. It has never been proved that body size was a covariable of pharmacokinetics and pharmacodynamics of anticancer agents in adults patients. Although the use of body surface area has been discouraged during clinical development, this practice remains the rule particularly for conventional agents. For few agents, alternative methods of dosing optimization include the integration of phenotypic or genotypic factors.

Abbreviations

AUC	Area under the concentration-time curve
BSA	Body surface area
CV	Coefficient of variation

106.1 Introduction

In pharmacotherapy, drugs are generally given to adult patients at a fixed (or flat) dose, independently of the size of the body, at least because it is more convenient. By contrast, in oncology, dosing of anticancer agents is traditionally adjusted according to estimated body surface area or, more

Table 106.1 Key features of anticancer chemotherapy

1. Chemotherapy is one of the modalities (besides surgery and radiotherapy) of anticancer treatment.
2. In oncology, chemotherapy defines the use of drugs (called anticancer agents or antineoplastic agents) that eradicate cancer cells.
3. Anticancer agents are mainly given intravenously and in combination.
4. Most of the anticancer agents are very toxic because they also destroy healthy cells (lack of selectivity).
5. Side effects of chemotherapy (digestive, hematologic, and infectious) may be prevented or treated by supportive care products.

This table lists the key facts of anticancer chemotherapy including the definition, the lack of selectivity, and the management of side effects

Table 106.2 Classes of drugs used in the treatment of cancer (referred to as chemotherapy)

Class	Clinical use	Route of administration
Conventional cytotoxic agents	All types of cancer	Mostly parenteral, oral
Hormonotherapy	Hormone-dependent tumors (breast and prostate cancer)	Mostly oral, parenteral
Monoclonal antibodies	Selected types of cancer (those expressing the target antigen)	Parenteral
«Targeted therapies» (enzyme inhibitors)	Selected types of cancer (those expressing deregulated enzyme activity)	Mostly oral, parenteral

This table lists the various types of drugs used in the treatment of cancer including the conventional cytotoxic agents, hormonotherapy, the monoclonal antibodies, and the "targeted therapies"

rarely, to body weight. In a general way, dosing based on body size is mostly used in pediatrics in relation with development and maturation of children.

Anticancer agents, also referred as chemotherapy (Tables 106.1 and 106.2), are known to have a low therapeutic index. This means that for most of them, the therapeutic dose is very close to the maximal tolerated or toxic dose. The activity of a drug (therapeutic or toxic) depends on its concentration at the site of action (pharmacodynamic relationship), which generally is the reflection of its fate in plasma after administration (pharmacokinetics) (Table 106.3). For a given dose, interindividual variability in drug exposure (pharmacokinetic variability) may occur, leading to severe side effects or insufficient anticancer activity (pharmacodynamic variability). Adjustment of dosing according to body surface area or body weight is based on the intuitive belief that the variability in drug exposure (i.e., the capacities of the organism to clear a drug) is related to body size in adults. Consequently, it is assumed that this approach decreases the pharmacokinetic variability and, hence, optimizes the exposure to anticancer agents and the therapeutic activity.

For 20 years, numerous critics have raised concerns on the dosing of anticancer agents adjusted to body size in adults. Currently, this practice remains the standard in adult oncology, but alternative approaches, in particular, genetic, are emerging. This chapter will present the principles and the limitations of the dosing of anticancer agents based on body size in adult patients.

106.2 Background

In 1958, Donald Pinkel suggested to use body surface area instead of body weight in the dosing of anticancer agents (Pinkel 1958). This was based on the observation that, for some anticancer agents (in fact, the few that were available at that time: methotrexate, mechlorethamine, 6 mercaptopurine,

Table 106.3 Key facts of pharmacokinetics and pharmacodynamics

1. Pharmacokinetics describes the behavior of drugs in the body after administration.
2. Drug disposition in the organism generally follows three steps (absorption, distribution, and elimination that include metabolism and/or excretion).
3. These processes may be quantified by parameters (pharmacokinetic parameters) estimated from the plasma drug concentration versus time curve.
4. The area under the plasma drug concentration versus time curve (AUC) defines the exposure of the organism to the drug.
5. Absorption relates the fate of the drug from the administration site to the blood (it does not apply to the intravenous or intra-arterial route). The process is characterized by the plasma concentration peak, the time for plasma concentration peak, and the absolute bioavailability.
6. Bioavailability is the fraction of the administrated dose which reaches the general circulation (i.e., available for the therapeutic effect).
7. Elimination corresponds to the irreversible loss of the drug from the body. The drug may be eliminated by metabolism (biotransformed in an inactive metabolite) and/or excreted via the bile in the feces or in the urine. These processes involve metabolizing enzymes and sometimes drug transporters that mediate active transcellular passage.
8. The elimination parameters are the total clearance (capacity of the body to clear the drug), which is calculated by dividing the amount of the drug in the body by the area under the plasma drug concentration versus time curve (AUC), and the terminal half-life (time over which the plasma concentration of the drug decreases by half).
9. Pharmacokinetics is also characterized by the intra- and interindividual variability of parameters. For a given dose, the extent of absorption (for example, bioavailability for an oral agent) or the rate of elimination may greatly vary among patients.
10. These variations of plasma concentrations may affect the clinical outcomes (tolerance and therapeutic effect). The relation between drug concentrations and clinical effects is called pharmacodynamics (i.e., the study of the impact of pharmacokinetic variability on the drug effects).

This table lists the key facts of pharmacokinetics and pharmacodynamics including the different steps of drug disposition in the organism, the area under the plasma drug concentration versus time curve (AUC), the corresponding parameters, and the impact of pharmacokinetic variability (pharmacodynamics)

actinomycin D, and thiotepa), the therapeutic dosages were comparable in humans and small laboratory animals (mice, rats, and hamsters) when related to body surface area and not to body weight. At the end of the fifties, body surface area arose as a criterion of drug dosage because it was estimated to correlate with physiologic functions. Since then, and without any scientific validation, drug dosage normalized to body surface area was used in phase I clinical trials (first administration of a drug in humans) and was included in the official labeling (or summary of the product characteristics) of almost all marketed anticancer agents.

Currently, this practice is relatively specific to oncology and, besides anticancer agents, also concerns supportive care products, such as some hematopoietic growth factors, antifungal agents, or antidotes (drugs used to prevent or cure symptoms related to the disease or to the toxicity of the anticancer treatments). Sometimes, this approach appears irrational (and rather confusing) within a class of anticancer agents, such as the therapeutic monoclonal antibodies. Monoclonal antibodies display comparable pharmacokinetic behaviors (limited distribution in the body and very low clearance), but are used either at a fixed dose or at a dose based on body weight or body surface area (Table 106.4). This heterogeneity may even be observed for a single drug, such as rituximab. Rituximab, a monoclonal antibody that specifically targets lymphocytes, is bizarrely given at a dose adjusted to body surface area in the treatment of cancer (375 mg/m² in non-Hodgkin lymphoma and 500 mg/m² in chronic lymphocytic leukemia) and at a fixed dose (1 g) in rheumatoid arthritis, a systemic non-cancerous inflammatory disease. Similarly, dacarbazine is a conventional agent whose dosing is based on body weight when administered as monotherapy and on body surface area when combined with another anticancer agent.

Table 106.4 Heterogeneity of dosing expression of monoclonal antibodies used in the treatment of cancer

Therapeutic monoclonal antibody	Expression of dosing
Rituximab	Body-surface-area-based; fixed dose in non cancerous diseases
Alemtuzumab	Fixed dose
Trastuzumab	Body-weight-based
Cetuximab	Body-surface area-based
Panitumumab	Body-weight-based
Bevacizumab	Body-surface area-based
Ibritumomab tiuxetan (coupled with a radioisotope)	Radioactive dose
Gemtuzumab ozogamicin	Body-weight-based

This table lists the various expressions of dosing of anticancer therapeutic monoclonal antibodies including the use of body surface area, body weight, the fixed dose, and the radioactive dose

However, fixed dosing tends to be used with recent anticancer agents and particularly the so-called «targeted therapies». Contrasting with conventional agents, the research of which is primarily based on the killing of tumoral cells in vitro, «targeted agents» interact with a relative specificity with predefined physiological or tumoral determinants (enzymes, such as kinases, in a general way). Currently, all approved «targeted therapies» in the European Union (gefitinib, erlotinib, sunitinib, sorafenib, imatinib, dasatinib, nilotinib, lapatinib, pazopanib, everolimus, and temsirolimus) are administrated at a fixed dose in adult patients. This is probably due to their low toxicity profile when compared with conventional agents and to their oral administration (except temsirolimus given by intravenous injection). Oral, fixed dosing is far more convenient than that adjusted to body size. In fact, and unless a liquid oral formulation is available, accurate adjustment to body size is not possible with solid forms (tablets or capsules).

106.3 Practical Considerations

Practically, and when compared with the fixed dose, body-size-based dosing is a complication necessitating calculations that can generate prescription, preparation, and administration errors (medication errors). The oncologist estimates body size area of the patient (in m^2) using weight and height and then calculates the dose by referring to the approved dosage expressed by m^2 (that mentioned in the official labeling). For example, for a patient of 1.66 m^2, the dose of rituximab to be administered is 375 mg/m^2 (approved dosage) × 1.66 m^2 = 622.5 mg (Table 106.5). Then, the pharmacist analyzes the order (in particular, checks the estimation of body surface area and the corresponding dosage) and delivers the product using the available dosage presentations, generally ready to be administered. Most of the anticancer agents are parenteral drugs and their preparation is generally performed in hospital pharmacies. For rituximab, the dose (622.5 mg) is prepared using the 100 mg and 500 mg marketed presentations. Hence, preparation of a dose of an intravenous form adjusted to body size may lead to wastage associated with significant financial consequences, given the prohibitive cost of anticancer agents.

Regarding oral anticancer agents (besides «targeted therapies»), dosing can also be complicated for the physician and the patient. For example, the recommended treatment schedule for capecitabine (a conventional agent used in breast and gastro-intestinal cancers) includes nine levels of dosing (i.e., the number of pills to be taken), depending on the body surface area of the patient.

Table 106.5 Practical considerations of drug dosing based on body surface area: an example using an adult patient treated by the therapeutic monoclonal antibody rituximab

Oncologist	Estimates body surface area of the patient using body weight and height: 1.66 m²
	Calculates the administrated dose: approved dosage of rituximab (375 mg/m²) × 1.66 m² = 622.5 mg
Pharmacist	Analyzes the prescription: checks the body surface area estimation and the corresponding dose
	Prepares the dose ready to be administered intravenously (622.5 mg) using the available marketed presentations of rituximab (100 and 500 mg)

This table lists the practical considerations followed by the oncologist and the pharmacist regarding the treatment of an adult patient with the monoclonal antibody rituximab

106.4 Limitations of Body-Size-Based Dosing

Scientifically, body-size-based dosing appears mostly either unjustified (i.e., not better than fixed dosing) or unvalidated (not proven that it is better than fixed dosing). In fact, body surface area or body weight should only be used if it has been demonstrated that size constitutes a significant factor affecting pharmacokinetic and pharmacodynamic (clinical) variability. When compared to fixed dosing, administration of anticancer drugs adjusted to body weight or body surface area should lead to the improvement of therapeutic outcomes (optimized antitumoral response and decreased toxicity).

Since 1990, numerous papers have been published highlighting the lack of relationship between body surface area and the elimination parameters (clearance) of anticancer agents (Grochow et al. 1990; Reilly and Workman 1993; Gurney 1996; Ratain 1998; Sawyer and Ratain 2001; Miller 2002; Newell 2002; Egorin 2003; Levêque 2007; Mathijssen et al. 2007). For most anticancer agents, including the recent monoclonal antibodies, body size is not a factor that significantly affects drug disposition in the organism or decreases exposure variability. It is not really a surprise because the physiological activities of the two main organs involved in the elimination of drugs (the kidneys and the liver) are not correlated to body size in adults. In addition, the variation of body surface area in adult patients is weak (15%) when compared with pharmacokinetic variability of anticancer agents (25–50%). It has to be stated that, in oncology, the dosage of anticancer agents is often tailored to the patient's clinical response. The standard dose is decreased in case of inacceptable toxicity or sometimes increased if the therapeutic response is judged insufficient. Curiously, these dosing modifications that may be significant (20–50%) remain based on body size (e.g., from 100 to 75 mg/m²). In all, estimated body surface area or body weight has not been shown to significantly correlate with pharmacokinetic or pharmacodynamic variability of numerous anticancer drugs. In other words, several anticancer agents could be administered at a fixed dose in adult patients because interindividual variability persists on using body-size-calculated dosing.

Some trials have compared body surface area dosing with fixed dosing of anticancer drugs in adult patients in terms of pharmacokinetic variability and clinical outcomes (Table 106.6). Variation in pharmacokinetics and toxicity was found to be similar in patients receiving irinotecan, an intravenous drug used for the treatment of colorectal cancer, either at fixed dose (600 mg, 26 patients) or adjusted to body surface area (350 mg/m², 47 patients) (De Jong et al. 2004). The coefficients of variation of irinotecan clearance were around 25% in both groups. Thus, flat fixed dosing of irinotecan did not major pharmacokinetic variability nor hematological toxicity. Paclitaxel is an intravenous conventional agent given in the treatment of lung, ovary, and breast cancer. Paclitaxel pharmacokinetics have been studied in 12 patients who received the anticancer agent both at a fixed dose (300 mg) and at a dose based on body surface area (175 mg/m²) in a randomized

Table 106.6 Features of clinical trials comparing body surface area dosing and fixed dosing of anticancer agents in adult patients

Anticancer drug	Method of dosing	Pharmacokinetic variability	Clinical outcomes	Reference
Irinotecan	Body surface area-based	16.7% (CV of AUC)		
	Fixed dose	29.9% (CV of AUC)	No difference in toxicity	De Jong et al. (2004)
Paclitaxel	Body-surface area-based	25.1% (CV of clearance)		
	Fixed dose	25.9% (CV of clearance)	No difference in toxicity	Miller et al. (2004)

This table lists the features of trials that have compared body surface area dosing and fixed dosing of irinotecan and paclitaxel, in terms of pharmacokinetic variability and clinical outcomes. CV, coefficient of variation; AUC, area under the concentration–time curve

Table 106.7 Expression of dosage of 148 investigational anticancer agents in 225 adult phase I trials reported at major oncology meetings in the years 2005 and 2006 (Levêque et al. 2008)

	Fixed dose (%)	Body-surface area-based (%)	Body-weight-based (%)
All trials	40.4	44	13.8
Trials with conventional agents	1.3	96	2.7
Trials with "targeted therapies"	78.5	16.4	2.7

This table lists the various expressions of dosage of investigational agents including conventional drugs and "targeted" therapies

crossover design (Miller et al. 2004). Exposures to paclitaxel determined by the area under the plasma concentrations–time curve (AUC) were comparable with the two dosing approaches and no difference in terms of hematological toxicity appeared. The variability was higher with flat fixed dosing compared with the traditional body-surface-area-based dosing (29.9% vs. 16.7%), but without clinical consequences (toxicity). These two a posteriori studies (i.e., undergone after drug approval) show that fixed dosing is not detrimental in terms of clinical impact when compared to body-surface-area-based dosing.

Consequently, in 2002, the abandonment of the use of body surface area in dosing of new agents in phase I studies was recommended by some authors (Baker et al. 2002). To see if these recommendations were effectively implemented, a survey assessed the expression of dosage of 148 investigational anticancer agents in 225 adult phase I trials reported at major oncology meetings in the years 2005 and 2006 (Levêque 2008). Dosages were still adjusted to body surface area and body weight in 44% and 13.8% of all trials. Only 91 studies (40.4%) exhibited a fixed dose (Table 106.7). Regarding the type of anticancer drug, virtually all trials (96%) involving conventional agents used body-surface-area-based dosing, whereas the majority of studies (78.5%) of targeted anticancer agents used a fixed dose, perhaps in relation with their low toxicity (when compared with cytotoxics) and to the fact that they were primarily oral drugs. Thus, recommendations were not really followed, particularly for conventional agents.

106.5 Alternative Approaches of Dosing Optimization

Fixed dosing is the simplest way to administer a medication until other factors or covariables are identified that significantly improve patient care. As discussed earlier, body size is not a factor that optimizes anticancer drug dosing in adult patients since it does not significantly decrease drug exposure

Table 106.8 Alternative approaches of dosing optimization of anticancer agents

Method	Advantage	Limits
Genotypic: identify genetic variants associated with pharmacokinetic/pharmacodynamic variability	Optimization a priori	Applies to very few drugs Partly explains pharmacokinetic/pharmacodynamic variability Still used as body-size dosing
Phenotypic: adjusting drug dosage according to elimination capacities of the patient	Validated by clinical trials	Applies to very few drugs Still used as body-size dosing
Physiologic: adjusting drug dosage according to the renal function of the patient	Not based on body size	Only applies to carboplatin

This table lists the alternative methods of dosing of anticancer agents including the genotypic, phenotypic, and physiologic approaches

variability and, in turn, does not affect clinical outcomes. The search for the causes underlying pharmacokinetic variability has led to the exploration of genetic or phenotypic factors as potential means to improve the dosing schedules of anticancer agents (Table 106.8).

Drug disposition in the organism (absorption, distribution, and elimination) is controlled by molecular determinants, such as metabolizing enzymes and transporters. Pharmacokinetic variability may be related to variations in the expression of these determinants. One cause of variation is genetic, due to polymorphisms that affect (in general decrease) the activities of enzymes or transporters. Regarding drug dosing, identification of patients with genetic variants (genotyping) before the initiation of treatment can avoid serious side effects related to defective elimination or decreased therapeutic activity due to insufficient anabolic formation of the active entity. Currently, only four anticancer agents (mercaptopurine, thioguanine, irinotecan, and tamoxifen to a lesser extent) are administered by dosing optimization based on genotyping (Walko and McLeod 2009). All of these are mentioned in the package inserts of three products (mercaptopurine, thioguanine, and irinotecan), at least in USA. For example, a dose reduction of irinotecan is recommended in patients with decreased activity of UGT1A1, an enzyme involved in the elimination of the anticancer agent, in relation to the gene variant *UGT1A1*28.* However, as mentioned in the official labeling of irinotecan (Camptosar® in the USA), the precise dose reduction is not known. To avoid excessive toxicity, dosage is reduced by 25% in homozygote patients with the gene variant *UGT1A1*28*, but is still based on body surface area. In addition, dose individualization based on genotyping of one determinant appears far from optimal. In fact, variability in irinotecan disposition and toxicity is multifactorial, involving both genetic and non-genetic factors, such as sex (Mathijssen 2009). Overall, dosing adjustment based on genotyping does not appear good enough for irinotecan and remains related to body size.

The variability of enzyme activity may also be extra genetic, as with fluorouracil, a drug characterized by a high and variable metabolic elimination when given by continuous venous infusion. Differences in fluorouracil exposure affect clinical outcomes (efficacy and tolerance). Fluorouracil dosing may be individualized based on the capacities of elimination of the patient that can be determined before treatment with a test dose or during treatment by measuring plasma concentrations (Gamelin et al. 2008). However, and like the genotypic approach, this phenotypic method of dosing still used body surface area.

Drug dosing may be adjusted to renal function, as in the case of carboplatin, whose elimination is highly related to the glomerular filtration rate (Calvert et al. 1989). Variations in elimination (i.e., in renal function) affect the tolerance (mainly hematological) of the drug. Carboplatin is the rare anticancer agent whose dosing is not based on body surface area but on the renal function of the patient.

106.6 Applications to Other Areas of Health and Disease

Besides chemotherapy, questioning the use of body size in the dosing of drugs in adult patients may apply to other therapeutic areas, such as anti-infective agents or drugs used in the treatment of autoimmune diseases. Avoiding dose calculation based on the weight or the body surface area of the patient may limit errors of prescription, dispensation, and administration.

106.7 Conclusion

Dosing of anticancer drugs is adjusted to body surface area or body weight, although it has never been proven that this practice leads to improvement of therapeutic outcomes in adult patients when compared to fixed dosing. Numerous marketed anticancer agents could be administered at a fixed dose, but, unfortunately, it is improbable that their official labelings will change. For oral agents, some simplifications may occur, as for capecitabine, which has recently been tested using a flat dosing (Traina et al. 2008). Regarding investigational agents, fixed dosing could be used until it is demonstrated that body size or another variable (genotypic, phenotypic) is a significant factor of clinical variability. Fixed dosing has at least the potential to reduce medication errors and perhaps to limit the wastage of costly products. Novel approaches of dosing improvement are emerging, but currently concern very few agents.

Summary Points

- The particularity of anticancer drug dosing is that it is to be adjusted according to body surface area or body weight in adult patients.
- When compared with a fixed (or flat) dose, this approach is a complication necessitating calculations that can lead to prescription and administration errors.
- Dosing according to body size should be used if it leads to improvement of therapeutic outcomes, when compared with a fixed dose.
- Dosing according to body size in oncology is mostly empirical and is very rarely validated, a priori.
- Variation in body surface area is weak in adult patients when compared with pharmacokinetic variability.
- Numerous studies have shown that dosing according to body surface area or body weight did not significantly affect drug exposure variability. It has never been proved that body size was a covariable of pharmacokinetics and pharmacodynamics of anticancer agents in adult patients.
- Although the use of body surface area has been discouraged during clinical development, this practice remains the rule particularly for conventional agents.
- For a few agents, alternative approaches of dosing optimization include the integration of phenotypic or genotypic factors.

Part XVII
Anthropometry in Exercise and Sport Activities

Chapter 107
The Meaning of Muscle Mass for Health, Disease, and Strength Exercises

Roberto Carlos Burini and Nailza Maestá

Abstract Skeletal muscle is the largest organ of the mature body having major contributions to endogenous amino acid supply, insulin-dependent glucose removal and total body energy expenditure. Muscle mass is a determinant of metabolic homeostasis, physical strength and daily living activities. Higher lean mass equates to higher nutritional reserve and strength whereas lower muscle mass (sarcopenia) is a major contributor to disability and increased mortality. The definition of sarcopenia is arbitrary and its diagnosis is dependent on the methodology of muscle mass assessment, reference groups and cut off points. Methods used to assess muscle mass such as anthropometry, BIA or DXA are unable to distinguish aqueous and non aqueous components of the muscle mass whereas this is accomplished with the more expensive CT or MRI. Data are referred as kg of muscle mass, % of the body mass or correcting either appendicular or total muscle mass for height (kg/m^2). The most used data comes from either DXA or BIA assessment in male and female populations of Rosseta, New Mexico (NM Elder Health Survey) and NHANES III studies with cut off points at −2 SD for both genders. There is no cut off for hypertrophic-muscle mass. There are also no consensual criteria for defining sarcopenic-obesity or the fat frailty, the worse condition with regard to the difficulties of performing physical tasks. For this purpose muscle mass must be associated with some type of functional test (strength and power) to assess muscle quality. This chapter highlights the roles of muscle mass, its measurements and variations in health and diseases, and the lack of data for correctly interpreting muscle mass and function in the presence of obesity and strength exercises.

Abbreviations

AIDS	Acquired immune deficiency syndrome
ASM	Appendicular skeletal muscle mass
BIA	Bioelectrical impedance
CT	Computerized tomography
DXA	Dual X-ray absorptiometry
MRI	Magnetic resonance imaging
NHANES	National Health and Nutrition Examination Survey

107.1 Introduction

107.1.1 Skeletal Muscle Role in Health

Skeletal muscle is the largest organ in the mature human body and the major reservoir of free amino acids, which are mobilized for the immune response in many diseases, or stressful events, or both (Evans 1997). It is also the most responsible for the insulin-dependent glucose removal from plasma and is the major contributor to whole-body energy expenditure (Elia 1992). As a major determinant of physical strength, the loss of lean mass is thought to be a major contributor to functional decline and disability (Janssen et al 2004a, b).

Multiple independent studies have so far reported that all-cause mortality and body mass index (BMI) show a U-shaped association in men and women: namely that, whereas there is a significant increase in all-cause mortality among persons with a BMI higher than approximately 25 kg/m^2, persons with a BMI lower than approximately 20 kg/m^2 also show increased mortality, even after adjusting for possible confounding factors.

Epidemiological cross-sectional studies have documented associations between low skeletal mass and physical disability (Baumgartner et al 1998; Janssen et al 2004a) or low physical performance. Subjects in the lowest quartile of cross-sectional thigh area had a higher risk (1.90 for men and 1.68 for women) of developing mobility disability than those in the highest quartile (Visser et al. 2005).

There is a positive association between muscle mass and strength and in improving functional performance and reduced disability (Rolland et al. 2008). Muscle strength is associated with lower mortality. The relationship between muscle mass and strength is linear, whereas the relationship between physical performance (such as walking speed) and muscle mass is curvilinear (Newman et al. 2006). Muscle strength is related to muscle mass, but the ability to perform activities of daily life also relies on other physiological characteristics, such as flexibility, coordination, praxis, and balance (Rolland et al. 2008).

Human skeletal muscle is dependent on genetic predisposition, exercise, nutrition, and the hormonal–inflammatory state. A decrease of muscle mass with aging results in sarcopenia, whereas an increase of fat mass results in obesity. Each of these conditions is believed to contribute, at least in part, to difficulties with physical function and increased levels of physical disability (Baumgartner et al. 1998).

Approximately 60% of fat-free mass is muscle and about 75% of muscle mass is appendicular (Morley 2008).

The control of skeletal muscle size is tightly regulated by the synergy between hypertrophy (anabolic) and atrophy (catabolic) processes (Leger et al. 2006). The quantity of protein in skeletal muscle is maintained by a continuous repair process, which involves both protein breakdown and synthesis. The total mass of skeletal muscle is determined by the balance between protein synthesis and protein breakdown (Miyazaki et al. 2008). Skeletal muscle is highly adaptable and can change its structural and functional properties in response to physiological simulation (Miyazaki et al. 2008).

Muscle inactivity, which can occur with immobilization and microgravity, causes muscle atrophy (Miyazaki et al. 2008). After the age of 40, skeletal muscle is lost at a rate of approximately 5% per decade. In the elderly, the muscle protein synthesis rate is reduced by 30% (Rolland et al. 2008).

With aging, there is a decrease in both muscle fiber size and number, with a greater loss of type II and an increase in hybrid type I and II fibers (Reeves et al. 2006). The loss of muscle mass is greater in the legs than in the arms, but the loss of muscle quality in the elderly seems more significant in the arms for men compared to women, whereas loss of muscle quality in the leg seems similar in men and women (Lynch et al. 1999).

Men and women present different trajectories in the decline in skeletal muscle with aging; men have a gradual decline, whereas women tend to have a sudden drop in muscle mass and function following menopause (Rolland et al. 2008).

It is well known that aging is associated with decreased functional capacity, free-fat mass, bone mass, maximal heart rate, and other factors that greatly increase the risk of chronic disease and reduced independence later in life (Evans 1997). VO_2 max declines at the rate of 3–8% per decade after 30 years of age, but, adjusted for muscle mass, VO_2 max no longer declines. This suggests that loss of muscle mass is a significant contributor to fatigue and decreased endurance (Rolland et al. 2008).

The large, and supposedly involuntary, loss of muscle tissue in the elderly is considered responsible in part for the age-related decline in functional capacity. Fatty infiltration of skeletal muscle common in the elderly is associated with reduced strength and functional status (Rolland et al. 2008).

After 50 years of age, muscle mass is reported to decline at an annual rate of approximately 1–2%, but strength declines at 1.5% per year and accelerates to as much as 3% per year after age 60 (Evans 1997). These rates are higher in sedentary individuals and twice as high in men compared to women (Gallagher et al. 1997). Age-related loss of skeletal mass, strength, and function ultimately causes about 15% of persons 65–75 years of age and 50% of persons >85 years of age to require assistance with daily living activities (Rolland et al. 2008).

Human skeletal muscle hypertrophy occurs with an increase in functional demands, seen with resistance training and with functional electrical stimulation after spinal cord injury and in the elderly following surgery (Leger et al. 2006). Increased muscle activity attributable to a resistance-exercise- and functional overload induces skeletal muscle hypertrophy (Miyazaki et al. 2008). High-intensity resistance training (above 60% of the one repetition maximum) causes large increases in strength and significant increases in muscle size (Evans 1997).

107.1.2 The Importance of Muscle Loss

In 1931, Critchley noted that, with aging, there was a loss of muscle mass, which was most noticeable in the hands and feet (Critchley 1931). This age-related loss of muscle mass was later called sarcopenia (from the Greek: sarx for flesh and penia for loss) by Irving Rosenberg (Rosenberg 1997).

Whereas originally sarcopenia was considered to be a generalized loss of muscle, it is now more conventionally used to describe a level of muscle loss substantially more than that seen in normal young persons. Sarcopenia is one of the four major causes of weight loss. The others are anorexia, cachexia, and dehydration (Morley 2008).

Sarcopenia is different from starvation and cachexia, which are also associated with loss of muscle mass but whose causes and therapeutic approaches are different. During starvation, protein–energy deficiency results in a loss of fat and muscle mass (Morley 2008), but these are reversible with

Table 107.1 Complications relative to loss of lean body mass (Demling 2006. Reproduction permission requested)

Lean body mass (% loss of total)	Complications (related to lost lean mass)	Associated mortality (%)
10	Impaired immunity and increased infection	10
20	Decreased healing, weakness, and infection	30
30	Too weak to sit, pressure sores, pneumonia, and no healing	50
40	Death, usually from pneumonia	100

replenishment. Cachexia results in both fat and muscle mass loss, but it accompanies chronic disease (Rolland et al. 2008). This progressive muscular abnormality, which affects several anabolic and catabolic systems and results in a progressive catabolic state, is a devastating condition seen after musculoskeletal trauma, catabolic diseases such as cancer, diabetes, sepsis, chronic obstructive pulmonary disease, chronic heart failure and AIDS denervation, neuromuscular disorders such as Duchenne muscular dystrophy and myotrophic lateral sclerosis, and critical illness myopathy (Leger et al. 2006).

Cachetic patients usually die from either opportunistic infections or wound-healing failure, both of which are related to the decrease of lean body mass (Table 107.1).

Sarcopenia is attributable to an imbalance between protein synthesis and degradation, or between apoptosis and the regeneration process, or both. However, sarcopenia is thought to mainly reflect an age-related decrease in the synthesis of muscle protein rather than an excess catabolic process associated with disease or from a reduced caloric intake, although some have hypothesized that low-grade, chronic inflammation with increased protein degradation may contribute (Rolland et al. 2008).

Lifestyle behaviors leading to sarcopenia are physical inactivity, smoking, and poor diet. The risk factors are age-related changes in hormones and cytokine levels. Postulated mechanisms are alterations in muscle protein turnover, muscle tissue remodeling, the loss of alpha motor neurons, and muscle cell recruitment apoptosis (Baumgartner and Waters 2006).

Causes of sarcopenia are: impaired muscle capacity to regenerate (deficiency in satellite cells and protein turnover alterations); increased oxidative stress; loss of motoneurons; reorganizations of neuromuscular junction disturbances of the endocrine system; deteriorization of the immune system; and development of a chronic inflammatory state (Combaret et al. 2009).

Sarcopenia has become an important area of clinical research because it is considered to be an important contributor to the age-related loss of physical function. Age-related muscle loss is a prevalent condition associated with disability and mortality. Sarcopenia plays a predominant role in the etiology and pathogenesis of frailty, which is highly predictive of adverse events, such as hospitalization, associated morbidity and disability, and mortality (Rantanen 2003).

Sarcopenia is assumed to be a major component in the development of frailty to the degree that the International Academy of Nutrition and Aging Screen for Frailty (IANA) definition for frailty is strongly related to sarcopenia (Abellan van Kan et al. 2008; Baumgartner et al. 1998). This condition is approximately twice as common as frailty (Morley et al. 2005). In USA, it is estimated that there are roughly 3.6 million persons with frailty (Morley 2008). It results in a decrease in muscular strength and endurance (Rosenberg 1997) and is strongly associated with disability (Janssen et al. 2004b) with a cost of approximately $ 18.5 billion or 15% of the total healthcare expenditure in USA (Janssen et al. 2004a, b). These costs will escalate as the population older than 65 years grows from 13% (1977) to 17% in 2020, and to 21% in 2040 (U.S. Census Bureau 2000).

Higher BMI is a risk factor for loss of muscle mass in postmenopausal women, as an excess accumulation of fatty acids around the muscle fibers may interfere with their functioning (Rolland et al. 2009) and thereby reduce muscle quality (muscle strength adjusted for muscle size). The age-related

increase in fat mass generally precedes the loss of muscle mass (Baumgartner and Waters 2006), but the reverse is also true. The loss of muscle mass results in lower physical activity, which, in turn, results in reduced energy expenditure, fat gain, and obesity (Rolland et al. 2009).

An increase of fat mass may be more predictive of self-reported disability, functional limitation, and poor physical performance than a decrease of muscle mass (Rolland et al. 2009). It has been recognized that persons who lose muscle, but remain obese, are at very high risk of disability and mortality (Baumgartner et al. 2004). This condition is called "obese sarcopenia" or "fat frail." In addition, when muscle contains large amounts of fat, there is an increased likelihood of poor outcomes, a condition termed myosteatosis (Rolland et al. 2008).

It has been hypothesized that sarcopenic obesity is associated with increased fatty infiltration of muscle (Baumgartner et al. 2004). Contractility, motor unit recruitment, or muscle metabolism decreases in the presence of fat infiltration (Rolland et al. 2008).

Sarcopenic obesity is the worst condition with regard to the difficulties of performing physical tasks that require strength (Rolland et al. 2009). Sarcopenia may only affect physical performance and function in the presence of increased fat mass. Furthermore, the occurrence of obesity and sarcopenia together has been reported to be a much more pejorative condition in the development of physical disabilities than either sarcopenia or obesity alone (Baumgartner et al. 2004). Sarcopenic obesity has been reported to predict the onset of disability more accurately than either sarcopenia or obesity alone.

While it is recognized that the factors that cause strength loss are different from those resulting in muscle loss (Rolland et al. 2009), sarcopenia usually results in a decline in strength and power, leading to frailty and disability. Metabolic syndrome and diabetes are associated with a decline in muscle strength and increased falls and hip fractures (Morley 2008).

In postmenopausal women, sarcopenia is not associated with physical difficulties, in the absence of obesity. However, in the presence of obesity, sarcopenia tends to render some physical functions more difficult (Rolland et al. 2009).

Janssen described severe sarcopenia (defined using BIA) as being only a modest independent risk factor for the development of physical disability. During the eight-year follow-up, the risk of developing disability was only 1.27 times higher for subjects with severe sarcopenia and the risk was not statistically significant in moderate sarcopenia (Janssen 2006).

In the elderly, the benefit of higher muscle mass in obese individuals offsets the associated cardiovascular risk factors, and low muscle mass is associated with decreased survival rates following acute illness and with a doubled risk of nosocomial infection in the care of the elderly (Rolland et al. 2008). The amount of lean mass in the obese is low compared to their total body weight and predicts functional limitation. High muscle mass may act as a nutritional reserve during a medical event and extremely high muscle mass may, in part, explain the lower rate of death in certain obese elderly (Rolland et al. 2008).

107.1.3 Skeletal Muscle Mass Measurements

Body composition methodology has changed considerably during the past two decades from underwater weighing to the availability of fan-beam DXA machines that can quantify muscle, bone, and fat mass in a few minutes. This period has also seen the introduction of very precise bone-tissue measurement methods, such as magnetic resonance imaging, and somewhat less precise techniques, such as bioelectrical impedance (Rolland et al. 2008).

Methods used to measure muscle mass are outlined in Table 107.2.

Table 107.2 Methods to estimate muscle mass (Reproduced with permission from Morley 2008)

Approach	Problems	Cost
DEXA	Cannot distinguish muscle from organ protein; problem when abdominal fat is present	$$$
Bioelectrical Impedance	Problems with hydration status	$$
Anthropometry	Operator-dependent crude approximation	$
Urinary creatine/Creatinine	Physical activity	$
	Non-muscle sources	
	Renal clearance	
CT or MRI	Cross-sectional	$$$$
Neutron Activation	Cannot distinguish muscle from organ protein	$$$
	Limited availability	

DEXA Dual energy X-ray absorptiometry; *CT* computerized tomography; *MRI* magnetic resonance imaging

Methods used to assess muscle mass, such as anthropometry, BIA, or DXA, are unable to distinguish aqueous and nonaqueous components of the muscle mass. Theoretically, this can be accomplished with CT or MRI (Rolland et al. 2008). DXA has limited ability to distinguish water retention of fat tissue infiltration within muscle. Kim et al. (2004) estimated that fatty infiltration of muscle can inflate skeletal muscle mass estimates from DXA by 1–8%. However, Chen et al. (2007) and others (Kim et al. 2004) reported strong correlations ($r > 0.94$) between DXA and MRI measures of skeletal muscle mass, indicating that this increasingly available method is useful for cross-sectional studies and screening.

Most studies measure appendicular muscle mass and adjust for height. Heymsfield et al. have summed the muscle mass of the four limbs from DXA scans as appendicular skeletal muscle mass (ASM), and defined a skeletal muscle mass index (SMI) as ASM/height^2 (kg/m^2) (Heymsfield et al. 1990).

All definitions of sarcopenia are arbitrary and open to criticism. An operational definition needs to differentiate those with sarcopenia from those not affected, and needs to define standards and be applicable across populations (Rolland et al. 2008).

The trigger to screen for sarcopenia should be a loss of muscle mass of 5% or greater, over a year or less (Morley 2008).

Calf circumference is regularly correlated to muscle mass, but this correlation is low and makes calf circumference a poor screening tool for sarcopenia (Rolland et al. 2003).

Sarcopenia was based on appendicular skeletal muscle mass measurements (Heymsfield et al. 1990), which correspond to the sum of the two upper and lower limb muscular masses in kilograms.

Individuals with an SMI two standard deviations below the mean SMI of a middle-aged reference male and female population from the Rosetta Study (Gallagher et al. 1997) were defined as gender-specific cutoff points for sarcopenia. Later, sarcopenia severity was divided into grade I (-1 SD) and grade II (-2 SD) among different populations using DXA (Baumgartner et al. 1998; Gallagher et al. 1997) as the method for skeletal muscle mass assessment (Table 107.3). This definition has been used by several authors (Baumgartner et al. 1998; Rolland et al. 2003).

The NHANES III study (Janssen et al. 2004a) (Table 107.4) used BIA methodology similar to our studies (Table 107.5) and has different resulting figures.

The Botucatu follow-up study (Mexa-se pró-saúde) is a prospective dynamic cohort study designed to evaluate the role of diet and physical activity on the occurrence of metabolic syndrome, its components, and comorbidities. All the participants were over 35 years, living in the urban area

of Botucatu (a city located in the midwest of São Paulo state (Brazil), which has a population of 120,800 (2007)). The participants were clinically evaluated following a maximum exercise test on the treadmill, along with nutrition, biochemistry, and other fitness assessments.

107.1.4 Diagnosis and Prevalence of Sarcopenia

By using different methods and references, sarcopenia was found to range from 5% to 13% in persons aged 60–70 years of age and from 11% to 50% in persons over 80 years of age (Baumgartner et al. 1998; Morley 2008). After the age of 60, the prevalence of moderate and severe sarcopenia has been estimated to be 53% and 11% in men and 22% and 9% in women, respectively (Janssen et al. 2004a, b).

The prevalence of sarcopenia estimated based on a bioelectric impedance equation from the New Mexico Elder Health Survey was 20% in men between the age of 70 and 75 years and about 50% in those over 80 years. Among women in the same age ranges, it was 25% and 40%, respectively (Baumgartner et al 1998). In a later study, by estimating sarcopenia based on dual energy X-ray

Table 107.6 Prevalence of sarcopenia in studies using bioelectrical impedance (BIA)

Studies	Gender (*n*)	Prevalence of sarcopenia – % (*n*)		
		Grade I	Grade II	Total
NHANES III (Janssen et al. 2004a)	Male (2,223)	53.1 (1,130)	11.2 (249)	64.3 (1,429)
	Female (2,276)	21.9 (498)	9.4 (214)	31.3 (712)
Botucatu's study	Male (58)	65.5 (38)	5.2 (3)	70.7 (41)
	Female (170)	21.2 (36)	3.5 (6)	24.7 (42)

NHANES III National Health and Nutrition Examination Survey III; Botucatu's study: using data from Table 107.5.

absorptiometry (DXA), it ranged from 8.8% in women and 13.5% in men aged 60–69 years, and up to 16% in women and 25% in men older than 80 years (Rolland et al. 2008).

Still based on the Baumgartner index, sarcopenia was detected in 10% of the female population 70 years of age and older in the French European Patient Information and Documentation Systems Study (EPIDOS Study), with cutoff points derived from a different reference group (from the Baumgartner's) (Rolland et al. 2008).

Using a similar definition (–2 SD) in the population based on NHANES III, 35% of the elderly had a moderate degree of sarcopenia and 10% a severe degree (Janssen et al. 2004a). In the Botucatu study, the prevalence of sarcopenia was twice as high in males as in females at similar ages (Table 107.6). By using yet another definition, 6–15% of persons over 65 years of age had sarcopenia (Rolland et al. 2008).

The large variability in sarcopenia prevalence is related to the differences in measurement and the cutoff points used to define it (Morley 2008).

One reason for the divergent prevalence of sarcopenia within and between groups is due in part to the changes in assessing muscle mass that have occurred over the past 20 years, and the fact that studies used different measures of relative muscle mass, reference groups, and cutoff points. Therefore, it is difficult to compare prevalence estimates among studies (Rolland et al. 2008). The recognition of the need for a consensus operational definition of sarcopenia occurred in 1995 (Chumlea et al. 1995). The best reference data set should include measurements that are correlated with and can discriminate sarcopenia and have a broad ethnic racial and age representation (Rolland et al. 2008).

Moreover, most obese adults have increased muscle mass in addition to a high fat mass, but a low muscle mass in relation to their total body weight (Newman et al. 2003), whereas the thin elderly have a high proportion of muscle mass in relation to their total body weight. Thus, the skeletal muscle mass index potentially misclassifies the obese elderly with a high SMI and mobility and functional limitations and the thin elderly with a low SMI and none or few mobility or functional limitations. Thus, Baumgartner's original estimates were adjusted for body fatness (Baumgartner et al. 1998).

There are no consensual criteria for defining sarcopenic obesity. One can create a continuous sarcopenic obesity index by adjusting muscle mass for weight or fat mass using a regression-based approach (Newman et al. 2003). Waist circumference instead of fat mass or percentage fat can be used to define obesity for sarcopenic obesity studies (Castaneda and Janssen 2005).

The approach in cross-classifying subjects by SMI and a measure of adiposity, however, is distinctly different in that it combines the joint effects of sarcopenia and obesity in a single categorical variable. From a statistical point of view, it makes little difference when studying associations of sarcopenia with other outcomes, whether adjustment for fat mass or body mass is made using a priori adjustment to the index or by regression adjustment during analysis (Rolland et al. 2008).

Table 107.7 Distribution of the skeletal muscle mass index obtained by BIA and waist circumference in a sample of subjects clinically selected (2004–2008) for a lifestyle modification program, including physical exercises (Botucatu, SP, Brazil)

		Skeletal muscle mass index			
Waist circumference	Gender	<P25 *n*(%)	P25–P75 *n*(%)	>P75 *n*(%)	Total
< P25	Male	18 (46)	21 (25)	2 (5)	41
	Female	59 (43)	69 (26)	9 (6)	137
P25–P75	Male	19 (49)	44 (53)	19 (45)	82
	Female	69 (50)	145 (54)	58 (41)	272
> P75	Male	2 (5)	18 (22)	21 (50)	41
	Female	10 (7)	54 (20)	75 (53)	139
Total	Male	39	83	42	164
	Female	138	268	142	548

The data used were calculated from Table 107.5

By crossing the quartile distribution of the Table 107.5 data with similar distribution of waist circumference (WC), we came to an arbitrarily classification of sarcopenic obese (SMI < P25/WC > P75), which was 5% (males) and 7% (females) (Table 107.7).

Skeletal muscle mass adjusted for both height and body weight and not height alone is a significant predictor of mobility limitation in a large sample of elderly men and women (Newman et al. 2003). Rather than adjusting statistically, Janssen et al (2002) used muscle mass relative to weight rather than stature. In a later study, Baumgartner cross-classified subjects by SMI and percent body fat and reported that associated disability was strongest in those who were both sarcopenic and obese. Newman et al (2003) used a residual method to adjust muscle mass for fat mass in addition to height and found that this index had stronger associations with lower-extremity functional limitation and disability than sarcopenia defined by SMI alone (Rolland et al. 2008).

By using data from NHANES III, in addition to operating curves, to determine the sex-specific skeletal mass cutoff point for physical disability risk, women whose SMI was below 5.75 kg/m^2 muscle mass had an increased risk for physical disability (OR = 3.31, 95% CI; 191–5.73) as were those whose SMI was below 8.5 kg/m^2 (OR: 4.71, 95% CI; 2.28–9.74). It is important to note that, in this study, total skeletal mass was predicted using a bioelectrical impedance equation (Janssen et al. 2004a). These new cutoff points were closely similar to those first proposed by Baumgartner et al (1998).

Differences among studies regarding the strength of associations of various definitions of sarcopenia with functional status are a function of the methods used to define functional status or disability and their sensitivity and precision (Rolland et al. 2008).

The main effect from a loss of muscle mass is reduced muscle strength, which is an important factor to consider in defining sarcopenia. The loss of muscle quality, also an important component of the definition of sarcopenia, supposes an assessment of both muscle strength and muscle mass (Rolland et al. 2008) (Fig. 107.1).

The Jamar dynamometer for grip strength is a simple estimation of total muscle strength (Rantanen et al. 2003), but is not useful for those with hand arthritis (Morley 2008). Leg muscle strength, assessed as maximal lower extremity muscle strength or power, is a good measure of functional status and is strongly associated with measures of mobility, but it is only properly measured with a dynamometer by a trained technician (Overend et al. 1992).

Lower limb strength and/or power can be measured by walking speed or stair climbing. The use of the Cybex and similar machines is useful for research, but requires expensive equipment and technical skill (Morley 2008).

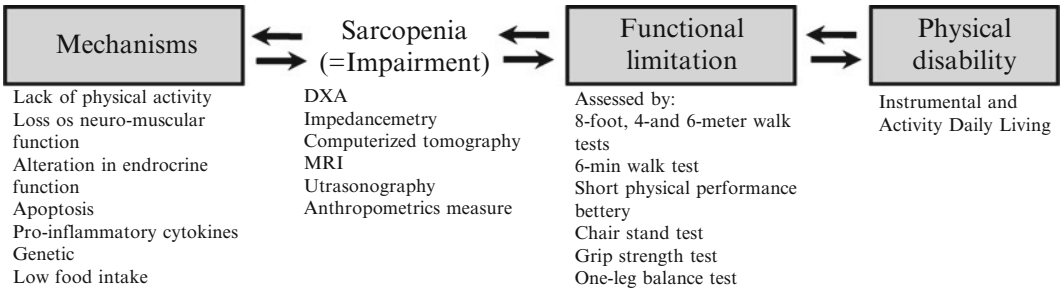

Fig. 107.1 Sarcopenia and the disability process (Reproduced with permission from Rolland et al. 2008)

Aging changes fiber patterns and this results in the slowing of twitch contraction time and a slowing of maximum shortening speed. For these reasons, it is important to measure muscle strength and power as well as mass (Morley 2008). Muscle power is defined as muscle work being either strength multiplied by speed or muscle strength multiplied by distance divided by distance. Muscle power declines with aging at a higher rate than muscle strength (Rolland et al. 2008).

Muscle power is more strongly related to functional limitation than muscle mass or muscle strength (Rolland et al. 2008). Muscle power includes muscle contraction speed and a measure of muscle quality, in addition to muscle strength (Morley 2008).

Muscle mass is strongly correlated to muscle strength and power but the same amount of muscle mass is able to produce different levels of strength and power. Thus, which measures of muscle strength should be used to define sarcopenia is unclear at this time, considering available data (Rolland et al. 2008).

Ultrasonic studies have shown that changes in tendons with alterations in pensation angles play an important role in the ability to generate power (Narici and Maganaris 2006). Electromyography can be used to determine loss in motor units; it should be recognized that loss of executive function interacts with sarcopenia to produce falls (Morley 2008).

107.1.5 Muscle Mass Gain and Sarcopenia Treatment

Behavioral treatments, such as exercise, increase muscle mass and strength; pharmacologic treatments, such as growth hormone, increase mass without a significant change in strength (Rolland et al. 2008).

The diagnosis of hypertrophic skeletal muscle still lacks cutoff points. By using the distribution of the data seen in Table 107.7, we could estimate that 5% of the males and 6% of females have higher SMI and lower WC values. Considering sarcopenia (mean-2SD) values and using hypertrophy as mean + 2SD, Table 107.5 shows us the equivalent muscle mass >39.5 kg for males and ≥24.2 kg for females, when both are over 60 years.

Treating sarcopenia by improving muscle strength or muscle power is more effective clinically for disability or mobility than increasing muscle mass. However, increasing muscle mass is more important for other outcomes, such as protein stores or thermogenesis (Rolland et al. 2008).

Skeletal muscle grows predominately in a hypertrophic manner after birth. This occurs by increasing myofibrillar diameter and length because of predominant protein synthesis over protein

breakdown. Protein synthesis is influenced positively by muscle contraction, growth factors, and leucine. Muscle protein synthesis is enhanced by anabolic factors, such as insulin, glucose, creatine, branched chain amino acids (BCAA), and glutamine, acting on cell hydration (Rivas et al. 2008).

Sarcopenia and poor performance in the elderly are associated with birth weight in both males and females, independent of adult weight and height (Yliharsila et al. 2007), and has a significant heritable component.

Potential candidate genes determining muscle strength (Rolland et al. 2008):

(a) Candidate genes for lower extremity muscle strength: the gene growth/differentiation factor 8 (GDF8), cyclin-dependent kinase inhibitor 1A (CDKN1A), and myogenic differentiation antigen 1 (Myod 1).
(b) Genes strongly related to muscle strength: the genes in the myostatin pathway including cyclin-dependent kinase 2 (CDK2), retinoblastoma (RB1), and insulin-like growth factor 1 (IGF-1).
(c) Genes related to loss of muscle power as well as muscle quality during adulthood: namely, lower quadriceps strength values – ciliary neurotrophic factor gene variant (CNTF A allele); and arm and leg strength (especially women) – IGF-2 genotype.
(d) Genes that influence knee extensor peak power in response to strength training: the actinin alpha 3 (ACNT 3) R577X genotype; and the angiotensin-converting enzyme (ACE) gene.
(e) Genes that may be associated with muscle strength: polymorphisms in the vitamin D receptor (VDR); genes associated with sarcopenia in elderly men; genes associated with muscle strength and body composition in postmenopausal women; and genes associated with muscle strength in older women.

107.2 Applications to Other Areas of Health and Disease

Muscle mass quantification is a suitable index for metabolic homeostasis (amino acids, glucose, and free fatty acid metabolism), human kinetics, and strength. Hence, it is important for nutritional and metabolic areas of health as well as for orthopedic and trauma areas. As a major bed of body oxygen and blood, skeletal muscle mass is important for cardio-respiratory systems and aerobic fitness. Skeletal muscle hypertrophy occurs with an increase in functional demands, such as resistance training or functional overload, which cause large increases in muscle size and strength – major goals of weight lifters and bodybuilders.

Summary Points

- Men and women present different trajectories in the decline of skeletal muscle with aging; men have a gradual decline, whereas women have a sudden drop following menopause.
- Loss of muscle is a significant contributor to fatigue, decreased endurance, and functional disability. Fatty infiltration of skeletal muscle is commonly associated with reduced strength and functional status.
- There is a positive association between muscle mass and strength and this relation is linear, whereas the relationship between physical performance and muscle mass is curvilinear.
- Skeletal muscle atrophy is attributable to an imbalance between protein synthesis and degradation, or between apoptosis and regeneration processes, or both.

- Lifestyle behaviors leading to skeletal muscle loss are physical inactivity, smoking, poor diet, and inflammatory states.
- Sarcopenia is considered a generalized loss of muscle at a level substantially higher than normal young persons.
- The loss of muscle mass results in lower physical activity, lower energy expenditure, fat gain, obesity, muscle fatty acid infiltration, and insulin resistance in a condition called obese sarcopenia, with poor outcomes.
- Human skeletal muscle is dependent on genetic predisposition, resistance exercises, nutrition, and hormonal and inflammatory states, by controlling the balance between hypertrophy (myofibrilar protein synthesis) and atrophy (protein breakdown).
- Human skeletal muscle hypertrophy occurs with an increase in functional demands seen with resistance training and with functional electrical stimulation after spinal cord injury.
- Behavioral treatments, such as exercise, increase muscle mass and strength; pharmacologic treatments (by hormones) increase mass without a significant change in strength.

Key Features

Table 107.8 Key facts on anthropometric measurements of muscle mass and health, diseases, and strength exercises.

1. Muscle mass is a determinant of nutritional reserves, metabolic homeostasis, and physical strength and related abilities. Lower muscle mass is a risk factor for functional disabilities (frailty) and increased mortality
2. The methodology to measure skeletal muscle mass has changed considerably in sensitivity, specificity, and cost. All definitions of either higher or lower muscle mass are arbitrary and open to criticism. Their large variability is related to the differences in measurement, reference groups, and cutoff points
3. Skeletal mass index is a single index used for the sum of the muscle mass of the four limbs
4. For defining sarcopenic obesity (or fat frail), muscle mass must be associated with some functional test (strength and power). Measuring muscle mass in the presence of muscle fat infiltration (myosteatosis) has been criticized

Chapter 108
Exercise, Nutrition, and Anthropometry of Bone Development in Term and Preterm Infants

Ita Litmanovitz and Alon Eliakim

Abstract The physiology of bone mass accretion in the early postnatal life has been studied extensively due to the development of reliable, precise, and noninvasive methods for bone mass assessments. Most of the studies address bone development in very low birth weight preterm infants. Given that the period of greatest bone mineral accretion in utero occurs during the last trimester of pregnancy and that it is very difficult to match bone requirements in the postnatal extra-uterine environment, metabolic bone disease remains relatively common in preterm infants. At birth, both bone mineral density measured by dual X-ray (DEXA) absorptiometry and bone strength measured by quantitative ultrasound measurements of bone speed of sound (SOS) were found to be significantly lower in preterm compared to infants born at term, with a strong correlation between tibial SOS and gestational age. Moreover, longitudinal studies demonstrated a decrease in bone mineralization by DEXA and in bone strength determined by bone SOS during the 1st weeks of post-natal life, emphasizing the importance of the intra-uterine environment for bone development. Interestingly, postnatal catch-up of bone strength in premature infants occurs only when the stress and the inflammatory state, which accompanies the early postnatal life of preterm infants, is reduced.

There is conflicting data regarding the beneficial effect of enriched post discharge formula (PDF) on bone metabolism. Enriched PDF, at least until corrected age of 40 weeks, was found beneficial for bone development, but there is still no convincing evidence to support its beneficial effect after this period.

There is mounting evidence to support the notion that assisted exercise (passive, range of motion, and flexion and extension with gentle compression of the large joints) attenuates the natural decrease of bone strength or even increase bone mineralization in premature infants. The mechanism for these beneficial bone effects is not clear; however, it may involve exercise-induced increase in bone formation, leptin, and insulin-like growth factor-I level. Whether the positive bone effects are related to the range of motion exercise per se, or whether the assisted exercise regimen leads to increased overall daily movement in preterm infants in not known. The optimal exercise regimen for this unique population also needs to be determined.

QUS	Quantitative ultrasound
SGA	Small for gestational age
SOS	Speed of sound
TF	Term formula
VLBW	Very low birth weight

108.1 Introduction

In healthy newborns, lean (predominately muscle), fat, and bone tissues, the key components of body mass, increase rapidly. The pattern of this increase is profoundly altered by premature birth. Although little is known about the mechanisms that control the early postnatal development of muscle, fat, and bone, there is mounting evidence that the factors regulating body composition among these compartments are distinct and lead to different rates of growth. In addition, in the case of muscle and fat tissues, for example, growth may be antagonistic (e.g., exercise-induced increase in muscle mass associated with decrease in fat mass). By contrast, in the case of muscle and bone, growth of the two tissues is usually synergistic.

Body composition is difficult to study in premature babies largely because of the limited tools appropriate for this fragile population. Recently, the use of three distinct techniques was shown to be useful to determine body composition in premature babies: (1) dual energy X-ray absorptiometry (DEXA), which measures lean, fat, and bone tissue for the whole organism and for specific anatomic regions, (2) limb ultrasound (LUS), which quantifies regional muscle and fat mass (Pereira-da-Silva et al. 1999), and (3) quantitative bone ultrasonography (QUS), which is related to bone strength (Littner et al. 2003).

Over the past two decades, overall birth rates have been steadily declining in the USA. However, the incidence of preterm birth (infants born at less than 37 weeks of gestation) increased and about 12% of infants in the USA are born prematurely. Furthermore, advances in perinatal care, such as the increased use of assisted ventilation in the delivery room and surfactant therapy, have improved the chances for survival of low-gestational-age and low-birth-weight infants. The rising incidence of preterm births, coupled with their improved survival as a result of highly evolving technologies, has placed increased need to address other diseases of prematurity that develop later in the neonatal period, such as osteopenia of prematurity.

Metabolic bone disease is relatively common in preterm infants because the period of greatest bone mineral accretion occurs during the last trimester of pregnancy, and because this is difficult to match

in the postnatal extrauterine environment. In addition, preterm morbidity, such as bronchopulmonary dysplasia, the use of steroid and diuretic treatment, and the common need for total parenteral nutrition further predispose preterm infants to osteopenia. Moreover, the common practice in the majority of Neonatal Intensive Care Units (NICUs) involves minimal handling, which may potentially increase the rates of osteopenia. Clinical osteopenia occurs usually in the 6–12 postnatal week and can cause fractures in up to 10% of very low birth weight (VLBW) infants. Currently, the diagnosis of neonatal bone disorders is based primarily on biochemical evaluation of serum alkaline phosphatase and radiological evidence of osteopenia and/or fractures, and, in rare cases, on measurements of bone mineralization by dual-photon X-ray absorptiometry (DEXA).

There is substantial evidence demonstrating the utility of quantitative ultrasound (QUS) measurement of bone speed of sound (SOS), which has become a viable alternative to assessing bone strength in infants (Littner et al. 2003), children (Eliakim et al. 2001), and adults (Njeh et al. 2001). We have previously shown that gestational age, birth weight, nutritional modifications, and assisted exercise influence measurements of bone SOS by QUS and bone strength in preterm infants (Nemet et al. 2001). In the present chapter, we aimed to summarize the available scientific information regarding the deleterious and beneficial effects of gestational age, body weight, nutrition, and assisted exercise on body composition and bone strength in term and preterm infants, and comment on the possible use of these techniques for monitoring the level and the therapeutic effect of osteopenia of prematurity.

108.2 Practical Method and Technique

108.2.1 Dual-Photon X-ray Absorptiometry

Two beams of relatively high and low energy levels are used to estimate total body mineral content (BMC) and bone mineral density (BMD). In the past, the accuracy of DEXA in small animals and human infants was questioned. In poorly mineralized bones, BMC may be underestimated, and, in small subjects, fat mass may be overestimated. However, with correctional equations (Rigo et al. 1988) and the development of the faster fan-beam scans, DEXA was found to be valid, reliable, and accurate in small animals. DEXA is now widely accepted as a reliable and accurate measure of body composition in infants and is currently considered the gold standard for bone mass measurements. However, the use of DEXA in the clinical setting is very limited by its relatively high cost and by the need to transport the patient to the device, making it unfeasible for very small or sick preterm infants (i.e., infants who are at the highest risk of developing metabolic bone disease).

108.2.2 Quantitative Ultrasound Measurements on Bone Speed of Sound

This method is based on the concept that the propagation of sound waves through a medium depends upon its physical properties. The denser the medium, the faster the sound waves propagate. Bone SOS is also influenced by other bone properties, such as cortical thickness, elasticity, and microarchitecture, providing a better picture of bone strength (Foldes et al. 1995). QUS is a relatively inexpensive, portable, and noninvasive method that involves no ionizing radiation and has been shown to correlate accurately with measurements by DEXA (Kang et al. 1999). A modest but significant correlation was found between bone quantitative ultrasound and both total body and regional

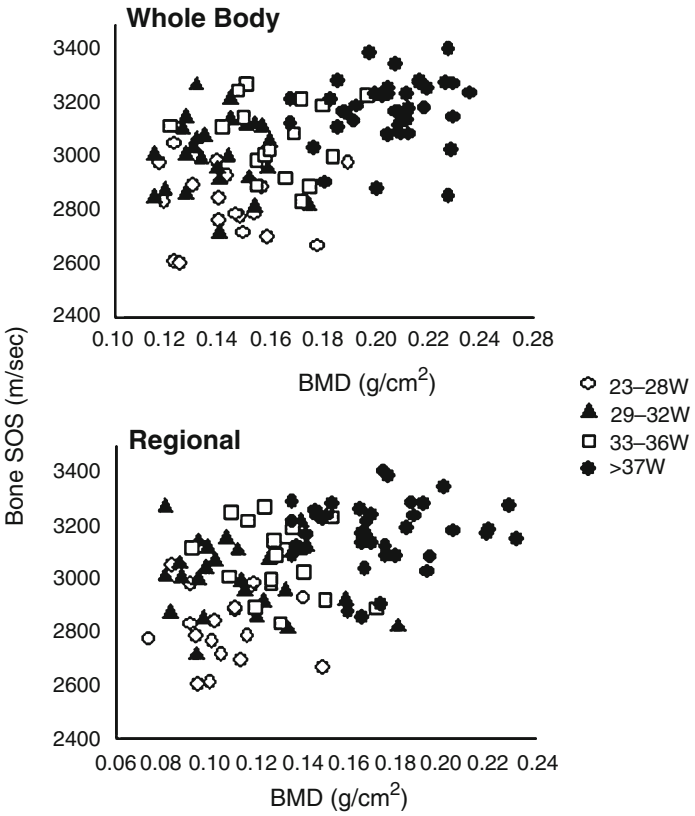

Fig. 108.1 Comparison of bone quantitative ultrasound with both whole-body bone mineral density (*BMD*) by dual-energy X-ray absorptiometry (*DEXA*) and regional DEXA by gestational age. Significant correlations were found between bone quantitative ultrasound and both whole-body BMD by DEXA (*upper panel*) and regional DEXA-derived BMD (*lower panel*)

Table 108.1 Key features of bone SOS

1. Quantitative ultrasound measurements of bone SOS determine bone strength.
2. The method is based on the concept that the propagation of sound waves through a medium depends upon its physical properties.
3. The denser the medium, the faster the sound waves propagate.
4. Bone SOS is influenced by bone density and by other bone properties, such as cortical bone thickness, elasticity, and architecture.
5. This method determines both quantitative and qualitative bone properties.
6. The method is non-invasive and involves no ionizing radiation.

This table lists the key facts of bone SOS measurements of bone strength and the rationale and advantages of the technique
SOS speed of sound

DEXA-derived BMD (whole body, $r = 0.48$; regional $r = 0.45$, Ahmad et al. 2009) (Fig. 108.1). Clearly, the two modalities measure different but related properties of bone in the newborn. While DEXA measures quantitative aspects of BMD, bone QUS is also influenced by qualitative factors that contribute to bone strength, such as bone elasticity, microarchitecture, and fatigue damage. Thus, although the two modalities are not interchangeable, a complementary use of both methods may better reflect "true" bone strength (Table 108.1).

108.3 The Effect of Gestational Age and Birth Weight

Both BMD measured by DEXA and bone strength measured by QUS were found to be significantly lower in preterm compared to term infants (Nemet et al. 2001; Littner et al. 2003; Ahmad et al. 2009). Figure 108.2 demonstrates significant strong correlation between tibial SOS and gestational age ($r = 0.78$, $p < 0.0005$) (Nemet et al. 2001). SOS was found to be much more closely correlated with gestational age than with birth weight, suggesting that maturity might be a more important determinant of bone development than birth weight (Littner et al. 2003).

Several studies examined the effect of birth weight on bone development, focusing on infants of diabetic mothers (IDM) born large for gestational age compared to infants born appropriate for gestational age (AGA). BMC measured by single photon absorptiometry and DEXA was found either decreased (Mimouni et al. 1988) or unaltered (Lapillonne et al. 1997) in IDM. Interestingly, infants of mothers with poorly controlled diabetes (especially during the first trimester of pregnancy) had significantly higher birth weight and reduced BMC (Mimouni et al. 1988). More recently, our group demonstrated significantly decreased tibial bone SOS in IDM compared to controls (Regev et al. 2004). The reduced bone SOS in the IDM group was not related to either postnatal hypoglycemia or maternal hemoglobin A1c levels when used as indices of poor glycemic control during pregnancy. However, there was an inverse correlation between birth weight and bone SOS. A possible mechanism for the decrease in bone strength in IDM is the reduced intrauterine mobility that correlates with the increased body weight of these infants.

A negative relationship between size at birth and bone SOS was also described in small for gestational age (SGA) infants. Opposite to large for gestational age infants, SGA infants have higher bone SOS than AGA controls (Littner et al. 2005). Given that BMD is reported to be low in these infants, the authors speculated that intrauterine growth restriction may affect BMD and bone protein matrix in opposite directions.

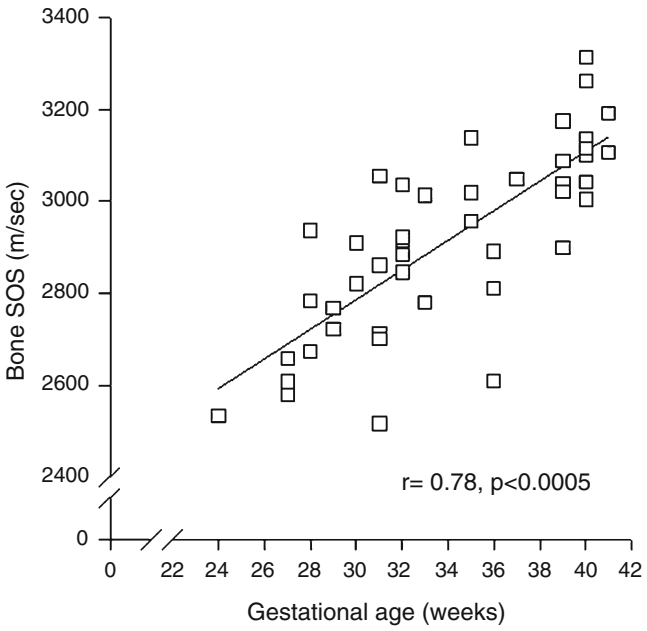

Fig. 108.2 Cross-sectional relationship between tibial speed of sound (*SOS*) and gestational age. Significant strong correlation is shown between the tibial SOS and gestational age

108.4 Postnatal Bone Strength Development

Several studies have shown by single- and dual-photon absorptiometry that VLBW premature infants, compared to a reference population at term, had a considerably lower BMC. Despite an overall growth after birth and during the 1st weeks of life, there was a relative decrease in BMC and progressive decrease in BMD in VLBW infants, indicating a disorder of formation or remodeling of the cortical bone. Similarly, we demonstrated a decrease in bone strength of VLBW preterm infants, determined by measurements of bone SOS during the 1st weeks of life (Litmanovitz et al. 2004; Eliakim et al. 2009). Tibial SOS was also significantly lower in premature infants who reached corrected age of full term (Nemet et al. 2001). The results emphasize, once more, the advantage of intrauterine growth for bone development compared to the standard care in NICU, and that, despite the major advances in neonatal intensive care and adequate nutrition, there is a significant decrease in bone strength during early postnatal life that could result from both quantitative and/or qualitative impairments of bone metabolism.

The relatively large sample size that was evaluated allowed us to determine bone SOS levels at different corrected ages and postnatal ages (Eliakim et al. 2009). The levels may now serve as reference values for the unique population of preterm infants (Fig. 108.3). Interestingly, bone SOS was increased in a small subgroup of the VLBW preterm infants. The bone SOS of this group at birth was significantly lower compared to the majority of preterm infants, who demonstrated a decrease in

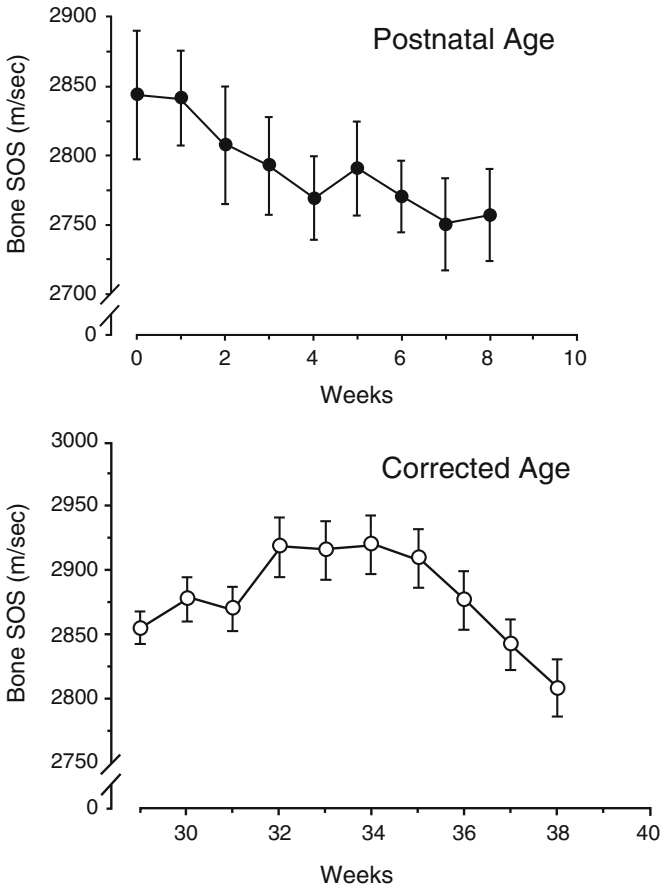

Fig. 108.3 Bone speed of sound (*SOS*) in preterm infants. Levels of bone SOS are expressed according to postnatal age (*upper panel*) and corrected age (*lower panel*)

bone SOS during the follow-up period. There were no significant differences in bone SOS between the groups at discharge from the NICU (in fact, bone SOS was even higher in the bone gainers). Moreover, evaluation of all the study participants revealed that there was a significant inverse correlation between bone SOS at birth and changes in bone SOS during the follow-up period. Therefore, the results suggest that the after-birth "catch-up phenomenon" is not limited only to body weight, body length, and head circumference, but may exist for bone strength as well.

As we previously published, during the 1st weeks of life, there is a significant increase in circulating growth factors and a significant decrease in circulating inflammatory markers in VLBW preterm infants. Of note is that circulating growth factors were higher and inflammatory cytokines were lower in preterm infants whose bone SOS increased during the study follow-up. However, only the difference in circulating interleukin-6 (IL-6) levels reached statistical significance (Ahmad et al. 2007). These results suggest that increases in bone strength in premature infants occur only when stress and inflammatory state, which accompany the early postnatal life of preterm infants, are reduced. These phenomena are not unique only for preterm infants. Recent studies demonstrate that there is an independent link between inflammatory mediators and growth, and that optimal growth occurs when the action of anabolic factors, such as insulin-like growth factor-I (IGF-I), mitigate the actions of stress-related inflammatory factors such as IL-6. In children with chronic inflammatory diseases, such as systemic juvenile idiopathic arthritis, inflammatory bowel disease, AIDS, and cystic fibrosis, high IL-6 levels are also associated with low IGF-I levels and growth restriction.

Recently, Ahmad et al. (2009) performed a prospective, cross-sectional, observational study in preterm and term infants and compared multimodal measurements of body composition, including limb ultrasound, bone QUS, and DEXA (Table 108.2). They used the postmenstrual age to compare AGA infants of different degrees of maturity. Considering that only the most premature group (born at 23–28 weeks) had a postmenstrual age equivalent to term at the time of discharge, they could compare them to the term infants and found that this group of preterm infants reaching term had significantly lower body weight, length, head circumference, muscle, fat cross-sectional areas, bone SOS, whole body and regional lean body mass (LBM), fat body mass (FBM), and BMD compared to term-born infants. However, similar to previous observation, these infants maintained LBM to FBM proportions similar to term infants. Interestingly, in the two other preterm group of infants (born at 28–32 and 33–36 weeks), who were discharged earlier from the NICU and did not reach term, fat percentage was lower and, thus, the ratio of LBM to FBM was higher. This is consistent with the fact that, during fetal life, premature infants appear to follow a similar pattern with an earlier accretion of LBM, followed by accumulation of FBM. Therefore, preterm infants who did not reach term mainly gained LBM, whereas those reaching term before discharge gained both LBM and FBM.

Limb ultrasound estimates of cross-sectional areas of lean and fat tissues in the leg region were remarkably correlated with regional and whole-body estimates of fat-free mass and fat obtained by DEXA and were significantly lower in preterm infants (Fig. 108.4). The results suggest the potential usefulness of muscle ultrasound as an investigative tool for studying aspects of body composition in preterm infants.

108.5 The Effect of Post-Discharge Nutrition

Increased risk of osteopenia in VLBW infants is attributed to limited accretion of bone mass in utero and to a greater need for bone nutrients. Despite the remarkable advances in nutritional support during hospitalization, at term, VLBW infants have considerably lower BMC and lower bone strength than term-born infants (Nemet et al. 2001; Ahmad et al. 2009).

This table lists the body composition measurements of term and preterm infants using ultrasound, whole-body DEXA, and regional DEXA measurements, showing significant difference between term and preterm infants born at 28–32 weeks reaching term (marked by *)

SOS speed of sound; *LBM* lean body mass; *FBM* fat body mass; *BMC* bone mineral content; *BMD* bone mineral density; *DEXA* dual-energy X-ray absorptiometry

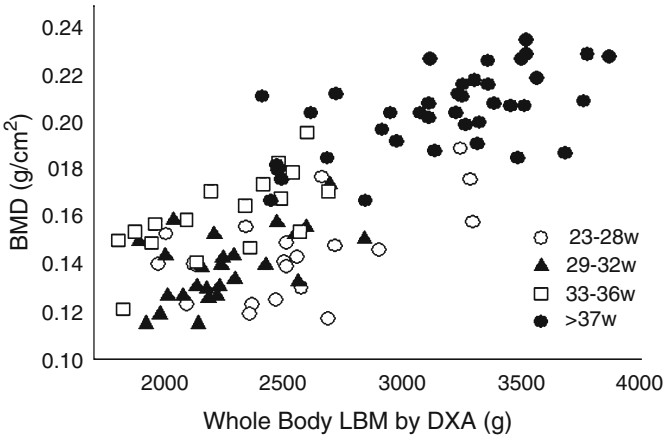

Fig. 108.4 Relationship between bone mineral density (*BMD*) and dual-energy-X-ray-absorptiometry (*DEXA*)-derived measurements of whole-body lean body mass (*LBM*) by gestational age. Significant correlation is shown between BMD and whole-body LBM by DEXA

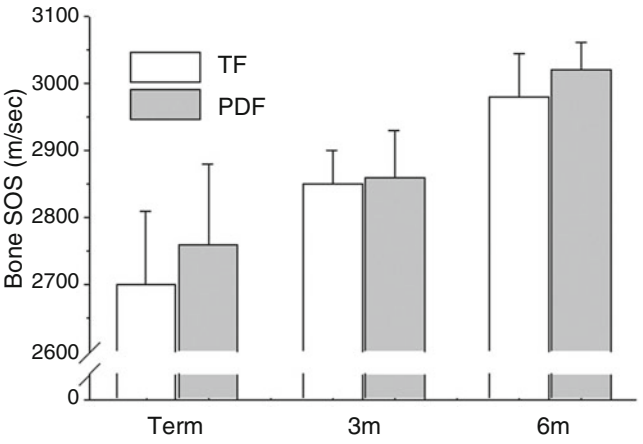

Fig. 108.5 Bone speed of sound (*SOS*) in very low birth weight (*VLBW*) infants fed enriched post-discharge formula (*PDF*) and regular term formula (*TF*). There is increased bone SOS in both groups, with no significant advantage for enriched PDF or TF

Avila-Diaz et al. (2001) found that preterm infants who were fed with human milk had lower BMC compared to full-term infants at 6 months. Helin et al (1985) reported a reduction in BMC up to 16 years of age in preterm infants who were fed by regular term formula (TF) after discharge; however, no information was provided on the source of early diet. Bishop et al. (1993) suggested that the use of enriched post-discharge formula (PDF), containing high concentrations of calories, minerals, vitamins, and trace elements enhances skeletal growth and bone mineralization of preterm infants. By contrast, two other studies, assessing body composition with DEXA, found no significant difference in bone area, bone mineral mass, BMD, or BMC between infants fed PDF or regular TF (Cooke et al. 2001; De Curtis et al. 2002).

We recently measured the effect of different formulas on preterm infants' bone strength and demonstrated that tibial bone SOS of VLBW infants increased progressively during the first 6 months post term, with no significant advantage for enriched PDF or TF (Fig. 108.5) (Litmanovitz et al. 2007a). The study differed from previous studies by the nutritional design (randomization to PDF or TF only after corrected age of full term) and by the method of evaluation of bone metabolism (QUS and bone turnover markers). The study was the first to assess the effect of diet intervention by the quantitative ultrasound technique, which, as noted earlier, in addition to quantitative measures, also assesses qualitative factors that contribute to bone strength. This is important because the increase in bone mass is not always accompanied by increase in bone strength, which is functionally the most important bone property. The finding that feeding after 40 weeks with nutrient-enriched PDF had no beneficial effect on bone SOS suggests the possibility that both quantitative and qualitative bone properties and overall bone strength were not affected by the enriched diet (Litmanovitz et al. 2007a).

Interestingly, at 3 months post term, the measurements of bone SOS in both groups were already comparable to that of a reference value of full-term infants (Zadik et al. 2003). A rapid phase of mineral accretion between 40 and 60 weeks post conception was also demonstrated among preterm infants who were fed standard neonatal formula. It was related to the consumption of higher volume that compensated for the increased need of these infants. Overall, it was suggested that the relative osteopenia observed in preterm infants resolves relatively early after discharge from the hospital.

In conclusion, special PDF with high contents of protein, minerals, and trace elements is mandatory, at least until a post-conceptual age of 40 weeks. There is still no convincing evidence to support the beneficial effect of its longer use for bone metabolism and development. Continued growth monitoring is required to adapt feeding choices to the needs of individual infants, to avoid underfeeding or overfeeding, and to monitor for signs of osteopenia.

108.6 The Effect of Exercise

Physical activity stimulates bone formation and increases BMD. This may be particularly important for premature infants because, during the prolonged hospitalization in the NICU (i.e., in small incubators and cradles), their standard care involves minimal sensory and/or tactile stimulation. Thus, it was suggested that the limited physical activity of hospitalized premature infants can play an important role in the development of bone demineralization and osteopenia. Therefore, in order to avoid that, efforts should be made to understand the mechanisms that link physical activity and bone metabolism in preterm infants, and to develop strategies to increase physical activity in this unique population.

There is mounting evidence to support the concept of the functional "bone–muscle unit" in which muscle activity can stimulate bone growth through mechanoreceptors and through the activity of hormones, such as IGF-I, which influence both muscle and bone. By contrast, absent or poor fetal movement is associated with impaired bone mineralization. Consistent with that, Gomez et al. (2007) found that bone was profoundly abnormal and poorly mineralized in fetal Myod-Myf5-deficient mice that lack striated muscle and have no functioning "bone–muscle unit" or in utero mechanical loading through muscle activity.

Spontaneous postnatal physical activity affects bone strength. The effect of reduced, spontaneous, unilateral limb movements on bone strength assessed by QUS measurements of bone SOS was evaluated in premature infants (Eliakim et al. 2002a). The relative unilateral reduced mobility was the result of a contralateral intracranial insult. Compared to unaffected legs, tibial bone SOS was significantly decreased in the legs with reduced spontaneous movements. By contrast, when spontaneous body movements in healthy control premature infants were normal and symmetrical, both legs had similar SOS. This indicates the important role of daily physical activity for bone strength even in the neonatal period. Moreover, the type of physical activity that premature infants usually perform is mainly spontaneous and is characterized by antigravity and flexion and extension movements and not by the classical weight-bearing activity. Our results suggest that even this modest type of daily activity can increase bone strength in this unique population.

Attempts to measure the effects of assisted exercise (which is also termed "kinesthetic stimulation" by a number of investigators) in human infants were first reported by White and Labarba (1976), who studied 12 (six control) preterm infants born at 34 weeks and showed significant increases in body weight in the treatment group after a 10-day intervention beginning on the second day of life. In 1995, Moyer-Mileur et al. studied the effects of a single daily session of passive range of motion movement with gentle compression of the upper and lower limbs in 13 intervention and 13 control preterm infants (born at 28 weeks). The intervention started at an average postnatal age of 2 weeks and lasted 4 weeks, and, compared to a group of control preterm infants, there was a significant increase in body weight by 33% and in BMD (measured by single-photon absorptiometry) by 34% in the exercise group. Later, the same group of investigators repeated this study using DEXA and corroborated their original observations in 16 intervention and 16 control preterm infants. The authors concluded that, when premature infants perform daily physical activity, in addition to the consumption of the recommended energy and nutrient intake, bone mass accretion is similar to the increase in bone indices in utero during the last trimester (Moyer-Mileur et al. 2000). This enhancement of bone mass by physical activity was not accompanied by changes in circulating levels of calcium, phosphate, alkaline phosphatase, parathyroid hormone, or vitamin D. Therefore, the mechanism for the exercise-induced increased bone density in premature infants was unknown. Using the Moyer-Mileur protocol (1995, 2000), Nemet et al. (2002) examined, in a randomized, prospective study, the effect of exercise on bone turnover markers in VLBW preterm infants and found that, compared to control

subjects, exercise led to a greater increase in body weight, to an increase in bone formation marker (bone-specific alkaline phosphatase), and to a significant decrease in bone resorption marker (cross-linked carboxyterminal telopeptide of type I collagen). It is important to note that the postnatal period in premature infants is characterized by increases in bone formation markers (Shiff et al. 2001); however, because changes were greater than in the control preterm infants, the results support the hypothesis that the relatively brief exercise-training intervention in the premature infants stimulated new bone formation independently of the ongoing postnatal increase of these markers.

The exercise training program in the premature infants led to changes in bone turnover markers in the range of 20–40%. This is consistent with previous reports of increased bone formation following 5 weeks of endurance-type exercise training in adolescent males and females (Eliakim et al. 1997). These results may emphasize the important role of exercise training for bone formation during critical periods of rapid bone development.

The same daily exercise protocol was also used to assess the effect of exercise on serum leptin level and on IGF-I, an anabolic hormone that is known to correlate with fetal growth and to increase in response to exercise in children and adults. The brief (4 weeks) passive range of motion daily movements of both the upper and lower extremities resulted in increased weight gain and increases in circulating leptin levels. The changes in leptin correlated with the changes in body weight (Eliakim et al. 2002b). Exercise also led to increased IGF-I circulating levels, which were greater in premature infants with bronchopulmonary dysplasia. It is not clear whether this suggests that daily movement exercise has a stronger effect in the more catabolic premature infants with bronchopulmonary dysplasia, and, therefore, this issue needs to be investigated in a larger sample size. Increases in IGF-I play a major role in exercise-induced muscle hypertrophy, suggesting possibly a greater increase in muscle mass in the preterm infants. Increased IGF-I levels in preterm infants improve brain development and protect from retinopathy of prematurity. Therefore, benefit of exercise-associated increase in IGF-I levels may not be limited only to the bone and muscle tissue.

The exercise intervention studies in premature infants were started mainly at postnatal age, 2–5 weeks after the critical period of the First days of life and when all the preterm infants were stable. Therefore, in a prospective randomized study, we used the same exercise protocol to evaluate the effect of early exercise training (i.e., at the first week of life) on bone strength in VLBW premature infants and found that the bone SOS decreases during the first four postnatal weeks in the control VLBW premature infants, and that the relatively brief, daily, passive range of motion physical activity attenuated the decrease in bone SOS (Litmanovitz et al. 2003). Consistent with previous reports, the results of this study suggested again that exercise has an important role in bone development during the immediate neonatal period and may contribute to the prevention of osteopenia of prematurity. It is still unclear why the same exercise protocol resulted in increased mineralization in the studies by Moyer-Mileur et al. (1995, 2000), but only attenuated the decrease in bone SOS in the study by Litmanovitz et al. (2003). The answer is probably related to the difference between the methods used. As already noted, single-photon absorptiometry and DEXA, as used by Moyer-Mileur et al. (1995, 2000), measure mainly quantitative aspects of bone mass, such as mineral density, whereas QUS, in addition to the quantitative measures (bone mineralization), also assesses qualitative factors that contribute to bone strength, such as bone elasticity, microarchitecture, and fatigue damage. Increase in bone mass is not always accompanied by an increase in bone strength, which is functionally the most important property of the bone. Apparently, the combination of reduced qualitative and quantitative bone properties contributes to the postnatal decrease in tibial SOS and bone strength in VLBW premature infants. Exercise was only able to prevent this decline.

In contrast to exercise interventions that started at a postnatal age of 4–5 weeks (Moyer-Mileur et al. 1995; Nemet et al. 2002), the early exercise intervention was not associated with a greater

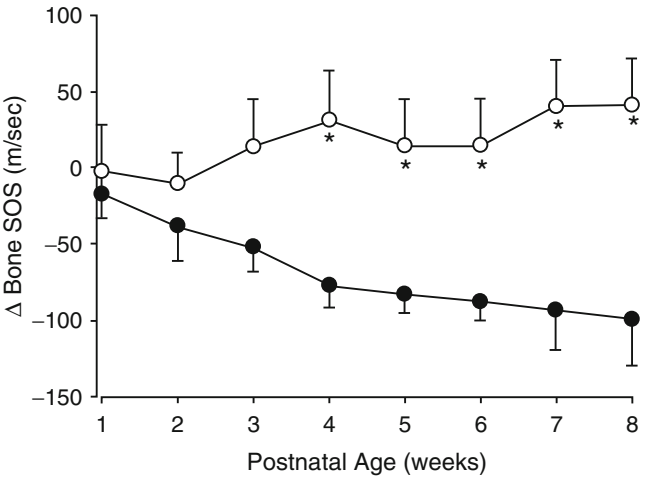

Fig 108.6 The effect of exercise on bone speed of sound (*SOS*) in preterm infants. A significant decrease in bone SOS is shown in the control group (*black circles*) during the first 8 weeks of life, and no change in the exercise preterm group (*white circles*)

increase in weight gain. This observation is in agreement with Moyer-Miller et al. (2000), who found that the increase in weight gain was significant only when the premature infants reached body weight of 1.8–2 kg. This suggests probably that the accelerated weight gain occurs only when exercise training is introduced later in the neonatal course (4–5 weeks vs. 1st week), and that the timing and duration of exercise influence the overall beneficial effect of assisted exercise in preterm infants.

The mechanism for exercise-induced weight gain in premature infants is not clearly understood. It was suggested that at least part of the exercise-induced weight gain is related to increased bone mineralization. This was supported by several studies indicating that leptin is secreted from human osteoblasts and promotes bone mineralization and by the observation that exercise led to increase in circulating leptin in premature infants (Eliakim et al. 2002b). However, considering that beneficial bone effects of exercise were not always accompanied by greater weight gain in preterm infants (Litmanovitz et al. 2003), this potential mechanism cannot fully explain the effect of exercise on body weight. It is possible that other changes in body composition, such as increased lean or fat mass, are responsible for changes in body weight. This needs to be clarified by further research. Whether the degree, frequency, and duration of exercise of 5–10 min/day, 5 days/week, and 4 weeks, respectively, constitute the optimal regimen for bone development in premature infants still needs to be determined. Therefore, recently, we examined the effect of 8 weeks of assisted exercise on bone strength and metabolism in VLBW premature infants (Litmanovitz et al. 2007b) and found that assisted, daily, physical activity prevented the decrease in bone SOS. The decrease in bone SOS in the control subjects was greater during the first 4 weeks of life (Fig.108.6). Therefore, the major protective effect of exercise occurred during this period. Moreover, exercise prevented the decline in bone SOS from the 1st week of life in the VLBW preterm infants. However, the effects of exercise on bone strength during the 2nd month (weeks 4–8) of postnatal life should not be ignored because bone SOS continued to decline in the control group, but remained stable in the exercising preterm infants.

These results suggest that mechanical stimulation is beneficial for bone strength and metabolism in preterm infants, and that exercise has an important role in bone development during the neonatal period. The exact mechanisms that lead to the exercise-induced bone changes in premature infants are yet unknown. The exercise protocol includes passive range of motion exercise with gentle compression at the end of flexion/extension in the exercised joints. This exercise regimen may cause an increase in joint pressure and muscle tension, leading to increased mechanical load on the bone–muscle unit, an increase in lean/muscle mass, and change in bone metabolism and mineralization.

It is also possible that the positive bone effects are not related only to the 5–10 min range of motion exercise, and that the assisted exercise regimen may also lead to increased overall daily movement in preterm infants.

108.7 Applications to Areas of Health and Disease

It is now well established that bone mineralization and strength are significantly lower in preterm infants, even in those reaching term. However, it is not known yet whether this osteopenia of prematurity is a self-resolving condition or a disease with long-term consequences. Reduced bone mineralization was recently demonstrated in prematurely born 7-year-old children (Chan et al. 2008). Even if bone mineralization improves spontaneously, the prolonged period of demineralization in early childhood may lead to overt rickets, bone fractures, and potentially reduce peak bone mass. Thus, the effect of reduced bone mineralization and strength in premature infants, and the possible relation to the development of osteoporosis later in life still needs to be determined.

In addition, we previously demonstrated reduced physical ability in prematurely born 5- to 8-year-old healthy children (Falk et al. 1997). The consequences of reduced physical ability and fitness early in life on the general health of adults who were born prematurely still need to be explored. However, early exercise interventions for preterm infants may increase muscle mass, may lead to earlier maturation of the neuromuscular–skeletal junction, and, if continued, may perhaps improve physical fitness later in life.

Finally, the relationship between the magnitude and rate of change of fat and muscle mass early in life, with conditions, such as obesity, and its accompanying insulin resistance and increased cardiovascular disease risk in adulthood, has gained great interest. The disproportionately higher rate of recovery of fat compared to lean tissue in preterm infants during early postnatal life (i.e., preferential "catch-up fat") may be a central event in the development of obesity and of diseases, such as insulin resistance and metabolic syndrome, seen in this population, particularly in infants who were born SGA.

Summary Points

- DEXA, the gold standard for bone mass measurements, is becoming more widely used in infants, but its availability is limited. An emerging method is QUS measurement of bone SOS, which is a noninvasive, inexpensive, portable method that is free of ionizing radiation, used for the assessment of bone development in premature infants.
- Preterm infants have decreased bone mineralization and decreased bone strength compared to term infants. There is strong positive correlation between bone strength and gestational age. Furthermore, there is a significant decline in bone mineralization and strength in early postnatal life, indicating the importance of intrauterine environment for bone development.
- Enriched PDF at least until the corrected age of 40 weeks were found beneficial for bone development, but there is still no convincing evidence to support beneficial bone effect for their use following this period.
- There is mounting evidence to support the notion that assisted exercise attenuates the natural decrease of bone strength or even increases bone mineralization in premature infants. The optimal exercise regimen for this unique population still needs to be determined.
- Postnatal catch-up of bone strength in premature infants occurs only when the stress and inflammatory state, which accompanies the early postnatal life of preterm infants, is reduced.

Chapter 109
Anthropometry and Race Performance in Endurance Athletes

Beat Knechtle

Abstract The main endurance disciplines are swimming, cycling and running. In studies of athletes performing in these disciplines, it is mainly the influence of body mass, body height, body mass index, length and girth of extremities, body fat and, in more recent studies, of skin-fold thicknesses, that has been investigated. Body mass seems to correlate with performance in runners and cyclists, but not in swimmers. Body height is associated with performance in female pool swimmers. Body mass index is correlated to performance in marathon and ultra-marathon runners. The length of extremities is a predictor variable in young pool swimmers; the circumference of limbs is related to running performance, depending upon the distance. Body fat is a main predictor variable in runners and swimmers. The thickness of skin-folds is related to running and swimming performance, but not to cycling performance. To summarise, there are different anthropometric variables related to performance in these endurance disciplines. In swimmers, body height is a main predictor variable; in cyclists, body mass is mainly associated with performance and in runners, the variables of body mass, body fat and skin-fold thicknesses are mainly related to performance.

109.1 Introduction

The main disciplines in endurance performance are running, cycling and swimming. In studies of athletes performing these disciplines, it is mainly the influence of body mass, body height, BMI, length and girth of extremities, body fat and, in more recent studies, of skinfold thicknesses, that has been investigated. The aim of this chapter is therefore to report findings of associations between these anthropometric properties and endurance performance.

109.2 Body Mass

The relationship between body mass and endurance performance has mainly been investigated in runners (see Table 109.3). Marathon performance time was slightly correlated to body mass in male marathoners (Hagan et al. 1981). In female non-elite marathoners, the correlation between body mass and finish time was not significant (Christensen and Ruhling 1983). In shorter distances, such as 3,000-m steeplechase, body mass was related to performance (Kenney and Hodgson 1985). In ultra-endurance runners, body mass showed no association with performance in a 24-h run (Knechtle et al. 2009c) or in a 100-km run (Knechtle et al. 2009g). Apart from runners, body mass also showed a relationship with performance in cyclists (see Table 109.2). Road cyclists with a lower body mass had an advantage in endurance cycling during climbing (Swain 1994). This was confirmed in off-road cyclists (Gregory et al. 2007; Impellizzeri et al. 2005). However, in track cyclists, body mass showed no association with performance (McLean and Parker 1989). In swimmers, body mass showed no association with performance in ultra-endurance swimmers (Knechtle et al. 2008a, 2009d). In triathletes, body mass showed no association with performance (see Table 109.4).

109.3 Body Height

Body height seems to be associated with swimming performance, especially in female swimmers (see Table 109.1), where body height was significantly related to a 100-m freestyle time in girls aged 12–14 years (Geladas et al. 2005). In another study of a 100-yard swim, body height was not related to performance in male swimmers, but was significantly related to each female swimmer's major competitive stroke (Siders et al. 1993). In 125 female breaststroke swimmers, body height was related to performance when only legs were used (Jagomagi and Jurimae 2005). Regarding the length of the swimming distance, body height was related to both short and long distances (from 50 to 800 m) in pool swimmers (Zampagni et al. 2008). However, in ultra-distance swimmers, body height showed no relationship to performance (Knechtle et al. 2008a, 2009d). Open-water ultra-endurance swimming seems to require a different body shape since these swimmers were smaller and lighter compared to pool swimmers (VanHeest et al. 2004). Also in ultra-distance runners, body height was not associated with race time in male 100-km runners (Knechtle et al. 2009g). Furthermore, body height showed no relationship with performance in long-distance triathletes (Knechtle et al. 2009h).

109.4 Body Mass Index

The association between body mass index and endurance performance was mainly investigated in long-distance runners (see Table 109.3). In female marathoners, body mass index was correlated to marathon performance time (Hagan et al. 1987). In ultra-marathoners, body mass index was negatively correlated to running speed in a 161-km trail run (Hoffman 2008). In ultra-endurance runners, however, body mass index showed no association with performance in either a 24-h run (Knechtle et al. 2009c) or a 100-km run (Knechtle et al. 2009g). Body mass index also was not related to performance in swimmers (see Table 109.1) and in long-distance triathletes (Knechtle et al. 2009h).

Table 109.1 Association of anthropometric variables with endurance performance in swimmers

Knechtle et al. (2008a)	12 male ultra-endurance swimmers in a 12-h swim	No correlation between body mass, length of legs and arms, body height, circumferences of extremities, skeletal muscle mass and fat mass to race performance
Knechtle et al. (2009d)	15 male ultra-endurance swimmers in a 26.4-km open-water ultra-endurance swim	The variables body mass, percent body fat, thickness of seven skinfolds, body height, length of arm, length of leg, number of years as swimmer, average weekly training volume in hours and kilometres and average speed in training were correlated to total race time. Speed in swimming during training was the only variable related to total race time ($r = –0.66$, $p = 0.0037$), whereas none of the other investigated variables showed an association
Geladas et al. (2005)	263 competitive swimmers (178 boys and 85 girls) aged 12–14 years	Upper extremity length, horizontal jump and grip strength were detected as significant predictors of 100-m freestyle performance in boys ($r^2 = 0.59$, $p < 0.01$). In girls, body height, upper extremity and hand length, shoulder flexibility and horizontal jump were all significantly related to 100-m freestyle time. Only 17% of the variance in performance was explained by a combination of body height, hand length and horizontal jump in girls
Sekulić et al. (2007)	40 male and 28 female swimmers	In males, body height was a significant predictor variable in 50-m freestyle swimming; in females, body weight was a significant predictor variable in 400-m freestyle swimming
Siders et al (1993)	43 female and 31 male swimmers	Significant partial correlations between swimming performance (100-yard swim of each swimmer's major competitive stroke) and body height ($r = –0.466$, $p < 0.01$), percent body fat ($r = 0.351$, $p < 0.05$) and fat-free weight ($r = –0.332$, $p < 0.05$) among the women, but no significant correlations among the men
Tuuri et al. (2002)	35 women, aged 21–73 years	Abdominal sagittal diameter was related to weekly swimming distance ($r^2 = 0.20$, $p = 0.03$)
Zampagni et al. (2008)	135 elite male and female master swimmers over 50, 100, 200, 400 and 800 m	Age, height and hand grip strength were the best predictors in short-distance events ($r = 0.84$ for 50 m, $r = 0.73$ for 100 m); age and height were predictors in middle- and long-distance events ($r = 0.75$ for 200 m, $r = 0.66$ for 400 m and $r = 0.63$ for 800 m)

109.5 Length and Girth of Extremities

The relationship of circumferences of limbs with performance has also been mainly investigated in runners (see Table 109.3). There seem to be differences between runners up to 5,000 m and ultra-endurance runners. (Tanaka and Matsuura 1982). Circumference of upper arm seemed to be related to performance in ultra-endurance runners (Knechtle et al. 2008b, 2009a). The association between upper arm circumference and performance might be influenced by the length of the race. In a 100-km run, no association has been found (Knechtle et al. 2009g), but it was observed during a multistage run over 333 km (Knechtle et al. 2009a) and one of 1,200 km (Knechtle et al. 2008b). Length of legs, however, showed no association with performance in male 100-km runners (Knechtle et al. 2009g). In contrast to runners, limb circumferences showed no association with performance in cyclists. In track cyclists, no significant correlation between girth of extremities, such as arm, thigh and calf, and endurance performance has been found (McLean and Parker 1989). In swimmers, upper extremity

length is a predictor variable of 100-m freestyle performance in both boys and girls aged 12–14 years (Geladas et al. 2005). The length of legs in swimmers might be influenced by race and gender. There is a difference in leg lengths between Chinese and Estonian girls, the Estonian girls having longer legs (Cicchella et al. 2009).

109.6 Body Fat

The relationship between body fat and endurance performance was mainly investigated in runners (see Table 109.3). Independent of the distances, body fat was related to performance. Body fat percentage was significantly associated with 12-min running performance in male conscripts (Mattila et al. 2007). In female non-elite marathoners, estimated body fat percentage and finish times showed no correlation (Christensen and Ruhling 1983). In another study of female marathoners, body fat was correlated to marathon performance times (Hagan et al. 1987). However, in ultra-endurance running, body fat percentage seems to be of no importance. During a 100-km run, percent body fat was not related to race time (Knechtle et al. 2009g). Also in a 24-h run, body fat showed no association with performance (Knechtle et al. 2009c). Body fat, however, seems to be related to performance in swimmers, especially in female swimmers (Table 109.1). In female adult swimmers, endurance swimming was mildly associated ($r^2 = 0.21$) with body adiposity (Tuuri et al. 2002). This means that female swimmers with a higher training volume showed lower body fat. In another study, percent body fat in competitive swimmers was significantly related to the 100-yard swim of each female swimmer's major competitive stroke, but not that of male swimmers (Siders et al. 1993). We must assume that body fat becomes of importance in very cold water (Keatinge et al. 2001; Knechtle et al. 2009k). In cyclists, body fat was not correlated to performance (see Table 109.2). In triathletes (see Table 109.4), the association between body fat and race performance might be influenced by the length of the competition and the gender. In male ultra-endurance triathletes of distances longer than the Ironman triathlon of 3.8-km swimming, 180-km cycling and 42.2-km running, body fat and race time were not correlated. In male Ironman triathletes, however, body fat percentage was significantly and positively related to race time, but not in females (Knechtle et al. 2009h). Body fat percentage was not only related to total race time in male Ironman athletes, but also to split times. Regarding the relationship to performance in the sub-disciplines in the race, percent body fat was related to swim performance ($r^2 = 0.25$; $p < 0.01$), bike performance ($r^2 = 0.43$; $p < 0.001$) and run performance ($r^2 = 0.27$; $p < 0.01$) (Knechtle et al. 2009i).

109.7 Skinfold Thicknesses

The association between skinfold thicknesses and endurance performance has mainly been investigated in runners (see Table 109.3) where studies of distances from 100 m to ultra-endurance had been performed. In male 10-km runners, the total sum of five skinfold thicknesses was related to performance (Bale et al. 1986). In marathoners, the sum of seven skinfolds was correlated to marathon performance times. There seem to be differences regarding the association of upper and lower body skinfold thicknesses with running performance times. High correlations have been found between the front thigh skinfold and 1,500- and 10,000-m race times, and between medial calf and 1,500- and 10,000-m race times in males. A significant and positive association between calf skinfold thickness and performance has also been found in male mountain ultra-marathoners during a

Table 109.2 Association of anthropometric variables with endurance performance in cyclists

Gregory et al. (2007)	11 male cross-country mountain bike riders in a laboratory-based maximum progressive exercise test and a 15.5 km mountain bike cross-country time trial	Physiological measures relative to total rider mass correlated more strongly to average course speed than did absolute measures
Knechtle et al. (2009e)	In 28 ultra-endurance cyclists at the 'Swiss Cycling Marathon' over 600 km, skinfold thickness at eight sites was measured pre-race. Single skinfold thicknesses, the sum of eight skinfolds and percent body fat were correlated with total race time.	There was no correlation between single skinfold thicknesses, the sum of eight skinfold thicknesses and percent body fat with total race time
Knechtle and Rosemann (2009)	In 36 male recreational mountain bike ultra-endurance cyclists at the 'Swiss Bike Masters' (120 km length and 5,000 m of altitude), the skinfold thicknesses at eight sites were measured. Body mass, percent body fat, skinfold thicknesses and training variables were correlated to race time.	There was no association between the sum of upper body skinfold thickness, the sum of lower body skinfold thickness, the sum of eight skinfold thicknesses and percent body fat with both race time and yearly training volume in cycling. Race time was negatively correlated to yearly cycling volume in road cycling ($r = –0.42$), total yearly volume in both road and mountain bike cycling ($r = –0.30$) and average speed in road cycling during training ($r = –0.35$)
Impellizzeri et al. (2007)	13 competitive off-road male cyclists in an incremental cycling test. Race time and final ranking were determined during a cross-country off-road competition	Race time and physiological parameters scaled to body mass ($r = –0.68$ to $–0.94$, $p < 0.05$) and final ranking and physiological parameters expressed relative to body mass ($r = –0.81$ to $–0.96$, $p < 0.001$) were correlated
McLean, Parker (1989)	35 elite male track cyclists	No significant correlation was seen between any anthropometric parameter (height, bicycle saddle height, thigh girth and body weight) and performance in an individual event.
Prins et al. (2007)	Eight competitive male mountain bikers participated in a cross-country race and subsequently did six performance tests	Outdoor tests correlated better with peak power output relative to body mass (both $r = –0.83$, $p < 0.05$) than with absolute peak power output (outdoor competition: $r = –0.65$; outdoor time trial: $r = –0.66$; non-significant)

seven-day mountain ultra-marathon over 350 km (Knechtle et al. 2009f). The length of a running performance may determine whether skinfold thicknesses are related to performance. In male ultra-endurance runners during a 24-h run, skinfold thicknesses showed no association with performance (Knechtle et al. 2009c). Also during a 100-km run, the sum of skinfolds was not associated with race performance (Knechtle et al. 2009g). The differences between upper and lower body skinfold thicknesses and the association with performance might also be due to gender. For females, high correlations have been observed for marathon race times and both the iliac crest and abdominal skinfold (Arrese and Ostáriz 2006). It is supposed that the skinfold thickness of the lower limb is due to training. Legaz and Eston (2005) found a significant increase in performance and a significant decrease in the sum of skinfolds, namely abdominal, front thigh and medial calf skinfolds, in both male and female top-class runners after 3 years of intense athletic conditioning. In cyclists, no association

Table 109.3 Association of anthropometric variables with endurance performance in runners

Arrese and Ostáriz (2006)	184 top-class runners (130 males and 54 females) over distances from 100 m to the marathon distance	In males, high correlations were found between the front thigh ($r = 0.78$, $p = 0.000$) and medial calf ($r = 0.55$, $p = 0.018$) skinfolds and 1,500-m run time and between the front thigh ($r = 0.59$, $p = 0.014$) and medial calf ($r = 0.57$, $p = 0.017$) skinfolds and 10,000-m run time. In female runners, the front thigh ($r = 0.71$, $p = 0.022$) and medial calf skinfolds ($r = 0.81$, $p = 0.022$) were highly correlated with 400-m run time
Bale et al. (1985)	36 female marathon runners	The number of training sessions per week and the number of years of training were the best predictors of competitive performance at both 10-mile and marathon distances
Bale et al. (1986)	60 male 10-km runners	Total skinfold, the type and frequency of training and the number of years of running were the best predictors of running performance and success at the 10-km distance
Christensen and Ruhling (1983)	23 non-elite women marathoners	The correlation between estimated percentage of both body fat ($r = –0.39$, $p > 0.05$) and body weight ($r = 0.16$, $p > 0.05$) with race time was not significant
Hagan et al. (1981)	50 male marathon runners	Marathon performance time was correlated with body weight ($r = 0.41$) and the sum of seven skinfolds ($r = 0.41$).
Hagan et al. (1987)	35 female marathon runners	BMI ($r = 0.52$), percent body fat ($r = 0.67$) and sum of skinfolds ($r = 0.51$) were correlated to marathon performance times
Hoffman (2008)	270 (216 males and 54 females) finishers of the 2007 Western States Endurance Run over 161 km	Average running speed and BMI were negatively correlated for both men ($r^2 = 0.10$, $p < 0.0001$) and women ($r^2 = 0.10$, $p = 0.02$)
Kenney and Hodgson (1985)	13 runners over 5,000- and 3,000-m steeplechase	Body weight ($r^2 = 0.94$, $p < 0.02$) was related to personal best times for the steeplechasers
Knechtle et al. (2009c)	15 male ultra-runners in a 24-h run	No significant association was found between the achieved distance and the anthropometric parameters body mass, body height, length of limbs, skinfold thicknesses, circumference of extremities, skeletal muscle mass, body fat and body mass index ($p > 0.05$)
Knechtle et al. (2009b)	19 male ultra-runners in a multistage ultra-endurance run over 1,200 km within 17 days (Deutschlandlauf)	A significant association of upper arm circumference with total running time was found ($r^2 = 0.26$, $p < 0.05$)

between skinfold thicknesses and race performance has been found, either in ultra-endurance road cyclists (Knechtle et al. 2009e) or in ultra-endurance mountain bikers (Knechtle and Rosemann 2009) (see Table 109.2). In female elite swimmers, skinfolds were the best predifctor variable of competition performance (Anderson et al. 2008). In triathletes, an association between skinfold thickness and performance has been found. In ultra-endurance triathletes competing in distances longer than the Ironman distance, the sum of eight skinfold thicknesses was related to race performance (Table 109.4). There seems to be a difference between total skinfolds and upper and lower body skinfold thicknesses in the relationship to race performance in long-distance triathletes. With regard to male Ironman triathletes, percent body fat ($r = 0.76$; $p < 0.0001$), the sum of upper body skinfolds ($r = 0.75$; $p < 0.0001$) and the sum of all eight skinfolds ($r = 0.71$; $p < 0.0001$) were related to total race time. Percent body fat ($r = –0.67$; $p < 0.001$), the sum of upper body skinfolds ($r = –0.63$, $p = 0.0004$) and the sum of all eight skinfolds ($r = –0.59$; $p < 0.001$) were also associated with speed in cycling during the race (Knechtle et al. 2009j).

Table 109.4 Association of anthropometric variables with endurance performance in triathletes

Knechtle and Kohler (2007)	Five male ultra-triathletes in a Triple Iron Triathlon over 11.4 km swimming, 540 km cycling and 126.6 km running	Race time was not significantly ($p > 0.05$) influenced by the directly measured variables body height, leg length, body mass, body fat, average skinfold thicknesses or circumferences of thigh, calf or upper arm
Knechtle et al. (2007b)	16 male ultra-triathletes in a Triple Iron Triathlon over 11.4 km swimming, 540 km cycling and 126.6 km running	No significant influence was observed between race time and body height, leg length, body mass, skeletal muscle mass, fat mass, skinfold thicknesses or circumferences of thigh, calf or upper arm
Knechtle et al. (2007a)	Eight male ultra-triathletes in a Deca Iron Triathlon over 3.8 km swimming, 180 km cycling and 42.2 km running per day for 10 consecutive days	Race time was not significantly ($p > 0.05$) influenced by the directly measured variables body height, leg length, body mass, body fat, average skinfold thicknesses or circumferences of thigh, calf or upper arm
Knechtle et al. (2009b)	29 male ultra-triathletes in a Triple Iron Triathlon over 11.4 km swimming, 540 km cycling and 126.6 km running	The sum of eight skinfold thicknesses was associated with total race time ($r^2 = 0.33$, $p < 0.001$)
Knechtle et al. (2009h)	27 male and 16 female Ironman triathletes	For the male athletes, percent body fat was related to final race time ($r^2 = 0.57$, $p < 0.001$) but not for females ($p > 0.05$)
Leake and Carter (1991)	16 trained female triathletes	Regression analysis indicated that training parameters were more important than anthropometric measurements (body height, biacromial and bi-iliac diameters, biepicondylar diameters, skinfold thicknesses and limb girths) in the prediction of performance

Summary Points

- The association between anthropometry and race performance in endurance athletes is mainly dependent upon the kind of exercise and partly upon the gender.
- In swimmers, body height is a main predictor variable for females but not for males.
- In cyclists, body mass is mainly associated with performance where only males had been investigated.
- In runners, body mass, body fat and skinfold thicknesses are mainly related to performance in both males and females.
- In triathletes, body fat and skinfold thicknesses are related to performance in male but not in female athletes.

Chapter 110
Anthropometry and the Response to Dietary Supplementation in Exercise

Review of the Anthropometric Methods Employed to Evaluate the Effectiveness of Popular Dietary Supplements to Alter Body Composition

Melissa Crowe

Abstract A high proportion of athletes consume dietary supplements in the belief that they will enhance performance or alter body composition. Therefore, research into dietary supplements should accurately evaluate alterations in body composition, specifically muscle and fat mass (FM). A number of factors need to be considered in the selection of anthropometric methodologies to evaluate body composition changes due to dietary supplementation. These factors include measurement details (reliability, validity, accuracy and sensitivity), ethical factors such as invasiveness, statistical effect size and practical considerations such as time, cost and equipment availability. Researchers should first consider the statistical effect size of the supplement under study. Does previous research indicate a marked effect of the supplement on body composition? If so, then a less sensitive methodology can be utilised. Where previous research indicates only a small or negligible effect on body composition, the more sensitive anthropometric methodologies should be employed. The validity and reliability of the anthropometric technique is important. However, there is a lack of research into the reliability and validity of various anthropometric methodologies when assessed in conjunction with dietary supplementation. Examination of recent research into the most popular dietary supplements including creatine monohydrate, β-hydroxy-β-methyl butyrate (HMB), chromium picolinate, Tribulus Terrestris, ephedrine and L-carnitine, reveals utilisation of a wide variety of anthropometric methodologies with no particular methodology associated with detecting significant effects on body composition. Ephedrine, when combined with caffeine, and creatine are amongst the few dietary supplements consistently reported to alter body composition. Changes in hydration status can lead to confounding errors when assessing body composition and researchers should aim to minimise or control alterations in hydration status. Future research is needed in the area of anthropometry and dietary supplementation, particularly investigating the validity and reliability of various anthropometric techniques to detect change in body composition as a result of dietary supplementation. A greater availability of this information would assist researchers to choose appropriate anthropometric methodology to assess the effects of dietary supplements on muscle and FM.

NIR	Near-infrared interactance
TBW	Total body water
W:H ratio	Waist to hip ratio

110.1 Introduction

Athletes and the general public consume dietary supplements in the belief they will enhance sports or exercise performance and/or alter body composition. Survey studies of athletes have shown that 94% of swimmers (Baylis et al. 2001) and a similar percentage of Canadian varsity athletes (Kristiansen et al. 2005) consume some form of dietary supplement. Dietary supplements are often heavily marketed on their ability to increase muscle size and strength and/or reduce body fat. It is therefore necessary to accurately assess changes in body composition when evaluating the effectiveness of supplements, specifically fat mass (FM) and fat-free mass (FFM). The methodology employed to assess body composition will affect the ability to detect changes due to dietary supplementation. This chapter will consider a number of factors important in the selection of anthropometric methods to assess body composition during dietary supplementation. Measurement, statistical, ethical and practical factors will be discussed. This will be followed by a review of the different anthropometric methods employed in research investigating dietary supplements, which reportedly alter body composition. The small number of studies which evaluate the reliability of different anthropometric methods for detecting change due to supplementation will also be examined. Although there are a large number of dietary supplements marketed for their ability to increase muscle size or reduce body fat, this chapter will focus on the main supplements utilised by the sporting community and the general public including creatine monohydrate, β-hydroxy-β-methyl butyrate (HMB), chromium picolinate, *Tribulus terrestris*, L-carnitine and ephedrine. These dietary supplements not only are of interest to athletes, but also have medical relevance with the possible treatment of obesity or muscle wasting diseases.

The term ‘anthropometry’ has been used in the general sense throughout this chapter, meaning measurement of the composition and dimensions of the human body rather than specifically referring to the assessment of skinfolds, girths and breadths.

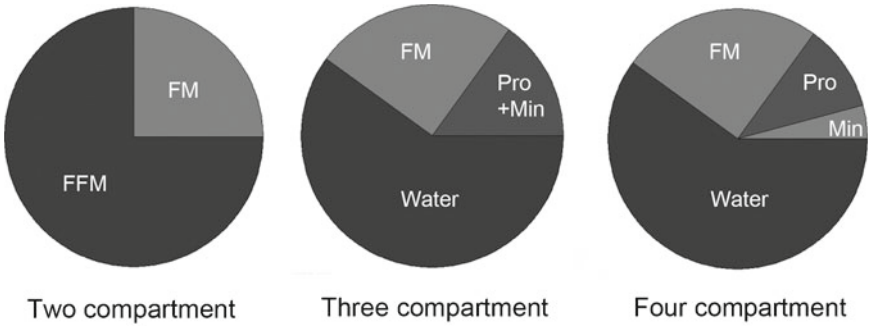

Fig. 110.1 Schematic representation of the two-, three- and four-compartment models of body composition. The two-, three- and four-compartment models of body composition showing the various components in each model. *FM* fat mass, *FFM* fat-free mass, *Pro* protein, *Min* mineral

110.2 Body Composition Compartment Models

In order to appreciate different anthropometric methodologies, it is first necessary to understand the compartment models upon which they are based. In estimating body composition, the body must be divided into its component parts. At a molecular level, there are two-compartment-, three-compartment- and four-compartment models. In the two-compartment model, the body is subdivided into FM and FFM. The three-compartment model further breaks down FFM into water and mineral plus protein. The four-compartment model includes water, mineral, protein and fat (Wang et al. 2005). These models are illustrated in Fig. 110.1. It is generally accepted that methodologies utilising the four-compartment model are more accurate than those based on the three-compartment model, with the two-compartment model methodologies being the least accurate. This is because a greater proportion of the body is accounted for with the four-compartment model. However, this concept has been questioned as greater error can be introduced with the estimation of more parts of the body (Wang et al. 2005). For example, body water may be determined using deuterium dilution, body mineral using dual energy X-ray absorptiometry (DXA), and FFM and FM using hydrodensitometry (underwater weighing). Each of these methods has a certain amount of error associated with it and these errors are additive. If body composition was simply determined using hydrodensitometry (two-compartment model), then only the error associated with this methodology would affect the measurement.

110.3 Factors to Consider When Assessing Alterations in Body Composition Due to Dietary Supplementation

When selecting methodology to evaluate changes in body composition resulting from dietary supplementation, researchers should consider a number of factors (Table 110.1), the most important of which include measurement factors such as accuracy, reliability, validity and sensitivity. Statistically, effect size should also be considered. Once these factors have been taken into account, ethical and practical factors will also influence the choice of methodology.

Measurement factors will influence the ability to detect change in body composition as a result of dietary supplementation. Accuracy, which refers to the closeness of a measurement to the true value (Norton and Olds 1996), is of importance in dietary supplement studies. However, reliability or the

Table 110.1 Factors to consider for selection of anthropometric methodology

Category	Factors
Measurement factors	Reliability
	Validity
	Accuracy
	Sensitivity
Statistical factors	Effect size
Practical factors	Cost
	Accessibility
	Time available
Ethical factors	Invasiveness

This table lists the factors to consider when selecting anthropometric methodology to assess changes in body composition in response to dietary supplementation including measurement, statistical, practical and ethical factors

closeness of repeated measurements (Norton and Olds 1996) is of greater value as the ability to detect change in the measurements is most important. Validity refers to how well the measurement actually measures the characteristic of interest (Norton and Olds 1996). A criterion reference is required to assess the validity of other methods. Hydrodensitometry was traditionally used as the criterion reference by which the validity of other anthropometric methods was compared. However, this is no longer necessarily the case as will be discussed below (see Sect. 110.5). If the error associated with a particular anthropometric methodology is greater than the change in body composition induced by the dietary supplement, then the induced changes will not be detected. Therefore, sensitivity, which is the ability to detect change in a measurement, is also important.

Effect size is relevant to the particular dietary supplement being investigated and will depend on the extent and quality of previous research. If a dietary supplement is expected to have a large effect on body composition, then a less sensitive methodology could be employed. However, if changes in body composition are expected to be small, then a more sensitive methodology with high reliability is required. Furthermore, a larger sample size would enhance the potential of detecting supplement effects, if the expected effect is only small. Meta-analyses are useful in helping to determine the expected effect of a supplement on body composition as the aim of a meta-analysis is to determine the average magnitude of an effect.

When measurement and statistical factors have been considered, researchers are still faced with ethical and practical considerations when choosing methodology to evaluate changes in body composition in response to dietary supplementation (Table 110.1). The principal ethical consideration is the invasiveness of the technique. Does the benefit gained from the study outweigh the risk to the participants? In the case of dietary supplementation studies, rarely does the outcome of the study justify exposing participants to high doses of radiation as would be the case with methodologies such as computed tomography (CT). Therefore, such techniques are rarely utilised in supplement studies. However, such methodologies could be justified when evaluating banned drugs, such as androgenic-anabolic steroids, human growth hormone and erythropoietin, where the side effects can be severe.

Practical considerations include factors such as cost, accessibility to equipment and time constraints. The most sensitive methodologies available to assess body composition are often the most expensive and most difficult to access. For example, modern technologies such as magnetic resonance imaging (MRI) cost in the order of millions of dollars and are usually only available in major hospitals and large private imaging practices. It would be an advantage to utilise MRI, if the dietary

supplement was expected to have only small effects on body composition. However, the cost and availability of such technology make this difficult. Therefore, when we examine the dietary supplement literature, it is unusual to find many studies employing the more sensitive methodologies such as MRI and CT due to the cost in purchasing and difficulty in accessing this type of equipment. By contrast, BIA requires little skill, costs relatively little and is easily accessible and quick to perform. These factors contribute to the increased number of dietary supplement studies utilising BIA. Skinfolds, girths and breadths are also relatively inexpensive and quick to perform by an experienced anthropometrist. However, there is usually greater error associated with these measures as indicated by reliability studies (Kilduff et al. 2007). Thus, practical factors often limit the type of anthropometric methodology selected to assess body composition changes with dietary supplementation.

In conclusion, a number of factors need to be considered when selecting methodology to assess changes in body composition in response to dietary supplementation. The expected magnitude of the supplement's effect on body composition should first be considered. If the dietary supplement has previously been shown to have marked effects on body composition, then a less sensitive methodology is sufficient. However, when the change in body composition is only small, then methodologies such as body mass index (BMI), skinfolds, BIA and DXA are not sufficient and more sensitive methodologies are required (e.g. deuterium dilution, CT or MRI). However, the invasiveness and risk to the participants need also be considered, as the knowledge gained from dietary supplement studies is unlikely to justify the use of high radiation doses such as those delivered with CT. Researchers may desire to use the more accurate methodologies such as MRI but may be limited by practical factors such as cost, time available and accessibility to equipment.

110.4 Past Dietary Supplement Research and Anthropometry

The following sections will examine the anthropometric methodologies employed in past dietary supplementation studies. The supplements reviewed include creatine monohydrate, HMB, chromium picolinate, *Tribulus terrestris*, ephedrine and L-carnitine. These supplements were chosen based on current popularity within the sporting community and with the general population as well as the availability of double-blind, placebo-controlled research. A general discussion of the body composition outcomes will also be provided. However, it is not the aim of this chapter to provide a detailed review of the findings on each supplement and readers are referred to relevant reviews and meta-analyses where possible. There are a number of other supplements available, which supposedly alter body composition, for example, arginine and ginseng. However, a lack of well-controlled research into these supplements with regard to body composition precludes them from this review. In general, by far the most common anthropometric evaluation in all these supplement studies is simple assessment of body weight. Where FFM and FM are determined, there are a wide range of different methodologies employed.

110.4.1 Anthropometric Methodologies Employed in Creatine Monohydrate Studies

Creatine monohydrate and other forms of creatine are by far the most researched dietary supplements on the market. Oral supplementation with creatine increases muscle phosphocreatine concentrations and thereby enables greater generation of adenosine triphosphate (ATP) from adenosine

Table 110.2 Key features of creatine

1.	The most popular dietary supplement for enhancing exercise performance.
2.	Shown to enhance short-term, high-intensity exercise and increase body mass.
3.	Performance is enhanced via greater energy supply in the form of ATP.
4.	ATP is generated from the phosphorylation of ADP by phosphocreatine.
5.	Supplementation is more effective in vegetarians because creatine is naturally found in meat.

This table lists the key features of creatine including the mechanism by which creatine enhances exercise performance and the main effects of creatine

diphosphate (Branch 2003). Theoretically, greater ATP availability facilitates greater short-term, high-intensity activity and therefore greater gains in muscle size and strength with resistance training (Branch 2003). An overview of the key features of creatine can be found in Table 110.2. Examination of the past 10 years of creatine research reveals a large variety of methodologies employed to assess changes in body composition (Table 110.3). Body mass is commonly assessed in most studies using simple weighing scales, with FFM and FM determined primarily by DXA (16 studies), BIA (14 studies), skinfolds and/or girths (12 studies) and hydrodensitometry (8 studies). Ultrasound and near-infrared interactance (NIR) were less commonly used, with air displacement plethysmography (ADP) used in a small number of studies (Table 110.3). For readers not familiar with NIR, a short summary of the key features of this technique can be found in Table 110.4. Skinfolds and/or girths were commonly used in creatine research in conjunction with other methodologies, with only five studies evaluating body composition by these methods alone. A meta-analysis of creatine research has indicated a significant effect of this supplement on body composition (Branch 2003). Furthermore, Kilduff et al. (2007) have shown that five different anthropometric methodologies, including skinfolds, BIA, NIR, ADP and hydrodensitometry, were all able to detect changes in body composition as a result of acute creatine supplementation. Similarly, significant increases in body weight and FFM and significant decreases in FM and %BF were detected by ADP following acute creatine monohydrate ingestion (Vukovich and Peeters 2003). Therefore, it is likely that all the anthropometric methodologies employed in past creatine supplementation studies were able to detect a difference in body composition (specifically FFM) had it occurred. Of 36 studies investigating changes in body composition as a result of creatine supplementation in various populations, only 11 studies reported no change in FFM (Table 110.3). Examination of these 11 studies did not reveal use of any particular anthropometric methodology, with all the methodologies listed above included, except NIR and ultrasound. However, it must be accepted that the dose and duration of creatine supplementation and the populations studied vary widely and that these factors will affect whether or not creatine supplementation increases FFM. Bearing this in mind, there exist many more positive studies showing increased FFM in response to creatine supplementation with various anthropometric methods than those that show no effect, indicating that the type of methodology utilised is unlikely to affect the ability to detect changes in body composition in response to creatine supplementation.

110.4.2 Anthropometric Methodologies Employed in β-Hydroxy-β-Methyl Butyrate (HMB) Studies

β-Hydroxy-β-methyl butyrate (HMB) is another popular dietary supplement. HMB is marketed to improve all types of exercise performance via anticatabolic effects (see Rowlands and Thomson 2009). A summary of the main features of HMB is provided in Table 110.5. The body of scientific research available on HMB is not as great as that available for creatine. A literature search of HMB and body

Table 110.3 Details and outcomes of studies assessing body composition with creatine monohydrate supplementation

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Cornish et al. (2009)	Randomised, double-blind, crossover	9 g/day plus protein and linoleic acid for 5 weeks	69 strength-trained participants (52 male, 17 female) CCP (Creatine, linoleic acid and protein) $n = 22$ CP (Creatine and protein) $n = 25$ P (protein) $n = 22$	BM FM and LBM (ADP) Muscle thickness (ultrasound)	↑ LBM: CCP > CP > P CCP, CP and P all ↑ muscle thickness No effect on %BF or FM
Spillane et al. (2009)	Randomised, double-blind	20 g/day for 5 days + 5 g/day for 42 days	30 non-trained males Creatine monohydrate $n = 10$ Creatine ethyl ester $n = 10$ Placebo $n = 10$	BM %BF, FM and FFM (DXA) TBW and compartment-specific fluid volume (BIA)	No effect of either supplement on body composition variables except FM where the monohydrate group had greater FM than the ethyl ester group
Eliot et al. (2008)	Randomised, double-blind	5 g/day for 14 weeks	42 males (48–72 years) Creatine $n = 10$ Whey protein $n = 11$ Creatine + protein $n = 11$ Placebo $n = 10$	Total and regional measures of body composition (DXA) TBW, ICW and ECW (BIA)	Training effect but no group differences
Gotshalk et al. (2008)	Randomised, double-blind	0.3 g/kg/day for 7 day	27 females (58–71 years) Creatine $n = 15$ Placebo $n = 12$	BM %BF (skinfolds –Jackson & Pollock equation)	Significant ↑ BM and FFM
Chilibeck et al. (2007)	Randomised, double-blind	0.1 g/kg/day for 8 weeks	18 rugby union players Creatine $n = 9$ Placebo/$n = 9$	BM FM and LBM (ADP)	No effect
Cribb et al. (2007a)	Randomised, double-blind	0.1 g/kg/day for 10 weeks	31 resistance-trained males Protein ($n = 10$) Protein/CHO ($n = 11$) Protein/CHO/creatine ($n = 10$)	BM FFM, FM and %BF (DXA)	Greater ↑ LBM in the protein/CHO/creatine group compared to other groups. Greater loss of FM and %BF in the protein/CHO/creatine and protein groups compared to the protein/CHO group.

(continued)

Table 110.3 (continued)

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Cribb et al. (2007b)	Randomised, double blind	0.3 g/kg/day for 1 week + 0.1 g/kg/day for 9 weeks	26 resistance-trained males Creatine/CHO (n= 8) Creatine/protein (n = 6) CHO (n = 7) Protein (n = 5)	BM FFM, FM and %BF (DXA)	No differences in BM, FM or %BF between groups. Greater LBM gain in the creatine/CHO group compared to the CHO group. All groups ↑ LBM over time.
Kilduff et al. (2007)	Reliability study, repeated measures	20 g/day for 7 days	55 male university athletes Reliability study n = 55 Creatine study n = 30	BM FM and FFM (hydrodensitometry, NIR, ADP, skinfolds and BIA)	↑ BM ↑ FFM detected by all five methods
Silva et al. (2007)	Randomised, double-blind	20 g/day for 21 days	16 junior female swimmers Creatine n = 8 Placebo n = 8	BM FM, FFM and TBW (BIA)	No effect
Glaister et al. (2006)	Randomised, double-blind	20 g/day for 5 days	42 physically active men Creatine n = 21 Placebo n = 21	BM %BF (skinfolds – Durnin and Womersley equation)	Statistical significance not reported. Infers ↑ BM and no effect on %BF
Ferguson and Syrotuik (2006)	Randomised, double-blind	0.3 g/kg for 7 days + 0.03 g//kg/day for 9 weeks	26 recreational strength trained females Creatine n = 13 Placebo n = 13	%BF, FM and LBM (DXA)	No effect
Hoffman et al. (2006)	Randomised, double-blind	10.5 g/day for 10 weeks	33 college footballers Creatine n = 11 Placebo n = 11 Creatine + alanine n = 11	BM %BF and LBM (DXA)	No effect on BM or FM Creatine + alanine had significantly greater change in LBM and %BF compared to placebo
Ahmun et al. (2005)	Randomised, double-blind, crossover	20 g/day for 5 days	14 rugby players	BM %BF (from four skinfolds)	No effect
Chilibeck et al. (2004)	Randomised, double-blind, single-side training	0.2 g/kg twice per week after training for 6 weeks	21 weight-trained participants (11 male, 10 female) Creatine n = 11 Placebo n = 10	Muscle thickness (ultrasound) Whole body and regional LBM, FM and bone mass (DXA)	Greater ↑ in muscle thickness on creatine days. Creatine males greater ↑ LBM than placebo males and females (creatine and placebo) No effect on FM or bone mass

Mendes et al. (2004)	Randomised, double-blind	20 g/day for 8 days	18 competitive swimmers (six female, 12 male) Creatine $n = 9$ Placebo $n = 9$	BM LBM, %BF (skinfolds, BIA and DXA) TBW (BIA)	Greater ↑ in BM, LBM and TBW but no change in muscle or bone mass. %BF result not stated
Volek et al. (2004)	Randomised, double-blind	0.3 g/kg/day for 6 weeks Overreaching program (4 weeks then 2 week taper)	17 resistance-trained males Creatine $n = 9$ Placebo $n = 8$	BM TBW (BIA) %BF, LBM and BMC (DXA)	Significantly greater BM and LBM in legs No effect on %BF and BMC
Brose et al. (2003)	Randomised, double-blind	5 g/day for 14 weeks	28 older participants (> 65 year) (15 male, 13 female) Creatine $n = 14$ Placebo $n = 14$	BM %BF and FFM (DXA)	Significant ↑ BM and FFM No effect on %BF
Kutz and Gunter (2003)	Double-blind	30 g/day for 2 weeks + 15 g/day for 2 weeks	17 active males Creatine $n = 9$ Placebo $n = 8$	BM %BF (hydrodensitometry) TBW (BIA)	Greater ↑ BM and TBW No change in %BF
Lehmkuhl et al. (2003)	Randomised, double-blind	0.3 g/kg/day for 7 days + 0.03 g/kg/day for 7 weeks	29 collegiate track and field athletes (17 male, 12 female) Creatine $n = 10$ Creatine + glutamine $n = 10$ Placebo $n = 9$	BM %BF, FM and LBM (hydrodensitometry and skinfolds)	↑ BM greater in creatine groups ↑ LBM greater in creatine groups from skinfolds. No difference between groups from hydrodensitometry No effect on %BF or FM from either method
Van Loon et al. (2003)	Double blind	20 g/day for 5 days + 2 g/day for 37 days	20 non-trained males Creatine $n = 10$ Placebo $n = 10$	BM %BF and FFM (hydrodensitometry)	Greater ↑ BM and trend for ↑ FFM ($p = 0.06$) No effect %BF
Dawson et al. (2002)	Randomised, double blind	20 g/day for 5 days + 5 g/day for 22 days	10 male and 10 female junior swimmers Creatine $n = 10$ Placebo $n = 10$	BM Skinfolds (sum of 6)	No effect
Huso et al. (2002)	Randomised, double-blind, crossover (4 weeks washout)	20 g/day for 4 days + 2 g/day for 17 days	10 recreationally active males	BM FFM and FM (ADP)	Significant ↑ BM with creatine Significant ↑ FFM with creatine and placebo Significant ↓ FM with placebo

(continued)

Table 110.3 (continued)

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Kilduff et al. (2002)	Double-blind	20 g/day for 5 days	32 resistance-trained males Creatine $n = 21$ Placebo $n = 11$	BM %BF, FFM and TBW (BIA)	Significant ↑ BM and FFM No effect on %BF and TBW
Warber et al. (2002)	Randomised, double-blind	24 g/day for 5 days	26 physically active males Creatine $n = 13$ Placebo $n = 13$	BM %BF (DXA)	Significant ↑ BM Greater ↓ %BF
Wilder et al. (2002)	Single-blind	Low dose: 20 g/day for 7 days + 5 g/day for 9 weeks High dose: 12 g/day for 7 days + 3 g/day for 9 weeks	25 male collegiate football players Low-dose creatine $n = 8$ High-dose creatine $n = 8$ Placebo $n = 9$	BM FFM and %BF (hydrodensitometry) Skinfolds (Hagerman, Starr and Murray equation)	No effect
Arciero et al. (2001)	Randomised, double-blind	20 g/day for 5 days + 10 g/day for 23 days	30 non-resistance trained males Creatine alone $n = 10$ Creatine + resistance training $n = 10$ Placebo + resistance training $n = 10$	BM FM, FFM (DXA) TBW (BIA)	Significant ↑ BM and TBW for creatine groups Significant ↑ in FFM with creatine + training and trend for creatine ($p = 0.07$) No effect on FM
Bemben et al. (2001)	Randomised, double-blind	20 g/day for 5 days + 5 g/day up to 9 weeks	25 male collegiate football players Creatine $n = 9$ Placebo $n = 8$ Control $n = 8$ All groups resistance trained	BM FFM and FM (hydrodensitometry) TBW (BIA)	Greater ↑ BM, FFM, TBW and intracellular water No effect on FM
Bennett et al. (2001)	Randomised, double-blind	20 g/day for 6 days + 6 g/day for 4 weeks	16 male soldiers Creatine $n = 8$ Placebo $n = 8$	BM LBM and FM (DXA) TBW (BIA)	Significant ↑ BM No effect on other variables
Burke et al. (2001)	Randomised, double-blind	0.1 g/kg/day for 6 weeks	36 resistance-trained males Whey protein $n = 12$ Whey + Creatine $n = 12$ Placebo $n = 12$	BM FM and LBM (DXA)	Greater ↑ BM for the whey and the whey/creatine groups compared to the placebo group Greater ↑ LBM in the whey/creatine group compared to the whey group, and in the whey group compared to the placebo group No effect on FM

Chrusch et al. (2001)	Randomised, double-blind	0.3 g/kg/day for 5 days + 0.07 g/kg/day up to 12 weeks	30 older men (60–84 year) Creatine $n = 16$ Placebo $n = 14$	BM LBM, FM and %BF (DXA)	Greater ↑ BM and LBM No effect on FM or %BF
Jowko et al. (2001)	Randomised, double-blind	20 g/day for 7 days + 10 g/day for 14 days	40 active males Creatine $n = 11$ HMB $n = 9$ Creatine + HMB $n = 10$ Placebo $n = 10$	LBM, FM and TBW (BIA)	Significant ↑ BM in all groups except placebo, with HMB/Cr significantly greater than HMB or Cr alone Significant ↑ LBM in all groups, with Cr significantly greater than placebo Significant ↑ FM in HMB/Cr compared to other groups Significant ↑ TBW in all groups, with Cr significantly greater than placebo
Syrotuik et al. (2001)	Randomised, double blind	0.3 g/kg/day for 5 days + 0.03 g/kg/day for 5 weeks	22 rowers (12 male, 10 female) Creatine $n = 11$ Placebo $n = 11$	BM Skinfolds (sum of 8) FM and FFM (hydrodensitometry) TBW (BIA)	No effect
Tarnopolsky et al. (2001)	Randomised, double-blind	10 g/day for 8 weeks (dose ingested post-exercise)	19 active males Creatine $n = 11$ Protein $n = 8$	BM %BF and FFM (DXA)	Greater ↑ BM for the creatine group compared to the protein group No effect on %BF or FFM
Volek et al. (2001)	Randomised, double-blind	0.3 g/kg/day for 7 days	20 healthy men Creatine $n = 10$ Placebo $n = 10$ (Exercise in heat)	BM Skinfolds (sum of 7) TBW (BIA)	Significant ↑ BM Significant ↑ TBW but not %TBW %BF and FFM not evaluated post-supplementation
Willoughby and Rosene (2001)	Randomised, double-blind	6 g/day for 12 weeks + resistance training for creatine and placebo groups	22 untrained males Creatine $n = 8$ Placebo $n = 8$ Control $n = 6$	BM %BF, FFM (seven skinfolds)	Greater ↑ BM and FFM for the creatine group compared to the placebo group and for the placebo group compared to control group No difference in %BF

(continued)

Table 110.3 (continued)

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Becque et al. (2000)	Double-blind	20 g/day for 5 days + 2 g/day up to 6 weeks	23 resistance trained males Creatine $n = 10$ Placebo $n = 13$	BM %BF, FM, FFM (hydrodensitometry) Upper arm circumference	Greater ↑ BM, FFM and upper arm circumference No effect on FM or %BF

Research studies from the past 10 years investigating the effects of creatine supplementation on body composition are shown. The dose and duration of supplementation, population studied, anthropometrical methods utilised and main outcomes are detailed. The majority of studies show a significant increase in FFM in response to creatine supplementation

ADP air displacement plethysmography, *BIA* bioelectrical impedance analysis, *BM* body mass, *BMC* bone mineral content, *BMI* body mass index, *CHO* carbohydrate, *CT* computed tomography, *DXA* dual energy X-ray absorptiometry, *ECW* extracellular water, *FM* fat mass, *FFM* fat-free mass, *ICW* intracellular water, *LBM* lean body mass, *NIR* near-infrared interactance, *%BF* percentage body fat, *TBW* total body water

Table 110.4 Key features of near-infrared interactance

1. Field method to assess %BF, which is quick, safe and non-invasive.
2. Assessment of %BF is made using spectrophotometry.
3. Infrared light of various wavelengths is emitted into a body part (usually the biceps brachii) and measurement made of the re-emitted light.
4. The measurement is expressed as an optical density.
5. Optical density is converted into an estimation of %BF via regression equations.

The key features of NIR are indicated in this table explaining the mechanism by which NIR assesses body composition

Table 110.5 Key features of β-hydroxy-β-methyl butyrate (HMB)

1. Metabolite of the amino acid leucine.
2. Claimed to increase strength and FFM and reduce FM.
3. Suggested to act as an anticatabolic agent preventing the breakdown of body protein.
4. Some evidence for increased strength in untrained participants.
5. Little evidence for increased strength in experienced resistance-trained athletes.
6. Little evidence for any effect on body composition.

This table lists the main features of HMB including the proposed mechanism of HMB action and the primary research findings on HMB

composition revealed 14 studies (excluding studies reported in abstract form only). A variety of anthropometric methodologies was used in these studies (Table 110.6), with BIA and DXA the most popular. Skinfolds and/or girths were assessed in 8 of the 14 studies. However, only three studies relied solely on these measures to assess body composition. Hydrodensitometry, CT, ultrasound and ADP were utilised in one study each. In general, the majority of these studies indicated no effect of HMB on FFM. Similar to creatine supplementation studies, there does not appear to be any commonality in the type of anthropometric method used for the few studies that did report significant increases in FFM compared to those that reported no effect of HMB. A meta-analysis conducted by Rowlands and Thomson (2009) on the effects of HMB on strength and body composition indicated a trivial effect of HMB on FFM and FM. Thus, the effects of HMB on body composition are likely to be small or non-existent and studies investigating HMB should utilise the more sensitive anthropometric methodologies such as MRI or a four-compartment model using combined methodologies.

110.4.3 Anthropometric Methodologies Employed in Chromium Picolinate Studies

Chromium has been suggested to increase the efficacy of insulin and may therefore play a role in protein accretion and decreasing fat stores (Vincent 2003). However, the majority of studies investigating the effects of chromium picolinate on body composition in healthy participants have failed to show any effects (Table 110.7). Hydrodensitometry (8 studies) and skinfold assessment (7 studies) were the most commonly utilised methodologies in chromium picolinate supplementation studies where body composition was evaluated (Table 110.7). However, skinfolds were employed in conjunction with other methodologies and were not the main methodology for determining body composition in any of these studies. DXA was employed in three chromium supplementation studies, whilst BIA

Table 110.6 Details and outcomes of studies investigating body composition alterations with β-hydroxy-β-methyl butyrate (HMB) supplementation

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplementation
Thomson et al. (2009)	Randomised, double blind	3 g/day for 9 weeks	22 resistance trained males HMB $n = 13$ Placebo $n = 9$	BM FM, FFM (BIA) Skinfolds (sum of 7)	No effect on BM or FFM Trivial effects on FM
Baier et al. (2009)	Randomised, double blind	HMB/lysine/arginine mix BM <68 kg – 2 g/day HMB BM>68 kg – 3 g/day HMB for 12 months	Elderly participants (≥65 year) (38 males, 39 females) HMB $n = 40$ Placebo $n = 37$	FM, FFM (BIA) FFM (DXA)	Significant ↑ in FFM and body cell mass No effect on FM
Kraemer et al. (2009)	Randomised, double blind	3 g/day HMB + amino acids (Muscle Armor) for 12 weeks with heavy resistance training	17 healthy males HMB/amino acids $n = 8$ Placebo $n = 9$	BM LBM, %BF (DXA) Girths (six sites) Ultrasound (patella tendon)	Greater ↑ in BM and LBM Greater ↓ in %BF Greater ↑ in thigh and chest girths No effect on patella tendon thickness
Lamboley et al. (2007)	Randomised, double blind	3 g/day for 5 weeks	16 active college students (8 male, 8 female) HMB $n = 8$ Placebo $n = 8$	BM LBM, FM (DXA)	No effect
O'Connor and a Crowe (2007)	Partly blinded	3 g/day for 6 weeks	30 elite rugby league players Control $n = 8$ HMB $n = 11$ HMB/Cr $n = 11$	BM Skinfolds, girths and breadths	No effect
Flakoll et al. (2004)	Randomised, double blind	HMB/lysine/arginine mix with 2 g/day HMB for 12 weeks	57 elderly women (62–90 year) HMB $n = 29$ Placebo $n = 28$	Girths (five sites) Study 1 – BIA Study 2 – ADP	Significant ↑ in average limb girth Trend ($p = 0.08$) for ↑ FFM No effect on BM, FM or %BF
Ransone et al. (2003)	Randomised, double blind, crossover (1 week washout)	3 g/day for 4 weeks	35 male collegiate footballers	BM Skinfolds -%BF (Jackson & Pollock equation)	No effect

Jowko et al. 2001	Randomised, double blind	3 g/day for 3 weeks	40 active males Cr $n = 11$ HMB $n = 9$ Cr + HMB $n = 10$ Placebo $n = 10$	LBM, FM and TBW (BIA)	Significant ↑ BM in all groups except placebo, with HMB/Cr significantly greater than HMB or Cr alone Significant ↑ LBM in all groups, with Cr significantly greater than placebo Significant ↑ FM in HMB/Cr compared to other groups Significant ↑ TBW in all groups, with Cr significantly greater than placebo
Slater et al. (2001)	Randomised, double blind	3 g/day for 6 weeks	27 male strength-trained athletes HMB $n = 9$ Time release HMB $n = 9$ Placebo $n = 9$	BM FM, LBM (DXA)	No effect
Vukovich et al. (2001)	Randomised, double blind	3 g/day for 8 weeks	31 elderly participants (15 male, 16 female) (Mean age 70 ± 1 year) HMB $n = 14$ Placebo $n = 17$	BM Skinfolds (eight sites – Jackson & Pollock equation) CT ($n = 20$ subset) DXA ($n = 23$ subset)	Greater %BF loss (by skinfolds and CT) Trend ($p = 0.08$) for ↑ FFM
Gallagher et al. (2000)	Randomised, double-blind	0, 38 or 76 mg/kg/day for 8 weeks	37 untrained college-aged men 38 mg/kg HMB $n = 12$ 76 mg/kg HMB $n = 11$ Placebo $n = 14$	BM Skinfolds (seven sites: Brozek and Jackson & Pollock equations)	38 mg/kg group had greater ↑ FFM compared to 76/mg/kg and placebo No effect on BM or FM
Panton et al. (2000)	Randomised, double-blind	3 g/day for 4 weeks	75 untrained participants (39 male, 36 female) HMB $n = 39$ Placebo $n = 36$	BM Skinfolds (sum of 7; Pollock & Wilmore equation) %BF, FFM (hydrodensitometry)	No effects at $p<0.05$ Trends for ↑ FFM and ↓ %BF ($p = 0.08$)

(continued)

Table 110.6 (continued)

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplementation
Kreider et al. (2000)	Randomised, double blind	3 g/day for 4 wk	28 NCAA division 1 footballers HMB $n = 14$ Placebo $n = 14$	BM TBW (BIA) FFM, FM, %BF (DXA)	No effect
Kreider et al. (1999)	Randomised, double-blind	0, 3 or 6 g/day for 4 weeks	40 male resistance-trained athletes 3 g/day HMB $n = 13$ 6 g/day HMB $n = 12$ Placebo $n = 15$	BM TBW (BIA) FFM, FM and %BF (DXA)	No effect

This table lists the available research on HMB and body composition. The dose and duration of supplementation, population studied, anthropometrical methods utilised and main outcomes are indicated. The majority of studies indicate no effect of HMB on FFM

ADP air displacement plethysmography, *BIA* bioelectrical impedance analysis, *BM* body mass, *BMI* body mass index, *CT* computed tomography, *DXA* dual energy X-ray absorptiometry, *FM* fat mass, *FFM* fat-free mass, *LBM* lean body mass, *%BF* percentage body fat, *TBW* total body water

Table 110.7 Details and outcomes of studies assessing body composition with chromium picolinate supplementation

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Lukaski et al. (2007)	Randomised, double-blind	200 µg/day for 12 weeks	83 females Cr n = 27 Picolinic acid n = 27 Placebo n = 29	BM Skinfolds (sum of 4) FM, fat-free mineral-free mass (DXA)	No effect
Campbell et al. (2002)	Randomised, double-blind	924 µg/day for 12 weeks	17 older females (54–71 year) Cr n = 9 Placebo n = 8	BM Skinfolds (sum of 8) %BF and FFM (hydrodensitometry)	No effect
Livolsi et al. (2001)	Randomised, double-blind	500 µg/day for 6 weeks	15 division one female softball players	BM %BF and LBM (hydrodensitometry)	No effect
Volpe et al. (2001)	Randomised, double-blind	400 µg/day for 12 weeks	Cr n = 8 Placebo n = 7 37 sedentary females Cr n = 20 Placebo n = 17	BM Girths (hip and waist) %BF, FM and LBM (hydrodensitometry)	No effect
Amato et al. (2000)	Randomised, double-blind	1,000 µg/day for 8 weeks	19 older participants (63–77 year) (9 male, 10 female) Cr n = 9 Placebo n = 10	BMI FM and FFM (DXA)	No effect
Crawford et al. (1999)	Randomised, double-blind, crossover	600 µg/day for 2 months	20 females	BM FM and FFM (BIA)	Significant loss of fat and muscle sparing
Campbell et al. (1999)	Randomised, double-blind	924 µg/day for 12 weeks	18 older men (56–69 year) Cr n = 9 Placebo n = 9	BM Skinfolds (sum of 8) Girths (chest and midthigh) TBW (deuterium oxide) Body density (hydrodensitometry) Calculated two- and three-compartment models	No effect

(continued)

Table 110.7 (continued)

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Walker et al. (1998)	Randomised, double-blind	200 μg/day for 14 weeks	20 male wrestlers Cr $n = 7$ Placebo $n = 7$ Control $n = 6$	FM and FFM (hydrodensitometry) Skinfolds (9 sites) Girths (10 sites)	No effect
Grant et al. (1997)	Randomised, double-blind	400 μg/day for 9 weeks	43 healthy, obese young women Cr no ex. Cr + ex. Cr nicotinate + ex. Placebo + ex.	BM %BF, FM and FFM (hydrodensitometry)	No effect except significant BM ↑ in Cr no ex. and significant BM ↓ in Cr nicotinate + ex.
Lukaski et al. (1996)	Randomised, double-blind	3.3–3.5 μg/kg/day for 8 weeks	36 untrained males Cr picolinate $n = 12$ Cr chloride $n = 12$ Placebo $n = 12$	FM and FFM (DXA) Skinfolds (four sites)	No effect
Hallmark et al. (1996)	Randomised, double-blind	200 μg/day for 12 weeks	16 untrained males Cr $n = 8$ Placebo $n = 8$	BM %BF, LBM (hydrodensitometry) Skinfolds (9 sites) Girths (9 sites)	No effect
Clancy et al. (1994)	Randomised, double-blind	200 μg/day for 9 weeks	21 footballers Cr $n = 9$ Placebo $n = 12$	%BF, LBM (hydrodensitometry) Skinfolds (9 sites) Girths (20 sites)	No effect

This table shows research studies, which assessed the effects of chromium picolinate on body composition. The dose and duration of supplementation, population studied, anthropometrical methods utilised and main outcomes are indicated. The majority of studies indicate no effect of chromium on FM or FFM

BIA bioelectrical impedance analysis, *BM* body mass, *BMI* body mass index, *Cr* chromium picolinate, *DXA* dual energy X-ray absorptiometry, *ex.* exercise, *FM* fat mass, *FFM* fat-free mass, *LBM* lean body mass, *%BF* percentage body fat, *TBW* total body water

Table 110.8 Details and outcomes of studies assessing body composition with *Tribulus terrestris* supplementation

Authors	Study design	Dosage/ duration	Participants	Parameters assessed	Effect of supplement
Rogerson et al. (2007)	Randomised, double-blind	450 mg/day for 5 weeks	22 elite male rugby league players *Tribulus* $n = 11$ Placebo $n = 11$	BM FFM (BIA)	No effect
Antonio et al. (2000)	Randomised, double-blind	3.21 mg/kg/day for 8 weeks	15 resistance-trained males *Tribulus* $n = 8$ Placebo $n = 7$	BM %BF (hydrodensitometry) TBW (BIA) Skinfolds (sum of 7)	No effect

This table lists the few research studies available, which evaluate the effects of *Tribulus terrestris* on body composition. The dose and duration of supplementation, population studied, anthropometrical methods utilised and main outcomes are indicated. Both studies indicate no effect of *Tribulus terrestris* on any aspect of body composition
BIA bioelectrical impedance analysis, *BM* body mass, *FFM* fat-free mass, *%BF* percentage body fat, *TBW* total body water

was rarely used (Table 110.7). It would be of interest to assess changes in body composition in response to chromium picolinate supplementation using more sensitive anthropometric methodologies to confirm that this supplement does not affect body composition in healthy participants.

110.4.4 Anthropometric Methodologies Employed in Tribulus Terrestris Studies

Tribulus terrestris is a herbal supplement, which is claimed to increase circulating levels of luteinizing hormone and testosterone and therefore increase muscle mass (Rogerson et al. 2007). Although *Tribulus* has been marketed to athletes for some years, very few scientific studies exist, which investigate the efficacy of this supplement. Two double-blind, placebo-controlled studies that examined body composition showed no effect of *Tribulus* on FFM or %BF in trained individuals (Antonio et al. 2000; Rogerson et al. 2007; Table 110.8). These two studies employed BIA and hydrodensitometry to evaluate body composition (Table 110.8). Future research investigating the effect of *Tribulus* on body composition should employ the more sensitive anthropometric methodologies (e.g., four-compartment model using combined methodologies) with large sample sizes as these initial studies failed to detect any effect using BIA and hydrodensitometry.

110.4.5 Anthropometric Methodologies Employed in Ephedrine/Ephedra Studies

Ephedrine is a sympathomimetic drug which stimulates the release of catecholamines in the body (Bouchard et al. 2002). Ephedrine and its herbal equivalent, ephedra, are claimed to enhance sports performance and to reduce body fat via thermogenesis (see Table 110.9 for the key features of ephedrine). There is a lack of scientific evidence to support the use of ephedrine to enhance sports performance

Table 110.9 Key features of ephedrine

1. A sympathomimetic stimulant drug.
2. Sympathomimetics mimic the effects of sympathetic nervous system stimulation.
3. Sympathomimetics induce the fight-or-flight response and stimulate the central nervous system.
4. Claimed to enhance endurance exercise performance but lacks scientific evidence to support this claim.
5. Claimed to induce fat loss via thermogenesis (increased metabolic rate).
6. Sufficient scientific evidence exists to support the claim of fat loss, but only when supplemented in conjunction with caffeine.
7. Carries considerable health risks, with numerous reports of adverse health effects (including death) resulting from dietary supplementation.

The main features of ephedrine are listed including the mechanism by which it is thought to affect exercise performance and body fat, the main research findings and significant health risks associated with the use of ephedrine

(Bouchard et al. 2002). The majority of body composition studies investigated weight loss in response to ephedrine/ephedra combined with caffeine. Performing research on ephedrine or ephedra is difficult as a large number of adverse health effects, including death, have been reported (Bouchard et al. 2002). Sale of ephedrine-containing products was prohibited by the Food and Drug Administration in USA in 2004 due to the high number of adverse health reports. Hence, research into ephedrine is limited. Research is also hindered by the use of herbal preparations where the constituent ingredients are not independently verified. For example, Coffey et al. (2004) examined the effects of a herbal supplement containing caffeine and ephedrine on body weight and FM in obese individuals. The herbal preparation was evaluated by two independent laboratories and found to contain half the stated concentrations of caffeine and ephedrine. Haller et al. (2004) assayed 35 commercial products containing ephedrine alkaloids and reported that 31% of the products contained greater than 110% and 6% contained less than 90% of the stated concentration of ephedrine. Therefore, one of the limitations of ephedrine research is a lack of independently verified supplement doses, particularly where herbal preparations were investigated.

The few double-blind, placebo-controlled studies of ephedrine where body composition was assessed have, for the most part, employed BIA (Table 110.10). One study utilised DXA (Greenway and Bray 2004) and one ADP (Boozer et al. 2001; Table 110.10). All these studies supplemented ephedrine in combination with caffeine and studied obese individuals. Under these conditions, the selected anthropometric methodologies appear sufficiently sensitive to detect changes in body composition as the majority of the listed studies showed a significant decrease in %BF and/or FM with supplementation (Table 110.10). Two early studies which evaluated ephedrine without caffeine assessed body weight and did not evaluate changes in FM (Pasquali et al. 1985, 1992). Interestingly, ephedrine alone did not affect body weight in these studies. There is a lack of research into the effects of ephedrine alone on body composition, where changes in FM and FFM are ascertained. The majority of studies into ephedrine have used herbal preparations, which combine ephedrine and caffeine in the one powder or pill and therefore did not investigate ephedrine in isolation (Molnár et al. 2000; Boozer et al. 2001, 2002; Coffey et al. 2004; Greenway and Bray 2004). Research into the effects of ephedrine on FM would be enhanced by further research where ephedrine's effects on FM can be differentiated from those of caffeine. Future studies investigating ephedrine in combination with caffeine could effectively employ most of the available anthropometric methodologies. However, investigating ephedrine alone may require the more sensitive techniques given that changes in body mass have not previously been detected (Pasquali et al. 1985, 1992).

Table 110.10 Details and outcomes of studies assessing body composition with ephedrine/ephedra supplementation

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Coffey et al. (2004)	Randomised, double-blind, clinical trial	Herbal formula (ephedrine, caffeine and other ingredients): 60 mg/day ephedrine and 360 mg/day caffeine for 12 weeks	102 overweight/obese patients (14 male, 88 female) Herbal *n* = 52 Placebo *n* = 50	BM Waist girth BMI %BF, FM (BIA)	No effect on %BF or FM Significant ↓ in BM, waist girth and BMI
Greenway and Bray (2004)	Randomised, double blind	Herbal formula: 72 mg/day ephedrine and 210 mg/day caffeine for 12 weeks	40 participants (seven male, 33 female) Herbal *n* = 20 (12 completed) Placebo *n* = 20 (19 completed)	BM %BF, LBM (DXA)	Significant ↓ in BM and %BF No effect on LBM
Hioki et al. (2004)	Randomised, double blind	Herbal formula (bofu-tsusho-san): 24 mg/day ephedrine and 280 mg/day caffeine for 24 weeks	81 obese Japanese women Herbal *n* = 41 Placebo *n* = 40	BM W:H ratio %BF, abdominal visceral fat (BIA)	Significantly greater loss in BM and abdominal fat. No effect on %BF
Boozer et al. (2002)	Randomised, double-blind, clinical trial	Herbal formula: 90 mg/day ephedrine alkaloids and 192 mg/day caffeine for 6 months	Weight-control patients (outpatient clinic) Herbal *n* = 83 (46 completed) Placebo *n* = 84 (41 completed)	BM W:H ratio FM (BIA)	Significantly greater loss of BM and FM No effect on W:H ratio
Boozer et al. (2001)	Randomised, double blind	Herbal formula: 72 mg/day ephedrine and 240 mg/day caffeine for 8 weeks	Overweight men and women Herbal *n* = 24 Placebo *n* = 24	BM W:H ratio %BF (ADP)	Significantly greater loss of BM, %BF and hip and waist girths
Molnár et al. (2000)	Randomised, double blind	Weight-dependent dose: <80 kg – 300/30 mg/day C/E; >80 kg – 600/60 mg/day C/E for 20 weeks	29 obese adolescents (male and female) Ephedrine/caffeine n = 16 Placebo *n* = 13	BM BMI %BF (BIA)	Significant ↓ in BM, BMI and %BF
Breum et al. (1994)	Randomised, double blind. No placebo group	60 mg/day ephedrine and 600 mg/day caffeine or 30 mg/day dexfenfluramine for 15 weeks	Overweight patients Ephedrine/caffeine *n* = 38 Dexfenfluramine *n* = 43	BM	No difference between groups

(continued)

Table 110.10 (continued)

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Astrup et al. (1992)	Randomised, double blind	60 mg/day ephedrine and 600 mg/day caffeine for 8 weeks	14 obese women Ephedrine/caffeine $n = 7$ Placebo $n = 7$	BM FM, FFM (BIA)	No effect on BM loss Greater loss of FM and less loss of FFM

This table lists the research studies, which have evaluated the effects of ephedrine on body composition. The majority of these studies investigated ephedrine supplemented in combination with caffeine. The dose and duration of supplementation, population studied, anthropometrical methods utilised and main outcomes are shown. The majority of studies show significant reduction in FM and/or %BF in response to ephedrine/caffeine

ADP air displacement plethysmography, *BIA* bioelectrical impedance analysis, *BM* body mass, *BMI* body mass index, *C* caffeine, *DXA* dual energy X-ray absorptiometry, *E* ephedrine, *FM* fat mass, *FFM* fat-free mass, *LBM* lean body mass, *%BF* percentage body fat, *W:H ratio* waist-to-hip ratio

110.4.6 Anthropometric Methodologies Employed in L-Carnitine Studies

Carnitine is involved in fatty acid oxidation within muscle and may therefore alter substrate utilisation (see Brass 2000). More recently, L-carnitine-L-tartrate has been suggested to play a role in protein synthesis by stimulating gonadotrophin releasing hormone and preventing the fall in testosterone following intense resistance exercise (Kraemer et al. 2009). The main focus of L-carnitine research has been assessment of the effects on exercise performance. However, a small number of studies have investigated the effects of L-carnitine on body composition, primarily in overweight or obese individuals. The majority of these studies show no effect of carnitine on FM and FFM (Table 110.11), whereas one study reported positive effects of carnitine on FM and muscle mass in elderly participants, with rapid onset of fatigue (Pistone et al. 2003). Three of these four studies employed BIA to assess body composition (Table 110.11). Similar to other dietary supplements where previous research shows little or no effect on body composition, future research should employ the more sensitive anthropometric methodologies. Similar to ephedrine, independent assessment of supplement dose should also be performed as the stated carnitine content of a number of preparations has been found to be inaccurate (Brass 2000).

In conclusion, a wide variety of anthropometric methodologies have been employed in dietary supplement studies, with BIA, DXA and hydrodensitometry most popular. There does not appear to be any trend in the type of methodology used in studies where significant effects on body composition were detected or those where there were no effects. A wider variety of anthropometric methodologies has been used to evaluate changes in body composition in response to creatine monohydrate supplementation compared to the other supplements. However, this most likely reflects the greater number of studies available on creatine compared to the number available on other supplements. Creatine and ephedrine (combined with caffeine) appear to be the only two supplements of those reviewed which have consistent reports of significant effects on body composition. Therefore, future research into these two supplements could employ any of the available anthropometric methodologies. The remaining supplements do not have clear research evidence to support a significant effect on body composition. Therefore, future research into these supplements should employ the more sensitive of the anthropometric methodologies.

110.5 Validity and Reliability of Anthropometric Methods in Dietary Supplement Studies

Only a small number of studies have examined the validity and reliability of various anthropometric methods in relation to detecting change as a result of dietary supplementation (Vukovich and Peeters, 2003; Van Marken Lichtenbelt et al. 2004; Kilduff et al. 2007). The types of supplements investigated in these studies are limited and include creatine monohydrate (Vukovich and Peeters 2003; Kilduff et al. 2007) and androgenic-anabolic steroids (Van Marken Lichtenbelt et al. 2004), the latter of which are classified as drugs rather than dietary supplements. Furthermore, problems arise in selecting a criterion methodology by which the validity of other methods can be assessed. Until recently, hydrodensitometry was considered the gold standard of anthropometric methods. However, with the development of new techniques, particularly in the field of medical imaging, other methods such as DXA (e.g. Fornetti et al. 1999) and four-compartment models using combined methodologies (Van Marken Lichtenbelt et al. 2004) are now used. Interestingly, when the validity of DXA was assessed in comparison to a four-compartment model, the estimations of body fat were higher and

Table 110.11 Details and outcomes of studies assessing body composition with L-carnitine supplementation

Authors	Study design	Dosage/duration	Participants	Parameters assessed	Effect of supplement
Lofgren et al. (2005)	Randomised, double blind	3 g/day for 10 weeks	70 overweight/obese women Carnitine $n = 35$ Placebo $n = 35$	BM BMI, W:H ratio %BF, FM, LBM and trunk fat (DXA)	No effect
Wutzke and Lorenz (2004)	Repeated measures (not randomised)	4.5 g/day L-carnitine-L-tartrate equivalent to 3 g/day L-carnitine for 10 days (after 10 days supplied regular diet)	12 overweight participants (5 male, 7 female)	BM TBW, FM and LBM (BIA)	No effect
Pistone et al. (2003)	Randomised, double blind	4 g/day for 30 days	84 elderly participants with onset of fatigue Carnitine $n = 42$ Placebo $n = 42$	FM, FFM (BIA)	Significant ↑ in muscle mass & ↓ in FM
Villani et al. (2000)	Randomised, double blind	4 g/day for 8 weeks	28 moderately overweight females Carnitine $n = 13$ Placebo $n = 15$	BM Skinfolds (four sites averaged) FM, FFM (BIA)	No effect

This table shows research studies, which assessed the effects of l-carnitine on body composition. The dose and duration of supplementation, population studied, anthropometrical methods utilised and main outcomes are indicated. The majority of studies indicate no effect of l-carnitine on FM or FFM

BIA bioelectrical impedance analysis, *BM* body mass, *BMI* body mass index, *DXA* dual energy X-ray absorptiometry, *FM* fat mass, *FFM* fat-free mass, *LBM* lean body mass, *%BF* percentage body fat, *W:H ratio* waist-to-hip ratio

the error relatively high compared with other methodologies such as hydrodensitometry and deuterium dilution (Van Marken Lichtenbelt et al. 2004). This shift away from hydrodensitometry as the gold standard of anthropometric methodologies generates a need for further research into suitable criterion methods for body composition assessment.

Kilduff et al. (2007) investigated the ability of different anthropometric methodologies to detect changes in body composition as a result of acute creatine monohydrate supplementation. Five two-compartment methodologies were employed including hydrodensitometry, ADP, BIA, NIR and anthropometry (assessment of seven skinfold sites). Initially, the reliability of each method was assessed using 55 volunteers, who were assessed twice, 7 days apart. This was immediately followed by 7 days' creatine monohydrate supplementation by 30 of the original 55 volunteers, using a standard loading dose (20 g per day). Body composition was again assessed at the end of the supplementation period using all five methodologies. Kilduff et al. (2007) reported high reliability of the five methodologies investigated with test–retest correlations ranging from 0.983 to 0.998. Although the 95% limits of agreement were within acceptable ranges for all five methods, the anthropometry method had the widest values (-2.4 to 2.6 kg FFM). The other methods had limits of agreement ranging from -1.4 to 1.7 kg FFM. Interestingly, all five methodologies detected the change in FFM due to creatine supplementation, indicating that any of these methods would be suitable to assess body composition changes with creatine supplementation. Others have also shown that ADP can detect changes in body mass and FFM following acute creatine monohydrate supplementation (Vukovich and Peeters 2003). Creatine is well known to cause a rapid increase in body mass, although the source of this increase in terms of FFM versus water retention is still under discussion (Lopez et al. 2009). Therefore, one would expect a significant effect size for creatine with regard to body composition. Indeed, Branch (2003) performed a meta-analysis examining the effect of creatine on body composition and reported a small but significant effect of creatine on body mass and lean body mass (mean ± SE effect size = 0.17 ± 0.03). The results of Kilduff et al. (2007) support this finding that creatine has significant effects on body composition, with all five methodologies investigated revealing significant increases in FFM. As was discussed above, creatine is one of the few dietary supplements consistently reported to have significant effects on body composition. Therefore, one cannot assume that the five anthropometric methodologies evaluated by Kilduff et al. (2007) would be equally as effective in detecting changes in body composition due to consumption of other dietary supplements such as HMB, chromium, or L-carnitine as past research shows little or no effect of these supplements on body composition.

Van Marken Lichtenbelt et al. (2004) assessed the validity of a number of anthropometric methodologies in comparison to a four-compartment criterion method using bodybuilders. The four-compartment model included a combination of deuterium dilution to assess total body water, DXA to assess total bone mineral content and hydrodensitometry to assess body density. This study also assessed the ability of the different methodologies to detect changes in body composition as a result of 8 weeks' strength training combined with androgenic-anabolic steroid use. Comparison of body composition assessment to the four-compartment criterion method showed that the largest errors were obtained from descriptive methods of body composition assessment including DXA and prediction equations based on BMI, skinfolds and BIA. The authors recommended avoiding these descriptive methodologies to assess changes in body composition in this population. The smallest error was associated with the three-compartment model incorporating total body water (derived via deuterium dilution). Interestingly, when changes in body composition as a result of training and steroid use were evaluated, large biases and large errors were associated with the BMI and BIA methods. The three-compartment model incorporating body water was again the best method when compared to the four-compartment model. However, it should be noted that the average decrease in percentage body fat (%BF) as a result of the training and steroid intervention was only small (1.2%). With such small changes in body

composition, the authors recommended that only the three-compartment water model was sensitive enough to detect changes. These authors also noted the importance of hydration status with the difference between the two- and four-compartment models mainly being attributed to changes in the hydration of the FFM. Given that hydration status can vary widely as a result of exercise and that dietary supplementation most often occurs in conjunction with exercise training, hydration status should be controlled for when assessing body composition changes with dietary supplementation.

Often, dietary supplements are tested on athletes or evaluated in combination with an exercise-training regime. It is therefore of relevance to examine the reliability of literature for anthropometric methods assessed in athletes or other populations undergoing training. Fornetti et al. (1999) examined the validity and reliability of BIA and NIR in comparison to DXA in female collegiate athletes. The study included a good sample size of 132 female athletes. The intraclass correlation coefficients for two trials performed on each participant showed high reliability for both BIA (0.993 and 0.997 for reactance and resistance, respectively) and NIR (0.978 and 0.980 for two optical density measures). Correlations of BIA and NIR with DXA were high and prediction errors were low (approximately 1.8% when values were converted to %BF). Thus, the authors concluded that both BIA and NIR were highly reliable and valid techniques for determining body composition in female athletes. Nelson et al. (1996) also examined female participants but of an older age group (50–70 years) and untrained. The sensitivity of various anthropometric methods to detect changes in soft tissue following 12 months' resistance training was examined. The anthropometric methods investigated included anthropometry (six skinfolds and five girths), BIA, hydrodensitometry, CT, DXA, 24-h total urinary creatinine, total body potassium from potassium-40 counting, total body nitrogen and carbon and tritium dilution. Interestingly, only hydrodensitometry detected the decrease in FM in the strength-trained females ($n = 20$) in comparison to the control group ($n = 19$). DXA, which, as mentioned above, has been utilised as a criterion method in other studies such as Fornetti et al. (1999), failed to detect the change in FM. However, one of the limitations of this study was that participants were required to remain weight stable within 1 kg for the 12-month duration of the training program to comply with a concurrent study. Although the resistance-training program was designed to elicit increases in muscle mass (three sets of eight repeats at 80% 1RM), the constraint on weight gain must be viewed as a limitation in terms of evaluating the ability to detect changes in body composition.

In conclusion, there is a lack of research into the validity and reliability of various anthropometric methods to detect body composition changes in response to either dietary supplementation or exercise training. Studies show that commonly used anthropometric methods have high reliability (Fornetti et al. 1999; Kilduff et al. 2007) and are sufficiently sensitive to detect changes in body composition as a result of creatine monohydrate supplementation (Vukovich and Peeters 2003; Kilduff et al. 2007). However, validity studies are not so positive, with large errors and biases associated with some anthropometric methods when compared to a four-compartment model (Van Marken Lichtenbelt et al. 2004). It is interesting that DXA is sometimes used as the criterion or reference method in validity studies (e.g. Fornetti et al. 1999). However, the results of Van Marken Lichtenbelt et al. (2004) question the validity of DXA. With the development of new imaging technology, the field of anthropometry requires greater numbers of validity studies and a thorough investigation of an appropriate criterion method.

110.6 The Influence of Hydration Status on Body Composition Assessment

It is important to consider the influence of hydration status on body composition as dietary supplements are often evaluated in conjunction with exercise testing and training. Exercise can alter body fluid distribution with plasma movement into interstitial spaces and possible sweat losses. In order to minimise

changes in hydration status, body composition assessment should be performed prior to any exercise testing. Attempts should also be made to standardise fluid intake in the 12–24 h prior to body composition assessment. Minimising changes in body fluid prior to body composition assessment is more important for certain anthropometric methodologies than others. For example, BIA has been reported to underestimate %BF when the participants are dehydrated and to overestimate %BF with rehydration or superhydration (Saunders et al. 1998). Hydration status can also influence measurements from ADP as was shown by Vukovich and Peeters (2003), where ingestion of 2 l of water was registered as an increase in FM rather than FFM values. By contrast, hydrodensitometry (Saunders et al. 1998) and DXA (Lohman et al. 2000) have been reported to be stable with different states of hydration. Thus, researchers should try to minimise changes in hydration status prior to assessing body composition when using methodologies, such as BIA and ADP.

110.7 Applications to Other Areas of Health and Disease

The type of anthropometric methodology selected when investigating the effects of dietary supplements on body composition can affect the ability to detect change. If the supplement is known to have significant effects on body composition, such as creatine monohydrate, then the choice of anthropometric methodology is unlikely to affect the ability to detect change. However, anthropometric methodology should be carefully selected, if past research shows little or no effect of the supplement on body composition. Similarly, in other areas of health and disease, the effect of an intervention on body composition should be evaluated using an appropriate methodology based on the effect size from past research. Where little previous research exists, it is recommended that researchers utilise the more sensitive anthropometric methodologies and larger sample sizes. A further consideration for assessment of body composition is that altered states of hydration can affect body composition estimations. For example, BIA and ADP estimations of %BF and FFM are altered by hydration status, whereas hydrodensitometry and DXA show less variation due to hydration status. Certain medications and disease states, such as cardiovascular disease and chronic obstructive pulmonary disease, also alter hydration status and the methodology used for assessing body composition in these cases should be carefully selected.

Summary Points

- Many dietary supplements reportedly alter body composition.
- Accurate assessment of body composition is necessary to detect changes due to dietary supplementation.
- Selection of anthropometric methodology should consider measurement factors (reliability, validity, accuracy and sensitivity), statistical effect size, ethical factors and practical considerations.
- Practical constraints, such as funding, accessibility and time available may limit selection of the most appropriate anthropometric techniques.
- Many dietary supplements claim to alter body composition; however, only a small number of these supplements have sufficient double-blind, randomised, placebo-controlled research to evaluate their effectiveness.
- Of the six dietary supplements reviewed in this chapter, only creatine monohydrate and ephedrine (in combination with caffeine) show consistent significant effects on body composition.
- The majority of recent studies into the reviewed supplements utilise BIA, DXA or hydrodensitometry to assess body composition, with a smaller number using ADP.

- Skinfolds are still commonly assessed, but are usually performed in conjunction with other anthropometric methods.
- Creatine monohydrate has been investigated with a wide variety of anthropometric methodologies.
- Methodologies including hydrodensitometry, ADP, BIA, NIR and skinfolds have all been shown to detect changes in FFM in response to creatine supplementation.
- Research investigating body composition changes with chromium picolinate, HMB, *Tribulus terrestris* or l-carnitine consistently show little or no effect. Therefore, future research into these supplements should employ the more sensitive anthropometric methodologies, such as those based on three- or four-compartment models.
- Few studies investigate the reliability and validity of anthropometric methods for detecting changes in body composition due to dietary supplementation.
- When supplements are known to have marked effects on body composition, most anthropometric methods are sufficiently sensitive to detect change. However, where effects on body composition are only minor, more sensitive methods are required.
- As hydration status affects assessment of body composition, research investigating change in body composition should try to limit changes in body hydration or control for these changes, particularly with methodologies such as ADP and BIA.

Key Features

Table 110.12 Key facts and features of anthropometry and the response to dietary supplementation in exercise

Validity, reliability, accuracy and sensitivity of anthropometric methodology are important in dietary supplementation studies.
Few studies examine the validity and reliability of various anthropometric methodologies to detect change in body composition as a result of dietary supplementation.
The expected size of the effect of the dietary supplement on body composition will determine the most appropriate anthropometric methodology to be used.
Meta-analyses are good sources of information to determine expected effect sizes.
Supplements with demonstrated significant effects on body composition can be investigated with most anthropometric methodologies, whereas supplements which show small or negligible effects require the more sensitive methodologies.
Practical considerations, such as cost, accessibility and time available, will also influence choice of anthropometric methodology.
A wide variety of anthropometric methodologies have been utilised in recent investigations into the most commonly used dietary supplements including creatine monohydrate, HMB, chromium picolinate, *Tribulus terrestris*, ephedrine and L-carnitine.
The most commonly utilised anthropometric methodologies to assess body composition in dietary supplement studies include BIA, DXA and hydrodensitometry.
Past research shows significant effects of creatine monohydrate and ephedrine (combined with caffeine) on body composition. However, past research into other commonly used supplements has failed to show significant effects on body composition.
Alterations in hydration status, which are often associated with exercise and exercise testing, should be minimised so as not to influence assessment of body composition.

This table summarises the important points to consider when selecting and executing anthropometric assessments of body composition in response to dietary supplementation. A summary of the main anthropometrical findings of research into six of the most popular dietary supplements is also included

BIA bioelectrical impedance analysis, *DXA* dual energy X-ray absorptiometry, *HMB* β-hydroxy-β-methyl butyrate

Chapter 111
Anthropometry in Premenarcheal Female Esthetic Sports Athletes and Ballerinas

Marjeta Misigoj-Durakovic

Abstract Body size and build influences performance in many sports, especially in those pertaining to the group of female esthetic sports like artistic gymnastics, rhythmic gymnastics and figure skating. These sports pose high specific demands upon the functional, energy, motor and psychological capacities of athletes; but also upon the size, body build and composition of the performers, particularly of elite level females. Similar can be seen in ballet, an artistic theatrical expression of dancing. Contrary to the majority of other sports, morphological predispositions for esthetic sports, rhythmic gymnastics in particular, and ballet are similar: a smaller size and body mass of female performers. Ballet and the group of esthetic sports are specific also because regular serious workouts begin early at the pre-school age and very soon the nature of training programs can be described as of high intensity, high frequency and long duration with the eventual demands of maintaining minimal amounts of subcutaneous body fat. The maintenance of the indispensable anthropometric characteristics and body composition over the years of training and competition frequently determine the kind of diet with a reduced energy intake.

Expectedly, ballerinas and female athletes in esthetic sports mostly belong to the group of late-maturing girls. Namely, body linearity, or slimness, is connected with later maturation. However, there is still an ongoing debate whether a long-lasting, high-volume and intense, early commenced training in gymnastics, along with modified nutrition, which does not follow the energy demands of the training process, may in some girls jeopardize growth and provoke later sexual maturation. In adolescence, female esthetic sports athletes have lower values of body mass index and a body fat percentage with adequate fat-free mass in comparison to non-athletes and female athletes in other sports. Such a body build and composition, typical for the premenarcheal aged girls, particularly artistic gymnasts contributes to the increased strength/weight ratio, stability and a decrease in the moments of inertia (Borms, J and Caine, DJ, In: Sands WA, Caine DJ, Borms J, editors. Scientific aspects of women' gymnastics. Medicine and sport science 45. Borms J, Hebbelinck M, Hills AP, editors. Karger, Basel. p. 110–127, 2003), thus improving the execution of the demanding elements, but also the esthetic impression of performance.

Fat percentage and endomorphy ratings are connected to the performance of esthetic female athletes as well as with the incidence and duration of recovery after injury in ballet dancers. A careful follow-up of the anthropometric characteristics in this group of female athletes and ballerinas,

111.1 Introduction

Morphological anthropometric measures are well researched in kinesiology and used in sports in the process of selecting male and female athletes for certain sporting branches, and also in the evaluation of training effects. In the selection, the measures of body size, particularly those of the longitudinal skeleton dimensions, are crucial due to their predominant heredity-like nature. In order to control the sports training effects, the measures of body parts' circumferences, body mass and skinfolds are monitored, as are the components of body composition: the proportions of body fat (% BF) and fat-free mass – the measures being sensitive to environmental influence and therefore changeable under the impact of various types, volumes, and intensities of training programs and modifications of the athletes' diet.

111.1.1 The Contribution of Anthropometrics to Performance in Esthetic Sports

Literature describes desirable model characteristics of top athletes in the form of basic anthropometric dimensions, their interrelations (ratios, i.e., indics), body composition components, and somatotypes (mostly using the Heath–Carter somatotyping method).

It has already been well documented that body size and body build contribute significantly to performance in many sports, particularly in esthetic sports and all kinds of dancing. Within the group of the so-called female esthetic sports, the most demanding sports are: artistic gymnastics, rhythmic gymnastics, and figure skating. These are sports that pose high specific demands upon functional and energy capacities and require athletes to have highly developed motor and psychological abilities and specific traits. These disciplines also impose high demands upon the body size, build, and composition of the performers, particularly of elite female athletes. Much the same can be seen in ballet, an artistic theatrical expression of dancing.

Studying the contribution of anthropometrics to a performance score in a sample of top female gymnasts competing at the World Championship in Artistic Gymnastics, Claessens et al. (1999) found that about 32–45% of the variances in the gymnastic performance score were explained with

the anthropometric dimensions and/or derived variables. Moreover, in the investigation of leaping ability, anthropometric dimensions, and body composition in rhythmic gymnasts for talent identification purposes, Di Cagno et al. (2008) found certain anthropometric measures, such as body height, thigh length, and fat-free mass, to be good predictors of a better performance.

Average body height and mass of female athletes in many sports, as in sports games, swimming, or tennis, to mention a few, corresponds to or is often above the median value of the average non-trained peer population of girls. Body mass of female athletes is characterized here with a higher fat-free mass and a lower contribution of fat in comparison to the average non-trained population.

However, in the group of esthetic sports, track disciplines of long-distance running and ballet, but especially in gymnastics, the key advantage is a smaller body size with a considerably reduced portion of fat in body composition and performance-related adequate fat-free mass in female athletes.

111.1.2 Specific Demands of Esthetic Sports and Ballet

Ballet and the group of esthetic sports are specific also because serious workouts begin early at the preschool age and, very soon, the nature of training programs can be described as: high intensity, high frequency, and long duration, with the eventual demands of maintaining minimal amounts of subcutaneous body fat. Dance and esthetic sports include, besides the technical value of performing movements with the body and apparatuses, also an artistic value, that is, the performance of movements should make an enchanting impression on the spectators, in accord with the music. Particularly due to the latter, female performers in esthetic sports strive for slimness and low body mass. This is even truer for ballerinas, for whom the artistic expression and magical impression of illusion and perfection that they make on their audience is everything. Already, at the age of 5 and 7, girls in esthetic sports pay more attention to their own body mass than female athletes in other sports and girls who are not engaged in sports (Davison et al. 2002). This is so because final performance grade in esthetic sports, as well as good performance in ballet, is based upon the judges' subjective evaluation of success in performing the assigned or compulsory elements and upon the esthetic impression, to which body shape contributes as well.

Hence, it is quite clear that the requirements for smaller body size with a low portion of fat and adequate fat-free mass condition the selection of girls for the mentioned sports and ballet, according to morphological criteria. The maintenance of the indispensable anthropometric characteristics and body composition over the years of training and competitions frequently determines the kind of diet with a reduced energy intake, and also with an altered intake of certain nutrients (Ziegler et al. 2002), and sometimes with other weight control measures, as shown in female figure skaters aged 16–22 years by Taylor and Ste-Marie (2001). The consequence is that nutritional habits of female athletes in esthetic sports often do not follow the actual energy demands posed by the high volume and intensity of training programs (Guerra et al. 2001).

Ballerinas and female athletes in esthetic sports mostly belong to the group of late-maturing girls (Vadocz et al. 2002; Thomis et al. 2005). It is expected since body linearity, or slimness, is connected with later maturation. However, there is still an ongoing debate whether or not a long-lasting, high-volume, and intense, early commenced training in gymnastics, along with modified nutrition, which does not follow the energy demands of the training process, may in some girls jeopardize growth and induce later sexual maturation (Theintz et al. 1993; Lindholm et al. 1994; Damsgaard et al. 2000; Caine et al. 2001; Georgopulos et al. 2002; Thomis et al. 2005).

Female artistic gymnastics is a well-investigated sport from the kinesiological, anthropological, nutritional, and health-related aspects (Claessens et al. 1992, 1999; Theintz et al. 1993; Lindholm

et al.1994; Damsgaard et al. 2000; Caine et al. 2001; Georgopulos et al. 2002; Sands et al. 2003; Thomis et al. 2005), where issues related to anthropometry, such as growth and maturation, eating disorders, talent selection, and early started training programs were in focus. In the last decade, the number of studies dealing with these aspects of scientific research in rhythmic gymnastics, figure skating, and ballet has been growing (Lockwood and Gervais 1997; Georgopulos et al. 1999, 2002; Guerra et al. 2001; Taylor et al. 2001; Oleson et al. 2002; Vadocz et al. 2002; Ziegler et al. 2002; Klentrou and Plyley 2003; Misigoj-Durakovic et al. 2005).

Although with regard to dance structures and from the esthetic point of view they show certain similarities, each of the mentioned sporting/artistic disciplines imposes very specific motor and energy supplying requirements upon the performers.

Female artistic gymnastics is a highly demanding sport for young athletes. Training is characterized by high-volume and high-impact loading and requires high self-discipline and motivation to perform endless skill repetitions. Female gymnasts compete in four events: vaults, uneven bars, balance beam, and floor exercise. They perform short routines up to 90 s of duration, depending on the competition event; routines consist of the performance of a large number of skills and movement structures, from vaults to swings, release moves, pirouettes, and dismounts on uneven bars; jumps, leaps, turns, handstands, acrobatic skills, and dance elements on a beam; and series of jumps, leaps, hops, turns, rolls, handstands, somersaults, acrobatic skills, and dance elements harmonized with instrumental music in floor exercise, just to mention some. These events require a highly developed energy supply and motor abilities, particularly strength - with high strength-to-body mass ratio, flexibility, and balance.

The basic motor structures of body movement in rhythmic gymnastics – the youngest sport in this group, are: leaps, pivots, balances, and flexibility/flowing movements. Rhythmic gymnasts also perform a series of supported and unsupported jumps, swings and body rotations, turns and various body shifts. They connect elements between the basic elements performed as the "loads" of various degrees. The specificity of rhythmic gymnastics in the group of esthetic sports is the apparatus manipulation (ribbon, ball, rope, clubs, and hoop). The shape of an apparatus determines the movements to be made with it. In rhythmic gymnastics, the anaerobic energy system fulfills high energy demands (for speed, explosive strength, etc.) in the short period of a minute and a half of one competition routine. With breaks, each competitor has to perform four high-intensity exercises. Due to that, and also because of the training programs system performed at various intensity levels, it is essential for female rhythmic gymnasts to develop optimally both systems of energy supply – aerobic and anaerobic alike.

Similar demands upon morphological and functional (energy supply) characteristics of female dancers are posed by ballet, but with certain specificities, particularly in relation to rotation and leg positions in performing dance movements and with characteristic compulsory figures (such as grand jeté, pirouette, plié, arabesque…).

Figure skating, which uses ballet and other kind of dance movements, has specific demands as it abounds in running starts, powerful take-offs, jumps (mostly with rotation), multi-revolution jumps, fast and multiple rockers and figures, with landings with skates on the ice or landing backward on a single leg on the ice (Lockwood and Gervais 1997). Figure skating develops and demands great aerobic strength.

111.2 Body Size and Proportions

Contrary to the majority of other sports, the morphological predispositions for esthetic sports and ballet are: small size and body mass of female performers. For gymnastics, young girls of a smaller and petite constitution are selected. Before a systematic training has commenced, one looks for a

small body size. One of the selective factors is also the parents' body size. Studying the effect of genetic factors, birth weight, growth during early childhood, sport, training volume, and pubertal status on the stature and body mass index of male and female athletes aged 9–13 years competing in swimming, tennis, handball, and gymnastics, Damsgaard et al. (2000) concluded that prepubertal growth is not adversely affected by competitive sport activity.

In adolescence, not surprisingly, female performers in esthetic sports have significantly lower values of body mass index (BMI) and percentage of body fat in comparison to their peers who are not engaged in sports (Guerra et al. 2001; Klentrou and Plyley 2003; Soric and Misigoj-Durakovic 2008).

111.2.1 Young Female Artistic Gymnasts

Thus, young female gymnasts are smaller and lighter in comparison with the control groups of girls engaged in other sports and with those not engaged in sports at all, with whom they have been compared in many investigations or in relation to reference values in the general peer population (Claessens et al. 1992; Theinz et al. 1993; Malina 1994; Lindholm et al. 1993; Georgulopulos et al. 2002; Erlandson et al. 2008; etc.). Their height and mass are under the 50th percentile (Lindholm et al. 1994; Georgulopulos et al. 2002; Soric and Misigoj-Durakovic 2008). In the study by Claessens et al. (1992), it was shown that elite female gymnasts compared with non-athletes also have narrower shoulders and hips, but they have proportionally broader shoulders relative to their hips. They do not differ from the non-athletes in relative leg length measures. Female gymnasts are also smaller in comparison to female athletes in other esthetic sports, such as rhythmic gymnastics (Georgopoulos et al. 2002; Soric and Misigoj-Durakovic et al. 2008), and in relation to the premenarcheal ballerinas (Soric and Mišigoj-Durakovic 2008) (Fig. 111.1).

Female performers in these sports often have later maturation (Claessens et al. 1992; Theinz et al. 1993; Lindholm et al. 1993; Erlandson et al. 2008; Klentrou and Plyley 2003). In the study by Erlandson et al. (2008), it was shown that elite-level female gymnasts in comparison to other elite female athletes in other sports, such as swimming and tennis, are significantly smaller during adolescence in each chronological age, whereas menarche onsets considerably later. During adolescence, the differences in body proportions, that is, the following ratios: standing height to sitting height measures, leg length to standing height measures, sitting height to leg length measures, between female gymnasts and female swimmers and tennis players do not exist. Significant differences in body height between gymnasts and swimmers and tennis players in adult age have not been found (Erlandson et al. 2008).

In a study of maturity-associated variation in the body size and proportions of elite female gymnasts, it has been shown that the elite premenarcheal gymnasts, the participants of the 24th World Championship in Artistic Gymnastics, Rotterdam, aged 14–17 years, had smaller body dimensions (body height, mass, sitting height, and bi-acromial and bicristal breadths) in all chronological age (CA) groups in relation to postmenarcheal gymnasts, although the significance of the differences among the groups varied (Table 111.1) (Claessens et al. 2006).

According to Lindholm et al. (1993), and later also to Georgopoulos et al. (2002), some female artistic gymnasts do not reach the height in adult age expected on the basis of their parents' height. In the study by Georgopoulos et al. (2002), it was reported that the female artistic gymnasts, in contrast to the female rhythmic gymnasts, followed a growth pattern that was lower than their predicted genetic predisposition. Caine et al. (2001) performed an extensive research of the data on growth and height of female gymnasts published in previous literature and concluded that, in

Fig. 111.1 Young female artistic gymnast. A young female gymnast performing a demanding skill on the balance beam, one of the four competition events in women's artistic gymnastics. The photograph provided by courtesy of the photographer Mr. R. Brandjolica

some gymnasts, attenuated growth during the years of intensive training and competition could be seen, followed during the period of lessened or ceased training (after retirement) by the catch-up growth.

How much smaller body size is desirable? A secular trend has been found in premenarcheal top-level female gymnasts toward ever smaller height and body mass (Borms and Caine 2003). Such a body build, characteristic for the premenarcheal age in girls, contributes to the increased strength/weight ratio, stability, and a decrease in the moments of inertia (Borms and Caine 2003), thus improving the execution of demanding elements, and also the esthetic impression of performance. The average height of female gymnasts at the Tokyo Olympic Games in 1964 was 157 cm (Carter 1984) and, at the 2000 Olympics in Sydney, it was 152 cm (Borms and Caine 2003). The average height of female gymnasts who won medals at the 2008 Olympics in Beijing was about 150 cm. One-third of the medalists were of Asiatic ancestry (based on the data retrieved on June 29, 2009, from the address: http//www.nbcolympics.com/gymnastics/index.htlml).

*$p < 0.05$

[a]Reference data are from a nationally representative sample of Belgian (Flemish) girls (Simons et al. 1990)

Source: Premenarcheal gymnasts were significantly lighter than postmenarcheal skeletally mature gymnasts in all chronological age (CA) groups. They were the shortest within each CA groups but the differences were not significant. They also had the smallest sitting height - the differences were significant at CA 14–16, and the smallest estimated leg length; however, the differences were not significant. Premenarcheal gymnasts had a slightly smaller biacromial and bicristal breadth, but the differences were significant at CA of 14 for biacromial and at CA of 16 for both measures. The ratio of sitting height to standing height was the highest in skeletally mature postmenarcheal gymnasts. The differences between premenarcheal and skeletally mature gymnast were significant at CA 15–17 (Claessens et al. 2006).

111.2.2 Young Female Rhythmic Gymnasts

In addition to the female artistic gymnasts, rhythmic gymnasts have a lower body mass index in relation to the control groups (Guera et al. 2001; Klentrou and Plyley 2003; D'Alessandro et al. 2007; Soric and Misigoj-Durakovic 2008). Among the Spanish female Olympic athletes, the lowest body mass index belonged to the rhythmic gymnasts (Capdevila et al. 2005).

Klentrou and Plyley (2003) observed in the samples of the Canadian and Greek female rhythmic gymnasts that the premenarcheal gymnasts (PM-RG) were significantly shorter and lighter in comparison to the postmenarcheal (M-RG) peer gymnasts, having a lower BMI and proportion of body fat (% BF). The former trained significantly longer per day and more frequently during a week.

Rhythmic gymnasts are taller (above the 50th percentile for their age; Georgopulos et al. 1999, 2001; Misigoj-Durakovic et al. 2005) than their peer female artistic gymnasts, although having a relatively low mass for their age (under the 50th percentile) (Georgopulos et al. 1999, 2001).

In a sample of 255 European rhythmic gymnasts participating in the 13th European Championships in Greece, Georgopulos et al. (1999) established a positive correlation of the height standard deviation (SD) score with the weight SD score (height and weight were, for statistical evaluation purposes, expressed as the SD score of the mean height and weight for age), the number of competitions, and body mass index. The predicted height SD score in adulthood was positively related to the weight SD score and negatively to body fat. The average year of menarche onset was significantly delayed in comparison to their mothers and sisters, and was positively related to the intensity of training and to the difference between the chronological and skeletal age, but negatively to the body fat of rhythmic gymnasts (Georgopulos et al. 1999). In later studies by Georgopulos et al. (2001, 2002), it was found that the delayed skeletal maturation found in female rhythmic gymnasts was compensated for by the accelerated linear growth and it even surpasses the predicted height in adulthood. The deterioration of growth, described in the samples of female artistic gymnasts, was not present in rhythmic gymnasts (Georgopulos et al. 2002) (Fig. 111.2).

111.2.3 Young Female Figure Skaters

The same has been found for female figure skaters. They belong to the group of girls with similar characteristics who have been included into relatively high-volume training process early in their childhood. They are lighter and thinner than female athletes in other sports, also with a pronounced control of their own body mass (Taylor and Ste-Marie 2001), a lower energy intake, and an inadequate intake of particular nutrients (Ziegler et al. 1999, 2002). Later maturation is also characteristic for female figure-skating competitors, particularly the elite ones (Vadocz et al. 2002). The features of their training loads are running starts, powerful take-offs, jumps with rotation, double and triple jumps, as well as landings with skates on the ice, which contributes to expressed density of their bones (Slemenda and Johnston 1993; Oleson et al. 2002). The demands of figure-skating training programs are reflected in the body dimensions of female skaters aged 10–11 years, who are more voluminous in comparison to the other female athletes in esthetic sports and ballerinas (circumferences of the upper and lower extremities). Skaters also have a more robust skeleton of the lower extremities (Tables 111.2 and 111.3) (Misigoj-Durakovic et al. 2005).

Fig. 111.2 Young rhythmic gymnast. A young female rhythmic gymnast performs a demanding skill manipulating two clubs. Source: Premenarcheal rhythmic gymnasts (PM-RG) had significantly lower body weight ($p < 0.01$), height ($p < 0.01$), body mass index (BMI) ($p < 0.01$), and body fat percentage (%BF) ($p < 0.01$) than menarcheal rhythmic gymnasts (M-RG). Training session frequency and length were higher in PM-RG ($p < 0.05$). Groups of PM-RG and M-RG were similar in years of training experience (Klentrou and Plyley 2003)

111.2.4 Young Female Ballet Dancers

Ballerinas have similar characteristics of body size as female performers in esthetic sports: they are smaller and lighter during childhood and early adolescence with the catch-up period of growth in later adolescence (Malina 1994). With body build and size, the 10–11-year-old ballerinas are most

BMI body mass index

Source: The comparison of anthropometric measures of the samples of young female ballet dancers, rhythmic gymnasts, and figure skaters showed no significant differences in body size (body height and mass, body mass index and skeletal dimensions, with the exception of the ankle diameter). The differences were however significant in four subcutaneous skinfolds (triceps, suprailiocristale, thigh, and calf skinfold) as well in body fat percentage ($p = 01$). Rhythmic gymnasts had the smallest joint dimensions, limb circumferences, and skinfolds of the lower limb, whereas figure skaters were more voluminous, with a more robust skeleton of the lower extremities (Misigoj-Durakovic et al. 2005)

Fig. 111.3 Young female ballet students. Young female ballet students in demi-plié (half-bending of the knee done without lifting the heels from the ground) executed from the fifth position of the feet (the feet are turned out with the heel of one foot placed in front and close to the toe of the other foot). Photograph provided by courtesy of the photographer Mr. R. Brandjolica

similar to their female rhythmic gymnast peers (Table 111.3). They have a relatively low mass for their height, shown by low body mass index values in comparison to their non-trained peers (Soric and Misigoj-Durakovic 2008) (Fig. 111.3).

In a study investigating the anthropometry and body composition of premenarcheal ballerinas and female athletes in esthetic sports, 24 anthropometric measures, body mass index, and the proportion of body fat have been analyzed on a sample of 57 premenarcheal female ballet dancers and esthetic sports athletes including rhythmic gymnasts and female figure skaters, aged 10.61 ± 1.45 years (Misigoj-Durakovic et al. 2005).

The dancers and esthetic athletes had been involved in their respective sports disciplines for an average of 5.5 years. The average height of the ballerinas and athletes was above the 50th percentile and their body mass below the 50th percentile for their age. The girls did not significantly differ in body size measures, such as height and mass, body mass index, and longitudinal skeletal dimensions. Significant differences were, however, found in body composition. Rhythmic gymnasts were the most slender young athletes in this sample, with the smallest lower-limb joint dimensions, limb circumferences, and skinfolds. The female figure skaters were more voluminous, with a more robust skeleton of the lower extremities, which corresponded to the specific requirements and loads of figure skating (Table 111.3) (Misigoj-Durakovic et al. 2005).

Compared to a similar sample of premenarcheal esthetic athletes and ballerinas (mean age 10–11 years), peer artistic gymnasts had the smallest linear and transversal skeletal dimensions as well as skinfold measures (Figs. 111.4–111.6) (Misigoj-Durakovic and Vucetic 2009).

However, the girth of the gymnasts' upper limb was similar or somewhat larger than in rhythmic gymnasts and ballerinas (Fig. 111.7) (Misigoj-Durakovic and Vucetic 2009).

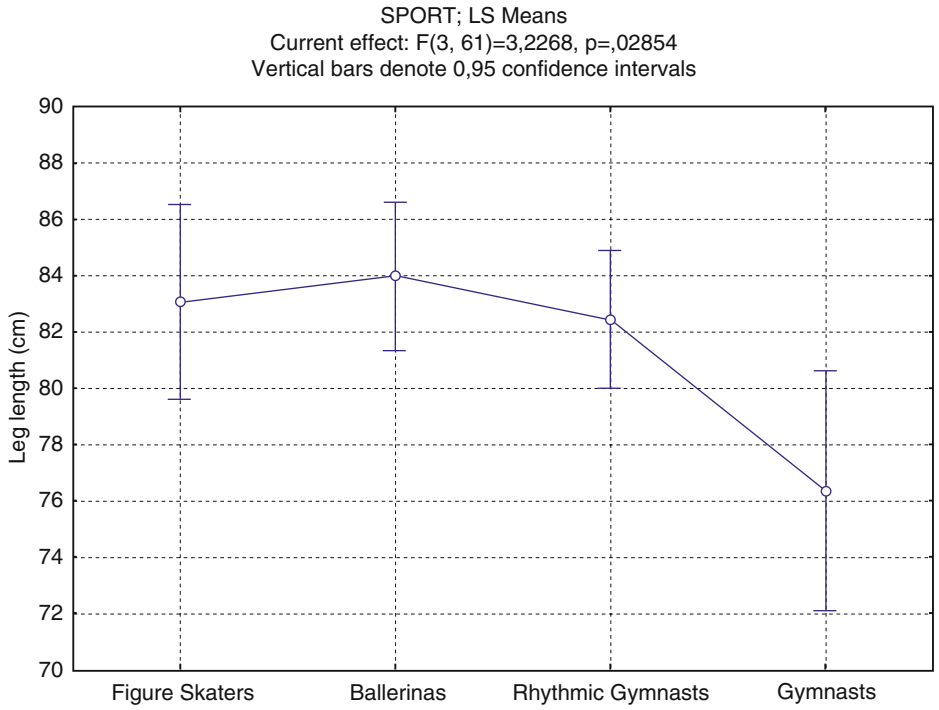

Fig. 111.4 Leg length (*basis – iliocristale*) in young female esthetic sport athletes (figure skaters, rhythmic gymnasts, and gymnasts) and ballerinas (Misigoj-Durakovic and Vucetic 2009). Compared to figure skaters, rhythmic gymnasts, and ballerinas aged 10–11 years, peer artistic gymnasts had the smallest leg length dimension

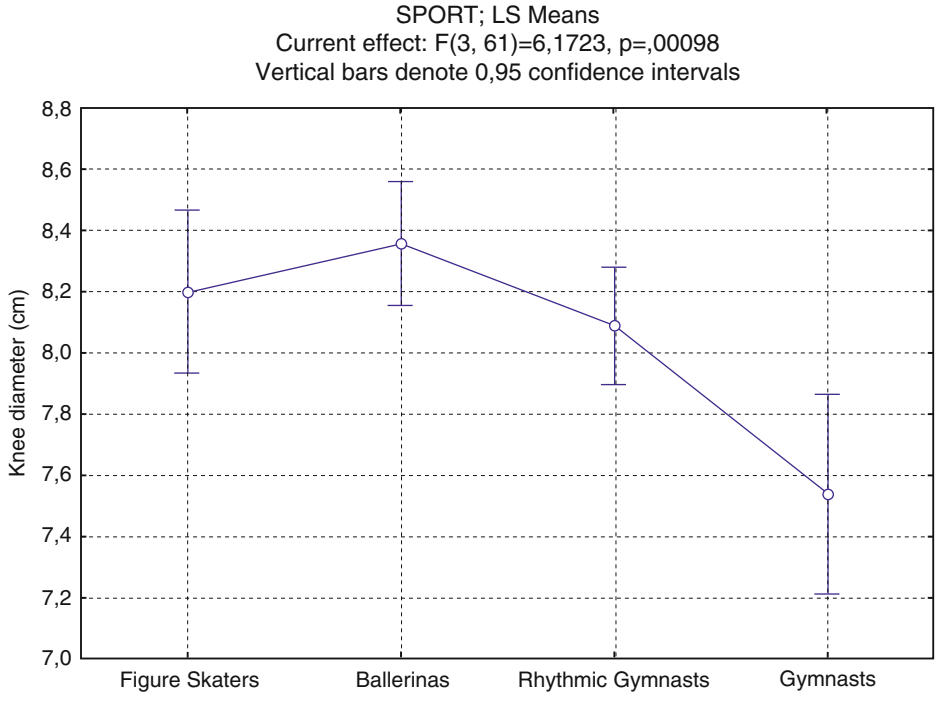

Fig. 111.5 Knee diameter (*femur bicondylar breadth*) in young female esthetic sport athletes (figure skaters, rhythmic gymnasts, and gymnasts) and ballerinas (Misigoj-Durakovic and Vucetic 2009). Compared to figure skaters, rhythmic gymnasts, and ballerinas, aged 10–11 years, peer artistic gymnasts had the smallest knee diameter

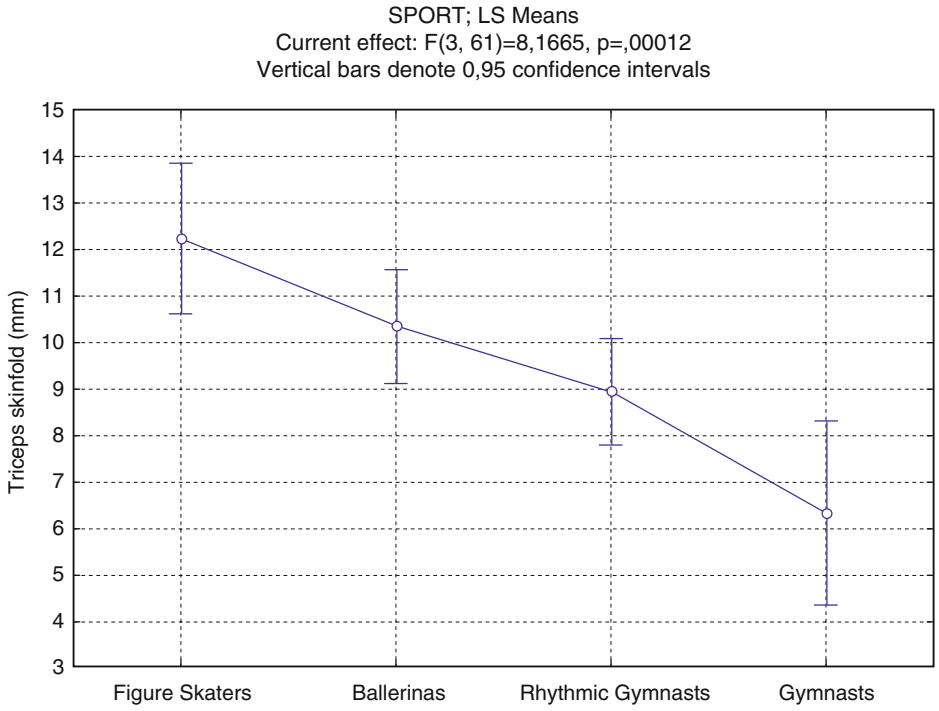

Fig. 111.6 Triceps skinfold in young female esthetic sport athletes (figure skaters, rhythmic gymnasts, and gymnasts) and ballerinas (Misigoj-Durakovic and Vucetic 2009). Compared to figure skaters, rhythmic gymnasts, and ballerinas aged 10–11 years, peer artistic gymnasts had the smallest triceps skinfold

111.3 Body Composition

Ballerinas and female performers of esthetic sports are characterized by slimness, that is, a low portion of body fat with adequate fat-free mass in comparison to non-athletes and female athletes of other disciplines (Guerra et al. 2001; Klentrou and Plyley 2003; Misigoj-Durakovic 2005; D'Alessandro et al. 2007; Soric and Misigoj-Durakovic 2008). The elite-level rhythmic gymnasts are characterized by a larger portion of fat-free mass in comparison to the sub-elite ones (Di Cagno et al. 2008).

Studying dietary intake and body composition of the young female esthetic athletes in a sample of 11-year-old prepubescent girls who compete in two esthetic sports (artistic and rhythmic gymnastics) and ballerinas, no significant difference has been found in the total energy intake between the groups of athletes/dancers and age-matched controls (Soric and Misigoj-Durakovic 2008). Artistic gymnasts reported a higher carbohydrate and a lower fat contribution to the total energy intake as well as a higher intake of carbohydrates relative to body weight than the rhythmic gymnasts, ballet dancers, or controls. The artistic gymnasts also had the lowest body fat percentage among the groups: the application of the Slaughter equation, based on two skinfolds measures, revealed approximately 12.5%. The reported mean daily intakes of most nutrients were higher in all the groups than the current daily recommended intakes. The exceptions were dietary fiber and calcium (Soric and Misigoj-Durakovic 2008). Unhealthy dieting behaviors and dieting itself are more often observed in female athletes aged 14 and onward (Guerra et al. 2001; Taylor and Ste-Marie 2001; Ziegler 2002).

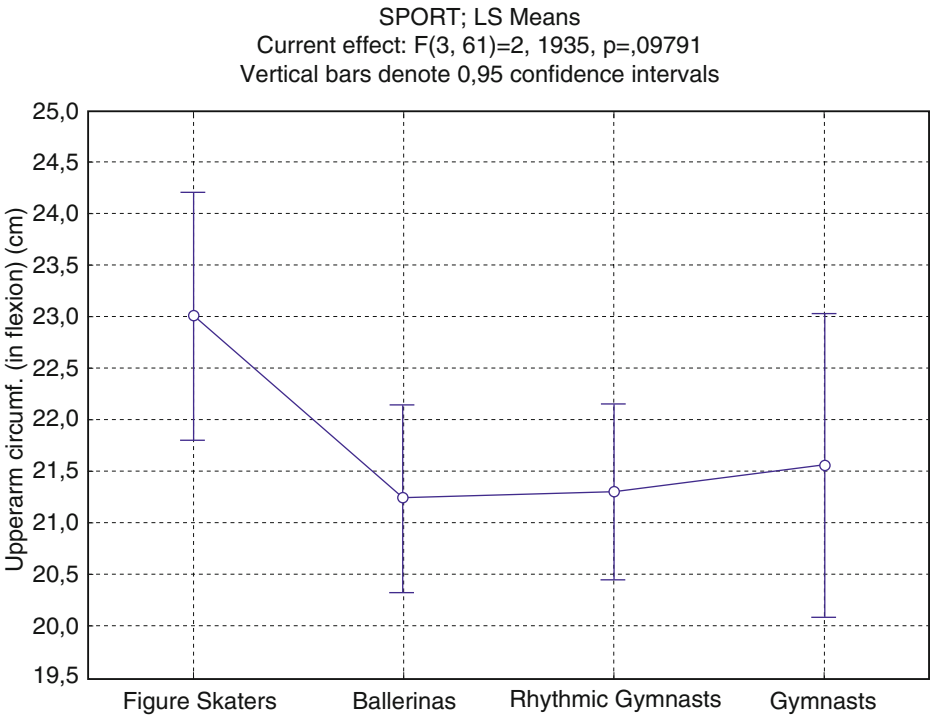

Fig. 111.7 Upper-arm circumference (*flexed and tensed*) in young female esthetic sport athletes (figure skaters, rhythmic gymnasts and gymnasts) and ballerinas (Misigoj-Durakovic and Vucetic 2009). Female artistic gymnasts, aged 10–11 years, had similar or somewhat larger upper arm circumferences (girths) than rhythmic gymnasts and ballerinas of the same mean age. Figure skaters had the largest upper arm girths

Ten- to 11-year-old premenarcheal rhythmic gymnasts and ballerinas, involved in specific training for an average of 5.5 years, have 14.4% and 15.3% of body fat, respectively, and figure skaters have 19.3% (Table 111.3) (Misigoj-Durakovic et al. 2005). The comparison of body fat percentage of young female artistic gymnasts to other female esthetic athletes and ballerinas is shown in Fig. 111.8.

With maturation, the body composition of girls changes, showing the trend of the increased proportion of the fat component. This is documented by the study of Klentrou and Plyley (2003) in 14-year-old elite rhythmic gymnasts: the percentage of body fat is 13.9% and 17.5% in the premenarcheal and the menarcheal gymnasts, respectively, as obtained by the Slaughter equation (Table 111.2).

Following near-infrared body composition analysis, Georgopoulos et al. (2002) reported 13.1% fat in rhythmic female gymnasts in a wide range of biological maturation and of chronological age ranging from 11 to 23 years.

111.4 Somatotype

Body fat percentage and the ratings of endomorphy in the somatotype are connected to the performance of esthetic female athletes (Claessens et al. 1999; Miletic et al. 2004), as well as to the injury incidence and recovery duration in ballet dancers (Twitchett et al. 2008).

In the study investigating the anthropological factors of performance in a sample of 7-year-old rhythmic gymnast beginners, 41% of success in performing basic body elements of rhythmic gymnastics (jumps, rotations, balances, and flexibility elements) was explained by the factors of

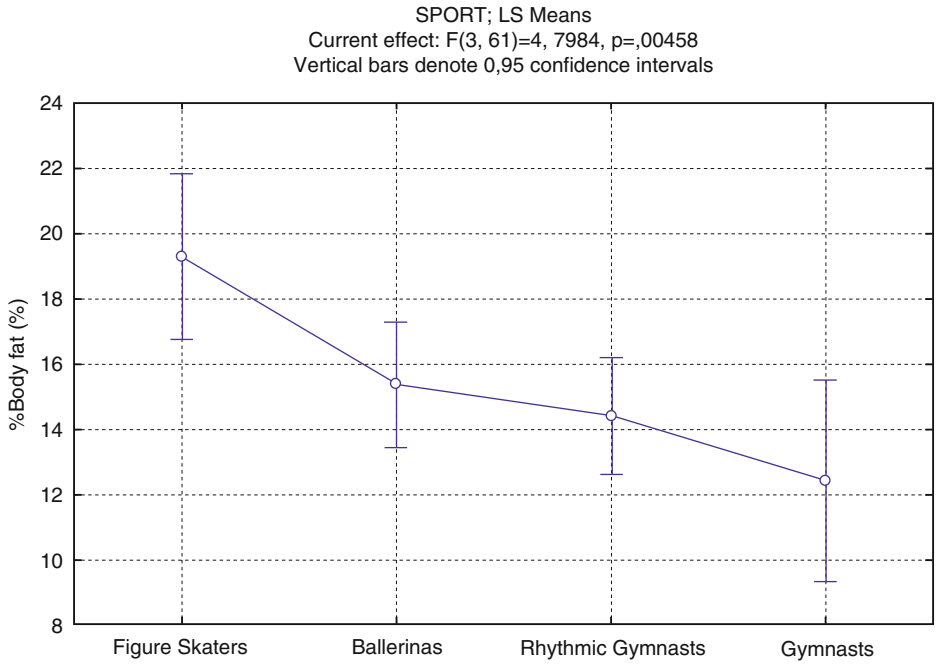

Fig. 111.8 Body fat percentage (% body fat) in young female esthetic sport athletes (figure skaters, rhythmic gymnasts, and gymnasts) and ballerinas (Misigoj-Durakovic and Vucetic 2009). Female artistic gymnasts, aged 10–11 years, have the lowest proportion of body fat among esthetic sport athletes and ballerinas of the same mean age. Figure skaters had the highest body fat proportion (Misigoj-Durakovic and Vucetic 2009)

Table 111.4 Regression analysis of motor and morphological latent space and routines in rhythmic gymnastics (Reproduced from Miletić et al. (2004). Table 4, p. 734 Copyright July 2009. With the kind permission of the publisher of the Coll Antropol)

	Basic body element^{L}	Specific manipulation with apparatus^{S}
Latent dimensions	BETA	BETA
Frequency of movements	0.19	0.44***
Explosive strength	0.25*	0.02
Flexibility	0.26*	0.07
Adipose voluminosity	–0.42***	0.13
Non-adipose voluminosity	–0.06	0.26*
RO	0.64***	0.52**

L movements with large amplitudes; *S* movements with small wrist amplitudes; *BETA* regression coefficient; *RO* multiple correlation

*$p < 0.05$; **$p < 0.01$; ***$p < 0.001$

Source: Multiple correlations between motor and morphological dimensions and the routine movements are significant and high. Flexibility has a significant positive predictive value (Beta coefficient) on the basic body elements (i.e., large amplitude movements) performance, whereas movement frequency, along with the non-adipose voluminosity dimension, significantly predicts proper and coordinated apparatus manipulation. The adipose voluminosity dimension has a significant negative predictive value on the basic large amplitude elements (Miletić et al. 2004).

flexibility, explosive strength, and adipose voluminosity, whereas the movement frequency and non-adipose voluminosity explained 26% of successful performance of RG-specific apparatus handling (club, ribbon, and ball wrist manipulation) (Miletic et al. 2004) (Table 111.4).

Elite female artistic gymnasts are characterized by an ecto-mesomorphic somatotype relatively homogeneously across the ages between 13 and 20 (Claessens et al. (1992). Values of the endomorphic component (showing fatness) are significantly lower than in the reference population and vary

between 1.4 and 1.9 throughout adolescence. Mean mesomorphy (showing muscular and skeletal development) is constant across the age period and varies mainly between 3.6 and 3.8. Mean ectomorphy (showing body linearity) varies between 3.3 and 2.8 (Claessens et al. 1992). Studying the contribution of anthropometric characteristics to performance score in the same sample of elite female artistic gymnasts, Claessens et al. (1999) found that almost one-half of variance (45.7%) in the total competition performance score is explained by the following: endomorphy, chronological age, calf girth, and sitting height. Endomorphy was the most important variable, appearing first (negatively) in the predicted total performance score and in the score in routines with apparatuses (Claessens et al. 1999).

Investigating possible associations between body composition, somatotype components, and self-reported injuries in male and female ballet students, it has been shown that a low percentage of body fat, high ectomorphy ratings, and low mesomorphy ratings in the somatotype of ballet dancers were positively connected to the reduction of injury incidence and duration of recovery (Twitchett et al. 2008).

A follow-up of anthropometric characteristics and the derived components of body composition and somatotypes is of special importance in young ballerinas and performers in esthetic sports due to the crucial selection criterion regarding the size, body build, and composition, further, because of the early commenced training that soon reaches high volume and intensity, and particularly because of the specific demands for maintaining a low body mass with reduced body fat. Therefore, careful control of anthropometric characteristics in this group of female athletes and ballerinas, besides giving information relevant to the monitoring of training program effects, will give an insight into the dynamics of growth and nutritional state of young female athletes. This will enable coaches to notice on time any nutritional deviations and to intervene by ensuring adequate energy intake through food, indispensable for growth and maturation during adolescence, so to prevent any possible behavioral issues, such as eating disorders, or dissatisfaction with one's own body shape, and the introduction of unhealthy body-mass control measures.

111.5 Applications for Other Areas of Health and Disease

More research and longitudinal studies are needed to elucidate the individual effects of and relationships between the process of sport selection, nutrition habits, and early commenced sports training in female esthetic athletes and dancers on their growth and maturation. A proper diet is extremely important in the period of growth, development, and maturation of a child. Long-lasting and intensive training during childhood and adolescence requires adequate energy intake through food for growth, development, and performance. Careful monitoring of anthropometric characteristics, body composition, and adequate nutritional intake is especially important in this group of athletes and dancers for early detection and the prevention of deviation in eating behaviors and body-shape expectations later during adolescence.

Summary Points

- It has already been well documented that certain size and body build contributes to performance in many sports. That is particularly evident in esthetic sports and all kinds of dancing.
- Ballet and esthetic sports such as artistic gymnastics, figure skating, and rhythmic gymnastics pose specific demands upon energy supply and motor and psychological capacities, and also upon

the size, build, and body composition of female competitors, particularly at the elite level, in a sensitive period of growth and development.
- Esthetic sports and dances require early inclusion of girls into specific training programs, which soon become highly intensive, frequent, and of long duration, with demands of maintaining minimal amounts of subcutaneous body fat.
- Contrary to the majority of other sports, morphological predispositions in esthetic sports and ballet are small body size and mass of female performers. For gymnastics, those young female athletes of small and petit constitution are selected.
- Ballerinas and female athletes in esthetic sports mostly belong to the group of late-maturing girls. Body linearity, or slimness, is connected with later maturation, and such a characteristic of body composition is desirable in the process of selection.
- Female athletes in esthetic sports and ballerinas have lower body mass values, body mass index, and the percentage of body fat in comparison to non-athletes and athletes engaged in other sports (except for female long-distance runners).
- The premenarcheal female esthetic athletes have a smaller body size and a lower proportion of body fat in relation to the postmenarcheal ones of the same chronological age.
- Within the group of esthetic female athletes and dancers, female gymnasts have a very low proportion of body fat. Elite female gymnasts are characterized by the ecto-mesomorphic somatotype.
- In some female artistic gymnasts, attenuated growth during the years of intensive training and competition could be seen, followed also in the period of lessened or ceased training (following retirement) by a catch-up growth rate.
- Rhythmic gymnasts have heights above the 50th percentile for their age in comparison to the female artistic gymnasts, although with a relatively low mass for their age (under the 50th percentile) (Georgopulos et al. 1999, 2001).
- Female figure skaters are, in comparison to female athletes in other esthetic sports, more voluminous, having a more robust skeleton of the lower extremities, which reflects figure-skating-specific demands.
- Ballerinas have similar characteristics of body size as female performers in esthetic sports. They have a relatively low mass for their height, shown by low body mass index values in comparison to their non-trained female peers.
- The portion of fat in body composition and the ratings of endomorphy in the somatotype are negatively connected to performance in esthetic female athletes.
- Low body fat percentage, high ectomorphy ratings, and low mesomorphy ratings in the somatotype of ballet dancers are found to be positively connected to the injury incidence and duration of recovery.

Key Facts of Morphology-Related Nutritional Concerns in Female Esthetic Athletes

- Body build and composition, being the morphological predispositions for success in esthetic sports and ballet, are defined as follows: a petite body build and lower body mass values, a lower body mass index, and a low proportion of body fat, that is, low values of endomorphic component with the appropriate fat-free body mass of female athletes.
- Such a build and body composition are characteristic of the premenarcheal age. The maintenance of such morphological characteristics and body composition throughout the years of a sports career frequently lead to a diet with a reduced energy intake.
- The nutritional habits of female athletes in esthetic sports and of ballet dancers often do not follow the actual energy demands imposed by strenuous workouts.

- Although a small body size and later maturation are constitutional predispositions and selective factors for top female gymnastics, there are still debates on the impact of high-volume and intensity training started early in childhood during the premenarcheal age when combined with an inadequate diet (inadequate regarding energy intake and quality) upon growth and maturation.
- Individual effects of selection, nutrition, and sports training have not been distinguished and investigated yet.

Key Facts of Endomorphy Ratings

- Endomorphy expresses relative body fatness.
- It is the first of three somatotype components according to the *Heath–Carter method* based on the Sheldon's somatotype classification.
- According to the *Heath–Carter anthropometric method of somatotyping*, the endomorphy rating is based on the sum of three skinfolds: subscapular, triceps, and supraspinale and is calculated by using *Heath–Carter somatotype rating form* or by using the equation derived from the rating form (Carter and Heath 1990; Carter 2002):

$$\text{ENDOMORPHY}\left(\text{height} - \text{corrected}\right) = -0.7182 + 0.1415(X) - 0.00068(X^2) + 0.0000014(X^3)$$

$$X = \left(\text{sum of skinfolds}\right)\text{multiplied by } 170.18 \,/\, \text{body height}\,\left(\text{cm}\right)$$

Key Facts of the Heath–Carter Anthropometric Somatotyping Method

- The somatotyping method, based on the Sheldon's somatotype classification, is the most commonly used one.
- Somatotype expressed in a three-number rating is the quantification of an individual morphological variation of body shape and composition.
- Somatotype three-number rating represents the quantification of three components always presented in the following order:
  - Endomorphy, the first component, expresses the relative fatness.
  - Mesomorphy, the second component, expresses the relative robustness of the musculoskeletal system.
  - Ectomorphy,the third component, expresses the relative body linearity.
- To calculate the three somatotype components, ten anthropometric measures should be used: body height, body mass, four skinfolds (subscapular, triceps, supraspinale/suprailiac, and medial calf skinfold), two joint diameters (elbow/biepycondylar diameter of the humerus and knee diameter/bicondylar diameter of the femur) and two limb circumferences (upper arm and calf) – all the measures are taken on the right side of the body.
- Anthropometric somatotype components are calculated using somatotype rating forms or equations derived from the rating forms (Carter and Heath 1990; Carter 2002).

Chapter 112
Fitness and Anthropometric Testing in Basketball Players

Eric J. Drinkwater

Abstract In intermittent high-intensity team sports such as basketball, there is a clear relationship between a player's body size and fitness and their success in competition. If this relationship is cause-effect is unknown, however. Before cause-effect can be determined there must be several methodological changes made to so-called "field testing" of athletes. Primarily, research implying the importance of body size and fitness to athletes is heavily reliant on individual test results from small (<100) numbers of players being correlated with measures of athlete success. No research has investigated how changes in an athlete's fitness relate to changes in game statistics; if an improvement in a player's size or fitness improves performance. In order to perform large-scale, long-term or meta-analyses research basketball must also agree to a standardised battery of tests with consistent protocols. Basketball research is impeded from progress by most data collection facilities using different variations on tests, thereby meaning test results cannot be compared across facilities. Standardising, for example, which vertical jump protocol is being used would contribute greatly to the academic integrity and use of field-test research. Most basketball research fails to report the reliability of any of its tests and is overly dependent on null-hypothesis significance testing rather than making magnitude-based inferences from effect sizes and confidence limits; while research involving small subject numbers can be useful, testing "statistical significance" is not appropriate and alternative methods of data analysis should be sought. In summary, to improve the quality of research investigating basketball fitness and anthropometry we must collect data over the long term using consistent testing methods and analysing it appropriately. While there are many other components that contribute to a player's success besides fitness, a player's size and fitness afford them the ability to capitalise on opportunities presented to them on the court, in skills development, and in the scouting process.

Abbreviations

∑7 skinfolds	Sum of seven skinfold sites collected from triceps, subscapular, biceps, supraspinale, abdominal, thigh, medial calf
1RM	One-repetition maximum strength test
CMVJ	Countermovement Vertical Jump

112.1 Introduction

The presupposition that a person's body size, shape and fitness level are related to sporting success has led to decades of research describing and comparing these characteristics in athletes of different sports at different competitive levels. Presumably, the end goal of such research is to develop objective measures that will allow sport scientists and coaches to identify people with the greatest potential for success. Identifying fitness levels of successful athletes would not only help coaches in selecting participants for high-performance programmes, but also assist in setting fitness goals for their current athletes. Considering that each gold medal won by Australian athletes at the 2000 Olympic Games in Sydney cost the Australian Federal Government an estimated AUD37 million or each medal of any colour AUD8 million (Hogan and Norton 2000), the appeal of ways to streamline the system in which sports funding is distributed as well as improve athletic training is clear.

Several recent reviews have summarised testing results of basic anthropometric and fitness tests in basketball (Drinkwater et al. 2008; Ziv and Lidor 2009); hence, these will not be reiterated here. However, as is often the case in the search for simple explanations, cause–effect conclusions are often drawn between fitness and competitive success when relationships between these two variables are identified. Success in sports, such as basketball, is a complex interaction of not just body size and fitness but also of perceptual, motor, cognitive and psychological measures as well as sport-specific skill performance (Trninic et al. 1999; Trninic and Dizdar 2000). To draw useful conclusions from anthropometric and fitness testing, we must instead begin investigating the influence body size and fitness have on game-related statistics in repeated-measures designs using appropriate statistical methods on a standardised battery of highly reliable tests. The purpose of this chapter is not to reiterate already available material describing basketball anthropometric- and fitness-testing techniques (Stapff 2000) and results (Drinkwater et al. 2008; Ziv and Lidor 2009), but more to highlight impediments to advancing the field of knowledge.

The term "fitness" in this particular context is not intended to imply just aerobic fitness, but all of the components of physical fitness necessary for basketball performance. These components of fitness include muscular strength, power, agility, flexibility, local muscular endurance and cardiovascular endurance. While alternative terms such as "performance assessment" could be suggested to indicate that tests must be specific to basketball performance (i.e. have context validity), such a term could also imply the assessment of game-related skills. A test of fitness for athletes should be sufficiently generic that the result is determined primarily by fitness rather than skill but still have sufficient context validity to be a useful determinant of game performance.

112.2 Current Tests in Basketball

Previous reviews (Drinkwater et al. 2008; Ziv and Lidor 2009) have justified the necessity for a standard battery of sport-specific anthropometric and fitness tests. Sport-specific tests are necessary to simulate the demands of the game, whereas a standardised test battery would allow sport scientists and coaches to compare and analyse results across studies. Even slight variations in protocols signify that results across studies cannot be compared. Several sporting bodies have standard batteries of tests, though these batteries have mostly not been adopted by basketball researchers.

112.2.1 National Basketball Association

There is little doubt that the US-based National Basketball Association (NBA) is the premier basketball league in the world and is the league to which elite players aspire to. In the 2006/2007 season, NBA teams paid 510 players $US1.93 billion in salaries, an average of $US3.78 million per player (Drinkwater et al. 2008). To evaluate players competing for NBA contracts each year, the NBA invites prospective players to a draft camp ("the NBA Combine"), which involves a myriad of assessments, including fitness testing. Considering that the goal of most elite players around the world is to secure an NBA contact, it is surprising that more testing systems are not based on the NBA Combine tests. Values for each position on each test averaged across the 2000–2008 NBA Combine are expressed in Table 112.1. The roles of different positions in basketball are outlined in Table 112.2.

112.2.1.1 Local Muscular Strength and Endurance

While strength is the force-generating capacity of a muscle, local muscular endurance is the capacity of a muscle to repeatedly contract. Muscular strength is most commonly measured by a one-repetition maximum (1 RM) test in which single repetitions of a resistance training movement (e.g. bench press and squat) are performed with progressively heavier loads, until the load is too heavy for the athlete to perform even a single movement (repetition). The 1 RM is then expressed in kilograms lifted.

Table 112.1 Results of different fitness tests, broken down by player position, from the 2000 to 2008 National Basketball Association Combine

Fitness component	Test	PG (N = 123)	SG (N = 118)	SF (N = 101)	PF (N = 197)	C (N = 101)
Strength	185-pound bench press (repetitions)	8.0	10.5	11.2	12.8	11.5
Power	No step vertical jump (cm)	74.7	75.2	75.7	72.3	67.7
	Run-up vertical jump (cm)	88.9	88.6	87.6	83.1	77.6
	Maximal touch (cm)	333.7	345.9	351.8	353.4	355.9
Speed	75-ft court sprint (s)	3.20	3.23	3.25	3.32	3.44
Agility	Lane agility (s)	11.16	11.34	11.37	11.73	12.17
Body size	Height (cm)	183.9	192.1	198.4	202.5	208.1
	Body mass (kg)	83.4	91.4	96.8	106.5	113.5
	Wing span (cm)	194.5	203.7	209.4	215.1	220.2

Table 112.2 Different classifications of basketball playing positions and major responsibilities of each (position)

Classification #1	Classification #2	Classification #3	Classification #4	Position's major responsibility
Smalls	Guards	1	Point guard	Ball control; coordinating the offence
		2	Off guard/ shooting guard	Distance shooting
	Forwards	3	Small forward	Mixture of distance and close-range shooting, particularly from awkward positions
Bigs		4	Power forward	aggressive play close in to the basket (e.g., rebounding and close-range shooting)
	Centre	5	Centre	Close-range shooting on offence; coordinating the team's defence

This table was originally published in Drinkwater et al. 2008, Design and interpretation of anthropometric and fitness testing of basketball players and has been reproduced with permission from Adis, A Wolters Kluwer business (Copyright Adis Data Information BV 2008. All rights reserved.)

The NBA Combine therefore does not test muscular strength per se, but a combination of strength and endurance. It assesses only upper body strength – endurance in the form of a bench-press test. While lying horizontally, the goal of the bench-press test is to press a 185-pound (84 kg) barbell vertically off the chest as many times as possible.

112.2.1.2 Anthropometry

Anthropometric tests of the NBA Combine include standing height measured twice, once with shoes and once without, and a test of body mass. They also measure arm span ("wing span"), which assesses the horizontal distance from fingertip to fingertip with the arms fully stretched out.

112.2.1.3 Lower Body Power

To assess lower body power, the NBA Combine uses a no-step countermovement vertical jump as well as a run-up vertical jump. The goal of both of these tests is to jump as high into the air as possible, either from a stationary position or from a run-up approach. Vertical jump tests are usually expressed relative to the athlete's standing height by taking the total height the athlete jumped off the floor and subtracting the height an athlete can reach with his/her hand maximally extended over his/her head while standing with heels on the ground (i.e. "standing reach height"). "Maximal touch" is then expressed as the total height the athlete reached from the floor from a run-up start.

112.2.1.4 Speed

There is a test of straight-line running speed that involves players starting stationary at one end of the court ("baseline") and running 75 ft (22.86 m) to the far free-throw line (Figure 112.1). The "Lane Agility Test" involves the athlete starting from a stationary position on one end of the free-

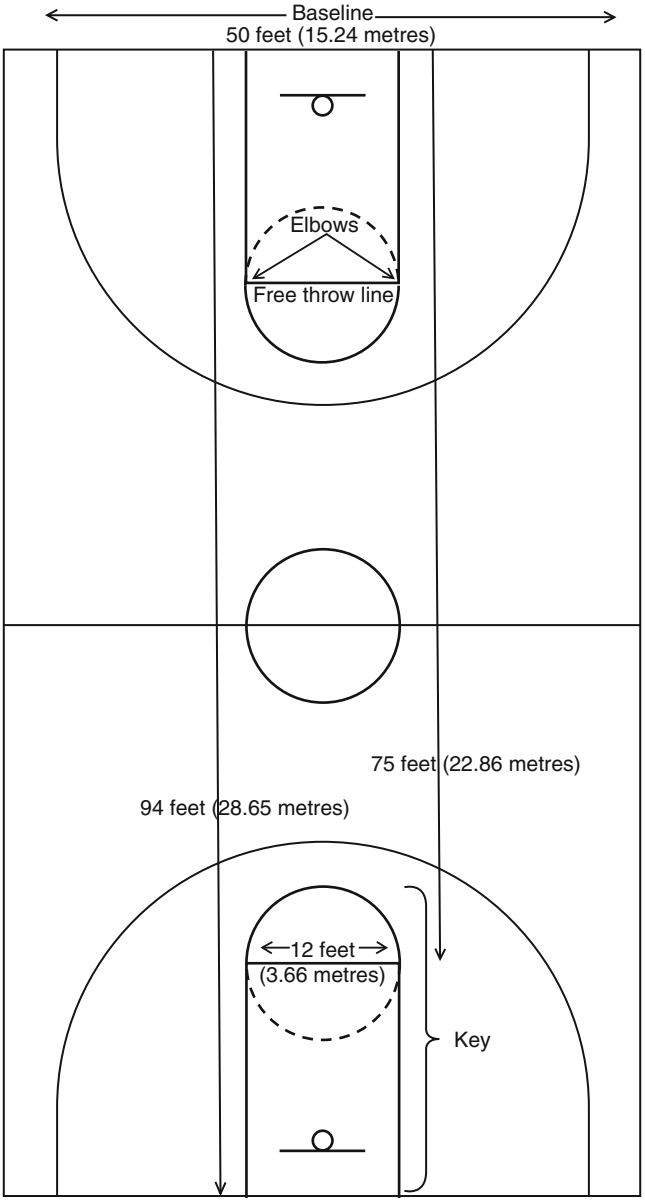

Fig. 112.1 Basic dimensions and terminology of a court for the National Basketball Association

throw line ("elbow") and sprinting towards the baseline, side-shuffling left along the baseline to the opposite intersection of the baseline and key, backwards running ("back peddling") to the opposite elbow and side-shuffling right along the free-throw line to the starting position, thus running a square while never changing facing on the court; the player then repeats this without pausing in the opposite direction to count as one repetition of the test.

112.2.2 Basketball Australia

In Australia, the National Sport Science Quality Assurance (NSSQA) programme has set test standards across a wide variety of sports, including basketball (Stapff 2000). Anthropometric tests include standing height without shoes, nude body mass and a summation of seven skinfold sites taken from the triceps, subscapular, biceps, supraspinale, abdominal, thigh and medial calf as an indirect measure of body fat. Fitness tests include a one-step maximal countermovement jump and a 20-m straight-line sprint from a standing start to assess lower body power, as well as a 20-m multistage shuttle run test to assess aerobic fitness. As a result of standardising a test battery, large-scale, long-term studies have been possible (Drinkwater et al. 2005, 2007).

112.2.3 Speed, Power, Agility, Reaction, and Quickness (SPARQ)

A recent commercial venture from Nike, Inc. (www.sparqtraining.com) has also implemented standard test protocols to assess what they refer to as Speed, Power, Agility, Reaction, and Quickness (SPARQ). The SPARQ test battery was devised to assist strength and conditioning coaches to monitor the training status of junior athletes (of 13–18 years) and also to be practical for self-administration. The battery comprises two tests of lower body power, including a countermovement vertical jump and an approach jump similar to the NBA Combine's maximum vertical jump; two agility drills to assess change-of-direction speed separately in offensive and defensive movement patterns; a medicine-ball chest pass to reveal upper-body power; and a multistage cross-court shuttle with short recovery intervals to reflect game-relevant endurance. For the anthropometric tests, both athlete stature and body mass are also collected. The results of each test are referenced against a geographically diverse normative data set ranking hundreds of teenage basketball players within each gender; a wide range of playing abilities is represented as well. The ranked result of each test is scored and these scores are combined into a single summary statistic, the SPARQ Rating. Although designed to precisely measure components of athletic performance specific to basketball, and to guide training prescription, the SPARQ Rating System has yet to be evaluated or utilised in peer-reviewed research.

112.2.4 Discrepancies in Fitness Tests for Basketball

Despite several sports bodies attempting to standardise testing protocols, consistency between research groups remains an ongoing problem as sport scientists attempt to blend a test's sport specificity (i.e. context validity) with the ability to compare its results over time, across data-collection facilities and between sports. Ziv and Lidor (2009) explicitly state the need for standard fitness-testing protocols in the recommendations. They also illustrate how even slightly different vertical jump protocols can elicit substantially different responses (Epub ahead of print). The advantage of tests, such as a run-up vertical jump or a one-step vertical jump, is their context validity. A standardised no-step vertical jump, while lacking context validity, would allow comparisons of basketball players across studies and between sports as many sports use countermovement vertical jump tests to assess lower body power. As it stands, the vertical jump heights from Drinkwater et al. (2007) cannot be compared to those from Apostolidis et al. (2004) due to the non-standardised jump protocol. Balancing standardisation against sport specificity continues to be debated.

For the purpose of establishing the sport specificity of a test, many "in-house" tests utilise court markings, such as agility tests that take place around the key (Apostolidis et al. 2004). Although convenient and having high context validity, court markings change, depending on the competition level. For example, a court used by high school programmes in USA is 22.56 m long, whereas an NBA court measures 28.65 m. As a result, data from Apostolidis (2004) and from Montgomery et al. (2008) on what is known colloquially as a "suicide run" cannot be compared because they had different running distances of 135.2 and 140 m, respectively. In October 2010, the dimensions of the International Basketball Federation (FIBA) key will change, thus making it impossible to compare previous agility testing results based on the old FIBA key dimensions with new ones. Therefore, caution should be used when designing fitness tests because making them highly sport specific makes their replication difficult over time and between testing facilities.

For historical perspective, though the FIBA acronym originally stood for Fédération Internationale de Basketball Amateurs, the 'Amateur' component was dropped from the official name in 1989 in favour of open competition rather than restricting competition to only amateurs. FIBA retained the 'A' in the acronym and recognised the French-to-English translation to the International Basketball Federation.

112.2.5 Fitness Tests to Consider

112.2.5.1 Aerobic Fitness

While tests of speed and agility are common in most basketball testing batteries, there is commonly debate over the necessity for a test of aerobic capacity. As reviewed by Ziv and Lidor (2009), most time–motion analysis studies highlight the anaerobic demands of basketball. These studies measure heart rate, blood lactate concentration and time spent in high-intensity activities. As test designs become increasingly sport specific by using time–motion analysis research to design test protocols, the role of aerobic endurance in successful performance is often neglected. However, the high frequency of alternating between high- and low-intensity activities and the ability to maintain the so-called "repeat sprint ability" is related to volume of oxygen consumed at maximal work rates ($\dot{V}O_2$ max, the benchmark of a person's maximal aerobic fitness) (Hoffman et al. 1999). It has also been recently shown that there is a relationship between $\dot{V}O_2$ max and proportion of time spent in live play in high-intensity activities, such as running and jumping ($r \approx 0.95$) (Narazaki et al. 2009). Erculj and Supej (2009) further illustrated that basketball-specific fatigue impairs free-throw shooting performance. Finally, that $\dot{V}O_2$ max levels have increased in ball-carrying positions (i.e. guards) since the FIBA rule changes in 2000 that require faster ball movement (Cormery et al. 2008) also seems compelling evidence that aerobic fitness is an important characteristic to assess in basketball testing.

If improving aerobic capacity in a basketball player allows the player to be more resistant to fatigue and able to recover more quickly, the real-world benefits of aerobic fitness seem obvious. As a result of being more aerobically fit, a player may progress their skill development faster because they are able to maintain high-quality practice for longer periods. A fitter player may also get more training or playing time (Hoffman et al. 1996; Hoare 2000) because they recover faster and are ready to be substituted back into the game earlier, thus increasing the quantity of playing and training. A fitter player is also less prone to fatigue-induced decrements in skill performance.

The reason that aerobic fitness is not included in many basketball fitness assessments is that it tends not to be considered sport specific. This is to say that time–motion analysis studies tend to

indicate a discontinuous nature of basketball, but most assessments of aerobic fitness tend to be continuous work protocols. To rectify the nonspecific nature of most tests of aerobic fitness, a discontinuous court running test has been developed, referred to as a Yo-Yo Intermittent Recovery test (Castagna et al. 2008). Whereas in tests, such as a 20-m multistage shuttle run test (Stapff 2000), participants run continuously in time with a series of audio tones, the Yo-Yo Intermittent Recovery test allows participants a 5-m recovery area at the end of each return trip of the court to walk and come to a complete stop before resuming the test (Krustrup et al. 2003). Despite the high context validity to high-intensity intermittent team sports, the Yo-Yo Intermittent Recovery test is not widely utilised, with only 30 articles in the National Library of Medicine listing as using it between 2001 and 2009.

112.2.5.2 Balance

Tests of balance are rarely included in published basketball fitness test batteries, probably due to the specificity in the types of balance (e.g. static vs. dynamic and stable vs. unstable surfaces). As a result, a widely accepted test of balance specific to basketball does not, as of yet, exist. However, a test referred to as the Star Excursion Balance Test has been demonstrated to reliably predict lower limb injury in both male and female high-school basketball players (Plisky et al. 2006). Although Emery and colleagues (2007) did not utilise the Star Excursion Balance Test, they did demonstrate the potential for focussed balance training to reduce the likelihood of injury.

112.2.5.3 Strength

Another component of fitness commonly omitted from basketball test batteries is strength. Whereas long-term monitoring of strength is standard practice in organised strength and conditioning programmes, strength testing results are rarely published as a routine subject descriptor. Although it is relatively easy to find normal values for anthropometric and fitness testing data on junior athletes from a wide variety of countries, ages and levels (Tables 112.1 and 112.3–112.5), finding strength testing results on basketball players from outside the US collegiate-based National Collegiate Athletic Association (NCAA) system is rare. This is unfortunate considering the value that strength can have on athletic performance (Liow and Hopkins 2003) and in the resistance to overuse injury (Gaida et al. 2004). When strength training is concurrently integrated with the routine court training, conventional beliefs regarding the detrimental impact of high-force, low-velocity training due to velocity specificity may not apply, particularly when it relates to acceleration (Liow and Hopkins 2003).

The only organisation that widely uses strength-testing data is the NBA Combine, though they only test upper-body strength – endurance. The usefulness of the 84-kg bench press used by the NBA is widely questioned due to its low context validity. For example, Kevin Durant scored zero on the bench-press test at the 2007 NBA Combine, yet was the second player drafted into the NBA; he continues to be one of the top players in the game today, albeit in a position generally not requiring physical strength.

Features of current tests in basketball:

1. Although several basketball organisations have standardised batteries of fitness and anthropometric tests, none are widely accepted outside their respective organisations.
2. Components of fitness include strength, power, aerobic endurance and body composition.

Table 112.3 A comparison of Australian junior National- versus State-level males and females on a standard battery of anthropometric and fitness tests ($n = 2000$) (Drinkwater et al. 2007)

	Height		Weight		Sum of seven skinfolds		One step vertical jump		20-m Sprint		Aerobic 20-m shuttle run	
	Mean	Variance ratio	Mean	Variance ratio	Mean	Variance ratio	Mean	Variance ratio	Mean	Variance ratio	Mean	Variance ratio
Men: National versus State	7.0 cm (3.6%)	0.95	6.7 kg (8.0%)	0.93	No difference	0.93	2.9 cm (4.6%)	1.14	–0.07 s (–2.3%)	0.83	0.7 levels (7.0%)	0.84
Women: National versus State	3.6 cm (2.0%)	1.18	4.0 kg (5.7%)	1.00	–7.5 mm (–7.8%)	0.86	No Difference	0.93	–0.04 s (–1.2%)	0.99	0.4 levels (3.7%)	0.92

"Mean" represents the difference between National- and State-level players. Note that in the categories of Sum of Seven Skinfolds and 20-m Sprint, lower scores represent a more favourable result. A "Variance ratio" of less than 1.00 indicates that variability in test results across National players were less than for State

Table 112.4 Summary of studies specifically investigating anthropometric- and/or fitness field test data in female basketball players, organised chronologically. Data expressed as means

[b]*CMVJ* Countermovement Vertical Jump

3. Typically, fitness test batteries include height, body mass, straight-line sprint, jump height and agility.
4. The wide variation of "in-house" test methods and court markings from different leagues limits the ability of researchers to compare data.
5. Aerobic fitness is important even in sprint-based sports, as it may improve recovery time between sprint efforts, reduce fatigue-induced decrements in performance and contribute to skill development by increasing the quality and quantity of practice.

112.3 Anthropometric and Fitness Testing For Basketball Talent Identification

The premise for using fitness and anthropometric tests for talent identification (TID) is not unfounded. Evidence exists to illustrate that anthropometric and fitness characteristics can help distinguish between different competitive levels in a wide range of sports including basketball (Hoare 2000; Drinkwater et al. 2007). Anthropometric and fitness test scores have also been linked with measures of success in individual basketball players (Hoare 2000; Drinkwater et al. 2007), their playing time (Hoffman et al. 1996) and skill performance (Apostolidis et al. 2004) as well as the success of the team (Carter et al. 2005). Hoare (2000) accounted for approximately 40% of performance of a player's playing time during a game using the player's anthropometric and fitness characteristics. Hoffman (1996) further calculated that up to 84% of the variance in the playing time that a player was given by the coach was determined by fitness test scores. Additionally, in a sample of over 2,000 male and female Australian junior basketball players, Drinkwater et al. (2007) demonstrated that national-level players scored higher with a greater consistency on a standardised battery of tests over the span of 7 years than their state-level counterparts (Table 112.3). Hence, if players improve their fitness alone, is that enough to improve their chance of being selected to the next level? The answer to this question may be positive.

Tests of fitness that have context validity can be used to assess a player's readiness to train and compete. Therefore, a bigger, stronger, fitter player may have greater opportunities presented to them, as coaches are more likely to perceive such a player positively (Hoffman et al. 1996). Examples may include a coach spending more time with an unskilled but very tall player to develop his/her basketball skills for the exact reason that the player is tall. A fitter player can train longer before fatigue-induced decrements in skill performance occur, thus allowing for even greater skill development. Faster players have a clear advantage in launching attacks quickly or retreating into defensive positions, thus allowing them the opportunity to execute their offensive and defensive skills. Although it is likely that players will always be selected by scouts based on their ability to play, a player must be fit enough to capitalise on opportunities that fitness affords. Whereas the direct influence of fitness and anthropometry on game-related statistics has not been empirically demonstrated, favourable fitness and anthropometry set the stage for successful performance.

112.3.1 Differences in Anthropometric Test Scores by Player Position

Players on a basketball team are designated to their playing position based heavily on their anthropometry and fitness. While it is widely accepted that basketball players in high-performance programmes are taller than those in the general population (Drinkwater et al. 2008) and often self-select to play basketball for this reason (Delorme and Raspaud 2009), there are substantial differences in

body size amongst players on a basketball team (Table 112.2). Considering that a regulation basketball hoop is 10 ft (3.05 m) from the ground, taller players are at an advantage when shooting on the goal or retrieving missed shots (Trninic et al. 1999). Therefore, a team with tall players close to the basket is at an advantage because shooting on goal and the retrieval of missed shots are the two most dominant game statistics that determine game outcome (Sampaio et al. in press). This strategy became particularly clear between 1980 and 1990 when the number of players in the NBA over 7 ft (213 cm) tall rose from 3.5% to 11% (Norton and Olds 2001).

Empirical research often struggles to demonstrate differences in playing positions that basketball coaches intuitively know, such as the difference between guards and centres on 20-m sprint speed (Hoare 2000) or agility (Latin et al. 1994). Data collectors often find it difficult to classify players by three- and five-position systems (Table 112.2) because many players cross in and out of, for example, the "guard" and "forward" positions (#2 as an "off guard" and #3 as the "small forward"). Such a player would therefore designate him/herself as a 2–3 (i.e. playing either the "shooting guard" or "small forward" position). Another player may be a 4–5 (i.e., playing either the "power forward" or "centre" positions), changing position depending on what is needed in the game at the time. Additionally, by subdividing teams into small subgroups, there is a dramatic decrease in statistical power; thus, a lack of statistical differences between groups more likely represents type II errors rather than a true finding. Therefore, perhaps a broader system of grouping players into "smalls" (comprising position #1–3) and "bigs" (comprising positions #4 and #5) may be useful.

112.3.2 Fitness Tests for Goal Setting

Summary tables of anthropometric and fitness-test values (Tables 112.4 and 112.5) are often viewed by coaches with the intent of establishing reference values for setting the fitness goals of players; if players can see the test scores of athletes in the next level of competition, they can set goals for themselves. However, many studies post overall averages for test scores, but do not distinguish between playing positions (Drinkwater et al. 2007) due to difficulty in classifying players. As a result, a player reaching the mean value on a test may actually be underperforming for his or her position. For example, according to Drinkwater et al. (2007), a state-level guard sprinting 20 m in 3.15 s is an "average" score across all positions, but would likely be sprinting quite slowly relative to other guards because one of the key roles of a guard is movement speed.

Typically, basketball coaches will divide an annual plan into three phases: the off-season in which they focus on developing players' aerobic and anaerobic conditioning, the pre-season in which they focus on the development of players' anaerobic and technical abilities and the in-season in which they focus on maintaining their players' fitness levels and keep training focussed on technical and tactical skills. Drinkwater et al. (2005) studied changes in fitness and anthropometric tests of high-level junior basketball players between phases (i.e., off-season, pre-season and in-season), and even across years in the programme. Whereas mean changes within groups were mostly trivial to small in size, individual responses typically exceeded small effect sizes. These results indicate that whereas the fitness levels of groups of players may be difficult to detect as a whole, individual players can make considerable personal improvements.

Features of anthropometric and fitness testing for basketball talent identification:

1. The direct influence of anthropometric and fitness testing on game-related statistics is unclear.
2. Favourable anthropometric and fitness tests probably allow a player to make the most of opportunities presented to him/her. This may be in favourable rankings of team selectors, higher quality and quantity of practice, or being in place during a game.

3. Anthropometric and fitness characteristics play a determining role in a player's playing position on a team.
4. Widely available anthropometric and fitness test scores on standardised tests allow coaches and players to more effectively goal set.

112.4 Problems with Using Anthropometric and Fitness Testing for Talent Identification

112.4.1 Exceptions

Critics of using anthropometric and fitness tests as a TID tool usually point to the medley of perceptual, motor, cognitive and psychological measures as well as sport-specific skills that are necessary for basketball performance (Trninic et al. 1999; Trninic and Dizdar 2000). Accounting for sporting success is not as easy as measuring a player's body size as there are many other components necessary for basketball success. For example, Spud Webb played 814 games over 12 seasons in the NBA with a height of only 167 cm and body mass of 60 kg. Whereas any TID tool will inevitably have exceptions, taller and stronger players will always have an advantage if they are sufficiently skilled, and, therefore, will be more valued in professional leagues. According to 1993 values, an NBA player was paid an additional $US43,000 over his playing career for every 1.0 cm of height or 1.3 kg of body mass (Norton and Olds, 2001). While, clearly, body size is highly valued in professional basketball, it should be noted that Norton and Olds (2001) did not conclude a cause–effect relationship between body size and remuneration.

112.4.2 Correlation Is Not Cause–Effect

Studies that postulate a relationship between body size or fitness and sporting success usually do so based on correlation-style analysis (e.g. Pearson, linear and multiple regressions). For example, this is how both Hoare (2000) and Hoffman et al. (1996) drew conclusions about the relationship between a player's fitness to playing time. Apostolidis and colleagues (2004) further showed that fitness, particularly peak power, correlates well with a variety of basketball-specific skills. However, correlations describe relationships but not cause–effect. There is clearly more to fitness testing than collecting data from an athlete once. Perhaps the greater value of anthropometric and fitness testing lies in repeat testing of the same player over time (Drinkwater et al. 2005). From this, sport scientists could investigate the interactions between body size, physical fitness and position-specific skill performance (Angyan et al. 2003).

112.4.3 Adolescence

The purpose of TID programmes is the identification potential for sporting success early in an athlete's career, preferably while still a child or adolescent. Predicting adult fitness from testing results of children and adolescents is difficult, however. Whereas the relationship between childhood and

adult fitness may be moderate for selected fitness parameters (e.g. grip strength), Trudeau and colleagues (Trudeau et al. 2003) did not find any that seem sufficiently stable to reliably predict adult sporting success. Considering that the onset of puberty occurs at different times and progresses at different rates, there seems only limited chance of using fitness-test results to predict adult fitness with sufficient precision to choose high-performance teams. However, as previously discussed, a player's size and fitness afford him/her the ability to capitalise on opportunities presented on the court, in skill development and in the scouting process.

To highlight how even the difference of a few months in maturation can make, there is a known "seasonal effect" by which coaches tend to choose teams consisting of children born early in the selection year (Brewer et al. 1995). This was likely due to their more advanced growth at that time. Since these children were played more and received more coaching, they tended to advance more quickly. Delorme and Raspaud (2009) found an over-representation of players born in the first half of the year of all registered basketball players, regardless of competitive level, and conclude that being taller is a major factor in children choosing to play basketball.

Features of using anthropometric and fitness testing for talent identification:

1. The field of talent identification in sport is heavily dominated by correlation-style data analysis.
2. Correlation statistics are used to describe relationships but are not inferential. Whereas original scholars of correlation research are often careful to not make inferences about their data, secondary sources of the original data often do make such inferences.
3. Talent identification is often about targeting children and adolescents for future sporting success, though there are few characteristics sufficiently stable through to adulthood to make such predictions.

112.5 Statistical Analysis and Test Reliability

112.5.1 Reliability

Reliability refers to the repeatability of a test in returning a consistent result when no intervention is made (i.e. test–retest). For example, the 20-m sprint test is unlikely to return the exactly the same result when performed twice, even when repetitions are separated only by several minutes of quiet rest. Sources of unreliability can come from test setup (e.g. measuring an exact 20-m distance), the test operator (e.g. stopwatch timing the 20-m sprint) or variation from the athlete (e.g. motivation to perform the test and hydration status).

In an age in which the near-universal approach to research is to accept or reject a null hypothesis based on an observed p-value, many exercise and sport science researchers give little thought to the reliability of their measures. However, if we know that the reliability of the 20-m sprint test is 1.3% and we show in an experiment that there was a change of 1%, we cannot be confident that the change was not due to unreliability of the test, regardless of the *p*-value. Whereas researchers can do their best to control as many sources of error as possible in a field test, to control all would be impossible. Therefore, reporting test reliability is vital to the process of interpreting test results in human performance research. Although a correlation coefficient of greater than 0.90 is considered by many researchers as "acceptable" reliability, there can never be quantitative descriptors for an acceptable level of reliability; it will always depend on the magnitude of observed changes or differences. Unreliability of 1.3% may be acceptable, if 10% changes are expected, but would be unacceptable, if 0.5% changes were expected.

For those researchers who do consider reliability, it is often assessed by testing for a statistically significant difference between the two repeat trials, by analysing variance (e.g. *t*-test). High variability in the differences between means would be described as "non-significant," though differences between trials fluctuating wildly would clearly indicate poor reliability. Furthermore, statistical significance is not a relevant question in reliability because the purpose of reliability is not to test *if* there is a difference between the two trials, but to describe *how much* difference there is there between two trials.

To consider reliability, other researchers will assess the statistical significance of the correlation between trials. However, since correlation coefficients only describe the reproducibility of the order of the data, two measures could be vastly different, but still correlate quite well, if the difference is consistent. For example, if the retest is consistently 300% higher than the original test, there would be an excellent correlation due to the consistency of the result, though, once again, the ability to compare the test and the retest is clearly poor. Therefore, neither correlation coefficients nor analysing variance between repeat trials sufficiently assesses reliability.

Both the standard error of measurement (SEM) and the typical error of measure (TEM) describe how much difference exists between the two measures in a useful metric (Newtons, centimetres, etc.). Whereas SEM is generally more conventional, TEM describes the true within-athlete variation. Reliability can be expressed as a percent of the mean total (i.e. coefficient of variation) (Drinkwater et al. 2007). By expressing reliability in a useful metric, an author can discuss the magnitude of the observed change relative to the magnitude of the error rather than in inferring qualitative terms of "good" or "poor" reliability, based on a statistically significant correlation coefficient and a statistically non-significant mean difference.

$$\text{SEM} = \text{SD}\sqrt{1-r}$$

$$\text{TEM} = \frac{\Delta\text{SD}}{\sqrt{k}}$$

SEM = standard error of the measurement, TEM = typical error of the measurement, SD = standard deviation of the trials, ΔSD = the standard deviation of the difference scores between trials, r = the correlation coefficient between trials and k = the number of trials.

112.5.2 Magnitude-Based Inferences

Considering that sport research often is conducted on individual teams, participant numbers, and, therefore, statistical power, are often low. As a result, the determination of statistically non-significant results may be more often the result of type II error rather than a difference actually not existing. Furthermore, when a statistically non-significant result is found, it is often misinterpreted to mean that no difference exists. Statistical non-significance simply implies that the result cannot be inferred to be greater than zero with 95% confidence; researchers should not misinterpret such a result to mean that no difference exists.

Human performance research should be about describing the magnitude and meaningfulness of differences between groups. Thus, null-hypothesis significance tests relying on a *p*-value of less than 0.05 are inappropriate for many studies in human performance research. By using statistical procedures, such as Cohen's d and confidence limits, researchers will be able to make "magnitude-based inferences" (Batterham and Hopkins 2006, p. 53) about their data, describing the likelihood that observed results may be meaningful in an applied setting. Simply because a result is statistically significant does not mean the result is meaningful with respect to performance. Rather than trying to

describe results with a simple dichotomous "yes" or "no" answer as in the null-hypothesis significance test, researchers can quantify the likelihood that an effect could have a meaningful influence on performance (Liow and Hopkins 2003).

Features of statistical analysis and test reliability:

1. Reliability relates to the stability of repeated test results.
2. Few exercise and sport scientists report reliability of their tests, despite reliability being a critical value in the interpretation of research results.
3. Reliability should not be established by correlation coefficients between repeat tests and null-hypothesis significance testing mean differences.
4. Reliability should be quantified by typical or standard error of the mean.
5. A statistically non-significant result does not mean no difference existed; a statistically significant result does not mean the difference is practically useful.
6. Human performance cannot be assessed by null-hypothesis significance testing. Magnitude-based inferences would allow researchers to quantify likelihood that an effect could have a meaningful influence on performance.

112.6 Allometric Scaling of Testing

As previously discussed, the anthropometric makeup of a player can play a determining factor for their role on a basketball team. However, the anthropometric makeup of a player can also give mechanical advantages as well. For example, it is well known that larger individuals tend to be stronger and, thus, they tend to score higher on tests of strength. However, it would also be expected that, when heavier players are working against their own bodyweight, such as in a chin-ups test, they would be at a disadvantage. VO_2 max is routinely expressed in oxygen consumption per kilogram of body weight. Aside from centres contesting for position under the basket, few events in basketball are heavily determined by force output; but, since considering centres contesting under the basket is a typical strategy on most plays, having greater body mass, and thus greater strength, is clearly an advantage for centres.

However, when making comparisons across positions, the CV between junior Australian players' height is approximately 4.5% and that between weight is approximately 13% (Drinkwater et al. 2007), thus representing a substantial range of heights and weights on a team. A coach may want to make relative comparisons when evaluating results from strength testing. Most allometric scaling for strength tests work on an exponent of 0.67. This is to say, normalised strength value (S_n) is equal to the result of the strength test (S) divided by body mass (m) to the 0.67 exponent (b):

$$S_n = \frac{S}{m^b}$$

This indicates that simply dividing the result of the strength test by body mass of the subject is not a sufficient correction for the relationship between strength and body mass (i.e. participants with greater mass tend to exert greater force); strength test results actually increase at a lower rate than body mass.

Most of the fitness-dependent components of basketball are dependent on muscular power (e.g., sprinting down court and jumping for rebounds). When evaluating tests of power, such as jumping and sprinting, there does not seem to be any way to correct for body size (i.e., $b = 0$). Unlike in tests where the body mass is entirely supported, participants with low body mass are at a clearer advantage

(b = -0.33); there are no events in basketball such as this. A similar relationship exists when considering height where taller people tend to be stronger (b = 1), less able to support body mass (b = –1.5) and height is unrelated to tests of speed (b = 0) (Markovic and Jaric 2004). It, therefore, can be concluded that mass is never a disadvantage in basketball, particularly when we specify to lean mass. This may seem like a non-intuitive conclusion as most coaches will rarely have seen a centre run faster than a guard. However, considering that the guard as well as forwards are running designated positions, it seems logical that players selected to the "small" positions have other mechanical advantages, such as fibre typing and muscle architecture, and spend more time training for speed running. Players selected to "big" positions are more commonly selected to play those positions for their size and strength and spend relatively less time training for speed and endurance (Latin et al. 1994).

112.7 Conclusion

It is unclear if an improvement in fitness or body size necessarily directly *causes* an increase in playing ability; however, a player's size and fitness likely affords him/her the ability to capitalise on opportunities presented, be that in direct competition with another player or in talent scouting. One of the major impediments to large-scale, long-term fitness and anthropometric research in basketball is the lack of standardised test protocols, due largely to disagreement among sport scientists and coaches about balancing the sport specificity of a test with its reliability. As sport researchers, we also struggle with low or incorrect reporting of test reliability and have an over-reliance on null-hypothesis significance testing rather than making magnitude-based inferences. Rather than analysing data collected repeatedly on an individual over the long term, most TID research draw their conclusions from correlation-based data analysis methods by comparing one-off test results with level of success. Most sample sizes probably lack statistical power to accurately detect statistically significant differences; hence, larger-scale research is required. To conduct large-scale, long-term research, however, we, as sport scientists investigating basketball, should endeavour to agree on a battery of tests with known validity and reliability and express our results using magnitude-based inferences.

112.8 Applications to Other Areas of Health and Disease

Health practitioners and researchers must be wary of conclusions of cause–effect relationships when they are drawn from correlation-based research; though two measures may covary, they may not be linked by a cause–effect relationship. Often, direct cause–effect relationships are not made by the original researchers but are implied in secondary sources.

As a scientific field, it is important for sports science to strive for a general consensus on the tests that will be used. Even slight variations in testing methods or in how they are executed can inhibit the growth of knowledge by making literature reviews difficult and meta-analyses impossible. Many scientists develop "in-house" tests for their specificity, but results from these test protocols lack the ability to be shared with colleagues or included in meta-analysis. This is not to say that researchers should not strive to develop more specific test protocols, but the tests' validity and reliability should be widely disseminated.

Reporting test–retest reliability of protocols should be a key statistical feature of all sport science research. Measurement error is not limited to only the measurement instruments, but is an inherent part of human performance research. Reliability should be reported as typical or standard error of

measurement rather than correlation coefficients and p-values so as to establish the true within-subject variability. Reliability expressed in absolute units of the test or as a coefficient of variation is necessary to assess if observed changes exceed the measurement error. This is true regardless of the presence of statistically significant differences.

There is a growing body of support for the notion that the near-universal approach of null-hypothesis significance testing is not appropriate in human performance research and that the meaning of the p-value is widely misunderstood. Researchers should investigate the use of magnitude-based inferences by expressing data as confidence limits and effect sizes.

Summary Points

- Exercise and sport scientists need to be cautious about drawing cause–effect relations from correlation-based research.
- Body size and fitness will always play a role in basketball, though the influence of each will be determined by the player's dominant role on the team. Data collection and analysis should include the player's position on the team.
- To advance the investigation of the influence of anthropometry and fitness on basketball performance, testing the same player over time and relating results to game-related statistics time would be very useful.
- Basketball as a community should develop a standardised battery of sport-specific tests that do not rely on court markings, so that results can be compared, tabulated, meta-analysed and culminated into large-scale, long-term studies.
- The standardised battery of tests should include tests of strength, balance and aerobic fitness in addition to the current tests of height, body mass, speed, agility and jumping.
- Although aerobic fitness is important in basketball, an intermittent test of fitness, such as the Yo-Yo Intermittent Recovery test, is required for a higher degree of sport specificity.
- Research should always report test reliability as standard error of the measurement or typical error of the measurement.
- Current basketball research relies mostly on null-hypothesis significance testing, though it should make magnitude-based inferences from effect sizes and confidence limits to indicate the likelihood of an effect being meaningful to performance.
- To compare the testing scores of players on a team, allometric scaling may be applied to strength and body-supporting exercises due to the respective advantage and disadvantage of larger players. Allometric scaling of propulsive activities is not indicated.
- Although a player's body size and fitness have not been shown to have a cause–effect relationship, a player's size and fitness afford them the ability to capitalise on opportunities presented to them on the court, in skill development and in the scouting process.

Chapter 113
Anthropometric Digit Ratio 2D:4D and Athletic Performance

Johannes Hönekopp

Abstract 2D:4D (the length of the second finger divided by the length of the fourth finger) appears to be a marker of prenatal testosterone levels, with lower 2D:4D indicating higher prenatal testosterone. 2D:4D has become a prominent tool for studying potential effects of prenatal testosterone on human development and behavior. Athletic performance is positively affected by circulating testosterone levels; similarly, prenatal testosterone may have a positive effect on athletic performance. In order to investigate this possibility, I here review studies on the relationship between 2D:4D and athletic performance. In line with expectations, most studies found a negative relationship between 2D:4D and various measures of athletic performance in either sex. There is some evidence that 2D:4D shows stronger relationships with measures of endurance than with measures of strength. This suggests that prenatal testosterone promotes some components of physical fitness more than others.

113.1 Introduction

In most species, the sexes differ in how much time and energy they invest in offspring. Necessarily, the sex that invests more (usually females) is more limited in the maximum lifetime number of offspring than the sex that invests less (usually males). This difference in parental investment and maximum reproductive success means that males and females optimize their evolutionary success with different strategies. In many species, males are evolutionary most successful by mating often and with many females in order to sire many offspring. Females, by contrast, do not need to mate often in order to achieve their maximum number of offspring. With offspring quantity being strongly limited, females usually optimize their evolutionary success by optimizing offspring quality, partly by choosing high-quality mates. As a consequence of this sex difference in optimal mating strategy, male reproductive success is limited by access to mates in many species. Therefore, males compete for access to females by fighting other males (intra-sexual selection) or by advertising their high

quality to potential mates by means of sexual displays, such as colourful plumage, impressive vocalization, and dances, which is known as inter-sexual selection. (For a very readable introduction to sexual selection, see Miller 2000).

Women invest, on average, more in their progeny than men. Consequently, we would expect to see adaptations for intra-sexual competition in men. Intra-sexual selection often leads to males' being bigger and stronger than females, a pattern also observed in humans (Gaulin and Boster 1992; Pheasant 1983). Indeed, given the ubiquity of male–male fighting throughout human prehistory (Keeley 1996), their fighting ability should have importantly contributed to our male ancestors' evolutionary success. Successful participation in sports often requires abilities, such as strength, endurance, aggressiveness, and dexterity, which would appear to prepare males for intra-sexual selection. Thus, intra-sexual selection in males may largely explain why men outperform women in virtually all sports. Physical features involved in sexual selection are often under the control of testosterone. Further, this also appears likely for characteristics that support successful athletic performance in humans because sex differences in performance usually emerge or greatly increase with puberty (Thomas and French 1985); the effects of doping with androgenic steroids to boost athletic performance point to a similar direction (Hartgens and Kuipers 2004).

Somewhat simplified, two actions of testosterone can be differentiated: circulating testosterone levels in adults have 'activational' effects, that is, the effects are relatively short-lived and wax and wane with testosterone levels. By contrast, testosterone during early development induces permanent, 'organizational' changes, which take place prenatally from gestational months three to six in humans (Cohen-Bendahan et al. 2005). Measurements of foetal testosterone levels are not readily available and longitudinal studies are laborious, which makes studying effects of prenatal testosterone in humans challenging. However, digit ratio 2D:4D (i.e., the length of the index finger divided by the length of the ring finger) appears to be a marker of prenatal testosterone levels in humans, with lower (and thus more male-like) values indicating higher levels of prenatal testosterone (see the chapters of Manning and Voracek in this volume). As 2D:4D can be easily measured, it has become increasingly popular as a (putative) tool for studying effects of prenatal androgenisation in humans (Voracek and Loibl 2009).

The emergence of sex differences in athletic performance during puberty and improved athletic performance after androgenic steroid doping indicate that the activational effects of testosterone have a beneficial effect on athletic performance. It appears plausible that the same might be true for the effects of prenatal testosterone. For this reason, a number of studies have looked at the relationship between 2D:4D and various indicators of athletic performance. To review these studies is the aim of the present chapter.

113.2 Some Methodological Considerations

113.2.1 Measurement of Athletic performance

Whereas the measurement of 2D:4D is relatively straightforward, studies have related digit ratios to aspects of athletic performance in very different ways. First, different sports have been considered, among them running, skiing, and fencing (see below); also, variables that do not pertain to a specific sport discipline have been used (e.g., hand-grip strength). Second, whereas some studies correlated the outcome of a specific athletic activity (e.g., running time) with 2D:4D, other studies have compared the digit ratios of athletes with those of nonathletes (see below).

These differences across studies can be expected to affect results in three important ways. First, physical fitness is multifaceted (Bouchard et al. 1994) and various sports differ in their requirements regarding athletes (a long-distance runner certainly needs other qualities than a weight lifter). Differences in the strength of the relationship between 2D:4D and athletic performance across various measures may therefore provide some insight into which facets of physical fitness (e.g., muscle strength and endurance, cardiorespiratory fitness, flexibility, and glucose tolerance; cf. Bouchard et al. 1994) may be (especially) susceptible to prenatal testosterone effects. Second, the strength of any relationship between two variables partly depends on the quality of the measurements and, ceteris paribus, more reliable measures will give rise to stronger relationships; however, it appears next to impossible to compare the reliabilities of the various measures that have been used in the domain reviewed here, and this aspect will therefore be ignored in this chapter. Third, the strength of the relationship between two variables (as measured by a correlation) will diminish when the variance in the variables is restricted. To take an arbitrary example, the correlation between brain size and IQ can be expected to be higher in a community sample than in a student sample, because IQ should show less variability in the latter than in the former.

The studies reviewed here differ greatly with regard to variance in performance. Some draw on samples that are relatively heterogeneous with respect to athletic performance; for example, Hönekopp et al. (2006) looked at the relationship between pupils' 2D:4D and their physical education marks. This sample can be expected to comprise talented as well as hardly talented individuals, and, accordingly, performance variability in such a sample is high. Other studies look at relatively homogeneous samples. Take Voracek et al. (2006) as an example, who studied elite fencers' national rank; necessarily, the variability in fencing performance in this sample will be relatively low because only people above a high performance threshold entered the study. Homogeneous samples, such as the latter, should tend to underestimate the relationship between 2D:4D and athletic performance in the population due to the range restriction in that sample. This is not true for heterogeneous samples, such as the pupils sample. Table 113.1 lists the studies that looked into the relationship between 2D:4D and athletic performance and it indicates, for each sample, whether or not a substantial restriction in the performance range is present; although necessarily rough, such a classification can shed additional light on the findings.

113.2.2 Effect Sizes

A recent meta-analysis into 2D:4D and athletic performance suggests that no hand's 2D:4D is a systematically better predictor of athletic performance than the other hand's 2D:4D (Hönekopp and Schuster, 2010). This chapter therefore does not differentiate between right-hand and left-hand 2D:4D here. Instead, results (which are largely based on Hönekopp and Schuster, 2010) were averaged across both hands, where separate results for each hand were reported in the original studies.

For each sample, the strength of the relationship between 2D:4D and the variable of interest is given as a Pearson correlation (r). This measure, immediately plausible for studies correlating 2D:4D with some athletic outcome (e.g., running time), may appear awkward for studies comparing the 2D:4D values of athletes and controls. In the latter case, measures of effect size that express the raw difference between groups in units of standard deviations (e.g., Cohen's d) are typically used. However, Cohen's d and r can be readily transformed into each other. Further, the meaningfulness of r for comparing differences between two groups is illustrated by the fact that the 'correct' r can be obtained directly from raw scores by correlating the dependent variable (e.g., 2D:4D) with two arbitrary numbers that code for group membership (e.g., 'athletes' and 'nonathletes').

In this review, *p*-values are not the point of focus because statistical significance is largely a function of statistical power (i.e., sample size) and focussing on significance instead of effect size (or some other descriptor of the effect at hand) may be detrimental for scientific progress (e.g., Cohen 1994).

113.3 The Relationship Between 2D:4D and Athletic Performance

Table 113.1 gives an overview over the relevant studies and their results. For ease of communication, all samples are numbered consecutively (left-most column). The reference for each sample can be found by matching the entries in the second column with the respective numbers in the reference list. Of the 28 samples listed in Table 113.1, 11 are female samples with an overall *N* of 1,406, 16 are male samples with an overall *N* of 2,292, and, finally, one mixed-sex sample comprises 144 participants.

All measurements of athletic performance in the original studies were coded such that higher scores denote better athletic performance. Consequently, we should expect negative correlations between 2D:4D and athletic performance. (This is because 2D:4D appears to be negatively related to prenatal testosterone [see above], and any relationship between prenatal testosterone and athletic performance should be positive.) Studies are listed according to effect size, that is, the correlation of athletic performance with 2D:4D. Multiple relationships between 2D:4D and measures of athletic performance were averaged into a single effect size for each sample.

When studying the results (Table 113.1), two key features are striking. First, all but one sample (#28) find a negative relationship between 2D:4D and athletic performance, which suggests that associations between athletic performance and 2D:4D are robust. Second, the strength of the relationship between 2D:4D and various measures of athletic performance differs greatly, from about zero to $r = –58$ (#1). Large differences in effect size are also found between studies with large samples (e.g., compare #6, #7, and #8 with #21, #22, and #28), which indicates that these differences reflect 'real' differences and do not simply emerge from random sampling error, a view that is confirmed by a more technical analysis in a recent meta-analysis (Hönekopp and Schuster, 2010).

As the results are so heterogeneous, can we then identify factors that account for the large differences in effect sizes across studies? One potential factor might be sex. This, however, does not appear to play an important role. First, the unweighted average correlation between 2D:4D and athletic performance is $r = .23$ for the female samples and $r = .31$ for the male samples, which is not a dramatic difference when we consider the heterogeneity of effect sizes within each sex. Second, and more importantly, comparable female and male samples tend to yield quite similar results whenever the same measure of athletic performance is used. Thus, correlations between pupils' physical education marks and 2D:4D are $r = –.17$ for girls (#19) and $r = –.16$ for boys (#20); correlations between a gym-based fitness test and 2D:4D are $r = –.24$ for females (#16) and $r = –.17$ for males (#18); the relationship between 2D:4D and opting-in versus not opting-in for physical education in school is $r = –.31$ for girls (#13) and $r = –.24$ for boys (#15); the correlation between 2D:4D and rank in fencing is $r = –.13$ for females (weighted average across #23 and #26) and $r = –.08$ for males (#27); finally, the relationship between 2D:4D and hand-grip strength is $r = .08$ in females (#28) and $r = –.24$ in males (weighted average across #12 and #17). Only the latter domain represents a sizable difference between the sexes regarding the predictive power of 2D:4D. Future studies will have to show if this particular difference represents more than chance.

Table 113.1 Overview of studies on 2D:4D and athletic performance

#	Reference	Conceptualization of athletic performance and sample	Age	Sex	*N*	*r* with 2D:4D	Range restriction
1	Latourelle (2008)	Athletes versus student controls		F	74	–0.58	No
2	Manning et al. (2003)	Reserve versus first team squad; professional soccer players		M	33	–0.53	Yes
3	Manning et al. (2003)	Times for six-mile race; participants in cross-country race	21	M	47	–0.52	Yes
4	Manning et al. (2007)	Mean rank across three races; participants in cross-country race	28	M	43	–0.51	Yes
5	Manning et al. (2007)	One-mile race; athletic club members	34	F	40	–0.41	Yes
6	Manning et al. (2003)	Self- and other-rated playing ability; soccer amateurs	19	M	108	–0.41	Yes
7	Manning (2002a)	Soccer professionals versus controls		M	839	–0.40	No
8	Manning (2002b)	Ski-race participants versus matched controls	21	M/F	144	–0.36	No
9	Manning (2002a)	Highest participation level for favourite sport; university sample	22	M	128	–0.35	No
10	Tester and Campbell (2007)	Highest participation level for favourite sport; sport team members	20	M	73	–0.34	Yes
11	Tester and Campbell (2007)	Highest participation level for favourite sport; sport team members	20	F	82	–0.33	Yes
12	Fink et al. (2006)	Hand-grip strength; students	23	M	52	–0.32	No

27	Voracek et al. (2006)	National rank; elite fencers	23	M	37	–0.08	Yes
28	van Anders (2007)	Hand-grip strength; university sample	24	F	99	0.08	No

The strength of the relationship between 2D:4D (the length of the second finger divided by the length of the fourth finger) and athletic performance is indicated as a correlation in the column '*r* with 2D:4D'. Negative relationships are expected (i.e., low, 'masculine' 2D:4D tends to coincide with good performance).

As sex can hardly explain the substantial differences in effect sizes between studies, can we identify any other characteristic as relevant? Looking at correlations between 2D:4D and running time, Hönekopp and Schuster (2010) found a significant relationship between running distance and effect sizes, indicating that the predictive power of 2D:4D significantly increases with running distance. This suggests that 2D:4D tracks an endurance component especially well. Further support for this idea comes from the fact that the four soccer samples (#2, #6, #7, and #22) tended to find strong relationships with 2D:4D, with weighted average $r = –.35$, and endurance appears to play an important role in soccer performance (Helgerud et al. 2001). In the group of the 23 non-soccer samples, only five showed larger effect sizes, three of which resulted from middle- and long-distance running. By contrast, those measures of athletic performance for which an endurance component does not appear particularly important (e.g., hand-grip strength, sprint speed, and fencing performance) tended to produce small effect sizes (unweighted average across seven samples: $r = –.13$). The very substantial relationships between 2D:4D and performance in soccer, and middle- and long-distance running ($r \approx .40$) are the more remarkable as most of these samples show a range restriction, which works against finding large effects (see Sect. 113.2.1).

113.4 Conclusions

Reporting bias (especially omission of non-significant results in the published literature) is a threat to the validity of any review or meta-analysis (for a brilliant account, see Palmer 2000). For the relationship between 2D:4D and athletic performance, a meta-analysis which included most of the studies reviewed here found no evidence for a substantial effect of publication bias (Hönekopp and Schuster, 2010). Moreover, 2D:4D research is a field in which non-significant and contradictory findings appear to be readily published (e.g., Puts et al. 2008; Putz et al. 2004). Therefore, optimism regarding the veracity of the data presented here appears justifiable.

The great heterogeneity of samples and, especially, methods (i.e., conceptualization of athletic performance) makes generalizations across studies difficult. Nonetheless, some conclusions appear warranted. First, negative relationships between 2D:4D and athletic performance are reliably found across domains. This suggests that prenatal testosterone either has a positive influence on some aspect of physical fitness that is relevant for athletic performance across a wide range of sports or positively affects various facets of physical fitness. Second, the present data suggest that prenatal testosterone affects athletic performance about equally strongly in both sexes. Future studies will have to show if strength is an exception, which is hinted at by results on hand-grip strength. Third, a comparison of effect sizes across domains suggests that prenatal testosterone has an especially strong effect on endurance, but probably a small effect (if any) on strength. This is remarkable because effects of doping with androgenic steroids appear to be particularly strong for muscle mass and strength (Hartgens and Kuipers 2004). This contrast then suggests that prenatal testosterone and adults' circulating testosterone affect various components of physical fitness in different ways. The results so far obtained for 2D:4D and endurance running suggest large effects (although it should be remarked that all relevant studies stem from the same group, and independent replication appears desirable). The effects are so large, in fact, that 2D:4D might prove a viable tool for early talent identification.

The next step for elucidating the relationship between 2D:4D and athletic performance should be to determine which components of physical fitness and, more specifically, which physiological aspects and/or morphological body characteristics are linked with 2D:4D and explain the relationship(s) between 2D:4D and athletic performance.

113.5 Applications to Other Areas of Health and Disease

The current review suggests a reliable link between 2D:4D and athletic performance, and the relationship with endurance appears to be particularly strong. Also, there is very good evidence for a negative relationship between cardiovascular fitness and mortality. In a large (N > 13,000) prospective study with an eight-year follow-up, participants with initially low fitness, as measured by a treadmill test, showed an increase in age-adjusted mortality of about 40% (Blair et al. 1989). Could 2D:4D then serve as an indicator of general health, life expectancy, or the like? Not much research has been undertaken regarding a link between 2D:4D and cardiovascular health; however, there is some evidence for a link. Testosterone may have a protective effect against myocardial infarction and, in affected males, a negative relationship between 2D:4D and age at infarction was found; thus, men with lower, more male-like 2D:4D had their infarction relatively late in life (Manning and Bundred 2001). More indirect evidence comes from a study that found a positive link between 2D:4D and neck circumference, a risk factor for coronary heart disease (Fink et al. 2006). Although there is therefore some evidence for beneficial effects of prenatal testosterone on cardiovascular health, it cannot be assumed that prenatal testosterone has a general protective effect on health because low 2D:4D has been repeatedly linked to autism and ADHD (e.g., de Bruin et al. 2006; Manning et al. 2001; Stevenson et al. 2007).

Chapter 114
Anthropometric Variables and Its Usage to Characterise Elite Youth Athletes

Cristóbal Sánchez-Muñoz, Mikel Zabala, and Karen Williams

Abstract Talent identification programs usually monitor several parameters, once of which is kinanthropometry. There are a variety of anthropometric techniques that are used in talent identification. With respect to youth sport performance, the focus of this chapter was upon the use of techniques to assist with talent identification and performance within the adolescent (from 8–18 years for girls and 10–22 years for boys) phase of growth as competitive sport is not a regular occurrence in children <8 years old. Using evidence from a variety of studies, information has been provided about how sports have used kinanthropometry for talent identification purposes taking into consideration physical growth and maturation, absolute size and proportionality, somatotyping and body composition. The sports covered include individual sports (cycling, figure skating, gymnastics, rock climbing, track and field), field sports (cricket, hockey, soccer), contact team sports (American football, Australian rules football, rugby), court sports (badminton, basketball, handball, netball, tennis, volleyball), weight classified sports (judo, taekwondo, sumo wrestling, weightlifting) and water sports (rowing, sprint kayaking, swimming). Athletes are characterised by a combination of body composition/body size traits which are believed to influence the chance of success in any given sport therefore it is suggested that the measurement of kinanthropometry is a crucial tool in the search for information to assist coaches and athletes in the quest for success at the highest level in sport.

114.1 Introduction

Ackland (2006) has written extensively about the talent identification process and has identified the following elements for successful programmes: (1) understanding the important aspects for success in competition, (2) recording a set of data on an athlete, (3) gathering a set of normative or comparative data, (4) using these data to construct a profile of an athlete and (5) interpreting the profile to guide the selection process or provide the basis for an ongoing training program.

Talent identification programs usually monitor several parameters, once of which is kinanthropometry. This is the study of human size, shape and form and how those characteristics relate to human movement and sporting performance (Eston and Reilly 2009). Ackland (2006) believes that the elements outlined above have not always been used in the most effective manner, with some talent identification programs running a large battery of tests without the importance of the selected parameters being taken into consideration. It is thought that, in certain situations, it may be better to measure fewer, but more discriminatory, variables. This is an approach which should be considered in the measure of anthropometrical measures, given the depth and breadth of techniques available. The aim of this chapter is to cover some of the kinanthropometry techniques that are used in the talent identification with some evidence of how they have been used in a variety of sports. For the purposes of its relation to youth sport and performance, the focus will be upon the techniques used within the adolescent (from 8 to 18 years for girls and 10 to 22 years for boys) phase of growth as competitive sport is not a regular occurrence in children <8 years old (Barker et al. 2009) (Table 114.1).

Table 114.1 Key features of Kinanthropometry

1. Kinanthropometry is the study of human size, shape, proportion, composition and maturation to assist in the evaluation of growth and of the effects of exercise, performance and nutrition.
2. Kinanthropometry utilises a combination of anatomy and movement from which data are collated and body composition predictions applied to the measurement and description of the human physique.
3. Growth is a reference to the increase in size of the body as a whole or the size attained by the specific parts of the body.
4. Maturation is the process of achieving a fully mature biological state.
5. There is a possibility that training for sport can accelerate growth and maturation; however, there are also concerns about the possible negative effects of rigorous training on growth and maturation, particularly in females compared to males.
6. Size and proportionality can play a fundamental role in selection, particularly when considering height and weight.
7. Talent ID generally monitors morphological and skeletal maturation status in young athletes; however, there are a number of growth spurts and plateaus which can affect both selection and performance.
8. The shape and proportions of an athlete are an important feature in talent identification; therefore, to increase the chance of success in sport, children should be directed towards sports for which they are physically suited. This is referred to as "morphological optimisation."

114.2 Physical Growth and Maturation

Growth is a reference to the increase in size of the body as a whole or the size attained by the specific parts of the body. The growth of the whole body is usually measured by assessment of changes in stature or by assessment of the specific parts of the body using appropriate anthropometric techniques (Beunen 2009). Maturation is the process of achieving a fully mature biological state. The predominant types of maturation that are monitored during talent identification are morphological and skeletal. The rate of development can differ significantly between individuals; however, selection bias of early maturers is a common occurrence in selection for sport based upon chronological age (Helsen et al. 2005). Rowley (1987) believed that, to be successful in sport at an international level, intensive training must begin before puberty. What must be considered, however, is the average age of elite competition. For example, gymnasts normally peak in their performance around 16 years of age compared to weightlifters who tend to peak around 30 years of age. This will affect the intensity and volume of training from a young age and can affect selection. It is believed that training for sport is important to support normal growth and maturation, although it has also been suggested that training for sport can accelerate growth and maturation (Malina et al. 2004). Moreover, there is concern about the possible negative effects of rigorous training on growth and maturation, particularly in females compared to males.

114.3 Size and Proportionality

With respect to success in specific sports, proportionality can play a fundamental role in selection. Height and body mass are two of the main discriminatory factors in selection for sport and subsequent success for both individual and team sports (see Tables 114.2–114.4). When considering height, there are two factors to consider. The first is success at sport during childhood, whereby, in the majority of sports, taller athletes are generally the more successful, although there are exceptions to this, such as in gymnastics, where a shorter stature is regularly a discriminatory factor (Malina et al. 2004). The second factor is prediction of adult height for talent identification. During adolescence, which is the growth phase we are concentrating on for this chapter, growth is fairly unstable. There are a number of growth spurts and plateaus which can affect both selection and performance. To attempt to overcome these, predictions of adult height have been developed and used through the years (Lowery 1978; Sherar et al. 2005).

Table 114.2 Key features of Somatotyping

1.	Somatotyping is a method whereby the body is described in terms of a number of traits that have a relation to body shape and composition.
2.	It is a classification of three empirically determined and visually rated extremes of body build.
3.	A somatotype of an athlete consists of a three-numeral rating, which describes the current morphological representation of an individual.
4.	The three numerals represent the three components of the physique, endomorphy, mesomorphy and ectomorphy.
5.	Endomorphy is a general indicator of an individual's adiposity level or "roundness."
6.	Mesomorphy refers to the level of muscularity of an individual.
7.	Ectomorphy is considered to be an indicator of linearity of an individual.
8.	The higher the rating of each component, the more prevalent it is in an individual.
9.	The results of somatotyping can be plotted on a somatochart, which allows the comparison between individuals and/or sports.

Table 114.4 Key features of body composition

1. Body composition is defined as the division of the relative percentages of body weight into several compartments, according to definable tissues.
2. Usually, body composition is expressed as a two-compartment model in which the body is divided into fat and fat-free compartments. A four-compartment model divides the body into a fat portion, and further subdivides the fat-free portion into bone, muscle and the remainder (organs, nerves, blood, vessels and fluids).
3. Body composition measurements are applied regularly in a variety of fields including medicine, anthropology, ergonomics, human growth and sport performance.
4. Body composition techniques on athletes have been largely directed towards estimating the amount of fat in the body.
5. Assessment of body composition and the resulting computation of relative fatness contribute significant information to determine an athlete's training and nutritional programmes. Body composition estimates provide important information about an athlete's physical profile and affect the athletes' training.
6. Estimates of the body composition can only be made at present by indirect laboratory and field techniques due to the only direct method of quantifying the different compartments or tissues being cadaver dissection.
7. Traditional laboratory procedures for the estimation of body fat, such as hydrostatic weighing and total body water, are comparatively cumbersome, expensive and not always readily available, whereas more expedient methods, such as anthropometry, suffer from concerns about validity and accuracy. The technique used most often for assessing body fat in athletes has been skinfolds, although recent technological advances offer a variety of new methods for body composition assessment.

Of considerable interest is the gender differences that exist that may influence performance. Peak height velocity (PHV) is the maximum rate of growth occurring during the adolescent growth spurt (Baxter-Jones and Sherar 2007). Girls usually begin their growth spurt between 8 and 10 years, which is two years before boys usually begin their growth spurt (at 10–12 years). This may present a transitory advantage until boys begin to progress through their PHV phase by which point they have already had two years additional pre-PHV growth than girls. The time frame for PHV is also longer in boys, with the resultant height advantage in boys compared to girls measuring approximately 13 cm. Growth in the lower extremities is evident in the early phase of the growth spurt for both boys and girls; however, gender differences exist in regional muscle mass development (Malina et al. 2004). Still, there may be as much as five years' difference in the occurrence of PHV between genders; therefore, the chronological age can differ significantly compared to biological age. This is important since, during adolescence, selection for sports is likely to be influenced significantly by biological age as evidenced by the early maturers having an advantage (Helsen et al. 2005).

The shape and proportions of an athlete is an important feature in talent identification since it has been suggested that children should be directed towards sports for which they are physically suited (Bloomfield 1992). This process of "morphological optimisation" (Norton et al. 1996) is particularly useful for sports where height and body mass are important performance predictors.

114.4 Somatotyping

Somatotyping is a method whereby the body is described in terms of a number of traits that have a relation to body shape and composition. Sheldon et al. (1940) introduced the method from studies of Kretschmer's (1921) classification of three empirically determined and visually rated extremes of body build and Viola's (1933) ratio of trunk and limb measures. Heath and Carter (1967) developed this further with the Heath–Carter somatotype method, which is now the most universally applied of the available methods and is the method we have focussed on in this chapter. A somatotype of an athlete consists of a three-numeral rating, always recorded in the same order, which describes the current morphological representation. The three numbers, expressed as 2-5-1, for example, describe the value of each component – endomorphy, mesomorphy and ectomorphy – of the physique.

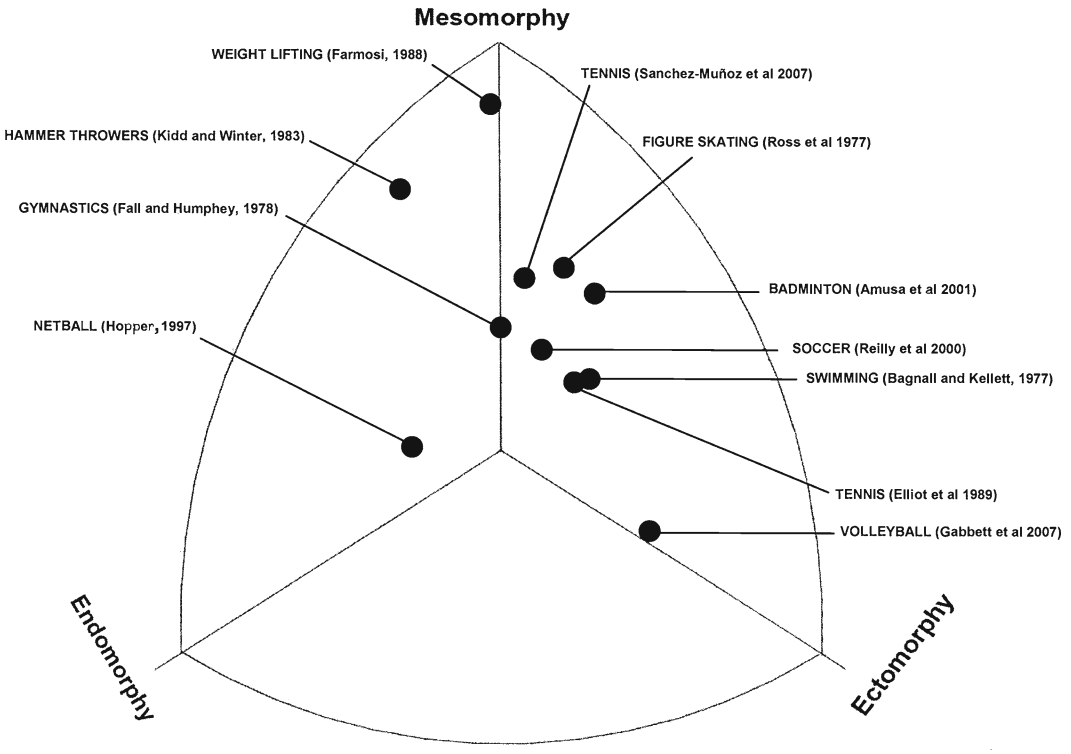

Fig. 114.1 Somatotype distribution of mean somatotypes for various youth male sports

The higher the rating of each component, the more prevalent it is in an individual. The results of somatotyping can be plotted on a somatochart, which also allows the comparison between individuals or sports (see Table 114.1 and Figs. 114.1 and 114.2).

114.4.1 Components

The first component, endomorphy, describes the relative amount of adiposity of an individual's body. It does not take into consideration the distribution. Endomorphy also provides descriptors of physical aspects, such as roundness, relative volume and the distal tapering of the limbs. Mesomorphy is the second component and describes the level of muscularity of an individual. It also refers to the descriptors of physical aspects, such as robustness, the relative volume of the trunk and other muscle mass within an individual. The measures of endomorphy and mesomorphy are considered to be an anatomical model of body composition. Ectomorphy is the third component and is a description of the linearity of the body. It also describes physical aspects of slenderness in the absence of muscle or fat mass. The category that an individual will be placed in is dependent upon the dominant component, with an indication of their secondary component. For example, a rating of 3-5-1 would suggest that an individual is an endomorphic mesomorph as they have a high mesomorphic value (5) as the primary trait and a relatively high (3) value on the endomorphic scale. If an individual has equal values in two of their ratings, they are considered to be a balanced body type as dictated by the dominant components. For example, a 1-5-1 would be considered to be a balanced mesomorph as the values for endomorphy and ectomorphy are equally low compared to the high value for mesomorphy.

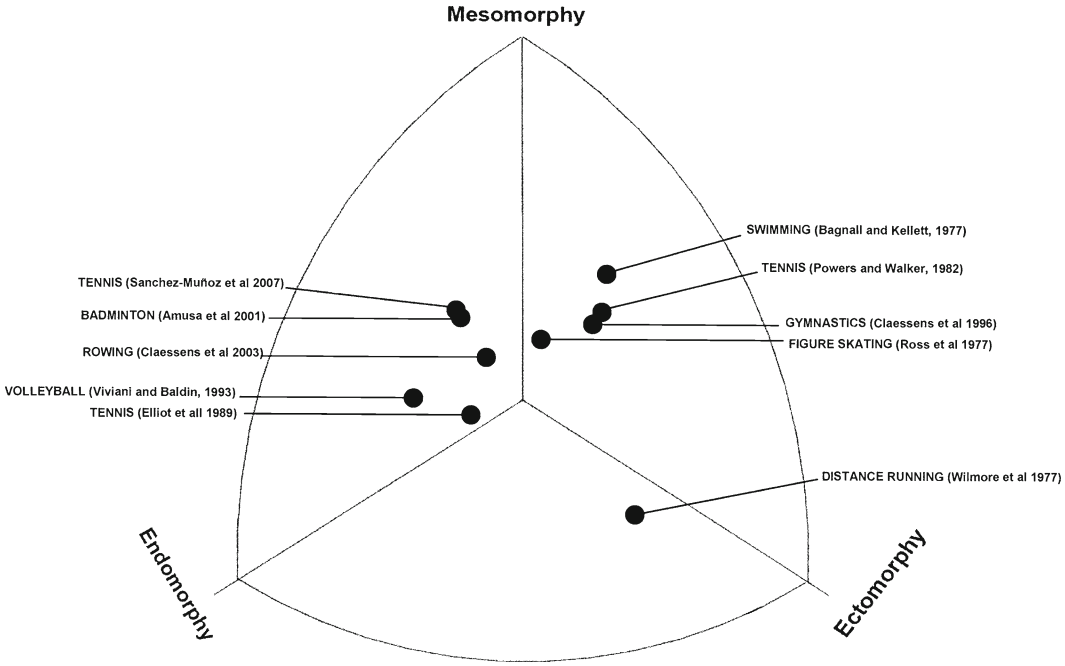

Fig. 114.2 Somatotype distribution of mean somatotypes for various youth female sports

A somatotype is an indication of the physique as a whole. It allows the assessment of the body as a whole, taking into consideration levels of adiposity, muscularity and linearity. Its application in sport and performance has been significant with the ability to compare body types across a huge range of sports and at all levels of competition. With respect to youth sport, somatotyping allows the monitoring of training, growth and maturation over time. Additionally, there is evidence to suggest that the physique characteristics of young athletes in a variety of sports are consistent with those of adult athletes in the respective sports (Heath and Carter 1990), which is potentially a useful tool in talent identification.

114.5 Body Composition

Techniques for the measurement of body composition give a more accurate indicator of what makes up an individual's shape, thereby allowing further selection criteria to be identified. There are a number of techniques available for the measurement of body composition, which range from simple to in-depth. One of the simplest estimates of body composition is body mass index (BMI); however, there are issues surrounding its accuracy, particularly in adolescent boys where the increase in body mass between 11 and 16 years may be more to do with an increase in muscle mass than adipose tissue, therefore giving an incorrect estimate of relative obesity. If BMI is used, then, an attempt to classify young people against age- and gender-specific cutoff points should be made (Cole et al. 2000). The usefulness of BMI is greater in sports that do not rely on high power/weight ratios, such as field and court sports, as opposed to sports, such as gymnastics or cycling, where body composition can have a large impact upon a height/weight ratio value (see Tables 114.1–114.3).

In addition to BMI, there are a number of techniques available to assess body composition, such as skinfolds, bioelectrical impedance analysis (BIA), hydrodensitometry, air displacement plethysmography (ADP) and dual-energy X-ray absorptiometry (DXA). Some of these techniques, such as

hydrodenistometry or DXA, require a high level of technical expertise and expensive equipment and can be quite timely to administer. One of the most used methods for the estimation of percentage body fat is skinfolds and body density. What must be taken into consideration is the effect of growth on the concepts associated with estimation of body density (Armstrong and Welsman 1997), since the water content of a child's fat-free mass and the increases seen in bone density during adolescence will affect those assumptions. Where an estimation of percentage body fat is attempted, child-specific equations should be used (Lohman 1992). To attempt to overcome this, some sports have opted to use the sum of skinfolds as an indicator of adiposity, which can also be used longitudinally. In sports, where rapid movements as well as movement of the body mass must occur, or in weight-classified sports, minimal body fat and a lean body shape is a distinct advantage (Tittel 1978). Such sports could include track and jumping sports, or combat sports. Talent identification in these types of sports should consider using a more in-depth estimation of body composition, such as skinfolds.

When considering team sports, positional differences should be accounted for, as different roles within a squad will have different energy requirements. For example, a midfielder in soccer will require a lower body fat than the goalkeeper due to the movement patterns of that position. Whilst body composition is an important element of the talent identification process, it is only one of the many factors that will contribute to success. Athletes can still perform at the highest level in the absence of the most favourable body composition, due to their excellence in other areas, such as physiology, tactics, technique and psychological approaches.

The factors outlined earlier have potential to affect performance prediction, the extent of which will depend upon a number of factors, such as the requirements and level of the sport, the application and the correct selection of techniques upon performance and their role in performance prediction. The use of the techniques in specific sports is outlined below and in Tables 114.5–114.7, with an attempt to compare the data to reference where possible. An effort to only use data from high-level youth sport had been made.

114.6 Individual Sports

114.6.1 Cycling

Track cyclists are known to be more powerful than road cyclists, especially those involved in the shorter distances, although there are similarities across both groups. Road versus track cycling should also be taken into consideration. Faria et al. (1989) indicated that youth cyclists were notably taller, heavier and leaner than non-athletes and when compared to junior swimmers and runners, and they were found to be similar to endurance athletes. Measures of body composition revealed a high

correlation between estimated percentage fat, triceps skinfold and suprailium skinfold, which suggests that these are the most appropriate skinfold measurements for this homogeneous population.

114.6.2 Figure Skating

The importance of morphological characteristics for most optimal performance in aesthetic sports has been noted. Monsma and Malina (2005) demonstrated that elite skaters had shorter leg lengths than pre-elite skaters; however, this may be due to maturation levels, as pre-elites are generally younger and in an earlier phase of their adolescent growth spurts. Additionally, lower-level test stream skaters had greater skinfold values than both pre-elite and elite skaters, suggesting an effect of level on kinanthropometry. Ross et al. (1977) demonstrated that, compared to Mexican Olympic athletes, Canadian Olympic skaters (senior and junior men and ladies) were ectomorphic/mesomorphic on the scales and that they closely resembled gymnasts in size, being relatively small, lean and only slightly less muscular.

114.6.3 Gymnastics

Success in gymnastics relies on attaining the highest score during competition. It is claimed that anthropometrics are the greatest predictor of performance in rhythmic gymnastics (Douda et al. 2008), accounting for 41% of the success in performances of basic body elements of difficulty, whereas non-adipose voluminosity accounts for 26% of rhythmic-gymnastics-specific manipulations with the apparatus (Miletic et al. 2004). Rhythmic gymnastics relies in part upon the ability to leap and hop. It was found that height accounted for 16% of variance in hopping height. Elite rhythmic gymnasts were taller and had significantly longer thigh lengths and higher values of FFM than sub-elites (Di Cagno et al. 2008), therefore supporting the use of these parameters to select gymnasts in the early stages of development.

When attempting to predict the best independent predictors of annual changes in bone mineral density (BMD) for total body, lumbar, spine, trochanter and femoral neck sites of highly trained gymnasts, Courteix et al. (1999) found that variations in lean mass, bone age and fat mass were the greatest independent predictors. With respect to male gymnasts, it was found that top male class II gymnasts were significantly leaner than class I and lower class II gymnasts. Additionally, class II gymnasts, when compared to other classes, were characterised as shorter in stature, were leaner and possessed more muscle mass (Faria and Faria 1989). The length of the arms with respect to trunk length and percentage body fat are key factors due to their potential impact on achieving skill at the highest level and should therefore be included in the talent identification process of high-level gymnasts.

114.6.4 Rock Climbing

The popularity of climbing continues to grow, with normative data on adult climbers beginning to emerge regularly. In evaluations of young competitive rock climbers, significant differences in height, mass, ratio of arm span to height, biiliocristal/bi-acromial ratio, sum of skinfolds and estimated percentage fat were found compared to age-matched controls. Watts et al. (2003) suggested that young competitive climbers have general characteristics similar to adult climbers, although young climbers

appearing to be more linear with narrow shoulders relative to hips. Continued monitoring of youth climbers is useful to form normative databases both for selection for elite levels and for comparison to adult climbers.

114.6.5 Track and Field

There is a plethora of data relating to kinanthropometry of runners of differing distances and a variety of ages. The data of Graves et al. (1987) showed that elite female runners had smaller girths than gymnasts, body builders and normative references. Male Kenyan runners had measures of BMI, height and mass that were smaller than age-matched Scandinavian athletes. This suggests that there may be an affect of race on performance (Larsen et al. 2004). Hollings and Robson (1991) indicated that, in a cohort of field and track athletes including throwers, sprinters, middle-distance runners and jumpers, throwers were a distinct group as far as body build was concerned. They were taller, heavier and had higher levels of subcutaneous fat than the other groups. Throwers had a low ponderal index with their limbs appearing as a series of relatively short levers, which would assist them in performance. Middle-distance runners were lighter than the other groups, whereas the sprinters and jumpers were similar to each other, suggesting that anthropometric variables can differentiate between groups of events in track and field athletes and should be considered for talent selection.

114.7 Field Team Sports

114.7.1 Cricket

Cricket is a sport which requires all players to field and bat and is supported by a set of skills that defines a player's role which will contribute to the success of the team. One of the aspects of crickets that can affect the potential for success is peak bowling speed (Stuelcken et al. 2007). A study of the anthropometric and strength correlates in junior cricketers revealed multiple predictors of success in achieving peak bowling speed, which included height, body mass and estimated percentage muscle mass. From these measures, it was found that body mass and estimation of percentage muscle mass were considered to be the most useful anthropometric predictors of peak velocity in junior bowlers (Pyne et al. 2006); therefore, they should be used as part of a battery of tests for talent detection in youth players.

114.7.2 Hockey

Field hockey requires intermittent running, accelerations and decelerations, requiring a high level of effort. Differences in anthropometric measures have been reported in players of differing levels (Ready and Van der Merwe 1986). A study of female players demonstrated that higher-level regional players had significantly lower skinfold thickness values and estimated percentage fat than the lower-level club players, suggesting that talent identification programmes should potentially use these anthropometric measures as part of the selection process (Keogh et al. 2003). A study of elite and sub-elite male and female junior players over three seasons demonstrated that elite male and female

players increased in height and mass. Males also reduced estimated percentage body fat over time. Elite players appear to score better than their sub-elite counterparts in a number of characteristics and it is suggested that players should be tracked into adulthood (Elferink-Gemser et al. 2004).

114.7.3 Soccer

Soccer is intermittent in nature and is multifactorial in terms of the elements required for success. A talent identification study by Reilly et al. (2000) demonstrated that elite-level junior players had significantly lower endomorphy scores than lower-level players. Additionally, elite-level players were leaner than lower-level players when considering both sum of skinfolds and estimated percentage fat. The sum of skinfolds also more clearly distinguished between the groups than did estimated percentage fat. With respect to positions, Gil et al. (2007) demonstrated that forwards were the leanest players, presenting the highest level of muscle. By contrast, the goalkeepers were found to be the tallest and heaviest players, with the largest skinfold values and the highest percentage fat values. For midfielders, height was one of the anthropometric discriminants of selection. Le Gall et al. (2010) demonstrated that graduate players from an elite youth academy were taller and heavier than amateurs. The findings of these studies suggest that anthropometric measures should be taken into consideration when attempting to detect talented for soccer.

114.8 Contact Team Sports

114.8.1 American Football

American football players are thought to have a morphological profile similar to rugby players due to the similarities in playing profiles involving discontinuous bouts of intensive exercise with high levels of tackling. Research indicated that BMI values of collegiate players were classified as overweight or obese; however, average body fat percentage estimations placed them into the acceptable age- and gender-referenced normal ranges (Kaiser et al. 2008). With respect to positional differences, morphology of the players in the study was consistent with the positional specialisation requirements. For example, positions specialised for the line-off scrimmage blocking and tackling were taller and heavier than players at other positions. The positions specialised for sprinting and dynamic agility demonstrated lower height, weight, body fat percentages and BMI compared to the overall group (Kaiser et al. 2008). It was also suggested that, as the level of competition increases, so do weight, height and fat-free mass (FFM) (Williford et al. 1994), highlighting the importance of monitoring body composition at all levels of development.

114.8.2 Australian Rules Football (ARF)

Like other contact field sports, ARF requires players to cover the majority of distances during a game at submaximal speeds, with shorter bursts of speed interspersed with longer periods of recovery. One of the main anthropometrical attributes for success is considered to be height, especially for key positions, such as forwards. A study to predict selection in an elite youth ARF team found that height and mass were anthropometric measures that could be used in a discriminant analysis to predict selection,

with height considered to be one of the two most important discriminators for selection in elite under-18 ARF players. Additionally, selected players were shown to be significantly taller and heavier than non-selected players (Keogh 1999). Selected junior players appear to be relatively similar to senior players in terms of height (Douge 1988), but not in terms of body mass, although anthropometric measurements, such as girths and body mass, increase significantly as teenage males mature (Housh et al. 1997), signifying that under-18 ARF players are still maturing physically, which is required if players are to compete at the senior level. Anthropometric measures should be monitored at junior through to senior levels to maximise the chance of selection of optimal body types for ARF.

114.8.3 Rugby

Rugby league is a collision sport that is intermittent in nature. The positions can be broadly classified into forwards or backs. Forwards are involved in significantly more collisions and tackles than backs and have a higher activity ratio of high:low intensity. Forwards also cover a larger distance than backs during a match. Studies of senior rugby league players have shown significant differences between positions in measures of height, body mass and skinfold thickness (O'Connor 1996). Research on junior elite rugby league players indicates that forwards are taller, heavier and have greater skinfold thicknesses than backs. When discriminating between starters and non-starters, elite starters were taller and heavier than non-starters, whereas sub-elite starters were taller than sub-elite non-starters (Gabbett et al. 2009). In a study attempting to identify and develop rugby talent, calf and upper-arm girths as well as humerus and femur diameters showed practical significance (Pienaar et al. 1998). The findings of the studies earlier indicate that physical characteristics of junior rugby players should be taken into account in talent identification models and should therefore be a consideration when setting realistic junior performance standards.

114.9 Court Sports

114.9.1 Badminton

Badminton is considered to be an agility sport, which requires movements to be executed by the upper extremities, although performance is multifactorial. A study by Amusa et al. (2001) showed that height, weight and arm span are the most important indicators for performance in junior national players. Somatotype measures indicated that, in male players, mesomorphic ectomorph was the predominant measure, whilst endomorphic mesomorph was the main measure for females. It was also suggested that, to allow free movement around the court, lower weight athletes with low BMI values would have an advantage.

114.9.2 Basketball

Basketball is an agility-based, intermittent sport that partially relies on jumping ability. Morphological proportions to support those activities is key; therefore; height is one of the key determinants of success, so are long limb lengths for defending, passing and shooting. In junior elite players, arm span was considered to be a predictor of overall success. When positions are considered, the best male

point guards were taller than the rest, though the best power forwards were significantly taller and had a longer arm span than the rest. The best small forward players were also taller than the rest of the players in that position (Hoare 2000). In female players, positional differences existed between centres and point guards demonstrating lower levels of FFM and smaller arm span values. In best versus rest tests, the best females had proportionally longer legs than the rest of the cohort. Since significant differences exist in certain anthropometric measures in young players, monitoring anthropometric attributes appears to be a successful tool for predicting success alongside other factors related to basketball performance (Hoare 2000).

114.9.3 Handball

Handball is a dynamic sport characterised by speed, agility, reaction speed, explosive power, endurance, strength and coordination. In handball, absolute size of the body is an important factor in handball for both youth and adults. It is also suggested that the size of the hand is an important factor when selection criteria for players are set. This is due to hand size and finger length being useful for throwing accuracy. In a study of male youth players for talent detection purposes, significant differences were seen between the elite and non-elite players for body mass, arm length, relative arm length, arm span and both upper limb muscle circumferences (stretched and flexed). For the long-term development of talented players, a careful follow-up of the maturation process, including growth of the most important body segments, is considered necessary. In a discriminant analysis, height was considered an important determinant for performance and corresponds well with characteristics suggested as essential in youth and adult handball (Mohamed et al. 2009).

114.9.4 Netball

Netball is a court sport that is intermittent in nature with agility and jumping two of the key skills for success. Bale and Hunt (1986) demonstrated that elite players were heavier, significantly taller and had significantly smaller femur bone widths than players classified as good. Elite players showed total skinfold and estimated fat levels which suggested a larger muscle mass but lower levels of adiposity in relation to their height. Somatotype analysis showed most players were of the mesomorphic endomorph type or balanced mesomorphs (Hopper 1997). With respect to positions, centres were significantly shorter, lighter and had less fat than attackers and defenders. Attackers and defenders were the tallest and heaviest of the players, whereas central players were more mesomorphic than the attackers and defenders who tended to show more ectomorphic traits. There are several parameters that should be monitored to assess ability, of which body composition is one.

114.9.5 Tennis

Tennis is characterised by explosive activities interspersed with intermittent bouts over a long period of time. A high lean body mass/height ratio is thought to be an advantage. A study of adolescent

junior players found the BMI and estimated percentage fat of players to be in the recommended range for young athletes (Juzwiak 2008), whereas, in a study by Elliot et al. (1990), it was indicated that, in male players, estimated percentage fat was lower in high-level players across age groups. The cohort of players were also shown to be more linear, expressing high ectomorphy levels, which is line agreement with the findings of Copley (1980), who suggested that ectomesomorphy is a required characteristic for successful tennis performance at the professional level.

For females, body composition was considered an important indicator of tennis performance from 11 to 15 years. Higher level players were leaner than the controls in both endomorphy levels and sum of skinfolds. Copley (1980) also showed that professional female players were more endomesomorphic than amateur players, although height and mass were not thought to discriminate between higher level and control subjects. A study by Sanchez-Muñoz et al. (2007) demonstrated that significant differences were observed in height and humeral and femoral breadths when comparing the first 12 and the lower ranked female players. The first 12 players were significantly taller than the lower ranked players, providing evidence for the use of talent identification in junior tennis.

114.9.6 Volleyball

Volleyball is an intermittent sport that requires players to participate in frequent short bouts of high-intensity exercise, followed by periods of low-intensity activity. Thissen-Milder and Mayhew (1991) demonstrated that height and weight were two of the anthropometric characteristics measured in high-school players that could discriminate amongst starters and non-starters. Data from Melrose (2007) suggested that lean body mass and shoulder, hip and thigh girths are the key anthropometric physical determinants of performance in adolescent female volleyball players. In measures of junior national and state players, significant differences were detected between levels for height, standing-reach height and skinfold thickness. Male players were found to be taller, heavier and leaner and with greater standing-reach height than female players. A study of somatotypes in elite players showed positional differences, with setters tending to be endomorphic ectomorphs, hitters and opposites tending to be balanced ectomorphs, and centres tending to be ectomorphic mesomorphs (Duncan et al. 2006). The analysis of performance standards for junior volleyball highlights the importance of some characteristics as the level of playing increases.

114.10 Weight-Classified Sports

114.10.1 Judo

Successful participation in Judo is thought to depend upon appropriate levels of technical skill, supported by a number of physical characteristics. In a study of junior males and female judokas, Little (1991) demonstrated that the estimated percentage body fat for junior males and females was less than the normative reference value. Given that the nature of Judo is to continuously grip your opponent whilst actively trying to remove them from a balanced stable position, it would seem that biological maturity would have an impact on performance and chance of success and performance differences, especially in junior males of the same chronological age, but contrasting maturity status,

the difference of which is most apparent between the ages of 13 and 16 (Malina et al. 2004). This indicates the importance of monitoring maturity in junior judokas.

114.10.2 Sumo Wrestling

Sumo wrestlers are well known for their very large bodies, which has often raised questions about their health status. The anthropometric dimensions of sumo wrestlers, such as stature, body weight, length and circumference of the limbs and trunk have been reported previously. A study of wrestlers in the higher leagues demonstrated larger bodies than those who belong to the lower leagues (Nishizawa et al. 1976; Hattori et al. 1999). In college-level sumo wrestlers, BMI and estimated percentage fat was very high compared to non-athletes and all were characterised as obese, although further measures of body composition also demonstrated that the wrestlers had excessive fat-free mass values. To monitor the health status as well as the talent detection element, accurate methods should be used to estimate body composition in junior sumo wrestlers.

114.10.3 Taekwondo

Taekwondo is a weight-classified combat sport using a variety of kicking and punching movements. Fleming and Costarelli (2007) showed that following an analysis of skinfold measurements, a cohort of international standard athletes were very lean, with low levels of fat mass and high levels of muscle mass. Measures of BMI were high, which may be due to their lean body mass/height ratio as opposed to their level of obesity. Evidence from other combat sports suggests that athletes regularly compete at 5–10% below their natural body weight (Filaire et al. 2001), highlighting the importance of body composition.

114.10.4 Weightlifters

Somatotyping by Orvanova (1990) indicated that the athletes at the higher levels showed greater levels of mesomorphy and lower levels of endomorphy. Depending upon their pubertal growth spurt, young lifters have varying levels of mesomorphy and ectomorphy. When separated into weight groups, the lighter athletes showed higher levels of mesomorphy, whereas the heavier athletes demonstrated higher levels of endomorphic mesomorphy. Ectomorphy decreases, whereas mesomorphy and endomorphy were shown to increase with weight class. Comparison of age groups revealed that the younger lifters in each weight class had higher endomorphy and lower mesomorphy levels than the adult lifters. Ectomorphy was found to be higher in the youngest lifters, but only below the weight class of 82.5 kg. All age and weight classes of weightlifters demonstrated greater mesomorphy and lower ectomorphy than non-athletes and the differences tended to increase with weight class. Measures of bone mineral density revealed that it is found to be much higher in junior weightlifters due to the influence of the chronic overloads experienced with training for that sport (Conroy et al. 1993). When attempting to predict performance, Fry et al. (2006) showed that body mass and relative fat are two of the five screening tools that should be utilised for detection in junior weightlifters.

114.11 Water Sports

114.11.1 Rowing

Extensively studied, anthropometric data from both males and females have emphasised the importance of body mass (Secher and Vaage 1983) and body size (Rodriguez et al. 1986) in rowing. In a cohort of youth rowers, from a selection of anthropometric measures, thigh girth and lean body mass, when entered into a regression table, were significant predictors of 1-km rowing performance (Mikulic and Ruzic 2008). Bourgois et al. (2000) also showed that male junior rowers had increased bicep, thigh and calf girths compared to reference data, whereas female junior rowers had increased biceps thigh, and calf compared to references and non-finalists. Of the rowers who reached the finals, all had larger measures in the biceps and thigh than the non-finalists. Therefore, anthropometric measures should be considered for performance prediction measures in rowing events for both males and females, as clear differences between athletes and reference data exist.

114.11.2 Sprint Kayak

Sprint kayaking requires the athlete to propel themselves predominantly using the upper body. Aitken and Jenkins (1998) showed differences in body mass, biceps girth, upper arm length, forearm length, thigh length, lower leg length and biliocristal breadth between elite kayakers and controls. The elite female paddlers had greater mass and bicep girths than the female controls. With respect to key determinants of performance in male paddlers, those who had greater bi-acromial breadth and extremity lengths demonstrated greater improvements following training. Additionally, the morphological proportions of kayakers who performed at Olympic level revealed that elite paddlers had distinct characteristics compared to the general population, which included a greater than average thigh length, shoulder and chest breadths along with proportionally large upper body girths (arm and chest girth) and proportionally narrow hips in males and lean physiques as demonstrated by low skinfold scores (Ackland et al. 2003). The data from previous studies clearly indicate that anthropometric measures can be useful in the selection of individuals for high-level performance and should therefore be considered in athlete monitoring protocols.

114.11.3 Swimming

Training for high-level swimming begins at an early age. Due to the large number of swimming events, research has attempted to classify the variety of characteristics which help to distinguish which event an individual should select and train for. Analysis of youth data for the prediction of 100-m freestyle performance suggested that upper extremity length was a significant predictor of 100-m freestyle performance, whereas body height, upper extremity and hand length were all significantly related to 100-m freestyle time (Geladas et al. 2005). In a variety of swimming events, Avlonitou (1994) showed that sprint and back swimmers were the tallest and heaviest among the events for both sexes. This group also had the highest values for upper and lower limbs and hand and foot lengths. The long-distance group was the shortest and lightest group for males and the lightest group for

females. The female fly group had the lowest values for height, upper and lower limb lengths as well as hip width. Significant correlations were obtained between performance and somatometric variables. For swimmers participating in different events, variation in body size and form is already present at an early age. Analyses of swimming performance including body composition measures found significant relationships between the energy cost of swimming (C_s) and body mass, FFM and body mass in prepubertal and pubertal swimmers, suggesting that body composition parameters have a significant impact on C_s (Jürimäe et al. 2007). It was also shown that, of the anthropometric measures, arm span was the best predictor of swimming performance. Swimming is clearly influence by anthropometrics; therefore, every effort should be made to clarify which anthropometric measures distinguish between events, thus allowing a talent identification option available for all events.

114.12 Practical Application to Sport and Performance

The data from these studies suggest that participants are characterised by a combination of body composition/body size traits which are believed to influence the chance of success in any given sport. It is also clear that success in sport is multifactorial and that the value of anthropometric measures in assisting with talent identification or predicting success is varied between and within sports. It is, however, clear that the measurement of kinanthropometry is a crucial tool in the search for information to assist coaches and athletes in the quest for success at the highest level in sport.

Summary Points

- Talent identification programmes usually monitor several parameters, once of which is kinanthropometry.
- For talent identification purposes, measurements of kinanthropometry take into consideration physical growth and maturation, absolute size and proportionality, somatotyping and body composition as measured by a variety of methods.
- Athletes are characterised by a combination of body composition/body size traits which are believed to influence the chance of success in any given sport.
- It is thought that, in certain situations, it may be better to measure fewer but more discriminatory variables for potential athlete selection purposes.
- Success in sport is multifactorial; therefore, the value of anthropometric measures in assisting with talent identification or predicting success is varied between and within sports.

Chapter 115
Anthropometry in Athletes with Spinal Cord Injury

Mina C. Mojtahedi and Ellen M. Evans

Abstract Whole body fat and lean soft tissue appear to be reduced in athletes with spinal cord injury (SCI) compared to sedentary able-bodied (AB), however this does not reflect distribution of lean soft tissue and fat mass throughout the body. Research findings using dual energy X-ray absorptiometry (DXA) assessing regional body composition indicate that as a result of upper-body exercise, athletes with SCI have increased arm and trunk lean soft tissue compared to sedentary AB, and decreased arm FM compared to sedentary SCI. Due to muscle atrophy following SCI, lower-body lean mass is reduced compared to sedentary AB, as found in sedentary individuals with SCI. Although DXA is currently the most feasible method for accuracy and for measuring regional body composition, it is not a practical tool for practitioners working with athletes. Therefore field methods such as skinfold measurements and bioelectrical impedance analysis (BIA) have been evaluated for use in athletes with SCI. Unfortunately, these field methods and prediction equations for estimating relative body fat do not appear to be accurate or reliable for use in athletes with SCI. Currently, limited body fat prediction equations for skinfold and BIA measurements have been developed specifically for athletes with SCI. Generally, limited research data is available on body composition assessment in athletes with SCI, and many of the studies are limited in sample size, varying methodology and inclusion criteria. Further research utilizing multicenter studies are likely needed to contribute to the literature and to create better prediction equations for the SCI athlete population.

Abbreviations

%BF	Body fat percentage
AB	Able-bodied
BIA	Bioelectrical impedance analysis
BMC	Bone mineral content
BMD	Bone mineral density
BMI	Body mass index
DXA	Dual energy X-ray absorptiometry
FM	Fat mass
HDL	High density lipoprotein

115.1 Introduction

Spinal cord injury (SCI) causes motor and sensory loss at and below the level of lesion. The resulting complete or incomplete paralysis of the affected limbs leads to alterations in body composition and bone which include reductions in regional lean soft tissue (LST) and bone mineral of affected limbs, and an increase in whole body and regional fat mass (FM) (Jones et al. 1998; Spungen et al. 2000; Maggioni et al. 2003). Effects of exercise on body composition are well documented (Williams et al. 2005) in able-bodied (AB) populations and are opposite to changes following SCI, that is, increased LST and bone mineral, and decreased FM.

This chapter focuses on anthropometry using the three-compartment model with regard to athletes with SCI: fat, water (lean), and mineral (bone). The term 'athlete' is defined as an individual who participates in elite and recreational sports, and has trained at a duration, volume, and intensity above the standard physical activity recommendations for the general population (Pollock et al. 1998).

115.2 Soft-Tissue Composition

115.2.1 Multicompartment Models

115.2.1.1 Dual Energy X-Ray Absorptiometry

A limited number of studies have been conducted in athletes with SCI, but generally these studies show that paraplegic athletes with SCI have less FM and more LST than sedentary SCI (Olle et al. 1993), but less FM and less LST compared with sedentary AB controls (Mojtahedi et al. 2008a, b, 2009; Sutton et al. 2009). A study with DXA (Mojtahedi et al. 2008a, b) reports that, in absolute values (kg), athletes with thoracic and lumbar SCI had 20% less whole-body LST and 25% less whole-body FM than sedentary AB.

However, several studies have shown that whole body values do not reflect distribution of LST and FM throughout the body in individuals with SCI (Spungen et al. 2000, 2003; Maggioni et al. 2003). Therefore, it is important to assess regional body composition, particularly in athletes with SCI, who are using only their upper body to generate muscle force and, thus, whose upper body primarily is impacted by physical activity. Mojtahedi et al. (2008a, b) have shown that arm LST is 24% more and arm FM is 23% less in athletes with SCI than in sedentary AB. This same study (Mojtahedi et al. 2008a) also showed that leg LST is about 50% less in athletes with SCI than in sedentary AB. Therefore, upper-body responses to physical activity are as would be expected when comparing SCI athletes with sedentary individuals, but lower-body muscle remains atrophied due to severed muscle innervation and disuse following SCI.

Table 115.1 Key facts of spinal cord injury (SCI)

1. Major causes of SCI include motor vehicle accidents, falls, sports, and violence.
2. An SCI results in paralysis of innervated muscles. A complete SCI results in total loss of sensation and function, whereas an incomplete SCI results in only partial loss.
3. The neurological level of injury determines the proportion of affected limbs. Cervical lesions result in complete and incomplete quadriplegia (also tetraplegia), affecting all four limbs and trunk. Thoracic and lumbar lesions result in complete and incomplete paraplegia, affecting the legs and part or all of the trunk.
4. Loss of innervation to muscles leads to muscle wasting of affected limbs, and is often accompanied by fat accumulation.

This table lists some key facts about spinal cord injury including basic terminology. *SCI* = spinal cord injury

No studies are currently available using DXA methodology to compare body composition of athletes with SCI to sedentary individuals with SCI. However, compiling findings from multiple studies show, surprisingly, that athletes have similar levels of arm LST, but, as expected, significantly less arm FM than sedentary SCI. Arm LST values of 7.3–8.3 kg have been reported in sedentary individuals with SCI (Spungen et al. 2000, 2003) and 7.6 kg in athletes with SCI (Mojtahedi et al. 2008a). Arm fat mass values were 3.2 kg (Spungen et al. 2003), which is almost twice the amount of 1.7 kg found in SCI athletes (Mojtahedi et al. 2008a).

Importantly, when body size differs between populations, absolute soft-tissue mass also differs. As shown in Table 115.2 (Mojtahedi et al. 2008a), although relative size (i.e., BMI) was not different, athletes with SCI differed in height and weight from sedentary AB. Therefore, comparisons of body composition compartments (i.e., fat mass) must be assessed in relative terms. Table 115.2 and Fig. 115.1 show that whole body and regional fat percentages did not differ and LST percentages did differ between athletes with SCI and sedentary AB (Mojtahedi et al. 2008a). Compiling data available from multiple studies indicates that relative body fatness in sedentary individuals with SCI ranges from 27 to 31% (Jones et al. 1998, 2003, 2004; Maggioni et al. 2003), which is somewhat greater than the 25% in athletes with SCI (Mojtahedi et al. 2008a). Many of these studies are, however, confounded by differences in gender, age range, spinal cord injury levels, and use of different DXA machines. Nevertheless, in summary, relative values indicate that:

- As a result of upper-body exercise, athletes with SCI have increased arm and trunk LST compared to sedentary AB, and decreased arm FM compared to sedentary SCI.
- As with sedentary individuals with SCI, lower-body lean mass is reduced in SCI athletes due to muscle atrophy.

115.2.1.2 Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has gained increased use over recent years in the area of body composition assessment, as it provides access to measuring specific adipose tissue depots, such as subcutaneous and intermuscular adipose tissue (IMAT, defined as adipose tissue located beneath the fascia lata and between muscle groups.) (Shen et al. 2003), which have been found to be associated with metabolic disorders (Goodpaster et al. 2003, 2005). This is relevant to individuals with SCI, as muscle disuse is known to increase IMAT and decrease muscle in AB individuals (Manini et al. 2007). Moreover, absolute and relative thigh IMAT areas are increased in the SCI population, both athletic (Mojtahedi et al. 2008a, b) and sedentary (Elder et al. 2004; Gorgey and Dudley 2007). Sedentary SCI appear to have more thigh IMAT than athletes with SCI (Fig. 115.2A and 2B). However, as the level of muscle disuse is similar in both groups, the mechanism for this apparent difference is as yet unclear.

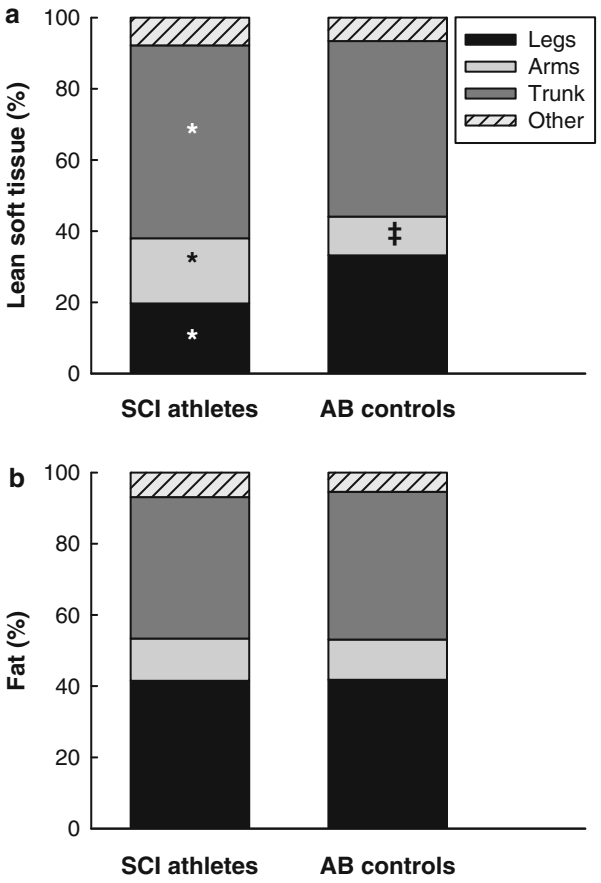

Fig. 115.1 Regional distribution of relative lean soft tissue (**a**) and fat (**b**). Whole body and regional lean soft-tissue percentages differ and fat percentages do not differ between athletes with SCI and sedentary AB. *SCI* = individuals with spinal cord injury, *AB* = able-bodied individuals. * Indicates significant group differences in the distribution of lean soft tissue ($p < 0.05$). ‡ Indicates within-group interaction ($p < 0.05$) between gender and the regional distribution of lean soft tissue in the arms (Reprinted with permission from Mojtahedi et al. 2008a)

115.2.2 Field Methods and Prediction Equations

115.2.2.1 Skinfold Prediction Equations

Body fat percentage (%BF) prediction equations combine a variety of skinfold sites often with other variables, such as age, weight, circumference, and measurements, to predict a gold-standard measurement of body composition. Equations are often developed for specific populations. Currently, no body fat prediction equation for skinfold measurements has been developed specifically for athletes with SCI. Nevertheless, a number of equations have been evaluated for acceptability for the SCI population.

Table 115.3 shows selected equations from three cross-validation analyses in athletes with SCI, comparing the accuracy of skinfold body fat measurements to hydrodensitometry and DXA. Equations that are used often in general populations and have been derived from AB populations include Durnin and Womersley (1974), Jackson and Pollock for men (Jackson and Pollack 1978) and women (Jackson et al. 1980), Sloan for men (Sloan. 1967), Sloan and Weir for men and women (Sloan et al. 1970), Katch and McArdle (Katch et al. 1973, 1975), and Wilmore and Behnke for men (Wilmore et al. 1969)

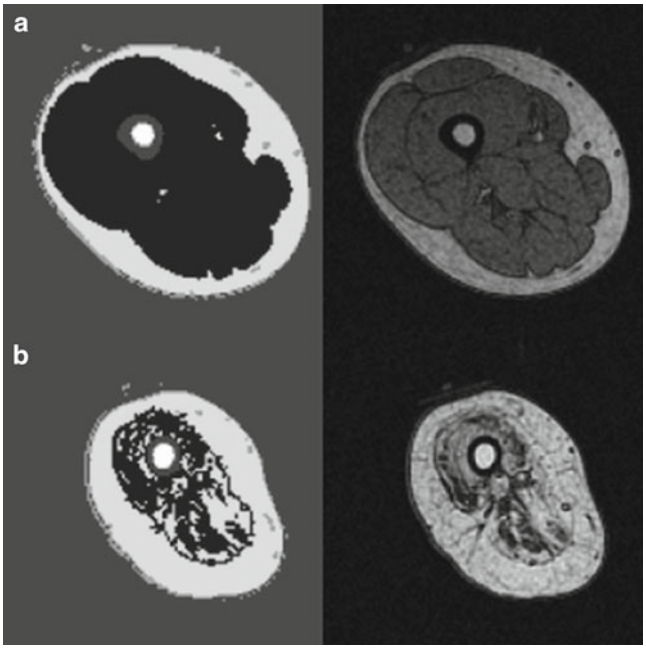

Fig. 115.2 Magnetic resonance cross-sectional analyzed and unanalyzed images of the right mid-thigh of a male sedentary able-bodied participant and a male athlete with spinal cord injury (SCI). Magnetic resonance cross-sectional analyzed and unanalyzed images of the right mid-thigh of a male sedentary able-bodied participant, (**a**: displayed in the upper half) and a male athlete with spinal cord injury (**b**: displayed in the lower half). In the analyzed images on the left, muscle is displayed in black and fat in white. Intermuscular fat (IMAT) is defined as adipose tissue located beneath the fascia lata and between muscles, and is displayed in white in the analyzed images (Reprinted with permission from Mojtahedi et al. 2008a)

and women (Wilmore et al. 1970). Many of these equations have been shown to be largely inadequate for use in athletes with SCI. Key features of other equations derived from AB populations but which have been evaluated and shown to better predict %BF in athletes with SCI include:

- Lean et al. (1996):
  - Derived from a Caucasian, broadly representative population;
  - Includes triceps skinfold, waist circumference, and age;
  - ~1–2%BF difference between skinfold prediction and DXA measurement; and
  - Directional bias compared with DXA %BF: predicted skinfold %BF decreases as measured DXA %BF increases.
- Evans et al. (2005):
  - Derived from athletic population;
  - Three-site equation includes abdomen, thigh and triceps skinfolds, gender, and race;
  - ~5–7%BF difference between skinfold prediction and DXA measurement; and
  - No directional bias compared with DXA %BF.

Although limited data exist, it appears that %BF estimations from many skinfold prediction equations correlate well with hydrodensitometry and DXA in athletes with SCI (Bulbulian et al. 1987; Olle et al. 1993; Mojtahedi et al. 2009); however, most prediction equations systematically underpredict %BF. Some of the first studies to assess %BF of athletes with SCI showed 7–12 lower %BF predictions from skinfold measurements compared with total body potassium (Lussier et al. 1983) and 1–8 lower %BF when compared with hydrodensitometry (Bulbulian et al. 1987). More recent

Arm lean soft tissue (%)[c]	18.3 ± 2.4	10.9 ± 1.5*

Absolute and relative values for whole body and regional fat and lean soft tissue show that while absolute fat differs between athletes with SCI and sedentary AB, fat percentages do not differ, due to difference in body size between groups. Absolute and lean soft-tissue percentages differ between athletes with SCI and sedentary AB. Results are mean ± SD

SCI = individuals with spinal cord injury. *AB* = able-bodied individuals

[a]Denotes percentage of body weight

[b]Denotes percentage of total fat stored in this region

[c]Denotes percentage of total lean soft tissue stored in this region

* Indicates significant difference between SCI and AB, $p \leq 0.05$

† Indicates $p = 0.012$ for gender by group interaction (SCI and AB females had similar values, whereas AB males had higher values than SCI males)

studies with somewhat larger sample sizes comparing skinfolds to DXA have shown similar results with under-prediction ranging from 1–4%BF (Sutton et al. 2009) to 2–12%BF (Mojtahedi et al. 2009), depending on the prediction equation used. Furthermore, Lohman's (1992) classification for prediction error based on the standard error of the estimate (SEE) and accuracy based on total error (TE) suggests that none of the equations (where data are available from cross-validation) are a good fit for predicting %BF in athletes with SCI.

Factors that may impact prediction error and accuracy are likely related to altered fat-free tissue distribution following SCI. First, as noted earlier, individuals with SCI have much more FM in their lower body than an age- and gender-matched AB individual. Equations that are based on an AB population will assume a regional LST distribution found in AB individuals, and may not be applicable to individuals with SCI. Therefore, the skinfold sites included in a prediction equation are of importance in gaining a representative sample of fat distribution throughout the body. However, a thick layer of subcutaneous fat can often be difficult to measure with skinfold calipers, especially if this is accompanied by little muscle mass, for example, due to atrophy found in individuals with SCI. Second, individuals with SCI often experience edema in the lower limbs, further compounding accurate skinfold measurements. Edema may also impact predicted %BF estimates by altering weight, and by changing the relationship between skinfold thickness and subcutaneous fat.

115.2.2.2 Bioelectrical Impedance Analysis Prediction Equations

To date, only one study has cross-validated BIA %BF prediction in athletes with SCI (Mojtahedi et al. 2009). Table 115.4 shows the prediction equation from this cross-validation analysis. Equations used in this analysis included a generalized one from Stolarczyk et al. (1997), Kocina and Heyward (1997) developed for the SCI population, Houtkooper et al. (1989) for female athletes, and Oppliger et al. (1991) for male athletes. It should be noted that the equation for individuals with SCI was derived from sedentary SCI, and that the equations derived from athletes were sports specific and did not match the sports of the population against which it was cross-validated.

Findings from Mojtahedi et al. (2009) indicate that BIA results in greater variation between and within individuals, but that mean predicted %BF tends to be closer to DXA body fat measurements than %BF predicted from skinfold measurements. In contrast to skinfold predicted %BF, BIA did not correlate well with measured DXA %BF in this population despite differences between BIA and DXA %BF ranging only 0.5–4%, which was much less than found with skinfold predictions. However, this equation was found to have increased measurement error with greater predicted BIA %BF. Moreover, SEE and TE classifications (Lohman 1992) indicated that none of the BIA prediction equations, including the SCI-specific one, were a good fit for this population (Table 115.4).

Several factors that impact the reliability of BIA measurements can create potential limitations for its use in athletes with SCI, and may explain the wide variation in measurements. First, hydration status plays an important role in BIA measurements in any population, and even more so in athletes, whose training can result in varied levels of hydration depending on the time since workouts and rehydration. Second, fluid retention is often experienced by individuals with SCI, as mentioned earlier, further compounding BIA measurements, as the electrical current passes through extracellular water. The hydration status of athletes can be standardized to some extent when taking BIA measurements; however, edema found in individuals with SCI is more difficult to control and measure. Lastly, %BF estimates from prediction equations, such as the typically used Siri equation (Siri 1956), assume a certain body density, which may not apply to athletes with SCI. Athletes have a higher water fraction in fat-free mass, resulting in lower fat-free mass density (Modlesky et al. 1996), and individuals with SCI are likely to have lower fat-free mass density because of bone mineral loss following SCI (Kocina 1997). Both these factors may lead to greater predicted %BF estimates.

115.3 Applications to Other Areas of Health and Disease

The prevalence of adiposity and risk for metabolic disease has been shown to be greater in SCI than in the AB populations, with impaired glucose tolerance and insulin resistance occurring at a younger age in those with SCI than in AB individuals (Bauman et al. 1999; Karlsson 1999; Bauman and Spungen 2001). The favorable effects of exercise on body composition and disease risk is well established in AB populations, but has received limited investigation in individuals with SCI.

Studies show that functional electrical stimulation of lower-limb muscles in individuals with incomplete paraplegia can increase LST of these limbs, and can have a favorable impact on metabolic disease risk (Mahoney et al. 2005). However, this kind of treatment is not feasible and accessible for all individuals with SCI, unlike physical activity. Unfortunately, some studies indicate that exercise is not associated with favorable changes in glucose regulation or insulin sensitivity (Midha et al. 1999; Manns et al. 2005), and therefore may not decrease disease risk at the same level found in AB individuals.

One explanation for this could be that favorable changes from physical activity in upper-body composition and metabolism may not be enough to counter effects from altered lower-body

Table 115.3 Selected body fat prediction equations for skinfold measurements used in athletes with spinal cord injury (SCI) (Reprinted with permission from Bulbulian et al. 1987; Mojtahedi et al. 2009; Sutton et al. 2009)

The accuracy and reliability of prediction equations can evaluated in several ways, including difference in mean %BF from reference method, correlation with reference method, TE, and SEE. Studies evaluating the accuracy of prediction equations for athletes with SCI vary as regards the sample population, methodology, and evaluation criteria. However, in general, prediction equations using skinfold measurements do not appear to accurately estimate %BF. Results are mean ± SD

BMI = body mass index. *%BF* = body fat percentage. *SKF* = skinfold. *SEE* = standard error of the estimate. *TE* = total error. *NA* = not available. *DXA* = dual energy X-ray absorptiometry

composition following SCI (decreased LST and increased FM) of individuals with thoracic and lumbar SCI, in terms of metabolic profile (Mojtahedi et al. 2008b). Increased IMAT, trunk fat, and whole body fat have been associated with insulin sensitivity in athletes with SCI, and therefore may contribute to health risks despite decreased upper-body fat (Mojtahedi et al. 2008b). However, at the same time, metabolic factors that can lead to disease and are known to be impacted by physical activity, that is, glucose and insulin responses to an oral glucose tolerance test as well has HDL cholesterol, were found to be better in athletes with SCI compared to sedentary AB, although this was not a statistically significant finding (Mojtahedi et al. 2008b). The non-significant finding could have been partly due to the small sample size, and provides a foundation for future, larger studies that should include a sedentary SCI comparison group.

115.4 Practical Methods and Techniques/Guidelines

115.4.1 What Is the Most Accurate and Practical Method of Assessing Body Composition of Athletes with SCI?

Anthropometry is standard for evaluating the effectiveness of training programs for athletes. Although whole-body soft-tissue composition can play a role in sports performance, as shown from data presented in this chapter, whole-body measurements of LST and FM do not represent regional distribution in athletes with SCI. As upper-body physical activity for individuals with SCI will naturally only impact upper-body body composition, it is useful to be able to assess regional changes resulting from a training program. However, this means access to use of equipment that is expensive, such as the DXA, and is not practical for use in the field. Field methods, such as skinfolds and BIA, are typically used by practitioners working with athletes. However, unfortunately, they do not appear to be accurate or reliable for use in athletes with SCI either.

The relatively small literature regarding body composition in the SCI athletic population is further confounded by: (a) small sample sizes, (b) inclusion of all types of physical disabilities in addition to SCI, (c) combining quadriplegic and paraplegic athletes in their analyses, and, (d) either do not include a sedentary comparison group or include a sedentary AB control group rather than a sedentary SCI group. Also, comparisons of studies are difficult because the body composition assessment methods used vary from field methods, such as skinfolds and BIA, to clinical methods, such as total body electrical conductivity (TOBEC), DXA, and MRI. It is likely that multicenter studies are needed to enable the use of larger sample sizes and standard methodology to create better prediction equations for the SCI athlete population.

115.4.2 What Is the Level of Physical Activity Needed to Result in Body Composition Changes in Individuals with SCI?

Exercise intervention studies have had equivocal results; nevertheless, most have found no association between physical activity and changes in body composition (Midha et al. 1999; Duran et al. 2001; Bizzarini et al. 2005). However, the duration and exercise intensity of these interventions vary

with a range of 6–10 weeks at 55–90% of maximum heart rate. These may not be sufficient to invoke changes in body composition or changes that are detectable by the sensitivity of methods used in these studies in the absence of a concurrent dietary intervention. Main factors that appear to be associated with change in body composition of athletes with SCI are training load and age (Inukai et al. 2006). Therefore, this chapter primarily presents studies where data were obtained from athletes of a variety of sports, competing at national and international levels, and whose training regimens involved high-intensity activity over several years. Thus, these data are not necessarily generalizable to individuals who perform habitual physical activity at a low or moderate intensity. Longitudinal exercise interventions that include different levels of intensity are needed to determine physical activity recommendations for SCI populations with respect to invoking favorable changes in body composition and health status.

Summary Points

- As with sedentary individuals with SCI, lower-body lean mass is reduced in SCI athletes due to muscle atrophy.
- Although %BF predicted from skinfold measurements are correlated with DXA %BF measurements in athletes with SCI, skinfold prediction equations underestimate measured %BF.
- %BF predicted from BIA results in wide variation and does not correlate well with DXA %BF measurements.
- Underlying body-density assumptions are likely to impact the inaccuracy of %BF prediction equations in athletes with SCI.
- It appears that long-term high-intensity physical activity is required to invoke body composition changes, and for these changes to contribute to health benefits.
- The current body of literature on anthropometry in athletes with SCI is limited, and further studies that include large sample sizes and standardized methodology are needed.

Key Features

Table 115.5 Key points of body composition assessment in athletes with spinal cord injury (SCI)

As a result of upper-body exercise, athletes with SCI have increased arm and trunk lean soft tissue compared to sedentary able-bodied individuals, and decreased arm fat mass compared to sedentary SCI.
Field body composition methods, such as skinfolds and bioelectrical impedance analysis, typically used by practitioners working with athletes, do not appear to be accurate or reliable for use in athletes with SCI.
Factors that impact prediction error and accuracy when using field body composition assessment methods in athletes with SCI include altered lean soft-tissue and fat-mass distribution depending on SCI level, difficulty of obtaining precise skinfold measurements at certain sites, fluid retention and hydration status, and inaccuracy of body density assumptions used in prediction equations.

This table lists key points of body composition in athletes with spinal cord injury discussed in this chapter.
SCI = spinal cord injury

Chapter 116
Anthropometry in 55–75-Year Olds in Response to Exercise

Melanie I. Stuckey, Anna M. Chudyk, and Robert J. Petrella

Abstract As the population ages, physical activity in older adults is increasingly important for the maintenance of health and independence to prevent further burden on the health care system and to preserve quality of life. As people age, they tend to do less activity at a lower intensity. This leads to decreased energy expenditure and ultimately body composition changes that have adverse effects. Increased fat mass is related to development of diabetes and other cardiovascular diseases. Decreased muscle mass leads to frailty, falls and loss of independence. Decreased bone mineral density often results in osteoporosis, which increases the risk of fracture and subsequent morbidity and mortality. While physical activity and exercise cannot necessarily reverse the aging process, these changes can be significantly attenuated if sufficient activity is performed. Aerobic exercise has positive effects on the cardiovascular system and may reduce fat mass. Unfortunately, it may result in reduced muscle mass and it does not have positive effects on bone mineral density unless it is weight bearing exercise of sufficient intensity. Progressive resistance training effectively maintains muscle mass and bone mineral density and may reduce fat mass, depending on the protocol. Resistance exercise improves glycaemic control in diabetics and it is the best type of exercise to reduce the risk of falling. One of the most effective ways to trigger a behaviour change in older adults is for the advice to come from a physician. Indeed, physician prescribed exercise has been shown to positively affect anthropometric indices, fitness and cardiovascular risk factors in older adults.

116.1 Introduction

Exercise and sport activities play an important role in older adults to maintain health and independence. Unfortunately, many people become more sedentary over time, exacerbating the effects of aging. As the population ages, the burden on the healthcare system will increase; hence, preventative interventions should be a priority. The following chapter will briefly review the normal aging process and associated diseases, then discuss how exercise attenuates these changes and improves health outcomes. Finally, practical applications will be discussed regarding how exercise programming can be best delivered in this population of adults aged 55–75 years.

116.2 Age-Associated Changes in Body Composition

Aging is accompanied by a number of anthropometric changes including decreased height and increased body weight. There is also often a decrease in upper-arm- and thigh circumferences associated with decreased muscle mass and an increase in waist circumference associated with abdominal obesity. Changes in body composition associated with aging generally include increased fat mass and decreased muscle mass and bone mineral density (BMD). These changes result partly from the natural slowing of metabolism with age and partly from decreased quantity and intensity of physical activity, which commonly occurs as people age. Changes in body composition may be difficult to assess because they often occur with no change in body weight, which is the most popular means by which people monitor themselves at home. Although a young adult and an older adult may have similar body weight and body mass index (BMI), the actual mass and quality of their muscle are not equal, nor is their adipose distribution (St-Onge 2005). This highlights the fact that specific tools and protocols are necessary to measure body composition in older adults. Dual energy x-ray absorptiometry (DXA) is useful to assess the three main compartments: fat mass, muscle mass, and BMD. The sub-compartments measured by computed tomography (CT) or magnetic resonance imaging (MRI) show more important differences than measures of the major compartments, but these are less often completed due to cost, equipment, and skill necessary to attain and analyze these measures. A study using DXA and MRI measures noted that, over a two-year follow-up period in 65-year-old women, skeletal and leg muscle mass and BMD decreased and visceral and intramuscular adipose tissue increased despite no change in either body weight or BMI (St-Onge 2005). Magnetic resonance spectroscopy (MRS) can be used to determine the location of fat within muscles and organs. Cross-sectional studies with MRS have found increased intramyocellular (inside the muscle cell) and liver fat content in older compared to young adults (St-Onge 2005). For more examples of body composition changes with aging, refer to the review by St-Onge (2005).

Numerous physiological changes occur with aging that lead to increased risk of cardiovascular diseases (CVD) and mortality. These include decreased cardiorespiratory fitness, decreased insulin sensitivity, and increased vascular stiffness. Whereas a discussion of these factors is beyond the scope of this chapter, it is important to keep them in mind, since exercise positively affects these and other factors important to quality of life and longevity in older adults.

116.2.1 Fat Mass

Aging is often accompanied by increased whole-body adiposity. Adults generally gain weight from young adulthood up until approximately 65–75 years of age. Thereafter, there is a steady decline in body weight associated with frailty and mortality. Increased fat mass is the primary cause of increased body weight. There tends to be a greater increase in central adiposity, increasing the risk of CVD including diabetes, hypertension, myocardial infarction, and stroke. A recent longitudinal study showed that, over an average 9.4-year follow-up period, women gained body weight and fat mass, whereas men did not change body weight, but fat mass measured by hydrodensitometry was significantly increased (Hughes et al. 2004). In this same study, there was an increase in waist circumference in women, but not in men. Interestingly, despite an increase in overall and central adiposity, there was a decrease in fat estimated by skinfold thicknesses (Hughes et al. 2004). Therefore, using skinfold thicknesses to estimate fat mass over a long-term follow-up period is inappropriate in older adults due to the redistribution of fat to central visceral locations.

116.2.2 Muscle Mass

The age-related loss of muscle mass, termed sarcopenia, results from a decreased number and size of muscle fibres. Quadriceps muscle mass can be decreased by 30% or more. Type II, or fast-twitch, fibres are affected most by this condition. Since these fibres are necessary for power and higher-intensity movements, loss results in decreased strength and power and may result in loss of independence when maximal strength drops below that needed for activities of daily living. In older adults, it has been shown that thigh circumference in women and arm circumference in men are significantly decreased over an average of 9.4 years (Hughes et al. 2004). These circumferences are associated with muscle mass and, in women, the decrease occurred despite the fact that self-reported physical activity levels were maintained. In men, there was a significant decrease in physical activity over the 10-year follow-up period, which may explain in part the loss of muscle mass.

Sarcopenic obesity is a relatively new category of obesity for the elderly. As the name suggests, this condition is a combination of decreased muscle mass and increased fat mass and it is thought that the adverse effects are potentiated by the presence of both. Currently, there is no specific definition for the disease. Some researchers classify sarcopenic obesity as a person with a fat mass in the upper two quintiles and a muscle mass in the lower three quintiles according to age and sex. Others use a DXA-derived appendicular skeletal muscle mass per height squared less than two standard deviations below the mean of a sex-specific group and body fat percentage greater than 27% in men and 38% in women (Zamboni et al. 2008). Although little research has examined sarcopenic obesity in detail, older adults with this condition may be more likely to have physical disabilities than those with only obesity or sarcopenia; however, findings are equivocal. More research is needed to study this newly recognized phenomenon to conclude whether or not it is harmful to the elderly population.

116.2.3 Bone Mineral Density

Loss of BMD occurs with normal aging in both men and women. Increased stress on the bone, which can occur with increased body weight or weight-bearing activity, is needed to increase or maintain BMD. Since abdominal obesity appears to protect bone, weight loss in the absence of exercise may have detrimental effects on BMD. Osteopenia is a preclinical decrease in BMD that often leads to osteoporosis. This condition is most common in postmenopausal women and increases the risk of fracture and disability. It is also important to note that once osteoporosis is diagnosed, special precautions must be undertaken during exercise. For example, forward flexion should be limited to prevent spontaneous fracture of the spine.

Although aging is associated with body composition changes, regular physical activity, and exercise can help to counter or attenuate these changes, reducing the risk of dependence, morbidity, and mortality. The following section will describe how different types of exercise alter anthropometric indices and health status in older adults.

116.3 Anthropometric changes in response to exercise

116.3.1 Active Living

Active living involves finding ways to incorporate physical activity into daily living. This includes lifestyle modifications such as walking instead of driving to the mailbox or taking the stairs instead of the elevator. Assessment of leisure-time physical activity is one way to capture the amount of activity completed over a range of intensities from sedentary (low physical activity) behaviors, such as reading and watching television, to vigorous activities, such as competitive sports and hard physical training. A study by Byberg and associates (2009) showed that all-cause mortality rate was significantly less in the high physical activity group than in either the low or moderate physical activity group. This study shows that although moderate activity, such as pleasure walking and cycling, offered benefits compared to sedentary behaviours, greater benefits resulted from higher activity levels. Additionally, active living may have positive effects on energy expenditure and mobility, but it does not attain the intensity necessary to elicit changes in BMD or muscle mass. Therefore, it is better for an older adult to be moderately active than sedentary, but maximal benefits are attained from higher intensities of physical activity.

116.3.2 Aerobic Exercise

Aerobic exercise is repetitive movement that increases heart rate and oxygen uptake (VO_2). Walking is most commonly performed in older adults because it is relatively low impact, inexpensive, and can be done almost anywhere. Other types of aerobic exercise are cycling, swimming, and aerobic dance. The American College of Sports Medicine (ACSM) 2009 guidelines recommend that older adults exercise at least three days per week at a minimum intensity of 60% of maximum oxygen uptake (VO_2max). Exercise can be completed in short bouts of 10 min as long as 30–60 min/day are completed for moderate or 20–30 min/day for vigorous intensity aerobic exercise (Chodzko-Zajko et al. 2009). Key facts about VO_2 are explained in Table 116.1.

Table 116.1 Key facts about oxygen uptake (VO_2)

VO_2…
• Is the amount of oxygen used by the muscle.
• May be expressed in absolute (L/min) or relative (ml/kg/min) units.
VO_2max
• Is the maximum amount of oxygen that can be used by the muscle.
• Is an index of aerobic fitness.
• Is linearly related to heart rate.
• Is estimated by measuring gas exchange at the mouth.
• Testing involves exercising to fatigue (usually on a treadmill or cycle ergometer).
• May be estimated with submaximal tests (i.e., exercising to a submaximal heart rate and estimating VO_2max based on its relationship with heart rate).
• Generally decreases with age, disease, and sedentary lifestyle.
VO_2peak
• Is the term used to describe the maximum amount of oxygen used by the muscle when there is doubt that a true maximum was reached during an exercise test.
• Is often used in populations of older adults or people with diseases.

This table highlights the importance of measuring maximal oxygen consumption, including its general meaning and relevance. *VO_2max*: maximal oxygen uptake; *VO_2peak*: peak oxygen uptake

Aerobic exercise is beneficial to older adults because it increases cardiorespiratory fitness and mobility and may decrease fat mass. However, a recent study (Nicklas et al. 2009) showed that calorie reduction decreased body weight and fat mass equally in all groups whether calorie reduction was through diet alone, diet plus moderate exercise, or diet plus vigorous exercise. There were also similar reductions in metabolic risk factors including cholesterol profiles, fasting glucose, and insulin (Nicklas et al. 2009), suggesting that changes in body composition and risk were due to weight loss, not exercise. This study also reported similar decreases in lean mass in all three groups, supporting previous findings that aerobic exercise is not a sufficient stimulus to maintain muscle mass (Nicklas et al. 2009).

116.3.3 Resistance Exercise

Resistance or strength exercise involves using muscular effort against an opposing force. The most common resistance exercise is weight lifting, but exercises can also be done using resistive tubing or body weight. The 2009 ACSM guidelines recommend that resistance exercises be performed at least two days per week. Eight to ten repetitions should be completed for eight to ten exercises to target upper and lower body (Chodzko-Zajko et al. 2009).

Strength training is especially important in older adults, as it is essential for the maintenance of muscle mass and BMD. Progressive resistance training (PRT) is a type of training where the load is constantly increased as strength is gained so that the intensity of the exercise is maintained. A 16-week PRT program was delivered to young and old men and women to assess the effectiveness of performing strength training three times per week for 16 weeks to counter sarcopenia (Kosek et al. 2006). This trial found that whereas there was no training effect for body composition improvements, strength was improved in all four groups. There were also changes in muscle composition that differed for older and young adults. There was an increase in type I muscle fibres in the young, but not older adults, whereas type IIa fibres hypertrophied in both young and old, though to a greater extent in young adults (Kosek et al. 2006). Additionally, there were no significant increases in fibre cross-sectional area in older women, though it tended to increase for type IIa fibres (Kosek et al. 2006).

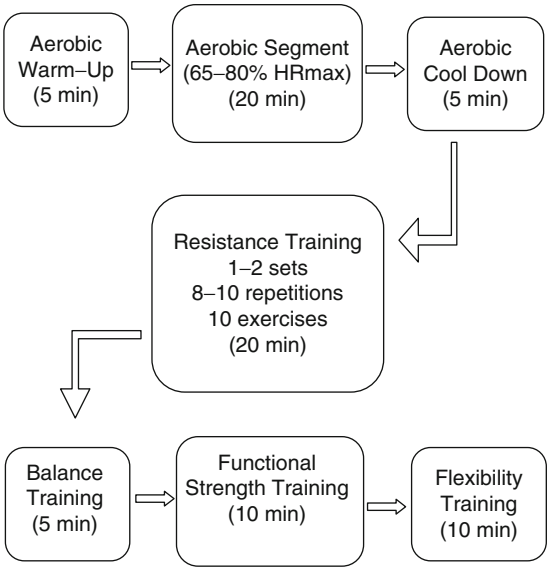

Fig. 116.1 Flowchart of the composition of a 75-min exercise class for older adults at the Canadian Centre for Activity and Aging. (Adapted from Tudor-Locke et al. 1997.) This figure shows the composition of a typical class delivered by the Canadian Centre for Activity and Aging in London, Ontario, Canada. Modifications are made for special populations. HR_{max}: Maximum predicted heart rate

This may be clinically significant, as sarcopenia affects primarily type II muscle fibres. Therefore, though overall muscle mass was not changed with 16 weeks of PRT, the cellular changes suggest that a longer training stimulus may increase muscle mass. This also highlights the generally accepted notion that improved strength in the first few weeks of PRT is primarily due to neural adaptations including improved motoneuron recruitment and decreased contraction of opposing muscle groups. Longer training programmes may be necessary to elicit changes in muscle mass in older adults.

116.3.4 Combined

Combined exercise is likely most beneficial to older adults to get optimal benefits for fat-mass reduction and muscle-mass- and BMD increases. The Canadian Centre for Activity and Aging incorporates this standard in its model for delivering community-based exercise programmes for older adults. Composition of a usual class is shown in Fig. 116.1, though this format is modified for special populations (Tudor-Locke et al. 1997).

A combined programme was recently used to examine the effects of exercise on body composition and BMD. The programme consisted of stretching exercises followed by two sets of 10–15 repetitions of seven resistance exercises for the upper and lower body and 45 min of aerobic exercise at 60–90% of peak oxygen uptake (VO_2peak) (Stewart et al. 2005). After six months of training, both men and women had significantly increased VO_2peak, strength, and total and percent lean mass assessed with DXA. There were also significant decreases in body weight, BMI, total and percent body fat, and visceral and subcutaneous body fat (Stewart et al. 2005). There were no changes in BMD in men and slight decreases in total and greater trochanter BMD in women. However, Pearson correlations showed that, in women, increases in femoral neck BMD were related to increased

Table 116.2 Exercise guidelines for older adults

Type	Frequency	Intensity	Duration
Aerobic	≥3×/week	≥60% VO_2max (moderate to vigorous)	Moderate intensity: 30–60 min/day. Vigorous intensity: 20–30 min/day.
Resistance	≥2×/week	Moderate to vigorous	Eight to ten exercises for the whole body. Eight to ten repetitions.

This table summarizes guidelines for aerobic and resistance training that should be followed by older adults. VO_2max: Maximal oxygen uptake

VO_2peak, decreased BMI and decreased body weight (Stewart et al. 2005). Therefore, although there was an overall decrease in BMD in women, those who had the greatest increases in VO_2peak (which usually occur at higher exercise intensities) actually increased BMD. Likewise, for men, increases in BMD were associated with increases in lean mass and lower body strength (Stewart et al. 2005). It appears that exercise intensity is important to elicit changes in BMD, whether it is high-intensity aerobic training (likely weight bearing) in women or high-intensity resistance training in men.

116.4 Summary of Exercise Training Protocols

Table 116.2 is a summary of current exercise recommendations for older adults.

116.5 Special Concerns for Older Adults

116.5.1 Dependence

Dependence not only imposes a significant burden upon the healthcare system, it, more importantly, decreases quality of life. As mentioned above, aging is associated with a decrease in muscle mass and cardiorespiratory fitness. Once, one or both of these variables reaches a threshold, activities of daily living can no longer be carried out. Multivariate modeling has shown that cardiorespiratory fitness is the most important determinant of independence in the elderly (Paterson et al. 2004), highlighting the importance of physical activity in older adults. In this study, body composition was not a significant determinant of independence, but BMI was the only index of body composition included. The limitations of BMI have been previously discussed. Another study found that although lean mass was not associated with future functional limitation, the ratio of lean mass to fat mass was (Haight et al. 2005). For women, the benefits of an increased lean mass-to-fat mass ratio were not as great in the absence of physical activity.

116.5.2 Falls

There are a number of changes that occur in older adults that increase the chance of falling (Table 116.3). Most important for this textbook is the decrease in muscle mass associated with aging. Interestingly, a study that examined the effects of three different training programmes (resistance, agility, and

Table 116.3 Changes with age that increase the risk of falling in older adults

Falling risk in older adults
Decreased muscle mass
Decreased balance
Slowed reaction time
Decreased vision
Joint disorders of the knee and hip
Gait and posture disturbances
Cognitive impairment
Orthostatic hypotension

This table lists some of the factors that are associated with falls in older adults

stretching) found that all three reduced the risk of falling (Liu-Ambrose et al. 2004). Stretching was the least effective, but still reduced the risk of falls by 20%. Agility training reduced the risk of falling by 48%, but resistance training was most effective, reducing the risk of falling by 57%. Considering that resistance training may also have had secondary effects, such as increased BMD, this training could significantly reduce the risk of fracture and dependence in this population. Since hip fracture is one of the leading causes of hospitalization and subsequent death in older adults, a resistance training programme is beneficial to aging populations.

116.5.3 Diabetes

Aerobic exercise is generally accepted as a safe and effective lifestyle intervention to complement medical control of blood sugar and insulin levels. The 2008 Canadian Diabetes Association Guidelines recommends that diabetics perform a minimum of 150 min of moderate to vigorous aerobic exercise each week spread over at least 3 days (Bhattacharyya et al. 2008). Exercise should be spread out over the week, as physical activity's effect on insulin and blood glucose lasts for longer than 24, but less than 48 h. One of the issues with this recommendation is that it is difficult to get sedentary people to adhere to a moderate to vigorous intensity exercise programme. A study (Hansen et al. 2009) found that when exercise expenditure was matched, there was a greater decrease in trunk fat mass in the moderate- to high-intensity group than in the low- to moderate-intensity group despite no significant differences in body weight, BMI, leg fat mass or trunk or leg lean mass. Although the moderate- to high-intensity group had greater anthropometric improvements during this 6-month intervention, this did not translate into greater glycaemic control. At 6 months, glycated haemoglobin (HbA1c), which gives an index of glycaemic control over the past three months, was improved equally in the low- to moderate- and moderate- to high-intensity groups (Hansen et al. 2009). Other measures of insulin sensitivity and glycaemic control showed similar results. Therefore, the intensity of the exercise may not be of utmost importance when prescribing exercise for diabetics. Although more long-term research with larger sample sizes is needed, at the current time, it is likely more important to get the diabetic patient to initiate and adhere to an exercise programme, irrespective of intensity. However, cardiovascular complications are one of the major concerns for diabetics and body composition modification may offer greater cardiovascular protection in this population.

Dunstan and colleagues (2002) showed that adding PRT to a weight-loss regimen for diabetic patients was beneficial. Whereas weight-loss groups with or without PRT both attained decreases in body weight, waist circumference, and fat mass measured by DXA, there was a significant group

Table 116.4 Cardiovascular risk factors

Modifiable	Non-modifiable
Obesity	Family History
High blood pressure	Sex
High cholesterol	Age
Smoking	
Psychological stress or depression	
Physical inactivity	
Diet low in fruits and vegetables	

This table lists factors that increase the risk of cardiovascular disease

time interaction showing that the PRT group increased lean body mass, while the group without PRT actually decreased lean body mass over the 6-month intervention. Additionally, HbA1c decreased from 8.1% to 6.9% over 6 months in the PRT group, whereas there was no change in the weight-loss-only group (Dunstan et al. 2002). This is clinically significant because the goal for diabetics is to reach an HbA1c level below 7.0%, which was accomplished in the PRT group. Additionally, each 1% improvement in HbA1c results in a 15–20% decrease in cardiovascular risk in diabetics. Further lowering cardiovascular risk, the 6-month PRT plus weight loss intervention also resulted in an average decrease of systolic and diastolic blood pressure by 6.7 and 4.4 mmHg, respectively (Dunstan et al. 2002). Systolic blood pressure was 145 mmHg at baseline; hence, whereas the diabetic target of 135 mmHg was not reached during this intervention, cardiovascular risk was decreased and a longer trial may have resulted in attainment of target blood pressure.

116.5.4 Cardiovascular Disease

CVD is the leading cause of mortality in North America. Although there is a genetic component often associated with early-onset CVD, later in life, CVD is often related to poor lifestyle habits including inactivity. Modifiable and non-modifiable cardiovascular risk factors are shown in Table 116.4. Essential hypertension is one of the leading risk factors of CVD and is highly prevalent worldwide, especially in developed and developing countries. Numerous studies have shown that aerobic exercise reduces blood pressure and limited studies have shown blood-pressure reductions following resistance exercise. A recent study examined the effects of exercise intensity on blood pressure in adult men and women aged 55 years and older (Cornelissen et al. 2009). This study found that, whereas both low-intensity (33% heart rate reserve (HRR)) and high-intensity (66% HRR) aerobic exercise lowered systolic blood pressure to a similar degree, only the high-intensity exercise improved body composition as evidenced by reduced body weight, BMI, body fat, and waist circumference (Cornelissen et al. 2009). Exercise sessions were held three times per week and consisted of treadmill walking or jogging, stationary cycling, stepping, or a combination of these exercises. Similar to the improvements in glycaemic control in the above-mentioned type 2 diabetic trial, improvements in blood pressure were independent of improvements in anthropometric indices. Long-term studies would be interesting to assess whether the reduction in body weight with high-intensity exercise provides additional cardiovascular protection.

Petrella and colleagues (2005) proved that commencing a supervised exercise programme later in life (average age 68 ± 5 years) provided beneficial effects on cardiovascular risk factors. Although many risk factors were not actually improved over an eight-to-ten-year follow-up period, the exercise

group had less of an increase in systolic blood pressure, total cholesterol, and low-density lipoprotein cholesterol compared to the sedentary group. The exercise group showed a slight increase in high-density lipoprotein cholesterol as opposed to a significant decrease in the sedentary group and a decrease in triglycerides as opposed to an increase in sedentary. Waist circumference was only increased by 2 cm in the exercise group, as opposed to 10 cm in the sedentary group. Additionally, the exercise group maintained their maximal activity level (expressed in metabolic equivalents: METs), whereas the sedentary group experienced a 13.79% decrease over 10 years. Interestingly, a recent study (Byberg et al. 2009) found that men, who increased their activity level between the ages of 50 and 60 years, had no difference in all-cause mortality compared to the sedentary group in the first five years, but, following ten years of increased activity, their mortality rate declined to the same as that of men who had been doing high physical activity previous to the beginning of the study. Collectively, this shows that beginning a relatively intense exercise programme later in life (50 years of age and beyond) effectively decreases the risk of CVD and all-cause mortality, but that more than five years of exercise is needed to achieve these long-term benefits.

116.6 Clinical Applications: Exercise Prescription

As discussed through this chapter, exercise is beneficial for older adults and considerable adaptations can occur, even if an exercise program is not taken on until later in life. One of the major issues, however, is how to get an older adult to commence one. One of the most effective ways to trigger a behaviour change in this population is for the recommendation to come from the family physician. Unfortunately, during physician visits, little time is devoted to physical activity counselling, which may be a result of lack of time, training, knowledge, or instruments and materials. The Step Test Exercise Prescription (STEP™) project was carried out to test the effectiveness of a short, simple test to predict VO_2max and prescribe physical activity to older adults (Petrella et al. 2003). The protocol for the STEP™ test is shown in Fig. 116.2 and key facts are explained in Table 116.5. Following the test, a few minutes were devoted to discussing physical activity goals and barriers and an individualized exercise prescription was written out. In healthy older adults, this prescription alone resulted in increased VO_2max compared to a group that did not receive a prescription at 6 or 12 months (Fig. 116.3). The STEP™ group also showed increased exercise self-efficacy and decreased systolic blood pressure and BMI compared to the control group.

As discussed in detail previously (Section 8 of this textbook), the metabolic syndrome is a clustering of risk factors that puts an individual at an increased risk of CVD. The Staged Nutrition and Activity Counselling (SNAC) study examined the effects of exercise prescription using the STEP™ protocol and physician recommendation to follow the Mediterranean diet in participants with and without the metabolic syndrome (Aizawa et al. 2009). Results showed increased VO_2 max in groups with and without the metabolic syndrome. The group with the metabolic syndrome showed improvement of risk factors at 24 weeks, as shown in Table 116.6. Changes were accompanied by decreased arterial stiffness, further improving cardiovascular health.

In a high-risk population, such as with metabolic syndrome, it may be worthwhile to monitor its risk factors more closely. The Diabetes and Technology for Increased Activity (DaTA) pilot study, utilized the STEP™ test and exercise prescription along with remote monitoring of risk factors to examine the effectiveness of increased activity to reduce the impact of metabolic syndrome. Participants received a Bluetooth™-enabled glucometer and blood-pressure monitor, a pedometer and a heart-rate monitor (Fig. 116.4). A BlackBerry® cellular telephone with HealthAnywhere® software

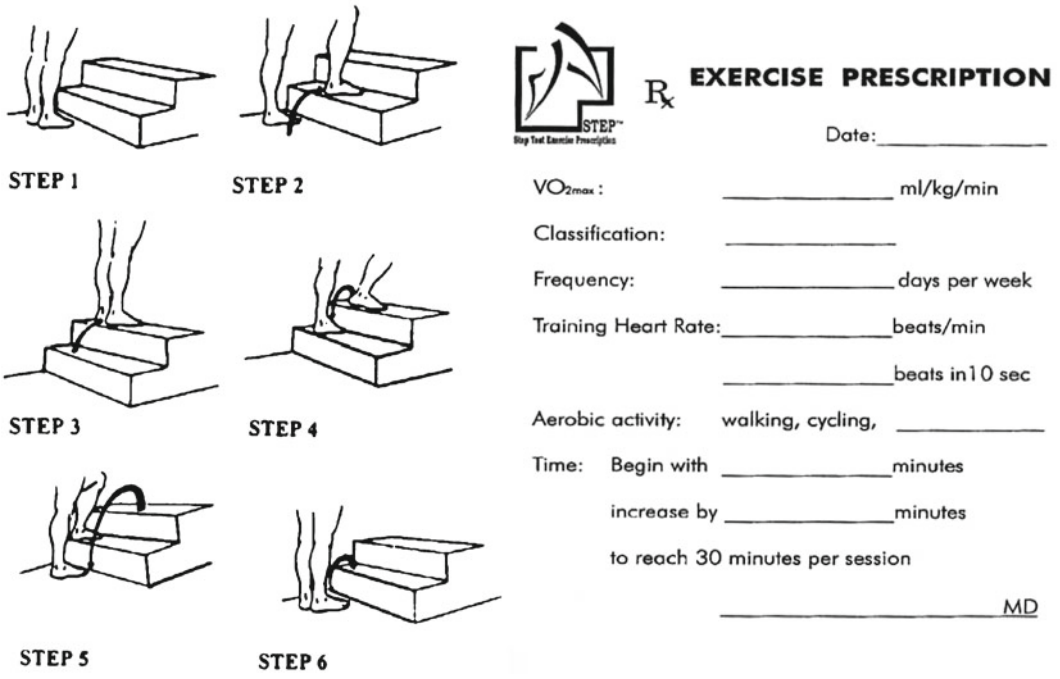

Fig. 116.2 STEP™ Test protocol. Patient steps up and down the stairs 20 times. Heart rate is assessed before and after the test. VO_2max is predicted using a validated equation that incorporates body weight, age, sex, time to completion of test, and heart rate at the end of the test. This figure shows how the STEP™ test is done. On the left, it shows one cycle of the test. The exercise prescription on the right would be filled out by the healthcare professional and given to the patient. VO_{2max}: maximal oxygen uptake

Table 116.5 Summary of key facts about the STEP™ test

STEP™ test
Protocol:
• The healthcare professional administering the test measures resting heart rate and blood pressure.
• The test is described and completed as shown in Fig. 116.4.
• At the end of the test, heart rate and blood pressure are measured.
• The following equation is used to calculate predicted VO_2max:
1. (1511/time) × weight/heart rate = _____
2. ([answer from step 1.] × 0.124) – (age × 0.032) – (sex × 0.633) + 3.9 = _____
3. ([answer from step 2.] × 1000)/weight = VO_2max
◦ where, 'time' is the time to complete the STEP™ test in seconds, 'weight' is body weight in kg, 'heart rate' is the heart rate at the end of the STEP™ test in beats per minute, age is in years, 'sex' is 1 for males and 2 for females, and VO_2max is expressed in ml/kg/min.
Significance:
• This test is a practical tool for exercise assessment in a clinical setting. Exercise stress testing is difficult for the patient, requires specialized staff, is time consuming, and is costly to the healthcare system. The STEP™ test is relatively short and simple to conduct.
• Tools and guidelines are provided to healthcare professionals for exercise testing and prescription. The intention is to increase the amount of time spent discussing physical activity habits and to provide safe and effective exercise advice to patients.

This table summarizes some key points about the STEP™ test and exercise prescription including how it is completed and why it is important. VO_2max: Maximal oxygen uptake

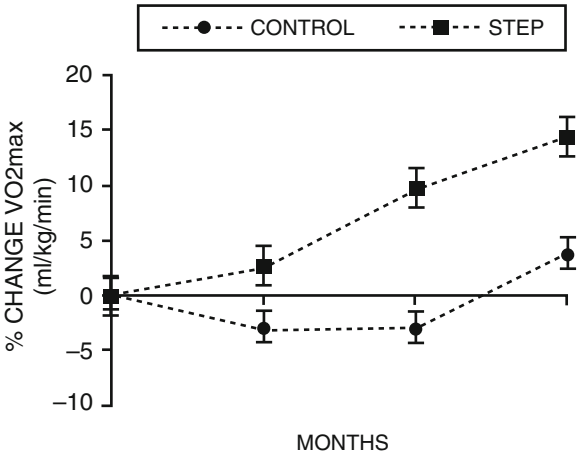

Fig. 116.3 Percent change in VO_2max at baseline, 3, 6, and 9 months following STEP™ assessment and exercise prescription or control. Reprinted with permission from Elsevier (Petrella et al. 2003). This figure shows the changes in VO_2max that occurred over a nine-month follow-up period when older adults either (a) were assessed using the STEP™ test and exercise prescription or (b) received usual care from their family physician. The STEP group had greater improvements in cardiorespiratory fitness than the control group. *VO_2max*: maximal oxygen uptake

Table 116.6 Summary of the changes in metabolic syndrome risk factors following a 24-week intervention in the SNAC study (Adapted from Aizawa et al. 2009)

Changes in metabolic syndrome risk factors
Decreased weight
Decreased BMI
Decreased waist circumference
Decreased systolic and diastolic blood pressure
Decreased fasting glucose
Decreased total and low-density lipoprotein cholesterol

This table shows what metabolic syndrome risk factors changed following a 24-week nutrition and physical activity intervention

acted as an interface for data to be transmitted from the devices to a secure database that was monitored by investigators. Over the two-month intervention period, physical activity increased as evidenced by an increase in predicted VO_2max from the STEP™ test and an overall increase in steps per day recorded by the pedometer (Russell-Minda et al. 2009). These were accompanied by decreased diastolic blood pressure, BMI, waist circumference and cholesterol. The pilot study was done to prove the feasibility of using the technology and showed that overall compliance was high (an average of 96.81 ± 3.98% of all measures was transmitted from the participants) and that it was not a great burden to the participants (Stuckey et al. 2009). Remote monitoring of diabetic patients using cellular telephone technology has been shown to be particularly effective in older adults (Kwon et al. 2004). A similar type of monitoring may be effective to promote increased levels of physical activity and to monitor anthropometric and cardiovascular risks in older adults. A larger study to assess clinical outcomes associated with using technology to remotely monitor high-risk adults is currently underway.

In summary, the STEP™ test is an effective tool for physicians to use to promote physical activity in older adults. People who were given a written physical activity prescription showed increased fitness, modified anthropometric measures, and decreased cardiovascular risk (Table 116.5). Physical

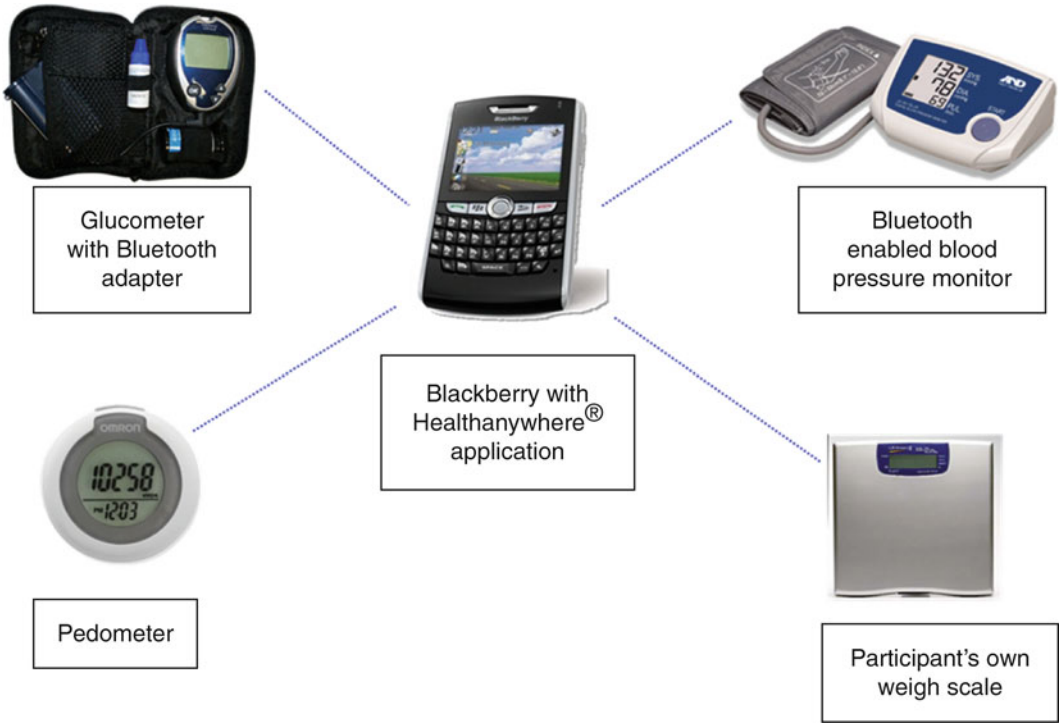

Fig. 116.4 Devices provided to participants of the DaTA pilot study. This figure shows the devices used for home monitoring of cardiovascular risk factors in the DaTA pilot study. Bluetooth-enabled glucometer and blood-pressure monitor were used for twice daily blood glucose and thrice weekly blood pressure evaluation, respectively. Pedometer was used to monitor daily activity with step count and the weigh scale was used to monitor weight weekly. All measurements were entered into the Blackberry and automatically sent to a secure database to be monitored by researchers

activity and exercise in older adults is a key component for maintaining health and fitness, and, ultimately, for retaining independence for as long as possible. Table 116.8 reviews key points to note about exercise in older adults.

Summary Points

- Aging is associated with a decline in muscle mass and bone mineral density and an increase in fat mass.
- Aerobic exercise training of sufficient intensity results in improved cardiorespiratory fitness and may reduce body weight, but only if negative calorie balance is reached.
- Resistance-exercise training following recommendations increases strength and may have positive effects on muscle mass, bone mineral density, and fat mass.
- Physical activity is important in older adults to prevent falls and maintain independence.
- Exercise helps to manage glycaemic control in diabetic patients and blood pressure in hypertensive patients.
- The STEP™ test is an effective means of assessing fitness in a clinic setting. Exercise prescription leads to positive changes in cardiorespiratory fitness, anthropometric indices, and cardiovascular risk.

Key Features

Table 116.7 Summary of changes in anthropometry, fitness, and cardiovascular risk after receiving an exercise prescription from a clinical setting

Modifications elicited by exercise prescription via the STEP™ test
Anthropometry
Decreased waist circumference
Decreased BMI
Decreased weight
Fitness
Increased VO_2max
Increased steps per day
Cardiovascular risk
Decreased systolic and diastolic blood pressure
Decreased cholesterol
Decreased arterial stiffness

This table summarizes the findings from different studies in which the STEP™ test was performed in a clinical setting and exercise prescription was given by clinic staff

Table 116.8 Summary of key facts about exercise in older adults

Key facts: Exercise in older adults
• Higher intensity exercise results in greater body composition modifications, though low intensity exercise is sufficient to improve glycaemic control and blood pressure.
• Higher exercise intensities elicit greater improvements in cardiorespiratory fitness, which are positively associated with longevity and independence.
• Exercise programmes adopted later in life are beneficial in reducing the chance of dependence and reducing the risk of morbidity and mortality.
• Written exercise prescriptions from a family physician or affiliated exercise specialist are effective means for triggering behaviour change and subsequent commencement of an exercise programme.

This table summarizes some key points that are important to keep in mind when prescribing exercise to older adults

Chapter 117
Anthropometry and Exercise in Obesity

Fusun ARDIC

Abstract This chapter aims to review the effects of exercise on body measurements in overweight and obese people. Firstly, obesity is described in detail with regard to frequently associated medical problems and weight-related health risk. The necessity of the inclusion of an exercise training program in obesity management is underlined, and exercise training and exercise prescription for obese patients described. An overview of the anthropometric measurements used in assessing body fat distribution and monitoring the changes in body composition over an exercise training program in obese people is presented. The most commonly used body measurement methods in obesity outcome studies include simple anthropometric measurements and body composition measurement techniques. The outcome of body composition alterations with exercise is summarized as a slight decrease in total body weight, prevention of decrease in fat-free mass and relative increase in visceral fat-mass loss. The magnitude of these changes varies directly with the intensity, duration, and type of the exercise, e.g., aerobic versus strength training. The implementation of resistance exercise improves body composition by increasing fat-free mass. Dissimilar results of exercises on genders should be taken into consideration in obese men and women. Studies with a longer follow-up duration would provide further information regarding the effects of regular exercise in overweight or obese people.

Abbreviations

WHO	The World Health Organization
BMI	Body mass index
WC	Waist circumference
CVD	Cardiovascular disease
HRmax	Maximum heart rate
HRR	Heart rate reserve
METs	Metabolic equivalents
RPE	Rating of perceived exertion
VO_2max	Maximum oxygen consumption

117.1 Introduction

This chapter aims to review the effects of exercise on body measurements in overweight and obese people. The World Health Organization (WHO) defines overweight and obesity as abnormal or excessive fat accumulation that may impair health. Body mass index (BMI), which is calculated by dividing the weight by the square of the height (kg/m^2), is commonly used in classifying obesity in adults. A BMI of 25–29.9 and ≥30 defines overweight and obesity respectively (WHO 2006). Because obesity is associated with an increased risk of multiple health problems including hypertension, type 2 diabetes, dyslipidemia, degenerative joint disease, and some malignancies, it still remains as an important public health issue. Anthropometric measurements allow cross-sectional analysis of the relationship between obesity and the risk of chronic diseases.

The central reason in the development of obesity is an excess of energy intake relative to energy expenditure. This occurs due to the storage of energy excess as adipose tissue. The inclusion of an exercise training program is a useful strategy for reducing obesity. Exercise prescriptions include specific recommendations for the type, intensity, frequency, and duration of any physical activity with specific objectives like weight loss, increase of fitness.

Distribution of fat mass is as important as the amount of fat. As abdominal obesity is more related with the severity of chronic diseases, monitoring changes in abdominal adiposity are becoming important in obesity treatment. Anthropometric measurements are used in assessing body fat distribution and in tracking changes in body composition over exercise training programs in obese people.

117.2 Applications to Disease

117.2.1 Weight-Related Health Risk

As sedentary lifestyle and obesity are important lifestyles related to public health problems throughout the world resulting with serious medical conditions, excess body fat must be taken seriously. Abdominal excess fat (abdominal adiposity) is more correlated with obesity associated complications than excess total body fat. Moreover, waist circumference (WC) has been included among the diagnostic criteria for the metabolic syndrome consisting of diabetes mellitus, insulin resistance, and

Table 117.1 Classification of overweight and obesity by BMI, waist circumference and associated disease risk

	Disease risk[a] relative to normal weight and waist circumference		
	BMI (kg/m^2)	Men ≤ 102 cm (≤40 in.) Women ≤ 88 cm (≤35 in.)	> 102 cm (> 40 in.) > 88 cm (> 35 in.)
Underweight	<18.5	–	–
Normal weight[b]	18.5–24.9	–	–
Overweight	25–29.9	Increased	High
Obesity (class 1)	30–34.9	High	Very high
Obesity (class 2)	35–39.9	Very high	Very high
Extreme obesity (Class 3)	≥40	Extremely high	Extremely high

Bethesda (2000).

[a]Disease risk for type 2 diabetes, hypertension, and CVD

[b]Increased waist circumference can also be a marker for increased risk even in persons of normal weight

hypertriglyceridemia (Alberti et al. 2005). Insulin resistance is associated with increased visceral fat mass and with alterations in fat deposition within the skeletal muscle (Fenkçi et al. 2006). The National Heart Lung and Blood Institute Expert Panel used an evidence-based methodology in developing key recommendations for assessing and treating overweight and obese patients. The recommended classification for overweight and obesity by the Expert Panel is shown in Table 117.1 (Bethesda 2000). This classification includes WC values besides BMI in assessing the risk of type 2 diabetes, hypertension, and cardiovascular disease (CVD). According to the guidelines, assessment of overweight involves the evaluation of three key measures – body mass index (BMI), waist circumference, and a patient's risk factors for diseases and conditions associated with obesity. WC measurement is particularly useful in patients who are categorized as normal or overweight. Men who have waist circumferences greater than 40 in. (102 cm), and women who have waist circumferences greater than 35 in. (88 cm), are at a higher risk of diabetes, hypertension, and cardiovascular disease because of excess abdominal fat.

Physical inactivity and excess body mass are independent risk factors for CVD. The prevalence of coronary artery disease and high blood pressure exhibits a significant linear relationship with BMI for both genders and all ages. The presence of overweight or obesity is moderately associated with high blood cholesterol which is observed in both sexes without an increase with BMI classes. The relationship with increased triglyceride, low HDL cholesterol, and altered composition of lipoprotein particles are stronger than a high cholesterol level. Increased body weight is also associated with an increased risk of certain forms of cancer, including colon cancer, endometrial cancer, and postmenopausal breast cancer (Hansen et al. 2007). Monitoring the alteration in body fat is important in understanding the impact of different types of weight loss interventions on health benefits and risks.

117.2.2 Exercise Prescription

Weight reduction is an important first step in controlling health risk factors. There is sufficient evidence supporting the role of exercise training in promoting weight loss (Shaw et al. 2006). Studies about the metabolic effects of exercise have yielded contradictory results. Differences in intensity, type (aerobic or resistance), and duration of exercise protocols employed might be responsible for the discrepancies among these studies. The degree of glucose intolerance and distribution of body fat of enrolled subjects may suggest other explanations for conflicting results. In some studies, calorie-restricted diets were given to subjects concomitant with an exercise regimen. Differences in these dietary programs may affect the outcomes of exercise protocols.

117.2.3 Exercise Training

Intervention programs aimed at reducing body weight should include an exercise component. The exercise not only improved the measures of obesity and the metabolic risk factors but also improved the physical fitness in terms of endurance, strength, and flexibility of performance.

117.2.4 Definition of Terms

Physical activity is a broad term that encompasses all forms of muscle movement. These movements range from various sports to lifestyle activities. Furthermore, *exercise* can be defined as a physical activity with planned, structured and repetitive movement of the body designed to enhance physical fitness. The FITT principle of exercise prescription features an individually tailored exercise program including how many sessions a week one should exercise (*F*requency), how intense (*I*ntensity) and how long (*T*ime) the workout should be and what modality should be used (*T*ype of exercise).

117.2.5 Exercise Types

1. *Aerobic (Cardiovascular Endurance) Exercise (AE)*:
Cardiovascular endurance represents the ability of the circulatory and respiratory systems to supply oxygen during sustained physical activity. Aerobic exercise is defined as any activity using large muscle groups which can be maintained continuously and rhythmically (walking, running, stair climbing, swimming, cycling, rowing, dancing, etc.). It is a type of exercise that overloads the heart and lungs causing them to work harder and offers the greatest improvement with maximum oxygen consumption (VO_2max) (Table 117.2). Various methods such as the percent age-predicted maximum heart rate (HRmax) (220 – Age), heart rate reserve (HRR) which takes into account the resting heart rate, metabolic equivalents (METs), rating of perceived exertion (RPE), or VO_2 max can be used for prescribing the intensity of exercise. The duration of the exercise should be increased with adaptation unless evidence of undue fatigue or injury occurs (Thompson et al. 2009).

2. *Resistance Exercise (RE)*:
Muscular strength is the ability of muscles to exert force. Resistance exercise (strength training) refers to any type of training using a resistance against the force of muscular contraction. The recommendations proposed by the ACSM for resistance training exercise are summarized in Table 117.3 (Thompson et al. 2009). A stretching exercise program is also recommended to be included to an exercise training program (Thompson et al. 2009).

117.2.6 Exercise Prescription for Obese Patients

The effectiveness of exercise was investigated in several designs as a weight loss intervention in people with overweight or obesity in the literature (Shaw et al. 2006). These are – comparison of exercise with no treatment, comparison of exercise with a diet, comparison of exercise in combination with

Table 117.2 Key features of Aerobic Exercise (AE)

1. Aerobic exercise is physical exercise that intends to improve the oxygen system. Aerobic means "with oxygen" and refers to the use of oxygen in the body's metabolic or energy-generating process.
2. Aerobic activity makes the heart beat faster and breathe harder than usual. Aerobic activity strengthens the heart and improves lung function.
3. Aerobic capacity is defined as the ability of the body to transport and use oxygen and is dependent on the effective integration of both the cardiac and the pulmonary systems. The terms aerobic capacity, cardio respiratory (CR) fitness, maximum oxygen consumption (VO_2max) and cardiovascular fitness are used synonymously. These terms refer to the maximal capacity to produce energy aerobically and are usually expressed in METs or ml O_2/kg/min. One MET (metabolic equivalent unit) is equal to approximately 3.5 ml O_2/kg/min.
4. Aerobic activities that involve large muscle groups over prolonged periods of time offer the greatest improvement in VO_2 max. Examples of aerobic activities include walking, running, swimming, and bicycling, etc.
5. Exercise recommendations to improve CR fitness include four components; Frequency (how many sessions a week one should exercise), Intensity (how intense), Time (how long) and Type of exercise (modality which should be used) also known FITT principles.

This table lists the key facts of aerobic exercise including definition, basic concept and FITT principles of aerobic exercise

Table 117.3 Key features of Resistance Exercise (RE)

1. Resistance exercises (strength training) improve the strength, power and endurance of muscles.
2. Free weights, machines with stacked weights or hydraulic resistance and elastic bands can be used for resistance.
3. A minimum of 8–10 exercises for training the major muscle groups with 8–12 repetitions per set for at least 2 days per week should be performed.

This table lists the key facts of resistance exercise including definition, intensity, frequency and duration of resistance exercise

diet to diet alone, and comparison of high with low intensity exercise. Exercise stimuli including *exercise intensity* was moderate to vigorous, *frequency* was 3–5 days a week for most trials, *duration* ranged from 20 to 60 min. Muscle strength training has been used either alone or in combination with aerobic exercise. The types of exercise include aerobic exercise as a walking/jogging/cycling/stair stepping/treadmill exercise/ball games/calisthenics or resistance exercise as a weights training/circuit training or combined aerobic and resistance exercise (Shaw et al. 2006).

Table 117.4 lists exercise recommendations for overweight and obese individuals from selected leading health organizations. The American College of Sports Medicine recommends minimal FITT framework for overweight and obese individuals (Thompson et al. 2009). These parameters are also consistent with the current guidelines such as The Institute of Medicine (IOM) (IOM 2002), The International Association for the Study of Obesity (IASO) (Saris et al. 2003) and The U.S. Department of Health and Human Services (DHHS) guidelines (DHHS 2008).

117.3 Practical Methods and Techniques

117.3.1 Assessment of Obesity Using Body Measurements

In clinical obesity treatment programs, it is important to obtain detailed body measurements, especially in evaluation of the alterations. These are used as outcome measures for effectiveness of interventions in obesity.

Table 117.4 Exercise recommendations for overweight and obese individuals from leading health organizations

Organization: The American College of Sports and Medicine (Thompson et al. 2009).
Recommendation: Minimal FITT framework is recommended.
Frequency: ≥ 5 session times a week
Intensity: Moderate (i.e., 40–60% VO_2R or HRR) to vigorous (50–75% VO_2R or HRR) intensity
Time: Starting with a total 150 min and progressively increasing up to 300 min of moderate intensity physical activity per week; 150 min of vigorous physical activity or alternatively accumulating intermittent exercise of at least 10 min in duration
Type of exercise: Primary mode should be aerobic exercise and resistance training exercise should be incorporated
Organization: The Institute of Medicine (IOM) (IOM 2002).
Recommendation: 60 min of activity per day, but the main purpose of these guidelines was to prevent weight gain.
Organization: The U.S. Department of Health and Human Services (DHHS) (DHHS 2008).
Recommendation: 150 min of moderate activity or 75 min of vigorous activity per week in bouts of 10 min emphasizing that activity for weight loss or maintenance the weight more activity may be required than the base amount needed to produce other health benefits
Organization: The International Association for the Study of Obesity (IASO) (Saris et al. 2003).
Recommendation: 45–60 min of moderate intensity activity each day to prevent excess weight gain.

This table summarizes the exercise recommendations for overweight and obesity from leading Health Organizations including The American College of Sports and Medicine, The Institute of Medicine, The U.S. Department of Health and Human Services, The International Association for the Study of Obesity

Table 117.5 Methods of body measurements commonly used in obesity outcome studies

Anthropometric measurements
• Weight
• Body mass index (BMI)
• Measurement of Circumference
– Waist circumference
– Hip circumference

• Skinfold thickness
Techniques for measuring body composition
• Bioelectrical impedance analysis(BIA)
• Dual-energy absorptiometry (DXA)
• Imaging techniques
– CT
– MRI

This table summarizes commonly used anthropometric measurements and techniques for measuring body composition in obesity outcome studies highlighted in this chapter

Anthropometric measurements include height, weight, skinfold thickness and waist circumference measurements. Monitoring of body composition is applicable in obese people by using various methods and equipments. Many methods have been used to estimate body composition and fat distribution but less is known about their suitability to assess the differential changes in body composition following endurance and strength training. Simple anthropometric measurements such as body mass index (BMI), skinfold thicknesses, and waist circumference are used as indirect and crude estimates of adiposity and abdominal obesity. Bioelectrical impedance analysis (BIA) is an inexpensive method to analyze total and regional body composition. However, BIA is not considered to be as accurate as underwater weighing, computerized tomography (CT), magnetic resonance imaging (MRI), or dual-energy X-ray absorptiometry (DXA) (Sillinpaa et al. 2008). Commonly used body measurements in obesity outcome studies are shown in Table 117.5.

117.4 Effects of Exercise Training on Anthropometric Measurements and Body Composition in Obesity

117.4.1 Weight – BMI

Measurements of height and weight provide vital information for evaluating obesity. Weight is measured with a standard scale. Height is assessed with a wall-mounted stadiometer. BMI is calculated as weight (kg) divided by squared meters of height.

A large amount of research on people who are overweight or obese has been undertaken to assess the effects of exercise on weight loss. While most trials reported weight change as kilograms lost, some trials reported weight change as change in BMI alone (Shaw et al. 2006). In the literature, the degree of weight loss varies from one study to another and the magnitude of weight loss after exercise was less than expected. Although a variety of exercise prescriptions for weight control exist, the literature reveals that the effects of exercise on body weight is rather small, but significant. In a meta-analysis of 28 exercise and weight loss studies, it was concluded that weight lost in exercise programs without caloric restriction is small and usually ranges from 2 to 7 kg (Garrow and Summerbell 1995).

Miller et al. state that while the average weight loss as a result of 16 weeks of combined endurance exercise and caloric restriction averages ~11 kg, only aerobic exercises provide a lesser extent (on average ~3 kg of bodyweight loss). This meta-analytical review reported that exercise causes decrease in body weight at a rate of about 0.2–1 kg/week and people do not lose weight as much as expected from the prescribed exercise. More information on long-term effects of exercise in weight control is needed (Miller et al. 1997). In a recent meta-analysis of 18 randomized trials, it was found that interventions including a combined diet + exercise program produced greater long-term weight loss than interventions that only included a diet program (Wu et al. 2009).

Many studies investigated the effects of exercise types (aerobic and/or resistance) on weight loss; while in some studies it was demonstrated that both exercises were ineffective (Wadden et al. 1997; Lambers et al. 2008) in the others, aerobic exercise (Ross et al. 2000; Mayo et al. 2003; Sasai et al. 2009) or both were found to be effective (Park et al. 2003; Ghroubi et al. 2009). These differences may depend on methodology and variety of patient groups in the studies. Some studies implicated patients with chronic diseases (Lambers et al. 2008), some applied different caloric restrictions (Ghroubi et al. 2009) and some without dietary restriction exercise training (Mayo et al. 2003, Sasai et al. 2009). The study suggesting that the type of exercise does not have a differential effect on weight regain and long-term weight loss was conducted by randomizing obese participants to one of four groups: (1) diet alone, (2) diet plus aerobic training, (3) diet plus strength training, and (4) diet with aerobic and strength training combined. After 48 weeks of treatment, there were no differences between any of the groups on measures of weight and body composition (Wadden et al. 1997).

In two studies conducted in our clinic, no diet restriction and physical activity training were applied during the training program. The first study was a randomized, prospective, controlled trial investigating the effects of aerobic and resistance exercises in obese women who were not under an energy restricted diet (Sarsan et al. 2006). At the end of the 12th week, the average weight of the AE and RE group decreased from 87.52 ± 11.68 to 84.00 ± 12.02 kg and from 83.77 ± 9.49 to 80.95 ± 9.52 kg, respectively. In the control group, no weight change was detected (86.82 ± 11.27 vs. 86.40 ± 11.46 (86.82 ± 11.27 vs. 86.40 ± 11.46 kg). While a significant weight loss compared to baseline was observed in both exercise groups, there was no significant difference compared to the control group in terms of actual weight loss (Sarsan et al. 2006). In a recent randomized study conducted in our clinic, we demonstrated that both combined aerobic resistance training and aerobic training programs were effective in weight loss and gender was not found as a factor on weight loss (Sanal et al. 2009). However, the shortcoming of this study was that it did not have a control group.

Table 117.6 Summary of body weight changes of the intervention groups in overweight or obese people from a meta-analysis (Adapted from Shaw et al. (2006). Copyright Cochrane Collaboration, reproduced with permission)

Intervention	Body weight	BMI
Exercise versus no treatment	Exercise increased weight loss compared with no treatment.	Exercise reduced BMI more than no treatment.
	Exercisers lost 0.5–4.0 kg.	Exercisers lost between 0.3 and 0.7 kg/m^2.
	No treatment changed weight from −0.1 kg loss to 0.7 kg gain.	No treatment changed BMI from 0.3 to 0.4 kg/m^2 gain.
High versus low intensity exercise	Increasing the intensity increased the weight loss if participants were not on a diet.	Insufficient data for analysis.
	High intensity exercisers lost 1.5 kg more than low intensity exercisers.	
	Range of weight change for high intensity exercisers was from 1.3 to 8.9 kg loss.	
	Range for low intensity exercisers was from 6.3 kg loss to 0.1 kg gain.	
High versus low intensity exercise with dietary change	Increasing the intensity did not increase the weight loss if they were on a diet.	Insufficient data for analysis.
	Range of weight change was 6.4–19.6 kg loss across groups.	
Exercise versus diet	Diet resulted in greater weight losses compared with exercise.	Diet resulted in greater BMI reductions than exercise.
	Dieters lost 2.8–13.6 kg of weight.	Diet resulted in a loss of 0.3–3.3 kg/m^2.
	Exercisers lost 0.5–4.0 kg of weight.	Exercise resulted in a loss of 0.3–0.8 kg/m^2.
Exercise and diet versus diet alone	Diet + exercise resulted in greater weight loss than diet alone.	Diet + exercise resulted in greater reductions in BMI than diet alone.
	Dieters + exercisers lost 1.1 kg more than dieters.	Dieters + exercisers lost 0.4 kg/m^2 more than dieters.
	Range of weight change for dieters + exercisers was from 3.4 to 17.7 kg loss.	Range of BMI change for dieters + exercisers was from 0.6 to 4.0 kg/m^2 loss.
	Range for dieters was 2.3–16.7 kg loss.	Range for dieters was 0.3–4.0 kg/m^2 loss.

kg kilograms, *BMI* body mass index, *WHR* waist–hip ratio
This table summarized results of a meta-analysis of 43 randomized controlled clinical trials consisting of 3,476 participants assessed exercise in achieving weight loss in overweight or obese individuals

A meta-analysis of 43 randomized controlled clinical trials consisting of 3,476 participants assessed exercise in achieving weight loss in overweight or obese individuals. Summary of body weight changes of the intervention groups are shown in Table 117.6 (Shaw et al. 2006).

117.4.2 Circumference and Skinfold Measurement

The need for having a simple, inexpensive, noninvasive and universally applicable technique of measuring changes in body and truncal fat during weight loss is important in weight loss programs. Waist circumference is the most practical tool a clinician can use to evaluate a patient's abdominal fat before and during the weight loss treatment.

Waist and hip circumference are taken at the smallest girth of the waist and widest girth of the hip. Waist-to-hip ratio (WHR) is preferred to an anthropometric method which was developed in epidemiologic studies as an indicator of fat mass distribution. Simple anthropometric measurements such as WC, WHR, and skinfold thickness provide a useful estimation of the proportion of abdominal or upper-body fat but they do not distinguish between accumulations of deep abdominal (visceral) fat and subcutaneous abdominal fat. These are used as indirect and crude estimates of adiposity and abdominal obesity.

There is insufficient evidence that exercise-induced weight loss is associated with reductions in abdominal fat. Limited evidence from non-randomized or controlled studies suggest that a modest reduction in waist circumference is observed in response to exercise-induced weight loss (*Ross and Jansessen* 1999). The authors stated that better-quality studies that investigated the impact of exercise on the components of abdominal fat were needed before any conclusions could be made. It was noted that the combination of endurance and strength exercises produced a more notable improvement in weight loss and waistline (Ghroubi et al. 2009). There is an agreement that changes in WHR, WC, weight, and BMI are not always evident in estimating visceral and total abdominal fat mass, however imaging techniques have to be used (Kay and Fiatarone 2006). Indeed, we have shown that after a 12 week training program, while the aerobic and combined exercises declined the fat mass of trunk measured with DXA, a statistically significant change in WHR was not observed (Sanal E et al. 2009).

Skinfold measurement is frequently used for estimating body fat dispersion and abdominal measurements are especially consequential for abdominal obesity. Skinfold technique can be preferred in epidemiologic studies with many subjects. Sillanpaa et al. compared the usefulness of different methods for the analysis of body composition to detect training-induced adaptations. They indicate that simple anthropometric measurements such as waist circumference and skinfold thickness seem to accurately assess changes in body fat percentage during exercise training as correlated with DXA (Sillanpaa et al. 2008). Mayo et al. conducted a study to investigate whether abdominal fat is reduced in response to substantial weight loss induced by exercise in young obese men. Thirty obese men in the army were evaluated before and after a 4-month training program comprising large muscle group activities at 40–60% maximum heart rate. Thirty obese male subjects without training were evaluated as control subjects. Fat free mass (FFM), fat mass and body fat percentages were determined from skinfold measurements. Substantial weight loss induced by exercise was found to be associated with maintenance of lean tissue, unlike diet-induced weight loss of the same magnitude (Mayo et al. 2003).

In our study, after a 12-week training program, both aerobic and combined exercises were found to be effective on decreasing WC and lowering all skinfold measurements, but no differences were observed between the two training groups (Sanal et al. 2009).

117.4.3 Fat Mass (FM) and Fat-Free Mass (FFM) Measurements

Weight reduction is the common goal in the treatment of obesity. An optimal weight reduction program should selectively deplete body fat while maintaining lean tissue. Fat-free mass is composed of muscle, bone, organs, and water, whereas fat is the underlying adipose tissue. Higher proportions of fat-free mass indicate an increase in muscle and thus enhanced physical workload capacity.

Several investigators have reviewed the effects of exercise on the reduction in total fat mass and/or visceral fat mass. A meta-analysis of 46 studies has evaluated the effects of endurance exercise

Table 117.7 Randomized controlled trials: (a) changes in abdominal imaging measures in the absence of changes in body mass and (b) a reduction in body mass and changes in imaging measures of abdominal fat (Taken from Kay and Fiatarone Singh (2006) by permission from John Wiley)

This table shows randomized controlled studies which assessed the effect of exercise alone on body composition in overweight/obese subjects. There is limited evidence that exercise can lead to a loss of visceral and total abdominal fat without a change in body mass by using new technologies that can quantify fat stores. Studies providing outcome measures of trunk fat mass or area, visceral fat mass, area or volume that were measured via ultrasound, DXA, CT or MRI were considered.

Pre- vs. post-Δ significantly different from control group $*P \leq 0.05$; $**P \leq 0.01$; $*** P \leq 0.001$.

Ex exercise; *A* aerobic exercise; *AWL* aerobic with weight loss; *I* interval training; *PRT* progressive resistance training; *ANL* aerobic with no weight loss; *C* controls; *CT* computed tomography; *DXA* dual-energy X-ray absorptiometry; *EWL* exercise with weight loss; *ENL* exercise with no weight loss; *MRI* magnetic resonance imaging

training on FFM preservation during diet-induced weight loss. The percentage of weight lost as fat-free mass for diet-plus-exercise subjects was approximately half of that for dietary restriction subjects of the same sex (Ballor and Poehlman 1994). In another review was published in 2006, using new technologies that can quantify fat stores, researchers concluded that there was limited evidence that exercise could lead to a loss of visceral and total abdominal fat without a change in weight or waist circumference (Table 117.7). However, the authors also pointed out that none of the studies they reviewed met the criteria of a "gold standard" randomized clinical trial and stressed that such trials needed to be conducted (Kay and Fiatarone 2006). In a recent review, it seems that the addition of physical exercise to a diet is important to prevent a decrease in fat-free mass, increase relative visceral fat-mass loss, improve dietary compliance and eventually maintain long-term weight control (Hansen et al. 2007).

Exercise type: Results vary regarding the effects of AE and RE on the protection of the FFM. Some studies have demonstrated that both AE and RE have no effect on FFM, (Wadden et al. 1997) but other studies have indicated that additional RE is more helpful in protecting FFM than only AE is (Ghroubi et al. 2009). Although all these studies suggest positive effects of exercise on different systems, the evidence is not conclusive.

Exercise intensity: A review researching dose–response effect suggested that aerobic exercise as a weight loss intervention had a dose-response relationship for significant visceral fat reduction; at least 10 METs_h/w was required in obese subjects, excluding groups with metabolic-related disorders (Ohkawara et al. 2007). In contrast to this finding, Nicklas et al. showed no influence of training intensity on selective loss of abdominal adipose tissue. 112 overweight and obese postmenopausal women were assigned to one of three 20-week interventions of equal energy deficit: calorie restriction (CR), CR plus moderate-intensity aerobic exercise or CR plus vigorous-intensity exercise (45–50% vs. 70–75% of heart rate reserve). They concluded that lean mass was preserved with a similar amount of total weight loss, but there was not a preferential loss of abdominal fat when either moderate- or vigorous-intensity aerobic exercise was performed during caloric restriction (Nicklas et al. 2009).

117.5 Determination of Effects of Exercise Training Program on Body Composition

Accurate measurements of body composition using reference standards are impracticable such as a 4-compartment model and underwater weighing, expensive such as magnetic resonance imaging (MRI) or involve a small dose of radiation such as dual energy X-ray absorptiometry (DXA) and computerized tomography (CT) (Garaulet et al. 2006). The techniques used during the assessment of the effects of exercise training program on body composition profile were as follows:

117.5.1 Hydrostatic Weighing

Hydrostatic weighing is a method of determining body composition using the Archimedes' principle of displacement. Hydrostatic weighing had been considered as the gold standard for body composition assessment, however, new and more practical and sophisticated techniques took the place of this method. Furthermore, this displacement method could not analyze the regional body fat distribution. Some studies were conducted to determine the effectiveness of exercises by this method. It was reported by applying underwater weighing that in obese subjects, the inclusion of resistance exercise to the diet prevented loss of FFM compared to aerobic training and diet, or diet only groups (Geliebter et al. 1997). Nevertheless, in a study with opposite results, Donnelly et al. investigated the effects of very-low-calorie diet and physical-training regimens (diet only, diet plus endurance exercise, diet plus weight training, or diet plus endurance exercise and weight training) on body composition in obese females. Hydrostatic weighing at residual volume was used to determine body fat percentage. They showed that preservation of FFM after RE was not found to be successful in obese people. This can be explained by a greater loss in FFM as a result of very low-calorie diet (Donnelly et al. 1991).

117.5.2 Bioelectrical Impedance Analysis

BIA is a body composition assessment technique used in tracking changes in body composition over exercise training program in obese people in a variety of settings (e.g., hospital based fitness facilities, wellness fairs, and health clubs). FM and FFM of the patients were measured by BIA after 10 h of fasting.

This technique is very portable, easy to use and reduces the overall time of assessing relative body fat in the general public. Although BIA has emerged as a popular method of assessing changes in body composition, its accuracy to identify these changes in overweight patients and during weight loss is not certain. In the most recent research, Aslam et al. reported that BIA underestimated total body fat changes in males and overestimated total body fat changes in females compared to DXA. They suggested that BMI, body weight, and WC provided a simple and more accurate estimate to that of BIA which estimated relative changes in total and truncal fat during moderate weight loss in adults (Aslam et al. 2009).

There are a small number of studies about the efficacy of pure exercise. We conducted a longitudinal, controlled clinical study with the endocrinology department to compare the effects of RE and AE on BMI, weight, FM, in obese women who cannot adhere to energy-restricted diets (Fenkci et al. 2006). A total of 60 obese women were randomly divided into three groups: control group with no exercise, AE group, and RE group. The AE group performed both walking and leg cycle exercises with increasing duration and frequency. The RE group performed progressive weight-resistance exercises for the upper and lower body. Before and after a 12-week period, all subjects were evaluated by anthropometric measurements. Percentages of total body FM and FFM were measured by BIA. In this study, significantly decreased BMI, waist, and weight measurements were observed in both study groups but reduced FM was seen only in the AE group. Lambers et al. conducted a double-blind, randomized controlled trial to investigate the effect of exercise in 42 obese patients with type 2 diabetes. No significant difference among the three groups (combined exercise, aerobic exercise or no training) was detected in anthropometric variables (weight, waist, and BMI) and fat mass assessed by BIA (Lambers et al. 2008). Ghroubi and colleagues suggested that the combination of dietary measures with exercise training including resistance exercise may contribute to improvements in body composition in the management of obesity. Eight-three obese patients were randomized into three groups: (1) control group (no diet-no exercise), (2) low calorie diet (25–30% decrease in calorie intake relative to previous levels) plus aerobic treadmill training, (3) diet plus aerobic exercise and segmental strength training of the arm, leg, and abdominal wall muscles. The aerobic treadmill training involved 45–60-min exercise sessions three times a week for a 2-month period and the intensity was set to 60% of the HRmax. The strength training was performed at 60% of the maximal voluntary force for each muscle group, with three sets of 20 repetitions. BIA analysis was applied to assess body fat mass and lean mass. They did not note any variations in lean mass in the patients having performed aerobic training; in contrast, patients having performed additional strength exercises displayed an increase in lean mass and a greater decrease in fatty mass (Ghroubi et al. 2009).

117.5.3 Imaging Techniques

Both whole body and regional measurements of fat distribution are required for the determination of whether abdominal fat is preferentially reduced in response to exercise. CT and MRI allow changes in intra-abdominal fat (visceral and/or subcutaneous) to be monitored. MRI provides results similar to CT without exposure to ionizing radiation. It demonstrates good reproducibility for total and visceral adipose tissue volumes. CT and MRI are both more accurate but impractical for routine clinical practice being expensive and time consuming. Additional limitations that include lack of portability and scanner size that may be too small for some obese individuals are shared by MRI and CT (Aslam et al. 2009).

Park et al. showed by CT that combined training (aerobic training plus resistance training) decreased abdominal subcutaneous fat and visceral fat more than aerobic training only (Park et al. 2003). Thirty middle-aged obese women were separated into a control group, aerobic training group

and a combined training group. The aerobic training was performed 60 min a day for 6 days a week at 60–70% of HRmax for a period of 1–24 weeks. The combined training group was composed by aerobic training plus resistance training which was performed 60 min a day at 60–70% of one-repetition maximum test for a period of 1–24 weeks. The levels for abdominal fat volume were measured by determining the subcutaneous fat volume and visceral fat volume by CT. They observed that subcutaneous fat and visceral fat decreased by combined training rather than by aerobic training alone. Also, the lean body mass (LBM) significantly increased only in the combined training group (Park et al. 2003).

A previous study using MRI reported that the combination of diet and exercise resulted in a greater reduction of adipose tissue and preservation of lean tissue and skeletal muscle compared with only diet in women. This report provides the evidence that lean tissues are preserved and adiposity is substantially reduced in response to weight loss induced by the combination of RE and moderate energy restriction (Ross et al. 1995). Another study applying MRI showed greater preservation of skeletal muscle and decrease of subcutaneous adipose tissue in the abdominal region, when compared with the gluteal/femoral region, following diet combined with either aerobic or resistance exercise in males (Ross et al. 1996). Ross et al. by MRI, have shown that 12 weeks of daily aerobic exercise without weight loss is associated with significant reductions in both abdominal and visceral fat (Ross et al. 2000).

In a recent study, the effect of aerobic exercise training in 19 sedentary obese men and women using MRI was assessed. It was shown that 4 weeks of aerobic cycling exercise did not alter body weight but significantly reduced hepatic lipids and visceral adipose tissue volume by 12% (Johnson et al. 2009).

117.5.4 Dual Energy X-Ray Absorptiometry

DXA, which is mainly known as the gold standard for assessment of bone mineral density, can also be used to assess fat mass and fat-free mass volume. DXA provides precise estimates of total and regional fat and skeletal muscle mass. It is an objective and reliable technique for measuring body composition and its changes. Simple anthropometric measurements seemed to be useful in the cross-sectional analyses but only DXA was able to detect the group differences in training-induced changes in lean body mass (Sillanpaa et al. 2008). Andersen et al. reported, by DXA, that the percentage of weight loss from FFM was significantly less in the diet plus AE group compared to the diet plus lifestyle group in obese women at the end of 16 weeks (Andersen et al. 1999).

Sasai et al found that participants classified as HIF obesity (high intra-abdominal fat >200 cm^2) exhibited greater reductions in intra-abdominal and total fat in response to regular aerobic exercise than those classified as MIF obesity (Moderate intra-abdominal fat <200 cm^2). Whole-body fat mass (FM), FFM, intra-abdominal fat and subcutaneous fat areas were measured by DXA before and after the 12-week aerobic exercise program (Sasai et al. 2009).

In a recent study conducted in our clinic, the effects of a 12-week combined aerobic resistance training (AR) versus aerobic training alone (AE) on changes in FM, FFM, and percent body fat (PF) in 65 untrained obese males and females were examined (Sanal et al. 2009). Before and after the 12-weeks of training body composition was obtained by DXA. We confirmed that while AR and AE exercises were effective on decreasing FM and PF of the whole body, only AR exercises were found to be effective on increasing FFM of the whole body (Table 117.8). In addition, when evaluating the regional body composition changes, we found that AR exercises were more effective on increasing FFM and decreasing PF of all regional measurements, decreasing FM of trunk and legs than AE exercises. As a conclusion, our findings indicate that AR exercises lead to more gains on regional and the whole body FFM than AE exercises.

Table 117.8 Changes in body composition at baseline and 12-week for aerobic (AE) and combined aerobic resistance (AR) training groups

	Group AE		Group AR		
	n = 33		*n* = 32		
Whole body composition	Baseline (mean ± SD)	12 week (mean ± SD)	Baseline (mean ± SD)	12 week (mean ± SD)	
FM (kg)	30.2 ± 9.4	28.0 ± 8.0*	33.9 ± 8.7	28.5 ± 6.9*	
Change %		(6.70 ± 6.1)		(14.1 ± 14.4)	#
FFM (kg)	51.4 ± 10.3	51.3 ± 9.7	50.7 ± 11.6	53.8 ± 11.2*	
Change %		(0.01 ± 6.0)		(−7.3 ± 13.5)	#
PF	35.8 ± 8.8	34.1 ± 7.8*	39.0 ± 8.6	33.8 ± 7.0*	
Change %		(4.0 ± 5.6)		(11.8 ± 13.9)	#

FM fat mass; *FFM* fat-free mass; *PF* percentage of fat

*$p < 0.001$, significant difference between baseline and 12-week, #$p < 0.01$, significance between group-change

Evaluating the whole body composition, findings indicate that only AR exercises increased whole body FFM and declining FM and PF were more significant for AR group than AE group. DXA measurements revealed that AR exercises were superior on increasing whole body FFM, and reducing whole body of PF and FM than AE. (Sanal et al. 2009) Unpublished data

117.6 Gender: Sex Differences in Fat Loss

In the literature, a few studies compared the effect of exercise training on body composition in both genders. Ballor and Keesey observed in their meta-analysis that men showed a larger bodyweight loss as a result of dietary restriction and exercise training, when compared with women (Ballor and Keesey 1991). In contrast, Andersson et al. showed that the bodyweight and fat-mass loss was comparable between obese men and women as a result of a 3-month combined intervention program. However, when we looked at the data in more detail, it revealed that the baseline fat mass was greater in the female participants. After correction for differences in baseline fat mass, the men had actually lost a higher amount of fat (Andersson et al. 1991). In HERIGATE Family Study, the effect of a 20-week aerobic training program on body composition was assessed in 557 individuals (258 men, 299 women) by hydrostatic weighing and CT. They reported that aerobic endurance exercises provided small but significant increase in the FFM of the whole body, a decrease in FM and PF in both men and women, but men lost a greater amount of abdominal visceral fat in comparison to women (Wilmore and et al. 1999).

Geer and Shen reviewed gender differences in body composition. They concluded that men and women differed in regard to body composition. For a given BMI, men had higher lean mass and more visceral and hepatic adipose tissue, whereas women had elevated general adiposity, SAT in particular (Geer and Shen 2009). Recently Kuk and Ross investigated how body fat was distributed in obese men and women and how it changed after some sort of weight loss program (Kuk and Ross 2009). The participants were 153 men (81) and women (72) with a starting BMI of over 27. Besides anthropomorphic measurements such as weight, waist, and hip circumference, body fat distribution was assessed by whole-body MRI scans initially and after 12–16 weeks. In this study, three weight loss methods were used: calorie restriction, exercise or both (calorie restriction & exercise). On comparison of men and women after the weight loss intervention it was found that there was no difference in total fat loss. Both men and women had lost about 6 kg (14 lb) of fat as was found by the MRI. The main finding of the study is that there are sex differences in visceral fat and lower body fat loss. While men lose more visceral fat, women lose lower body, total subcutaneous fat as a percent of weight loss. It seems impossible to distinguish the cause between whether it is the sex difference or starting fat distribution. The findings of this study suggest that there are sex differences in the

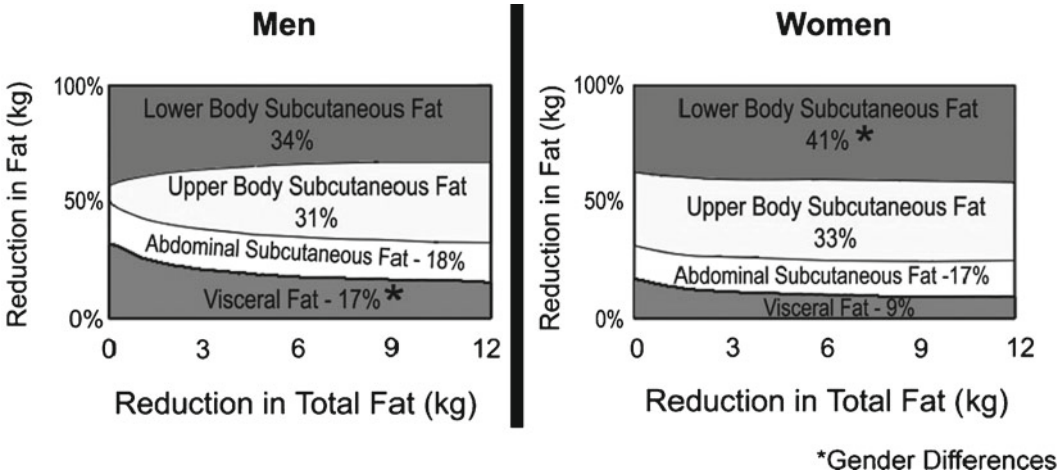

Fig. 117.1 Contribution of visceral and regional subcutaneous fat loss in relation to total fat loss. The main finding of the study is evidence of sex differences in visceral fat and lower body fat loss. Men lose more visceral fat and women lose lower body weight (and total subcutaneous) as percent of weight loss. Taken from Kuk, Ross. (2009) by permission from Macmillan Publishers Ltd: *International Journal of Obesity*

regional adipose tissue loss, not in total adipose tissue loss observed for a given reduction in body weight or WC. The relationship between total and regional adipose tissue loss is shown in Fig. 117.1. The limitation of this study is the variety of diet and/or exercise interventions which induce a wide range of weight losses. It is unclear whether diet and/or exercise interventions are effective in the pattern of fat loss, or whether the sex difference is a factor for the results observed in this study. However, in our study we have investigated the effects of 12-week combined aerobic resistance training versus aerobic training alone in both genders of non-dieting, overweight and obese individuals.

- AR; ↓ trunk and whole body mass ♀>♂
  AR exercises were more effective on lowering mass of trunk and whole body in women in comparison with men.
- ♂; AR> AE arm, trunk and whole body FFM ↑
  In regards of evaluating the effectiveness of the type of exercises in men, AR exercises were more effective on increasing the FFM of arms, trunk and whole body than AE exercises.
- ♀; AR> AE FM and mass of legs ↓

In assessing the effectiveness of the type of exercises in women, AR exercise was observed to be superior on FM and mass of legs compared to AE exercise. When women were usually considered as gynecoid type body shape, more fat mass in legs, this result showed the importance of AR exercises (Sanal et al. 2009). We can conclude that, as there was no calorie restriction and not too much weight loss in our study group, an increase in FFM instead of a decrease was observed. RE exercises have a favorable impact on body composition by preventing the loss of FFM.

Summary Points

- Anthropometric measurements are used as outcome measures for the effectiveness of interventions in obesity. It is important to obtain the detailed body measurements, especially in evaluation of the alterations.

- Most commonly used body measurement methods in obesity outcome studies include simple anthropometric measurements such as weight, BMI, WC, hip circumference, WHR and skin-fold thickness and body composition measurement techniques such as BIA, CT, MRI, or DXA.
- Exercise is an effective weight loss intervention, particularly when combined with dietary interventions.
- With respect to body composition alterations with exercise, slight decreases in total body weights were observed.
- The magnitude of body composition changes vary with the intensity, duration and the type of the exercise program.
- Including resistance exercises increases FFM.
- Dissimilar results of exercises on genders must be taken into consideration prescribing exercises in overweight and obese men and women.
- Studies with a longer duration of follow-up would provide further information regarding the long-term effects of regular exercise in people who are overweight or obese.

Chapter 118
Anthropometry and Exercise in Down Syndrome

Manuel Rosety-Rodriguez, Francisco Javier Ordoñez, Gabriel Fornieles-Gonzalez, Miguel Angel Rosety, Natalia Garcia Gomez, Antonio Diaz-Ordonez, Jesus Rosety, Alejandra Camacho Molina, and Ignacio Rosety

Abstract In recent years, there has been a growing concern as to the importance of exercise in the holistic management of individuals with Down syndrome (DS). In fact, several studies have reported that regular exercise may improve the health of these individuals, since it may help reduce obesity, insulin resistance and oxidative damage, among other problems. Similarly, exercise may improve the quality of life of individuals with DS by promoting their functional independence as well as their social integration in the workplace, since most of their jobs are based on physical tasks. In addition, an increasing number of sport events are being organised all over the world for individuals with DS by national federations and international institutions, such as the Special Olympics and International Paralympics Committee. In this regard, improving the physical performance of high performance athletes with mental retardation also requires specialised attention from a multidisciplinary team.

Fortunately, anthropometric assessment, including body composition and somatotype analysis, may help these professionals not only achieve all these goals, but also achieve them safely. It should also be noted that this assessment is inexpensive, easy to perform and non-invasive. However, anthropometric assessment is not widely used by professionals in their daily practice to date, which may be explained, at least in part, by the dearth of available information in the literature.

Consequently, this chapter has been written to provide an update on this topic for healthcare providers and sport-related professionals who work with individuals with DS.

Abbreviations

BMC	Bone mineral content
BMD	Bone Mineral density
DS	Down syndrome
DXA	Dual X-ray densitometry
H/A	Height for age
volBMD	Volumetric Bone Mineral Density
W/A	Weight for age

Table 118.1 Key facts on exercise and down syndrome

1. Several studies have reported that low to moderately intense aerobic exercise may improve the health status, quality of life and social integration of individuals with Down syndrome.
2. The HRmax = 194.5 – (0.56 × age) equation should be used to determine intensity, since it takes chronotropic incompetence into account.
3. Since hypotonia is very common in Down syndrome, resistance training may improve quality of life and social integration in job settings.
4. Training programmes originally designed for the general population should not be copied or applied, since they are difficult to follow for participants who are predisposed to sport-related injuries.

118.1 Anthropometry and Exercise in Down Syndrome: An Update

It is widely accepted that obesity is a serious problem that is overwhelmingly prevalent in the general population. However, the magnitude of this problem is even worse in individuals with mental retardation in general and Down syndrome in particular. Although individuals with Down syndrome are born with a genetic predisposition for becoming overweight, obesity is actually nurtured throughout childhood and adolescence when they develop food and lifestyle choices (Grammatikopoulou et al. 2008; Hawn et al. 2009) (Table 118.1).

Regular exercise may improve the quality of life and health for a variety of population profiles. However, there is a lack of information on the effectiveness of exercise in individuals with Down syndrome. Fortunately, recent studies have reported that regular exercise may help this population, which may be explained, at least in part, by the reduction in their fat mass percentage.

Similarly, there is an increasing interest in improving the high performance of athletes with mental retardation. In this respect, it is generally accepted that athletes with intellectual disabilities have less muscle strength compared with their athletic peers without mental retardation (Van de Vliet et al. 2006). Accordingly, assessing the muscle mass of these individuals would be of interest, especially if we accept the premise that muscle strength may play an important role in ensuring their quality of life and job-related social integration.

With the increasing life expectancy of individuals with DS, concerns have been raised about bone mass in terms of reducing the risk of osteoporosis and falls that may ultimately impair their health (Hale et al. 2007; Guijarro et al. 2008).

Consequently, in order to be safe and effective, intervention programmes based on physical activity to reduce fat mass or improve fat-free mass should be adequately designed and supervised during their application by a multidisciplinary team. In this regard, anthropometric assessment may play an important role in achieving these goals. However, the lack of information on the reliability of anthropometric measurements in subjects with mental retardation means that the use of anthropometric assessment at institutions and schools for individuals with intellectual disabilities is rare.

118.2 Fat Mass and Exercise in Individuals with Down Syndrome

Current findings suggest that more attention needs to be paid to the rising fat mass percentages seen in individuals with Down syndrome in order to minimise negative, long-term health consequences (Sohler et al. 2009) (Table 118.2).

Anthropometric measurements are widely used as a reliable way to quantify body composition and estimate the risks of being overweight in healthy subjects and patients. However, information on

Table 118.2 Key facts on exercise and fat mass in individuals with Down syndrome

1. The prevalence of obesity in Down syndrome is higher than in the general population, even at early life stages.
2. Fortunately, regular, low to moderately intense exercise reduces fat mass.
3. Test-retest reliability and feasibility for several anthropometric variables are acceptable for subjects with mental retardation. Furthermore, most of these variables are strongly correlated to the serum lipid profile.
4. Potentially confounding factors include misunderstanding, motivational problems and agitation.

the reliability of anthropometric measurements in subjects with severe intellectual and sensory disabilities is lacking. Accordingly, their use at institutions and schools for individuals with intellectual disabilities is limited (Ohwada and Nakayama 2004). Fortunately, test-retest reliability and feasibility for several anthropometric variables (body weight; body height; body mass index; waist circumference; fat skinfolds) are acceptable in subjects with severe intellectual and sensory disabilities, according to Waninge et al. (2009). Furthermore, anthropometric measurements are a universally applicable, inexpensive, non-invasive and painless technique.

On the other hand, potentially confusing factors include motivational problems, agitation and misunderstanding, e.g., some of these subjects do not understand why they are being pinched during fat skinfold measurements and may become agitated. Conversely, researchers have more time to read measurement values when subjects are relaxed, thus ensuring more accurate measurements (Waninge et al. 2009).

Percentile distributions of anthropometric indexes such as weight for age (W/A) and height for age (H/A) specific to children and adolescents with Down syndrome have been reported by several authors in different countries, which reflects the lower pace of growth and restricted height observed in this group. The distribution compiled in the United States (Myrelid et al. 2002) is one of the most often cited in the literature covering the 2- to 18-year-old age group. However, there is no consensus on the reference distributions and classification criteria to be used in assessing the nutritional status of children and adolescents with Down syndrome. Fortunately, assessment using the Spanish distribution (Pastor et al. 1998) makes it possible to implement interventions for reducing the body fat of those categorised above P95 for W/A. In any case, the need to use distributions produced specifically for individuals with Down syndrome is based on the recognition of their different rates of growth and development (Lopes et al. 2008).

Our research group reported that adolescents with Down syndrome were able to reduce their fat mass percentage significantly when they completed a 12-week aerobic training programme on a treadmill. This programme consisted in 3 sessions/week and included a 15-min warm-up followed by a 20- to 35-min main section (that was increased by 5 min every 3 weeks) at a work intensity of 60–75% of the peak heart rate according to the HRmax = 194.5 – (0.56 age) formula that takes their chronotropic incompetence into account (Fernhall et al. 2009) and a 10-min cooling-down period (Ordonez et al. 2006). In a similar study, Mendonca and Pereira (2009) concluded that young adults with Down syndrome decreased their fat mass from 27.3 ± 11.2 to 23.5 ± 11.1% ($p < 0.01$) and increased their absolute fat-free mass from 48.4 ± 8.6 to 50.8 ± 9.3 kg ($p < 0.01$) after a 28-week training programme. In this respect, the most striking feature was that our protocol lasted only 12 weeks, which may facilitate its follow-up by participants.

Also of interest is the role of anthropometric variables as potential biomarkers of clinical parameters in order to facilitate the medical follow-up of participants in training programmes. In this respect, anthropometric measurements such as waist circumference, waist or hip ratio and body mass index have been strongly correlated to serum lipid profiles in adolescents with Down syndrome (Ordonez et al. 2005). Furthermore, a weak correlation to antioxidant enzyme activities was also

Table 118.3 Influence of a 12-week aerobic training program in anthropometrical parameters in young adolescents with DS. Control group included 7 age, sex, and body mass index matched adolescents with trisomy 21

	Down syndrome (n = 19)	Controls (n = 7)	P value
Age	16.1 (1.7)	16.4 (1.6)	ns
Height (cm)	155.2 (5.7)	155.3 (5.6)	ns
Weight (kg)	76.8 (4.5)	73.9 ()	<0.05
Body mass index (kg/m^2)	31.7 (2.9)	30.7 (2.5)	<0.05
Fat mass (kg)	28.7 (2.4)	26.3 (2.6)	<0.05
Fat free mass (kg)	47.3 (3.5)	47.6 (3.3)	<0.05
Waist circumference (cm)	103.4 (5.9)	100.2 (5.2)	<0.05
Hip circumference	107.5 (7.1)	105.6 ()	<0.05
Waist to hip ratio	0.96 (0.03)	0.94 (0.02)	<0.05

Results are expressed as mean (sd). Significance was ascertained at p value <0.05. ns (no significant)

shown (Ordonez et al. 2007). Accordingly, anthropometric assessment may be considered easier to carry out, more economical and faster when compared with biochemical assessment.

It is widely known that individuals with Down syndrome exhibit lower peak aerobic capacities and maximal heart rates when compared with healthy peers, which may be explained, at least in part, by a different catecholamine response to exercise (Fernhall et al. 2009). Accordingly, intervention programmes based on regular exercise should be designed by taking Down syndrome individuals' chronotropic incompetence into account to prevent sessions that are moderately intense for the general population from becoming exhausting for participants with Down syndrome and leading to undesired results.

It should also be emphasised that no sport-related injuries were reported during the whole experience, which may indicate not only the effectiveness, but also the safety of our 12-week programme, which is based on low to moderately intense aerobic exercise for individuals with Down syndrome. This is of particular interest, since injuries and discomfort may lead participants to interrupt their programmes (Table 118.3).

Finally, since children and adolescents with Down syndrome tend to obesity, increasing participation in exercise programmes may be appropriate for preventing obesity and promoting lifelong health (Whitt-Glover et al. 2006).

118.3 Fat Free Mass and Exercise in Individuals with Down Syndrome

118.3.1 Muscle Mass

It is generally accepted that individuals with Down syndrome suffer from hypotonia, which may have a negative impact not only on their health status but also on their quality of life and work-related aspects.

Along these lines, Mercer and Lewis (2001) reported that children with DS had significantly lower mean peak torque values for hip abduction and knee extension than age- and gender-matched peers without mental retardation. Similarly, Carmeli et al. (2002) reported that the situation of individuals with Down syndrome was even worse when compared with other individuals with mental retardation (Table 118.4).

Table 118.4 Key facts on oxidative stress and body composition in individuals with Down syndrome

1. Individuals with DS have been described as having higher oxidative damage than their healthy siblings do.
2. Oxidative damage has been proposed as a pathogenic mechanism of early aging, neurodegeneration, carcinogenic events and immunological disorders in individuals with DS.
3. Oxidative damage has been associated with obesity in both the general population and individuals with DS and regular exercise may reduce oxidative damage by boosting the antioxidant system.
4. Since antioxidant enzyme activities and products derived from the oxidation of lipids and proteins have been correlated to body fat distribution indices, the latter can be used as potential biomarkers in an easier and non-invasive manner

Hand-held dynamometry can be used to obtain reliable measurements of isometric muscle strength in children with Down syndrome. Furthermore, regression analyses indicated that weight, body mass index, height, activity level and gender were significant predictors of peak torque production in the sample (Mercer and Lewis 2001).

Progressive resistance training is a safe and feasible fitness option that can improve muscle performance and physical functioning in adults with Down syndrome. One progressive resistance training programme consisted in six exercises using weight machines carried out twice a week for 10 weeks. Participants completed two to three sets of 10 to 12 repetitions of each exercise until they were fatigued. It should also be emphasised that no major adverse events were noted during the intervention (Shields et al. 2008).

118.3.2 Bone Mass

With the increasing life expectancy of individuals with Down syndrome, concerns have been raised about bone mass, since it may reduce the risk of osteoporosis and falls (Hale et al. 2007), above all, if we take into account that individuals with Down syndrome have lower lumbar spine bone mineral density not only in comparison with healthy controls (Baptista et al. 2005), but also in comparison with intellectually average, age, sex and race-matched subjects (Angelopoulou et al. 2000).

In fact, individuals with trisomy 21 present a number of features (muscle hypotonia, sedentarism, poor calcium and vitamin D intake, hypogonadism, growth retardation and thyroid dysfunction) that may contribute to substantial impairments in skeletal maturation and bone-mass accrual, which predisposes these patients to fragility fractures (Hawli et al. 2009). In this regard, independent body composition variables selected by stepwise regression indicated that muscle mass was the main variance predictor of upper and lower limb-adjusted bone mineral content (BMC), lumbar spine-adjusted BMC and volumetric bone mineral density (volBMD) in young males and females (ages 14–40) with Down syndrome (Baptista et al. 2005). Fat mass was also the main predictor of composite indices of femoral neck strength (conversely, no body composition predictor for femoral neck adjusted BMC or volBMD was found) (Table 118.5).

In a recent study, Guijarro et al. (2008) reported that young adults with DS had a reduced area bone mineral density (aBMD) in all regions (spine, hip and total body) measured by dual X-ray densitometry (DXA). In this respect, it is widely accepted that area BMD as measured by DXA is influenced not only by the "true density" of bone tissue, but also by bone size. Therefore, given a series of bone samples with the same BMD but different sizes, smaller bones tend to have lower area BMD values than larger bones. This confusing effect of body-size differences has prompted authors to analyse not only the usual area BMD, but also the volBMD estimated from the DXA output after modelling bones as cylinders (Guijarro et al. 2008) (Table 118.6).

Table 118.5 Resting, submaximal, and peak physiological responses at pre- and post-training periods in young adults with down syndrome (Mendonca and Pereira 2009)

Variable	Pre-training	Post-training
Rest		
VO_2 (ml/kg/min)	3.1 (0.8)	3.3 (1.0)
HR (bpm)	69.5 (12.5)	68.8 (13.1)
Submaximal		
VO_2 (ml/kg/min)	9.1 (2.6)	10.3 (3.9)
HR (bpm)	90.7 (14.8)	90.5 (12.9)
RER	0.91 (0.11)	0.83 (0.05) *
Ventilation (l/min)	17.1 (4.2)	18.7 (4.7)
Maximal		
VO_2 (ml/kg/min)	20.9 (4.7)	26.7 (7.6) *
HR (bpm)	145.6 (19.5)	151.0 (21.9)
RER	1.19 (0.09)	1.16 (0.10)
Ventilation (l/min)	49.9 (13.8)	60.4 (20.1) *
Time to exhaustion (min)	44.0 (9.0)	39.0 (9.5) *

Values are expressed as mean (sd). VO_2 Oxygen uptake. *HR* Heart rate, *RER* Respiratory exchange ratio

* Significance level at p value <0.05

Table 118.6 Key facts on resistance training and muscle mass in individuals with Down syndrome

1. Individuals with DS are described as having lower muscle strength when compared not only with healthy controls but also with individuals with other intellectual disability.
2. Hypotonia may impair daily activities of individuals with DS as well as their workplace activities.
3. Progressive resistance training improves upper- and lower-limb muscle mass and strength.
4. Participants should be supervised during training sessions to prevent withdrawals and injuries.

Similarly, Baptista et al. (2005) concluded that Down syndrome was shown to be a risk factor for low volumetric bone mineral density (volBMD) in the lumbar spine. Furthermore, some studies (Sornay-Rendu et al. 2007) have shown that volBMD is more closely associated with fractures than area BMD is. In any case, although lean mass is the body component that shows a stronger correlation with area BMD, fat mass was also correlated with volBMD (Guijarro et al. 2008).

It should be also pointed out that skeletal resistance depends not only on bone mineral density and quality, but also on bone size (larger bones resist higher loads). The reduced stature in Down syndrome is mainly the result of the disproportionate shortening of the legs. Thus, the reduced skeletal size of individuals with Down syndrome may be associated with a reduced absolute resistance. Furthermore, the largely reduced femoral neck, particularly the narrowest femoral neck, might be associated with diminished bone strength relative to the loads that the femoral neck must bear.

Further studies on this topic are needed to identify the true dimension of this problem and the efficacy of the various preventive or curative procedures put forward (Zylstra et al. 2008). However, an active lifestyle and increased physical activity should be instituted to maintain and/or improve bone mineral density and prevent the development of osteoporosis in young adults with Down syndrome (Angelopoulou et al. 2000) (Table 118.7).

Table 118.7 Bone mineral density in young adults with Down syndrome and healthy matched controls (Guijarro et al. 2008)

	Down syndrome (n = 39)	Controls (n = 78)	P value
Age	26 (7)	27 (7)	Ns
Fat mass (kg)	15.4 (6.8)	16.1 (6.3)	Ns
Lean mass (kg)	37.7 (6.4)	45.0 (9.3)	Ns
Calcium intake (mg/day)	754 (209)	728 (275)	Ns
Spine BMD (g/cm^2)	0.919 (0.100)	1.056 (0.108)	<0.001
Spine Area (cm^2)	43.65 (4.93)	50.13 (5.72)	<0.001
Spin volBMD (g/cm^2)	0.140 (0.017)	0.149 (0.017)	0.007
Femoral neck BMD (cm^2)	0.815 (0.111)	0.908 (0.134)	<0.001
Femoral neck area (cm^2)	4.65 (0.55)	5.37 (0.69)	<0.001
Femoral neck volBMD (g/cm^2)	0.327 (0.055)	0.315 (0.069)	Ns
Total Hip BMD (g/cm^2)	0.872 (0.108)	1.023 (0.133)	<0.001
Total Hip area (cm^2)	32.85 (4.72)	38.00 (6.79)	<0.001
Total Body BMD (g/cm^2)	0.929 (0.067)	1.051 (0.097)	<0.001
Total Body area (cm^2)	1445 (140)	1870 (214)	<0.001

Results are expressed as mean (sd)
BMD Bone Mineral Density; *volBMD* volumetric BMD; *ns* not significant

118.4 Somatotype and Sport in Individuals with Down Syndrome

Several studies have concluded that not only body composition, but also somatotype may be predictors of high performance in healthy athletes. Somatotypes may also play an important role in determining their sport modality and even their different playing positions in each sport (Carter et al. 2005). In this regard, future research that seeks to explain the sources of variation in high performance should consider including somatotype as an independent variable.

In recent years, an increasing number of athletes with Down syndrome have taken part in Special Olympics events all over the world (Tassone and Duey-Holtz 2008). Since they also may be considered high performance athletes, they need to be assessed by multidisciplinary teams, just as non-disabled athletes are. Anthropometric assessment may play an important role within this context. However, there is no information in the literature regarding the endomorphic, mesomorphic or ectomorphic components of athletes with Down syndrome. In fact, there is only one study, by Bronks and Parker (1985), on adults with Down syndrome, which concluded that all subjects had high endomorphic components. Accordingly, further studies on this topic are also needed, since an accurate assessment of somatotypes may provide valuable insight into the ideal conditions for the optimal physiologic function of athletes with Down syndrome.

Furthermore, the association between somatotype and the prevalence of several chronic diseases in the general population recently reported by Koleva et al. (2002) suggests the importance of somatotype assessment for both athletes and non-athletes with Down syndrome. Conversely, Malousaris et al. (2008) concluded that somatotype does not influence the incidence of sport-related injuries.

118.5 Applications to Other Areas of Health and Disease

Anthropometric assessment may play an important role for healthcare providers and sport-related professionals who work with individuals with DS. In this line it may be of interest not only in Sports Medicine but also in several medical specialties such as: Family Medicine, Paediatrics, Cardiology, Endocrinology, Internal Medicine, Trauma, Preventive Medicine, among others.

Summary Points

- Obesity, hypotonia and osteoporosis are very common in individuals with Down syndrome and may play a role in undermining their health status and quality of life.
- Fortunately, intervention programmes designed by multidisciplinary teams and based on regular exercise specifically for this group may help solve these problems.
- Similarly, there is a growing interest in boosting the physical performance of individuals with Down syndrome, given the many national and international sport events for individuals with DS.
- An anthropometric assessment that includes body composition and somatotype analysis may help healthcare providers and sport-related professionals not only to achieve all these goals, but also to achieve them safely.
- Furthermore, long-term follow-up studies on this topic are sorely needed to confirm these findings, which may ultimately increase their use in daily practice.

Part XVIII
Anthropometry in Metabolic Disease and Obesity

Chapter 119
Value of Waist Circumference in Metabolic Diseases

V. Saroja Voruganti and Anthony G. Comuzzie

Abstract Obesity is a global health problem affecting adults, adolescents, and children alike. It has reached epidemic proportions in the United States with approximately 34% of adults classified as clinically obese and additional 34% overweight. Abdominal obesity, characterized by excess visceral fat, is associated with an increased risk for several metabolic diseases including type 2 diabetes, cardiovascular disease, and metabolic syndrome. Imaging modalities are the best measures for abdominal obesity, but are not always feasible in clinical settings. Waist circumference is an anthropometric measurement that is easy, cost effective, informative, and well suited for assessment in nearly all clinical settings. It is strongly correlated with, and used as a surrogate marker for, abdominal fat mass and has been associated with all-cause mortality. Increased waist circumference is closely associated with alterations in carbohydrate and lipid metabolism as well as inflammation and atherosclerosis. Other metabolic diseases such as asthma, sleep apnea, and certain types of cancer have also been associated with an increase in waist circumference. In addition, a larger waistline is generally associated with an overall decrease in cardio-respiratory and general physical fitness and health-related quality of life. In conclusion, waist circumference is an easily obtainable measure that can be used to quickly assess an individual's susceptibility to cardiometabolic disease risk.

Abbreviations

ApoB	Apolipoprotein B
BMI	Body mass index
CRP	C-reactive protein
CVD	Cardiovascular disease
GLUT4	Glucose transporter 4
HDL	High-density lipoprotein
ICAM 1	Intercellular adhesion molecule 1
IDF	International Diabetes Federation
IL6	Interleukin 6
IRS-2	Insulin receptor substrate-2

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_119,

LDL	Low-density lipoprotein
NHLBI	National Heart, Lung and Blood Institute
PAI-1	Plasminogen activator inhibitor 1
T2DM	Type 2 diabetes mellitus
TNF α	Tumor necrosis factor alpha
VLDL	Very low-density lipoprotein
WHR	Waist to hip ratio

Key Features

Table 119.1 Key messages

- Waist circumference is a major risk factor for metabolic disorders
- Carbohydrate as well as lipid metabolism pathways are adversely affected by increase in waist circumference
- Measurement of waist circumference as part of routine health check will provide a clinical marker for metabolic diseases

119.1 Introduction

Obesity is a global health problem affecting adults, adolescents, and children alike (Vega 2002). It has reached epidemic proportions in the United States with approximately 34% of adults classified as clinically obese and additional 34% overweight (Flegal et al., 2010). Obesity is a clearly recognized risk factor for metabolic diseases such as type 2 diabetes mellitus and cardiovascular disease (CVD) (Klein 2001). Central or abdominal adiposity is more closely associated with cardiometabolic risk than gluteofemoral obesity and is generally thought to worsen the metabolic disorders that are associated with overall obesity (Poirier and Despres 2003). Women are more likely to have gluteofemoral obesity as compared to men. However, with weight gain, women too tend to accumulate more abdominal fat (Pi-Sunyer 2002). Several studies have shown that excess abdominal fat is an independent predictor of metabolic diseases (Poirier and Despres 2003; Klein et al. 2007; Despres and Lemieux 2006).

Overweight and obesity are usually characterized by body mass index (BMI). However, BMI, which is calculated as weight in kilograms divided by height in meters squared (kg/m^2), does not take into account the regional variation in adiposity. Hence, there is a need for a measure of body fat that is easy to obtain and is a strong indicator of regional, particularly abdominal, adiposity. Traditionally, the waist to hip ratio (WHR) was considered to be a good measure of central obesity. Although WHR has been considered as a measure of abdominal adiposity, waist circumference and hip circumference capture two different aspects of body composition. The WHR provides information on the relative accumulation of abdominal fat and includes the combined effects of adiposity, skeletal muscle, and body frame (Seidell et al. 2001). The WHR remains unchanged if both waist and hip circumferences increase in the same proportion, resulting in misleading results. Waist circumference, on the other hand, provides an estimate of the absolute amount of abdominal adipose tissue (Despres and Lemieux 2006). Abdominal fat is best measured by imaging modalities such as magnetic resonance imaging or computerized tomography. However, Sabir et al. found that visceral fat accumulation as measured by ultrasound correlates significantly with waist circumference. Therefore, waist circumference provides a reasonably accurate estimate of abdominal obesity that can be computed in clinical settings.

Waist circumference alone has been found to be an informative measure of central obesity and has been associated with all-cause mortality. The National Heart, Lung and Blood Institute (NHLBI) has recommended that waist circumference be included as a part of any initial assessment in weight loss therapy, and is now widely recognized as an indicator of metabolic abnormalities (Klein et al. 2007). In this chapter, we describe the utility of waist circumference as a measure of abdominal obesity in the evaluation of an individual's cardiometabolic risk.

119.2 Abdominal Obesity and Waist Circumference

Abdominal obesity, characterized by the accumulation of excess visceral fat, is associated with an increased risk for several diseases including cardiovascular disease (CVD) (Table 119.2). Individuals with abdominal obesity show greater metabolic complications than those with peripheral obesity (Despres and Lemieux 2006). Abdominal obesity is associated with an increased supply of plasma free fatty acids that are directly drained into the portal vein (Bosello and Zamboni 2000). Fat in this area has a high turnover rate and is metabolically active. These fatty acids cause insulin resistance, especially in skeletal muscle and liver by interfering with the activities of insulin receptor substrate-2 (IRS-2) associated phosphatidyl inositol 3 (PI 3) kinase and the glucose transporter, GLUT 4 (Schinner et al. 2005). Visceral obesity is associated with impaired levels of triglycerides, increased very low-density lipoproteins (VLDLs) and lower HDL cholesterol. Higher levels of VLDL diminish HDL cholesterol because of an exchange of core lipids, which is mediated by cholesterol ester transfer protein (Ginsberg 2003). High triglycerides and low HDL cholesterol levels are associated with a greater risk of atherosclerosis (Ginsberg 2003). Figure 119.1 depicts a simplified presentation of how abdominal fat is an integral risk factor for metabolic disorders.

An increase in waist circumference is also associated with a hypertrophic form of obesity. Hypertrophic obesity is characterized by an increase in fat cell (adipocyte) size, which is associated with several metabolic alterations (Aronne 2002). Adipocyte hypertrophy leads to increased lipolysis, activation of proinflammatory cytokines and chemokines, reduced adiponectin release and insulin resistance (Gustafson et al. 2009). Visceral adipocytes, in particular, are known to be hyperlipolytic,

Table 119.2 Metabolic disorders associated with abdominal obesity

Disorders associated with abdominal obesity (Increased waist circumference)
• Impaired glucose tolerance
• Insulin resistance
• Hypertriglyceridemia
• Dyslipidemia
• Endothelial dysfunction
• Inflammation
• Hypertension
• Microalbuminuria
• Atherosclerosis
• Fatty liver disease
• Asthma
• Sleep apnea
• Several types of cancer
• Osteoarthritis

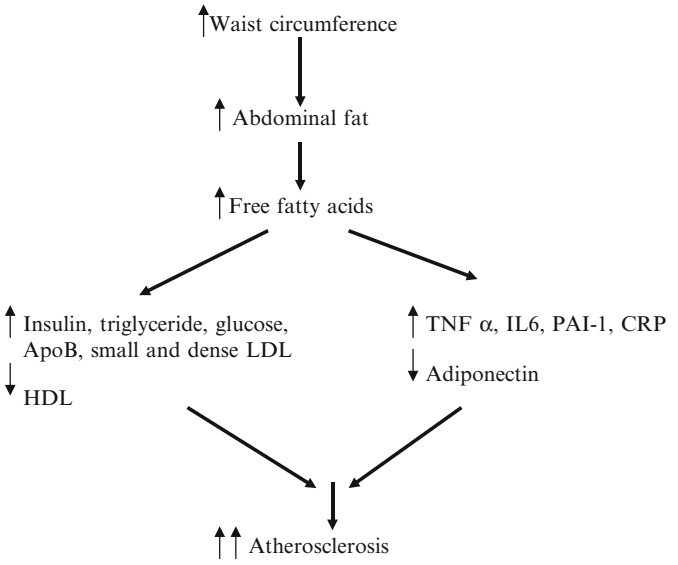

Fig. 119.1 Simplified presentation depicting how high abdominal fat affects cardiometabolic profile (Adapted from Poirier and Depres 2003)

highly sensitive to catecholamines and poorly sensitive to insulin. Enzyme lipoprotein lipase (LPL) plays an important role in lipolysis and subsequent release of fatty acids. Both lipolysis and adipose LPL activity were found to be elevated with increased waist circumference in normal to obese men (Biovin et al. 2007). Increased flux of fatty acids through the portal vein is known to overwhelm the liver leading to hypertriglyceridemia, hyperinsulinemia, and glucose intolerance (Mathieu et al. 2009). Given these implications of increased waist circumference, a consensus statement issued by the Association of Weight Management and Obesity Prevention, NAASO, The Obesity Society, the American Society for Nutrition and the American Diabetes Association in 2007 describes the usefulness of waist circumference in evaluating patients at risk for cardiometabolic complications (Klein et al. 2007). Individuals with similar BMI but different waistlines show distinct differences in their risk for cardiometabolic disease. The risk for a metabolic disease is increased with a larger waist circumference even in individuals with normal weight and BMI (Despres and Lemieux 2006). Waist circumference provides useful information along with BMI in the management of metabolic disorders and weight loss therapy (Fig 119.2).

119.3 Waist Circumference in Metabolic Diseases

119.3.1 Carbohydrate Metabolism

Cells metabolize nutrients (carbohydrates, proteins, lipids) supplied through our diets to provide energy. Alterations in these metabolic pathways or processes increase the risk for diseases such as diabetes, metabolic syndrome, cardiovascular disease, and several cancers. Carbohydrates are broken down into six-carbon glucose molecules, which are used for either building other compounds or for producing energy.

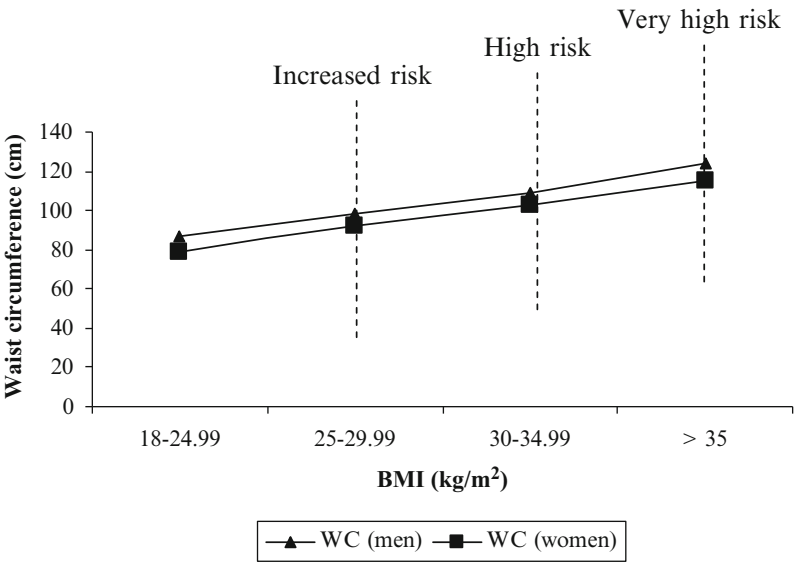

Fig. 119.2 Combination of BMI and waist circumference in identifying the risk for cardiometabolic disease (Ref: Klein et al. 2007)

1. *Glucose intolerance*: For optimum functioning, the body needs to maintain blood glucose levels within limits (80–100 mg/dl), with both high and low blood glucose levels being deleterious. Impaired glucose tolerance, also known as pre-diabetes, is a condition where fasting glucose values are between 100 and 124 mg/dl. Higher waist circumference seems to have a negative effect on glucose metabolism. In individuals with impaired fasting glucose levels, higher waist circumference indicates a greater risk for coronary artery disease than those with normal fasting glucose (St-Pierre et al. 2002). In a study conducted to investigate the effect of Roux-en-Y gastric bypass surgery in individuals with normal and impaired fasting glucose levels, it was observed that reduction in waist circumference, as a result of the surgery, was significantly associated with improvement in fasting glucose as well as insulin sensitivity (Gomez-Ambrosi et al. 2007).
2. *Insulin resistance*: Insulin resistance is a condition in which glucose uptake by insulin-sensitive tissues is diminished. The resultant hyperglycemia is compensated by an increased production of insulin by the pancreatic beta cells. Initially, increased secretion of insulin is effective, but gradually, beta cells are overburdened, and their function is adversely affected, leading to the development of type 2 diabetes. Insulin resistance is a strong predictor of type 2 diabetes and CVD risk (Schinner et al. 2005). When evaluating the risk for metabolic syndrome, the International Diabetes Federation included waist measurement as the first criterion in identifying individuals at risk for metabolic syndrome. This was controversial as some felt that insulin resistance was the most prominent factor in the metabolic syndrome and not waist circumference. However, insulin resistance and excess abdominal fat are highly correlated and visceral obesity seems to be the driving factor in the pathogenesis of insulin resistance (Bosello and Zamboni 2000).

Insulin resistance is highly prevalent in individuals who are abdominally obese (Despres and Lemieux 2006). A lower waist circumference (<100 cm) is believed to exclude the risk of insulin resistance in both men and women (Wahrenberg et al. 2005). Waist circumference was also found to be an independent predictor of insulin resistance in young individuals aged between 8 and 17 years (Lee et al. 2006). The homeostatic model assessment method (HOMA) is often used to estimate insulin resistance.

Table 119.3 Significant correlations between waist circumference and metabolic risk factors

	Correlation coefficient (r^2)	Population	References
Glucose	0.363–0.475	European and Chinese women	Lear et al. (2002)
Insulin	0.563–0.662	European and Chinese men and women	Lear et al. (2002)
HOMA*	0.521	Caucasians	Kressel et al. (2009)
Total cholesterol	0.298–0.452	European and Chinese men and women	Lear et al. (2002)
	0.344	European men	Han et al. (1995)
		European women	Han et al. (1995)
Triglycerides	0.378–0.655	European and Chinese men and women	Lear et al. (2002)
LDL* cholesterol	0.209–0.404	European and Chinese men and women	Lear et al. (2002)
HDL*	(–0.273) – (–0.369)	European and Chinese men and women	Lear et al. (2002)
	–2.1	Caucasians	Kressel et al. (2009)
	–0.269	European men	Han et al. (1995)
	–0.261	European women	Han et al. (1995)
Systolic blood pressure	0.336	European men	Han et al. (1995)
	0.372	European women	Han et al. (1995)
Diastolic blood pressure	0.371	European men	Han et al. (1995)
	0.374	European women	Han et al. (1995)

**HOMA* Homeostatic model assessment method,
**LDL* Low-density lipoprotein,
**HDL* high-density lipoprotein
**Only significant correlations ($p < 0.05$) are shown in the table

Waist circumference was significantly correlated with HOMA in Caucasians (Kressel et al. 2009), and glucose and insulin were also positively correlated with waist circumference (Lear et al. 2002). Table 119.3 shows the significant correlations between metabolic risk factors and waist circumference.

119.3.2 Lipid Metabolism

Lipids are preferred as sources of energy after carbohydrates. They are important as energy reserves. Increased waist circumference reflects increased visceral adipose tissue. Free fatty acids released from visceral adipose tissue can interfere with normal lipid metabolism by disrupting cholesterol and triglyceride metabolism.

1. Cholesterol: As described earlier, excessive lipolysis from expanded visceral adipose tissue releases free fatty acids into the portal circulation leading to a cascade of events contributing to increased production of triglyceride-enriched LDL cholesterol. By the further action of hepatic lipase, these LDLs tend to become small and dense which tend to damage vascular walls and are atherogenic in nature (Mathieu et al. 2009). Individuals with higher waist circumference tend to have higher levels of small and dense LDLs (Lemieux et al. 2000). Increased levels of small and dense LDLs are also associated with lower levels of HDL cholesterol. In individuals with larger waistline, HDL levels were found to be low. In addition, they were found to have higher levels of small HDL, indicating that small HDL particle size is another feature of dyslipidemia that accompanies visceral adiposity (Burns and Arslanian 2009). Also, oxidized LDL, a significant marker of atherosclerosis, was closely associated with waist circumference independent of BMI (Weinbrenner et al. 2006).

The fatty acid (main constituent of fats) composition has been related to metabolic disease risk. Polyunsaturated fatty acids (PUFA) have been associated with beneficial effects on lipid metabolism and blood pressure. Omega-3 fatty acids (n-3 PUFA) are known to improve lipid profile and reduce blood pressure, insulin resistance and inflammation (Lee et al. 2008). Studies conducted with plasma fatty acid composition have shown that waist circumference was positively correlated with saturated and trans fatty acids and negatively with PUFAs (Lee et al. 2008). Steffen et al. (2008) investigated fatty acid composition in plasma, cholesterol esters, and phospholipids in adolescents between 13 and 17 years of age in relation to metabolic disease risk factors. These children were classified as normal and overweight based on their BMI percentiles. Waist circumference was significantly higher ($p \leq 0.001$) in overweight as compared to normal weight children. Waist circumference was correlated positively with plasma stearic acid and inversely with linoleic and oleic acids, indicating an adverse fatty acid profile for children with higher BMI and larger waist circumference.

2. Triglycerides: The delivery of free fatty acids to the liver contributes to the synthesis of VLDLs enriched with triglycerides (Mathieu et al. 2009). Hypertriglyceridemia or increased triglycerides usually arises due to increased production or reduced clearance of VLDLs and tend to increase the production of small and dense LDLs. Individuals with increased waist circumference, small and dense LDLs, apolipoproteins B and triglycerides are known to be at high risk for coronary events. Lemieux et al. (2000) reported a clinical phenotype 'hypertriglyceridemic waist" which includes higher waist (≥90 cm) in conjunction with higher triglyceride (≥177 mg/dl) to indicate cardiometabolic risk. An important step in VLDL production is the production rate of apolipoprotein B (ApoB) (Lewis and Steiner 1996). Abdominal adiposity and impaired liver insulin signaling are known be associated with higher levels of ApoB. Excess abdominal fat also leads to increased deposition of triglycerides in liver (Jakobsen et al. 2007). Studies using waist circumference as a measure for abdominal obesity have shown a positive correlation between increased waist circumference and liver steatosis (Sabir et al. 2001).

   A study conducted by Han et al. (1995) used waist circumference categories to stratify the risk for metabolic disease, particularly hyperlipidemia and hypertension. They determined two action levels of waist circumference (based on an earlier study by Lean et al. (1995)) to identify people at health risk. Accordingly, action level 1 included men and women with waist circumference greater than or equal to 94 and 80 cm, respectively and action level 2 included men and women with waist circumference greater than or equal to 102 and 88 cm, respectively. The prevalence of total cholesterol, LDL cholesterol, and systolic and diastolic blood pressure increased with increase in action levels of waist circumference in both men and women. Waist circumference action levels can also be utilized to predict the risk of metabolic disease related to hyperlipidemia or hypertension (Han et al. 1995).

119.3.3 Protein Metabolism

Proteins are the least preferred sources of energy. Amino acids (breakdown products of proteins) are catabolized only when other sources of energy are not adequate. Abdominal obesity has been associated with alterations in glucose and lipid metabolism. However, not much is known about its effect on protein metabolism.

119.3.4 Hypertension

Greater visceral adiposity is known to be positively associated with hypertension, a major CVD risk factor (Mathieu et al. 2009). Visceral adipose tissue is known to express higher amounts of angiotensinogen which is converted to angiotensin, and is activated in hypertension (Mathieu et al. 2009). Blood volume as well as pressure is actively regulated by angiotensin II along with epinephrine, norepinephrine, atrial natriuretic peptide (ANP), and antiduretic hormone (ADH). Waist circumference is known to have a greater impact on blood pressure than BMI. It was observed that a decrease in waist circumference, and not BMI, was associated with a reduction in blood pressure and angiotensinogen in women (Engeli et al. 2005). Investigations into the usefulness of anthropometric measurements in predicting hypertension have shown that waist circumference is an independent risk factor for hypertension and is closely associated with it, particularly in men (Yalcin et al. 2005).

119.3.5 Inflammation/Endothelial Dysfunction

Increased lipolysis as a result of adipocyte hypertrophy has wide ranging implications. On the one hand, it causes the cell to become insulin resistant and on the other hand it induces the activation of proinflammatory cytokines such as interleukin 6 (IL6), interleukin 8 (IL8) and macrophage chemoattractant protein 1 (MCP1). Hypertrophic obesity also leads to the infiltration of macrophages into the adipose tissue, resulting in inflammation (Gustafson et al. 2009). In addition, biomarkers of endothelial dysfunction are known to increase with adipocyte hypertrophy (Burns and Arslanian 2009). These markers, intercellular adhesion molecule 1 (ICAM1) and E-selectin, play an important role in plaque formation and inflammation. In a study conducted in children, a higher waist circumference was associated with increases in ICAM1 and E-selectin (Burns and Arslanian 2009). The CRP is an acute phase reactant protein and is a sensitive marker of systemic inflammation. In a study in adolescents, waist circumference was positively associated with CRP and complement factors C3 and C4 (Warnberg et al. 2006). Higher waist circumference was also associated with oxidative stress and higher valvular inflammation in patients who were undergoing aortic valve replacement surgery (Cote et al. 2009).

Increased proinflammatory cytokines (due to increased visceral adiposity) may affect the integrity of the endothelial wall, which may also lead to microalbuminuria. Microalbuminuria is defined as urinary albumin excretion of 30–300 mg/24 h. It is a known cardiovascular risk factor and is known to predict the progression of diabetic nephropathy (Thoenes et al. 2009). In a large study of about 21,000 individuals, it was found that microalbuminuria was positively associated with waist circumference (Thoenes et al., 2009). However, the mechanism is not clear. Likewise, another risk factor for CVD, end stage renal disease (ESRD) is also affected by changes in waist circumference. It has been observed that patients with ESRD and larger waist circumference have high risk of death due to CVD as compared to those with smaller waistlines (Postorino et al. 2009).

119.3.6 Other Metabolic Diseases

Several other diseases are affected by an increase in abdominal obesity and waist circumference. Obesity is a risk factor for asthma, several types of cancer, osteoarthritis, restless leg syndrome, sleep

apnea, etc. Abdominal obesity, measured by waist circumference, has been associated with esophageal and breast cancer and cancer mortality (Steffen et al. 2009). Visceral obesity is known to affect pulmonary function. Of all anthropometric measurements, waist circumference was found to have the greatest impact on markers of pulmonary function (e.g., forced vital capacity, forced expiratory volume, total lung capacity, and vital capacity) (Wei et al. 2009). Waist circumference has been positively correlated with the incidence of asthma even in women with normal body weight (Von Behren et al. 2009). When compared with BMI, waist circumference was more strongly associated with asthma and its severity in children (Musaad et al. 2009). Larger waistlines have also been associated with osteoarthritis; individuals with a larger waist circumference having reduced cartilage volume increasing the risk for patello femoral osteoarthritis (Teichtahl et al. 2008).

119.4 Application to Other Areas of Health and Disease

119.4.1 Physical Fitness

An increased waist circumference is associated with decreased physical fitness. Increased physical activity, aerobic and cardio-respiratory fitness have been consistently associated with lower waist circumferences. In young adults, waist circumference was inversely associated with cardio-respiratory and neuromuscular fitness (Sakuragi et al. 2009). Increased waist circumference was also associated with lower maximal isometric and isokinetic knee extensor strength (Thomson et al. 2009). Likewise, in boys and adolescents, muscular and cardio-respiratory fitness were negatively associated with waist circumference. In adolescents, handgrip strength was positively associated with waist circumference (Moliner-Urdiales et al. 2009).

119.4.2 Quality of Life

Obesity, in general, negatively affects an individual's quality of life, particularly in women, and is considered to be a significant predictor of poor psychological well being and health-related quality of life. Health-related quality of life encompasses several aspects of lifestyle, including physical health, work-related health, routine life, sexual life, diet distress, and pain/discomfort. Abdominal obesity, as measured by waist circumference, was associated with a lower quality of life and increased ill health (Han et al. 2009) with women being affected more than men (Akinpelu et al. 2009).

119.5 Conclusion

Waist circumference is a simple anthropometric measurement that is practical and relatively easy to obtain in clinical settings and strongly correlates with abdominal obesity. Waist circumference is closely associated with alterations in carbohydrate and lipid metabolism. Waist circumference can be used to screen individuals who are at greater risk for metabolic diseases and raise awareness of the need for proper management of weight.

Summary Points

- Obesity, particularly abdominal obesity, is a major risk factor for several metabolic diseases.
- Waist circumference is a simple anthropometric measurement that correlates highly with abdominal obesity.
- Waist circumference is easily measured in clinical settings and requires no complicated equipment or calculations.
- Larger waist circumferences are associated with increased risk for metabolic alterations such as impaired glucose tolerance, dyslipidemia, hypertension, inflammation/endothelial dysfunction and atherosclerosis.
- The risk for diseases such as arthritis, some types of cancer and asthma also seems to increase with an increasing waist circumference.
- The quality of life and general physical fitness are adversely affected with an increase in waist circumference.
- Waist circumference is easy to measure and provides important information in identifying individual's at risk for metabolic disorders.

Chapter 120
Waist Circumference for the Clinical Diagnosis of Metabolic Syndrome in the Japanese Population: Optimal Cut-Point to Predict Early Arteriosclerosis

Yuka Matoba, Toyoshi Inoguchi, Atsushi Ogo, and Ryoichi Takayanagi

Abstract Metabolic syndrome (MetS) has been proposed as a syndrome in an individual with clustered metabolic dysfunction including increased abdominal adiposity, raised blood pressure, raised triglyceride and/or reduced HDL cholesterol and raised fasting plasma glucose. At the time of writing, several definitions for clinical diagnosis of MetS have been proposed by different organizations. Clinical methods to evaluate visceral adiposity include abdominal computed tomography, body mass index, and waist and hip circumference; in which waist circumference is the most available, but is highly dependent on the ethnicity. Current MetS definitions include waist circumference as a surrogate marker for visceral adiposity and adapt cut-points of waist circumference for each ethnic group to optimize their predictive values. For Asians, the International Diabetes Federation (IDF), the American Heart Association and the National Heart, Lung and Blood Institute have provided the waist cut-points as 90 cm for men and 80 cm for women as recommended by the World Health Organization. By contrast, the previous IDF definition and the Japanese Committee for the Diagnostic Criteria of Metabolic Syndrome adopted waist cut-points of 85 cm for Japanese men and 90 cm for Japanese women which were derived from the cut-points of visceral fat area by computed tomography to identify clustered risk factors. After the MetS definitions were published, waist cut-points for the Japanese population have been re-evaluated in several studies. Our recent studies obtained optimal waist cut-points (87 cm for men and 80 cm for women) from the relation between waist circumference and risk factor clustering in a Japanese population. It showed superior sensitivity and specificity to the conventional IDF (90 cm), which is also the cut-points for Japanese women (90 cm), to predict intima-media thickening; it also agreed with the revised IDF definition (80 cm) for women. These studies suggest that the waist cut-points of 90 cm for men and 80 cm for women are relevant for Japanese population to define MetS with a short-term risk of development of atherosclerosis. Further studies with larger population and longer follow-up period may validate these waist cut-points for the clinical diagnosis of MetS with a substantial risk of cardiovascular events and/or onset of type 2 diabetes.

120.1 Introduction

Metabolic syndrome (MetS) has been proposed as a syndrome in an individual with clustered metabolic dysfunction including increased abdominal adiposity, raised blood pressure, raised triglyceride and/or reduced HDL cholesterol and raised fasting plasma glucose (Alberti and Zimmet 1998). The predominant pathological states for MetS are visceral adiposity and insulin resistance, which contribute to a dyslipidemic state, prothrombotic profile and a state of inflammation, which increases the risk for type 2 diabetes and atherosclerotic cardiovascular diseases (Lakka et al. 2002; Dekker et al. 2005; McNeill et al. 2005; Kawamoto et al. 2005; Katzmarzyk et al. 2006; Isomaa et al. 2001; Takeuchi et al. 2005). At the time of writing, several definitions for clinical diagnosis of MetS have been proposed by different organizations. The American Heart Association and the National Heart, Lung, and Blood Institute (AHA/NHLBI) published its revised MetS definition in 2005 (Grundy et al. 2005). In the same year, the International Diabetes Federation (IDF) proposed a worldwide definition that recommends the ethnicity-specified waist circumference criteria for each region in consideration of the ethnic differences in the prevalence and characteristics of MetS (Alberti et al. 2005). The Japanese Committee for the Diagnostic Criteria of Metabolic Syndrome has also published a definition exclusively for the Japanese population in 2005 (The Japanese Committee for the Diagnostic Criteria of Metabolic Syndrome 2005). All the above definitions employed waist circumference as a surrogate marker for abdominal adiposity and defined its cut-points based on different rationales. In order to optimize MetS diagnosis for the specific ethnic group, each definition considers waist circumference criterion specific for Asians or for exclusively the Japanese population (Table 120.1). The purpose of this review is to describe the rationale of each cut-point of waist circumference employed in each MetS definition and to discuss how to determine the optimal waist cut-point for MetS diagnosis to identify subjects at high risk for future cardiovascular diseases.

120.2 Evaluating Visceral Adiposity for the Clinical Diagnosis of MetS

Visceral fat accumulation has long been suggested to cause an adverse metabolic profile with issues such as glucose intolerance, hypertension and dyslipidemia and to be associated with cardiovascular diseases (Eckel et al. 2005; Alberti et al. 2005; Despres and Lemieux 2006). The visceral adipose

Table 120.1 Feature of criteria for clinical diagnosis of metabolic syndrome for Asian or Japanese

Diagnosis	AHA/NHLBI (2005) Any three of the following five features	IDF (2005) Increased WC plus any two of the following five features	Japanese (2005) Increased WC plus any two of the following four features
WC (cm)	≥ 90 in men ≥ 80 in women for Asian	≥ 90 in men ≥ 80 in women for Japanese	≥ 85 in men ≥ 90 in women
FPG (mg/dl)	≥ 100 or On medication for elevated glucose	≥ 100 or On medication for elevated glucose	≥ 110 or On medication for elevated glucose
BP (mmHg)	Systolic ≥ 130 Diastolic ≥ 85 or On medication for elevated BP	Systolic ≥ 130 Diastolic ≥ 85 or On medication for elevated BP	Systolic ≥ 130 Diastolic ≥ 85 or On medication for elevated BP
Dyslipidemia (mg/dl)	TG ≥ 150 or On medication for elevated TG HDL < 40 in men HDL < 50 in women or On medication for reduced HDL	TG ≥ 150 or On medication for elevated TG HDL < 40 in men HDL < 50 in women or On medication for reduced HDL	TG ≥ 150 or HDL < 40 or On medication for elevated TG or reduced HDL

Above all definitions employed waist circumference as a surrogate marker for abdominal adiposity. Each definition accustoms waist circumference criterion specific for Asians or for exclusively Japanese. In Japanese definition, cut-points of 85 cm for men and 90 cm for women were decided as the respective values of the waist circumference correspond to 100 cm^2 of visceral fat area

tissue is now known to secrete pro-inflammatory (e.g., IL-6, TNF-α) and anti-inflammatory (e.g., adiponectin) cytokines and play a central role for developing insulin resistance and MetS (Ridker et al. 2003; Freeman et al. 2002; Bermudez et al. 2002).

1. Computed tomography

Computed tomography (CT) scanning is the most accurate method to evaluate the visceral fat. Theoretically, serial scanning may determine the volume of visceral as well as subcutaneous fat. Indeed, visceral fat area determined by CT at the umbilical level is well correlated with the clustering of risk factors, which is adopted for the concept of the Japanese definition (Japan Society for the Study of Obesity 2002). The weakness of the method, however, is the availability of the equipment and the exposure to radiation.

2. Body mass index

Body mass index (BMI), a well-known parameter determined by the weight and the height, has been widely used to describe obesity in clinical settings. Increased BMI is associated with an increased probability of metabolic abnormalities (Whitlock et al. 2009). The World Health Organization (WHO) generally defines obesity as BMI ≥ 30 kg/m^2, and overweight as BMI ≥ 25 kg/m^2. Since several studies have shown that Asians have higher amounts of body fat at lower BMI than Western populations, the Western Pacific regional office of the WHO, the International Association for the Study of Obesity (IASO) and the International Obesity Task Force (IOTF) collaborated to create the new recommendations for BMI cutoffs among Asian populations in 2000. In these recommendations, obesity is defined

as BMI ≥ 25 kg/m^2 and overweight is defined as BMI ≥ 23 kg/m^2 for Asians. Since BMI measures total body mass, it is largely influenced by structural divergence of the subject's body including ethnicity, muscularity and dominance of visceral or subcutaneous fat, which affects the accuracy of BMI, in order to evaluate the visceral adiposity.

3. Waist and hip circumference

Measuring waist and/or hip circumference is a simple and costless approach to estimate visceral adiposity. Yusuf et al. (2005) showed that waist circumference, hip circumference and waist hip ratio (WHR) were closely associated with the risk of myocardial infarction even after adjustment for risk factors other than BMI in a case control study with 27,000 participants. Winter et al. (2008) showed that waist circumference and WHR were strongly associated with the risk of stroke/TIA, independent of other vascular risk factors in a case–control study with 1,137 participants. More recently, in the EPIC-Norfolk study that followed subjects for 9 years, waist circumference was associated with an elevated CHD risk, whereas a large hip circumference appeared to be protective against CHD after adjusting for confounding variables including BMI. Above all, these studies suggested the predictive value of waist circumference for cardiovascular diseases that is associated with visceral adiposity, and thus, current definitions of MetS employ waist circumference as an indicator of visceral adiposity.

120.3 Ethnicity in Cut-Points for Waist Circumference

A number of studies have shown that the relationship of waist circumference and visceral adiposity is affected by age, gender and ethnicity (Han et al. 1997; Lemieux et al. 2006; Lemieux et al. 1996; Pascot et al. 1999; Hayashi et al. 2007; Despres et al. 2000; Misra et al. 2005). The National Institutes of Health clinical guidelines for obesity adopted the waist cut-points for central obesity as 102 cm for men and 88 cm for women in the USA (National Institutes of Health 1998). These cut-points were employed by ATP III to define central obesity and correspond approximately to a BMI of 30 kg/m^2, or clinical obesity, in European populations.

Although the WHO report in 1998 suggests that 94 cm in men and 80 cm in women should be the appropriate measures in Europeans, these cut-offs are not suitable for Asian populations. Asians appear to have higher morbidity at lower cut-points for waist circumference than do white Caucasians (Wildman et al. 2004; Deurenberg et al. 1998). The WHO Asian report suggested lower waist cut-points for Asians, 90 cm for men and 80 cm for women, because Asians have an increased propensity to abdominal obesity and they also have an absolute increase in risk at any particular waist measurement.

IDF adopted the waist cut-points for south Asians and Chinese, 90 cm for men and 80 cm for women, as recommended by the WHO and validated in a series of studies (Wildman et al. 2004; Tan et al. 2004). Also, for the Japanese, because of new supportive data, IDF has adopted the waist cut-points of 90 cm for men and 80 cm for women, instead of the original value of 85 cm for men and 90 cm for women that was derived from the Japanese waist criteria (The IDF consensus worldwide definition of the metabolic syndrome, available at http://www.idf.org/webdata/docs/MetS_def_update2006.pdf). The AHA/NHLBI also recommended the waist cut-points for Asian Americans, 90 cm for men and 80 cm for women, when they modified NCEP/ATP criteria in 2005 (Grundy et al. 2005). By contrast, the cut-points of the waist circumference in the Japanese definition are 85 cm for men and 90 cm for women that featured the larger waist cut-point for women rather than men (The Japanese Committee for the Diagnostic Criteria of Metabolic Syndrome 2005) (Table 120.1).

These cut-points in the Japanese definition are derived from the relation with the visceral fat area as determined by computed tomography to identify individuals with multiple obesity-related diseases including hyperglycemia, dyslipidemia and hypertension (Japan Society for the Study of Obesity 2002).

120.4 Optimal Waist Cut-Points for Japanese Population

Current Japanese waist criterion was published in 2002 (Japan Society for the Study of Obesity 2002), which were adopted into the Japanese MetS definition. The Japanese waist cut-points were based on the report from the Examination Committee of Criteria for "Obesity Disease" in Japan, which showed that the optimal cut-point of visceral fat area determined by computed tomography (CT) for identifying individuals with plural obesity-related disorders, (1) hyperglycemia: FPG ≥110 mg/dl; (2) dyslipidemia: TC ≥220 mg/dl and/or TG ≥150 mg/dl and/or HDL-C <40 mg/dl; (3) hypertension: systolic blood pressure ≥140 mmHg and/or diastolic blood pressure ≥90 mmHg. The number of disorders was greater than 1.0 at 100 cm^2 in a study sample that combined both men and women. Japanese waist cut-points 85 cm for men and 90 cm for women were decided as the respective values of the waist circumference in men and women which correspond to 100 cm^2 of visceral fat area. Based on this approach, the waist cut-point for Japanese women might be greater than that for men because women generally tend to have more subcutaneous fat than men.

Since the Japanese definition was published in 2005 (The Japanese Committee for the Diagnostic Criteria of Metabolic Syndrome 2005), several studies have re-evaluated the cut-points for Japanese population; Hayashi et al. (2007) examined the waist cut-points based on the value of their visceral fat area separately in men and women using modified IDF definition in 639 Japanese-American subjects. In the study, they found that the optimal cut-points of visceral fat area differed by sex. They reported that the appropriate visceral fat area and waist circumference cut-points were 51.5 cm^2 and 81 cm (age ≦ 56 years) and 86.3 cm^2 and 89 cm (age >56 years) in women and 88.6 cm^2 and 90 cm (age ≦ 57years) and 96.1 cm^2 and 87 cm (age >57years) in men. Hara et al. (2006) reported that the waist cut-points to identify the subjects with multiple risk factors in the MetS definition were ~80 cm in women and ~85 cm in men, using the NCEP/ATP III definition in 692 general Japanese people. Also, Miyawaki et al. (Miyawaki et al. 2005) reported that the optimal visceral fat area and waist cut-points to identify the subjects with multiple risk factors of the MetS were 100 cm^2 and 86 cm for men and 65 cm^2 and 77 cm for women, respectively, using the Japanese definition in a study of 3,574 middle-aged general Japanese people.

Recently, we investigated the optimal waist cut-point to identify subjects with clustered metabolic dysfunction in general Japanese employees (Matoba et al. 2008). We reviewed cross-sectional data from 1,658 men and 1,116 women aged 49 ± 10 years and 47 ± 10 years respectively, who had annual medical checkup services provided by the companies that they work for. Waist circumference was measured at the level of the umbilicus. Blood pressure was measured at rest using an automatic sphygmomanometer. All blood samples were drawn after an overnight 10-hour fast. Mean carotid intima-media thickness (IMT) was measured by ultrasonography (SDU-2200, Shimadzu Co., Ltd., Kyoto, Japan) that was equipped with IMT measurement software (Intimascope, Media Cross Co., Ltd., Tokyo, Japan) (Yanase et al. 2006). We diagnosed MetS with waist circumference (WC) and at least two of the following risk factors, using the IDF definition: (1) blood pressure (BP), systolic ≥130 and/or diastolic ≥85 mmHg, (2) triglycerides (TG) ≥150 mg/dl, (3) HDL-cholesterol <40 mg/dl in men and <50 mg/dl in women, (4) fasting plasma glucose (FPG) ≥100 mg/dl; and using the Japanese definition: (1) blood pressure, same as the IDF, (2) triglycerides ≥150 mg/dl and/or HDL-cholesterol <40 mg/dl, (3) fasting plasma glucose ≥110 mg/dl.

Table 120.2 Basal data of the subjects

	Male		Female	
	MetS (+)	MetS (−)	MetS (+)	MetS (−)
Number (%)	415 (25.0%)	1,243 (75.0%)	34 (3.0%)	1,082 (97.0%)
Age (year)	50.4 ± 8.7*	48.2 ± 10.1	52.7 ± 9.1*	46.4 ± 10.4
BMI (kg/m2)	25.8 ± 2.8*	22.9 ± 2.7	28.6 ± 2.8*	20.8 ± 2.6
WC (cm)	93.2 ± 6.3*	84.3 ± 7.6	98.9 ± 7.4*	77.1 ± 7.9
SBP (mmHg)	125.2 ± 14.7*	113.0 ± 13.6	128.1 ± 14.2*	106.5 ± 14.8
DBP (mmHg)	78.0 ± 10.5*	69.5 ± 9.6	75.9 ± 39.8*	64.0 ± 9.9
FPG (mg/dl)	112.7 ± 30.0*	98.0 ± 14.8	105.8 ± 17.0*	91.2 ± 9.9
HbA1c (%)	5.5 ± 1.0*	5.0 ± 0.5	5.4 ± 0.6*	4.9 ± 0.4
TC (mg/dl)	211.7 ± 35.0*	204.5 ± 33.4	217.0 ± 35.0*	202.6 ± 35.2
TG (mg/dl)	216.6 ± 207.3*	116.1 ± 99.5	134.1 ± 63.8*	75.9 ± 39.8
HDL-C (mg/dl)	44.7 ± 10.0*	54.5 ± 12.5	51.0 ± 8.8*	65.2 ± 13.4
Mean IMT (mm)	0.639 ± 0.125*	0.592 ± 0.109	0.649 ± 0.10*	0.566 ± 0.10

In the MetS group, all of the following components, age, body mass index (*BMI*), systolic and diastolic blood pressure (*SBP*), fasting plasma glucose (*FPG*), HbA1c, total cholesterol (*TC*), triglyceride (*TG*), waist circumference (*WC*), carotid IMT were significantly higher and HDL-cholesterol (*HDL-C*) was significantly lower than non-MetS *$P<0.05$; vs. MetS (−) group

Table 120.3 Key Features of ROC curves and Youden index

1. Receiver operating characteristic (ROC) curve is a graphical representation of the relationship between the sensitivity and specificity of a measurement.
2. The area under the ROC curve indicates the appropriateness of the measurement.
3. Youden index is defined as maximum (sensitivity + specificity − 1), which is maximum vertical distance between the ROC curve and the diagonal line when equal weight is given to sensitivity and specificity.
4. Youden index provides the optimal threshold value of the measurement.

This table lists the key facts of ROC curves and Youden index
AUC area under the curve; *ROC curve* Receiver operating characteristic curve

The baseline characteristics of the study subjects are shown in Table 120.2. The prevalence of MetS as defined by IDF in men and women was25.0% and 3.0%, respectively, while that defined by the Japanese was 14.9% and 1.3%, respectively. In the MetS group, all of the following components – age, body mass index, systolic and diastolic blood pressure, fasting plasma glucose, HbA1c, total cholesterol, triglyceride, waist circumference, carotid IMT – were significantly higher and HDL-cholesterol was significantly lower than non-MetS (Table 120.2).

We plotted ROC curves to determine optimal waist cut-points (87 cm in men and 80 cm in women) to identify subjects with multiple risk factors with maximum sensitivity and specificity using the Youden index for both definitions (Table 120.3, Fig. 120.1a–d). Using the optimal cut point of 87 cm for men, the sensitivity and specificity were 68% and 62% for the IDF and 70% and 57% for the Japanese definition, whereas the cut point of 90 cm, compared with 87 cm, showed lower sensitivity of 51% for the IDF and 53% for the Japanese definition (Fig. 120.1a and b). Using the optimal cut point of 80 cm for women, the sensitivity and specificity were 74% and 70% for the IDF and 84% and 68% for the Japanese definition. The former IDF and Japanese cut point of 90 cm showed inadequate sensitivity of 33% for the IDF and 38% for the Japanese definition (Fig. 120.1c and d).

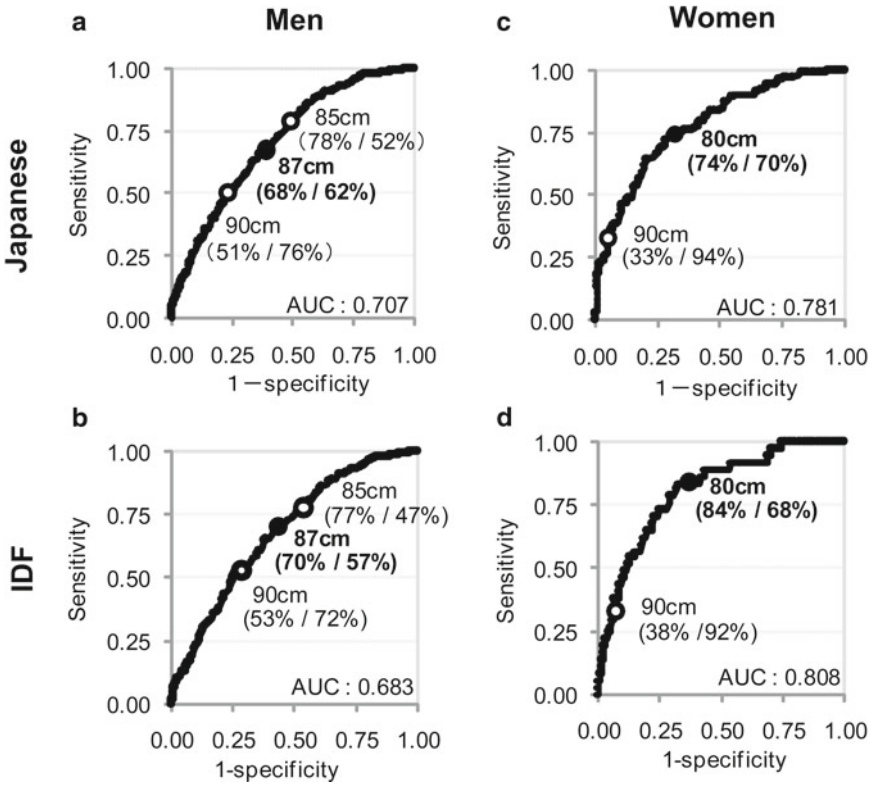

Fig. 120.1 ROC curves for waist circumference. ROC curves for waist circumference were plotted (**a**–**d**). Closed circles (●) on the ROC curve indicate the optimal cut-point with maximum sensitivity and specificity determined using the Yoden Index. Open circles (○) indicate the cut-point of the conventional and revised IDF waist cut-points. The numbers in parentheses under the waist circumference indicate sensitivity (%)/specificity (%) at each cut-point. The area under ROC curve is abbreviated to AUC

120.5 Validation of the Waist Cut-Points for MetS Diagnosis

Conceptually, the diagnosis of MetS would identify individuals at a high risk of cardiovascular diseases and type 2 diabetes. Indeed, waist cut-points and MetS diagnosis themselves are proven to predict future cardiovascular events (Wildman et al. 2004). In order to validate the above-determined waist cut-points, we divided the study subjects into subgroups by abdominal adiposity using the conventional and the optimal cut-point, and evaluated their predictability of increased intima-media thickness (IMT) (Matoba et al. 2008). Among 1,658 men, the cut-points of 85, 87, and 90 cm identified 25.0%, 21.9%, and 16.2%, respectively, of subjects with the metabolic syndrome, for the IDF definition; for the Japanese definition the cut-points were 14.9%, 13.4%, and 10.2%, respectively. In subgroups with abdominal adiposity, IMT increased significantly in metabolic syndrome subjects with multiple risk factors, suggesting the feasibility of the cut-points of 85, 87, and 90 cm (Fig. 120.2a and b). Among 1,116 women, the cut-points of 80 and 90 cm identified 7.0% and 3.0% of metabolic syndrome subjects, respectively, for the IDF definition and 2.8% and 1.3% of subjects, respectively, for the Japanese definition. In subjects with waist circumference ≥90 cm, there was no significant difference in IMT using either definition. In contrast, when we used the cut point of 80 cm, the IMT increased significantly in metabolic syndrome subjects (Fig. 120.2c and d), suggesting the feasibility

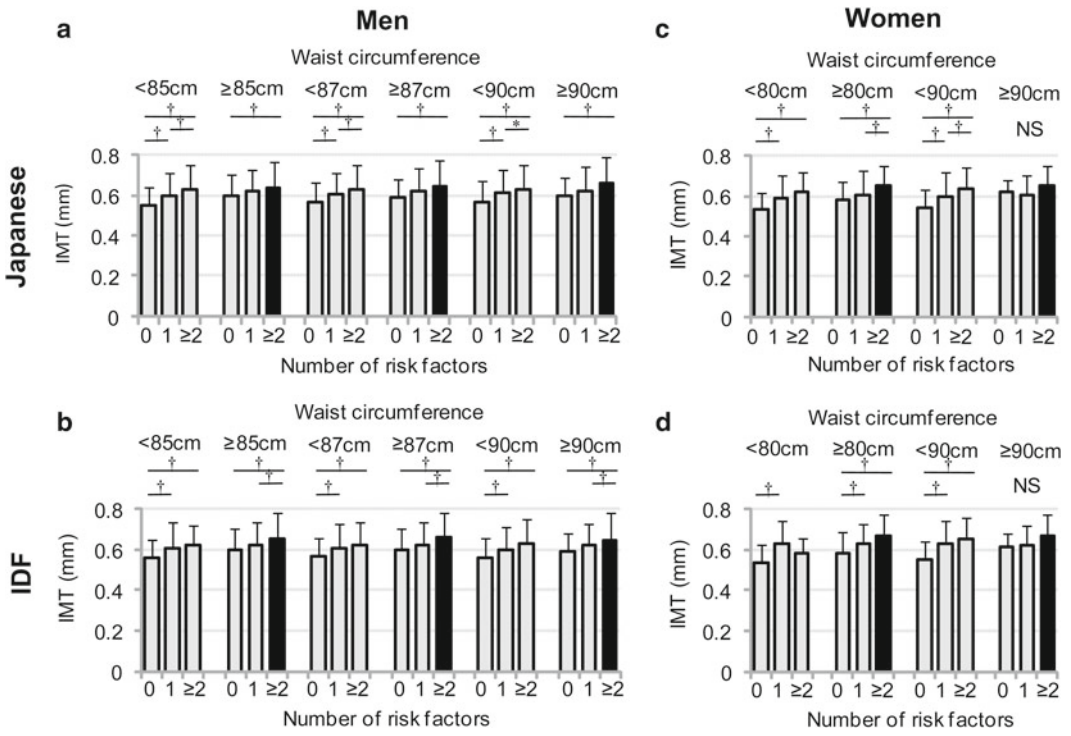

Fig. 120.2 Intima-media thickening in MetS subjects. Mean IMT were obtained in subgroups using the optimal or conventional waist cut-points and the IDF or the Japanese definition (**a**–**d**). Black bars indicate that the IMT increased significantly with the number of risk factors in subjects diagnosed as MetS

of the optimal cut-points (80 cm) and the revised IDF definition. The increasing IMT in metabolic syndrome subjects was more specific using the IDF definition (Fig. 120.2c and d).

In our subsequent study (Matoba et al. 2009), we followed up 769 men and 502 women of the above study subjects (means ± SD age: 48.8 ± 9.8 and 46.8 ± 10.4 years, respectively), for 1.2 ± 0.4 years under the hypotheses that MetS and an accumulation of individual risk factors predict future atherosclerosis. We excluded 107 subjects on medications for dyslipidemia. Subjects diagnosed as having MetS at baseline received instruction for lifestyle modification and were referred to a clinic if they had untreated hypertension, diabetes or dyslipidemia. We diagnosed MetS using the IDF definition for Japanese population. Student's *t*-tests were used to compare the mean basal IMT adjusted for age and the annual changes in IMT adjusted for age and basal IMT between the groups with or without MetS or the individual components of MetS. Multiple comparisons with Tukey's test were used to compare the mean IMT adjusted for age and the annual difference in IMT adjusted for age and basal IMT among four groups, namely subjects without risk factor and with 1, 2, and 3 or more risk factors (RF 0, RF 1, RF 2, and RF ≥3, respectively) diagnosed at baseline. Subjects were regrouped based on the MetS diagnosis at the baseline and at the time of follow-up; MetS (baseline/follow-up): MetS (–/–), (–/+), (+/–) and (+/+). The statistical analyses were performed using JMP 7.0 software (SAS Institute, Cary, 76 NC). Statistical significance was inferred at $P < 0.05$. At baseline, 108 (14.0%) males and 37 (7.3%) females had MetS. IMT was significantly greater in subjects of both sexes with MetS (Table 120.4). Some risk factor components of MetS were also significantly related to an increase in baseline IMT (WC, BP, TG, and HDL in males and WC, BP, TG, HDL, and FPG in females) after adjustment for age (Table 120.4). Increase in the number of RF including WC

Table 120.4 Baseline IMT adjusted for age relates with MetS and its risk factors

		Male			Female		
		N (%)	IMT (mm)	*P*	*N* (%)	IMT (mm)	*P*

At baseline, 108 (14.0%) males and 37 (7.3%) females had MetS. IMT was significantly greater in subjects of both sexes with MetS. WC, BP, TG and HDL in males and WC, BP, TG, HDL, and FPG in females were also significantly related to an increase in baseline IMT after adjustment for age. Increase in the number of RF including WC was also significantly related to an increase in baseline IMT in males and females (RF 2 and RF ≥3 group). Statistical significance was inferred at $P < 0.05$.†; vs. RF0 group

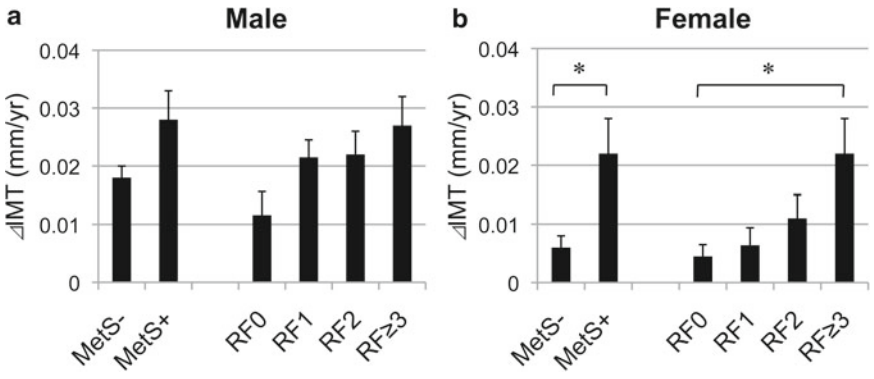

Fig. 120.3 Impact of MetS and its components on annual changes of IMT. Annual changes of IMT after adjustment for age and basal IMT in the groups with or without MetS and the groups of accumulation risk number of the MetS at the base line in males (**a**) and females (**b**)

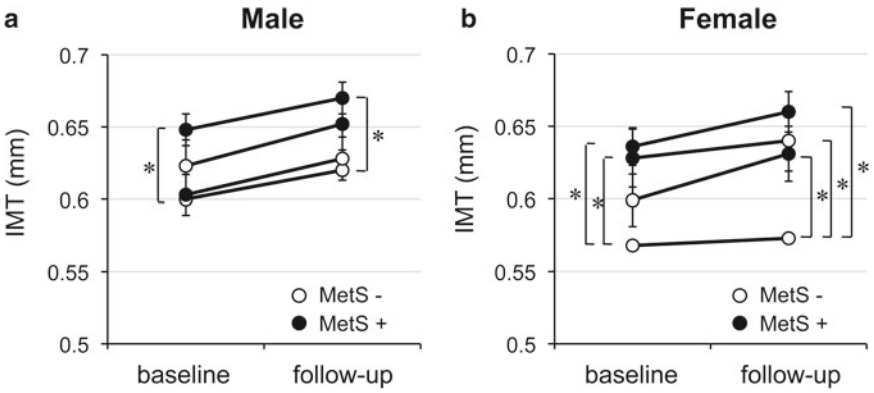

Fig. 120.4 Mean IMT after adjustment for age in the groups with or without MetS at the baseline and at the follow-up. In females, IMT at baseline was significantly greater in the MetS (+/–) and MetS (+/+) groups than in the MetS (–/–) group. Similarly, IMT at follow-up was significantly greater in the MetS (–/+), MetS (+/–) and MetS (+/+) groups than in the MetS (–/–) group. Data are means±SEM. *$P < 0.05$

was also significantly related to an increase in baseline IMT in males and females (RF 2 and RF ≥3 group) (Table 120.4). We analysed annual IMT increase in each subject after 1.2 ± 0.4 years follow-up. In both males and females, annual IMT increase tended to be larger in subjects with the MetS compared with subjects without MetS, and in subjects with an increasing number of RF (Fig. 120.3a and b). This difference was statistically significant in females (MetS+ and RF ≥3 group). Among individual RF, WC in males (0.017 mm/year vs. 0.027 mm/year, $P < 0.05$), WC in females (0.004 mm/year vs. 0.012 mm/year, $P < 0.05$) and HDL in females (0.006 mm/year vs. 0.020 mm/year, $P < 0.01$) were related to larger annual IMT increase. These results indicate that MetS as well as an increased number of individual risk factors are associated with an increased IMT at baseline, and that MetS predicts annual increase in IMT particularly in females when we used 80 cm waist cut-point just as provided for Japanese in the IDF definition. We analyzed baseline IMT and annual IMT changes based on a diagnosis of MetS at baseline and follow-up. In males, 635 (82.7%), 26 (3.4%), 40 (5.2%) and 68 (8.9%) subjects were diagnosed as MetS (–/–), (–/+), (+/–) and (+/+), respectively. Among the four groups, the IMT in the MetS (+/+) group was significantly greater than that in the MetS (–/–) group at baseline and at follow-up (Fig. 120.4a and b). In females, 452 (90.0%), 13 (2.6%), 11 (2.2%)

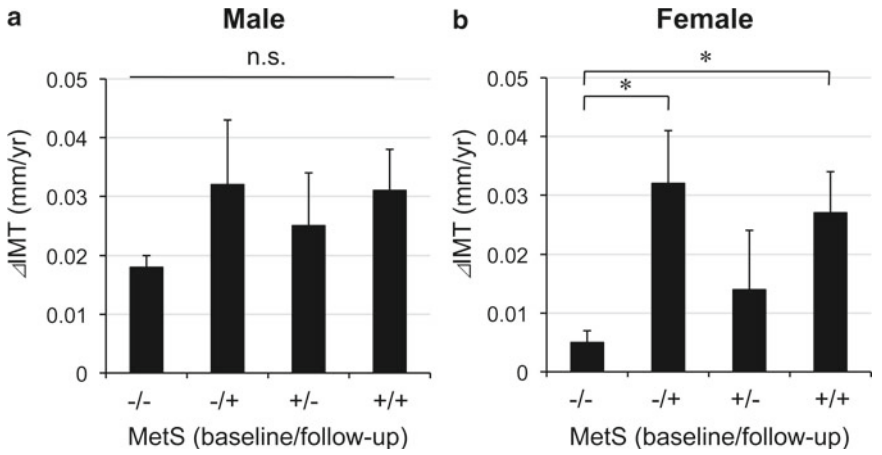

Fig. 120.5 Annual changes of IMT after adjustment for age and basal IMT in the groups with or without MetS at the baseline and at the follow-up. In females, the annual IMT change was significantly greater in the MetS (–/+) and MetS (+/+) group. Of interest was the fact that the annual increase in IMT in the MetS (+/–) females was not significantly different from that in the MetS (–/–) females. Data are means±SEM. *$P < 0.05$

and 26 (5.2%) subjects were diagnosed as MetS (–/–), (–/+), (+/–) and (+/+), respectively. IMT at baseline was significantly greater in the MetS (+/–) and MetS (+/+) groups than in the MetS (–/–) group (Fig. 120.4b). Similarly, IMT at follow-up was significantly greater in the MetS (–/+), MetS (+/–) and MetS (+/+) groups than in the MetS (–/–) group (Fig. 120.4b). Next, we assessed the annual IMT changes among these groups. In males, the annual IMT changes were not significantly different (Fig. 120.5a). In contrast, in females, the annual IMT change was significantly greater in the MetS (–/+) and MetS (+/+) group (Fig. 120.5b). Of interest was the fact that the annual increase in IMT in the MetS (+/–) females was not significantly different from that in the MetS (–/–) females, which may indicate a beneficial effect of medical intervention in MetS on IMT. These IMT changes were not significant in the same subjects when we used 90 cm as the waist cut-point for females.

120.6 Conclusions

MetS is a cluster of multiple metabolic risk factors based on visceral adiposity and insulin resistance, which retains future risk for cardiovascular diseases and type 2 diabetes. Diagnostic criteria proposed by the IDF, AHA/NHLBI and the Japanese Committee for the Diagnostic Criteria of Metabolic Syndrome of MetS include waist circumference as a surrogate marker of visceral adiposity and current definitions adopt cut-points of waist circumference for each ethnic group to optimize their predictive values.

Our data provided optimal waist cut-points for Japanese, 87 cm for men and 80 cm for women using relations with the clustered risk factors. The optimized waist cut-points showed superior sensitivity and specificity to the conventional IDF and the Japanese cut-point for women (90 cm) in order to predict intima-media thickening, and agreed with the revised IDF definition (80 cm) for women. Moreover, the follow-up study suggested that the presence of MetS determined by the optimal waist cut-points of 90 cm for men and 80 cm for women identified subjects with a short-term risk of development of atherosclerosis. Further studies with larger population and longer follow-up period may validate these waist cut-points for the clinical diagnosis of MetS with a substantial risk of cardiovascular events and/or onset of type 2 diabetes.

Summary Points

1. MetS is a cluster of multiple metabolic risk factors based on visceral adiposity and insulin resistance, which retains future risk for cardiovascular diseases and type 2 diabetes.
2. Clinical methods to evaluate visceral adiposity include abdominal computed tomography, body mass index and waist and hip circumference; in which waist circumference is most available but highly dependent on the ethnicity.
3. Current MetS definitions include waist circumference as a surrogate marker of visceral adiposity and adapt cut-points of waist circumference for each ethnic group to optimize their predictive values.
4. For Asian or Japanese people, the International Diabetes Federation, the American Heart Association and the National Heart, Lung and Blood Institute provided the waist cut-points of 90 cm for men and 80 cm for women.
5. The Japanese Committee for the Diagnostic Criteria of Metabolic Syndrome adopted waist cut-points of 85 cm for men and 90 cm for women as the waist cut-points that derived from the cut-points of visceral fat area by computed tomography to identify clustered risk factors.
6. Several studies, including our recent studies obtained optimal waist cut-points, suggest that the waist cut-points of 90 cm for men and 80 cm for women are relevant for Japanese population to define MetS with a short-term risk of development of atherosclerosis.
7. Further studies with larger population and longer follow-up period may validate these waist cut-points for the clinical diagnosis of MetS with substantial risk of cardiovascular events and/or onset of type 2 diabetes as hard end-points.

Chapter 121
BMI, Waist Circumference, and Metabolic Syndrome: Lessons from Japanese Perspectives

Masaru Sakurai, Tsuguhito Ota, Katsuyuki Miura, Hideaki Nakagawa, Shuichi Kaneko, and Toshinari Takamura

Abstract The prevalence of overweight and obesity in Japan is much lower than in Western countries: about 30% for Japanese men and 20% for Japanese women. Despite this low rate of obesity, the prevalence of metabolic abnormalities related to cardiovascular risk factors such as hypertension, dyslipidaemia, and diabetes is not lower in Japan than in Western countries. Visceral fat accumulation is also closely associated with metabolic abnormalities in the Japanese. Among the anthropometric variables, waist circumference is an indirect measure of abdominal fat accumulation. The waist circumference cutoff points for the Japanese have been proposed as 90 cm for women and 85 cm for men, which correspond to a 100-cm^2 area of visceral fat at the umbilical level on computed tomography imaging. However, subcutaneous fat strongly influences waist circumference in relatively lean Japanese women, and waist circumference does not effectively predict the existence of metabolic syndrome. In relatively lean Japanese women, BMI rather than waist circumference is reported to be more strongly associated with metabolic syndrome and may be more appropriate as an index for total and abdominal fat accumulation. Normal weight is associated with increased cardiovascular risk factors in Japanese. The difference in the association between obesity and metabolic abnormalities in Asian and Western countries may be due to genetic factors, different lifestyles, or sensitivity to metabolic disorders of obesity. Japanese have more total body fat and visceral fat than Caucasian men with the same degree of obesity, and the difference in body fat distribution also contributes to these differences. Furthermore, there is a J-shaped relationship between waist circumference and subsequent risk for type 2 diabetes in relatively lean Japanese; lower pancreatic B-cell function may also increase the diabetes risk in very lean Japanese. Recently, nonalcoholic fatty liver disease has been reported to be closely associated with metabolic syndrome in Western and Asian populations. Not only fat accumulation in the visceral area, but fat accumulation in the liver may also contribute to the development of metabolic syndrome. Therefore, when we consider the association between obesity indices, such as waist circumference and BMI, and metabolic syndrome, we should consider the gender/ethnic differences of these associations, insulin deficiency, and fatty liver-associated insulin resistance.

121.1 Introduction

The prevalence of obesity is quite low in Japanese and Asian populations. About 30% of the Japanese are overweight (body mass index (BMI) ≥ 25 kg/m^2), but only 3.2% are obese (BMI ≥ 30 kg/m^2), whereas 32.2% of Americans are obese (Organisation for Economic Cooperation and Development (OECD) Health Data 2008). However, despite the low prevalence of obesity, the prevalence of metabolic abnormalities related to cardiovascular risk factors such as hypertension, dyslipidaemia, and diabetes is not lower in Japan than in Western countries (Ota et al. 2002; Yoon et al. 2006). These differences in the association between obesity and cardiovascular risk factors are derived from genetic factors, different lifestyles, different body fat distributions, and/or sensitivity of metabolic disorders to obesity, as compared to Western people. We should consider such racial/ethnic differences when evaluating the association between obesity and metabolic syndrome (MetS).

In this chapter, we first provide an overview of obesity in the Japanese and then discuss the gender differences in anthropometric variables, such as BMI and waist circumference, and their association with MetS in the Japanese population.

121.2 Epidemiology of Obesity and Metabolic Abnormalities in Japanese

The prevalence of overweight (BMI ≥ 25 kg/m^2) and lean (BMI < 18.5 kg/m^2) people and changes in these figures in the last three decades are shown in the results from the National Health and Nutrition Survey of Japan (Ministry of Health, Labour, and Welfare 2009; Fig. 121.1). The prevalence of overweight is much lower than in Western countries: about 30% for Japanese men and 20% for Japanese women. However, the prevalence of overweight has increased, especially in middle-aged Japanese men, and these trends are similar to other Asian countries (Ge 1997; Ko et al. 1997; Yoshiike et al. 1998). However, mean BMI has decreased in the last two decades in young women; lower body weight and its associated health problems, such as anaemia, eating

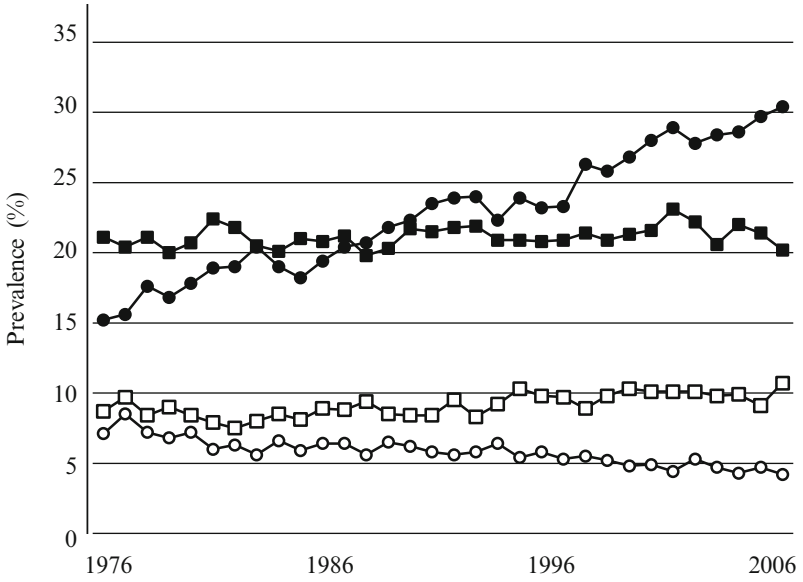

Fig. 121.1 Prevalence of overweight (BMI ≥25 kg/m^2) and lean (BMI <18.5 kg/m^2) people in the Japanese population: Results from the National Nutrition Survey (1976–2002) and the National Health and Nutrition Survey (2003–2007). (●) Overweight men; (■) overweight women; (○) lean men; (□) lean women

disorders, irregular menstruation, and reduced foetal growth in pregnancy, have become important problems in young Japanese women (Takimoto et al. 2004; Ministry of Health, Labour, and Welfare 2009).

Although the prevalence of obesity is much lower in Asian than Western countries, the prevalence of type 2 diabetes is similar (Yoon et al. 2006), suggesting that the association between obesity and metabolic abnormalities may be different in Asian and Western countries.

The relationship between obesity and metabolic abnormalities is also observed in relatively lean Japanese men and women. Ota et al. examined the relationship between BMI and metabolic abnormalities among 21,050 healthy Japanese men and women aged 35–60 years in a cross-sectional study (Ota et al. 2002, 2006). As BMI increased, systolic and diastolic blood pressure, total cholesterol, triglycerides, and fasting plasma glucose increased, and HDL-cholesterol decreased linearly (Fig. 121.2). Furthermore, increasing BMI was also associated with increasing alanine aminotransferase and uric acid, indicating that obesity is also associated with fatty liver disease and hyperuricemia (gout) in Japanese men and women. When participants were classified using the WHO obesity classification, all but one of the components were significantly higher (only HDL-C was lower) for the pre-obese participants (BMI of 25.0–29.9 kg/m^2) than the normal body weight participants (BMI of 18.5–24.9 kg/m^2) ($P < 0.001$). Furthermore, the mean levels of total cholesterol, fasting plasma glucose, systolic and diastolic blood pressure, and uric acid were higher, and HDL-cholesterol was lower in normal body-weight than in underweight participants (BMI < 18.5 kg/m^2). These results show that normal weight also involves increased cardiovascular risk factors in Japanese. In these reports, the BMI threshold for significantly increasing levels of metabolic variables such as blood pressure and serum lipid levels was around 21–23 kg/m^2. Because Asian people, including the Japanese, tend to have a higher risk for cardiovascular disease even with normal body weight, the WHO proposed the BMI cut-off points for pre-obesity as 23 kg/m^2 for the Asian population (WHO Expert Consultation 2004).

(**a**) Serum triglycerides; (**b**) serum HDL-cholesterol; (**c**) serum total cholesterol; (**d**) fasting plasma glucose; (**e**) systolic blood pressure; (**f**) diastolic blood pressure; (**g**) number of metabolic syndrome components defined by ATP-III; (**h**) alanine aminotransferase (Ota, Sakurai, and Takamura, unpublished data). Black column, men; white column, women. The values are means. (Ota et al. 2006)

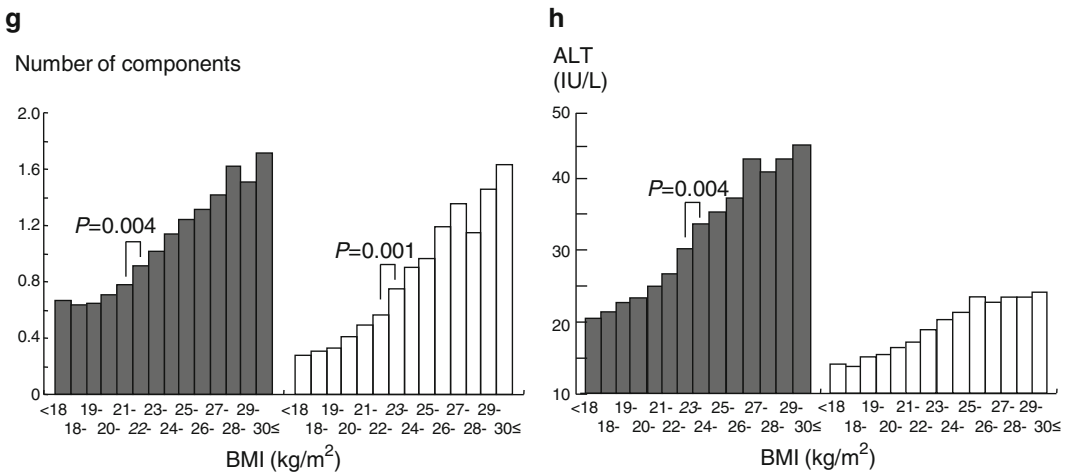

Fig. 121.2 (continued)

121.3 Visceral Adiposity and Metabolic Abnormalities in Japanese

Although obesity is less common in Japanese men and women, concealed abdominal fat may play an important role in the development of MetS. Ito et al. examined body fat distribution by dual-energy X-ray absorptiometry (DXA) in 2,728 Japanese men and women and showed that the percentage fat mass (FM) (trunk)/FM (legs) most accurately detected abnormalities in blood pressure, serum lipid levels, and fasting plasma glucose (Ito et al. 2003). Oka et al. examined the subcutaneous and visceral fat area at the level of the umbilicus using computed tomography (CT) in about 2,000 middle-aged Japanese men and women and reported that the visceral fat area was more closely associated with metabolic abnormalities than the subcutaneous fat area (Oka et al. 2010). Furthermore, the relationship between visceral fat area and metabolic abnormalities was significant even after adjusting for BMI and waist circumference, indicating that visceral fat accumulation is closely associated with metabolic abnormalities in relatively lean Japanese people.

Abdominal fat accumulation is considered an important etiological factor in the development of MetS. Among the anthropometric variables, waist circumference and variables associated with waist circumference, such as waist-to-hip ratio, are indirect measures of abdominal fat accumulation. Waist circumference is included as one of the key criteria for defining MetS. The Japan Society for the Study of Obesity defined a 100-cm^2 area for visceral fat at the umbilical level on CT imaging as a risk factor for cardiovascular disease in Japanese (The Examination Committee of Criteria for 'Obesity Disease' in Japan 2002). The waist circumference cutoff points for Japanese were then proposed as 90 cm for women and 85 cm for men, which correspond to a 100-cm^2 area of visceral fat at the umbilical level on CT imaging (The Examination Committee of Criteria for Metabolic Syndrome 2005). These cutoff points for Japanese are unique in that the value for women is larger than that for men, and they remain controversial. In contrast, the International Diabetes Federation (IDF) proposed a waist circumference cutoff point of 90 cm for men and 80 cm for women (Arberti et al. 2005), and some reports have proposed lowering the waist circumference cutoff point for Japanese women. Indeed, many studies have been conducted to re-evaluate the association between waist circumference and cardiovascular risk factors and have also proposed lowering the waist circumference cut-off points for Japanese women (Hara et al. 2006; Ohkubo et al. 2006; Oizumi et al.

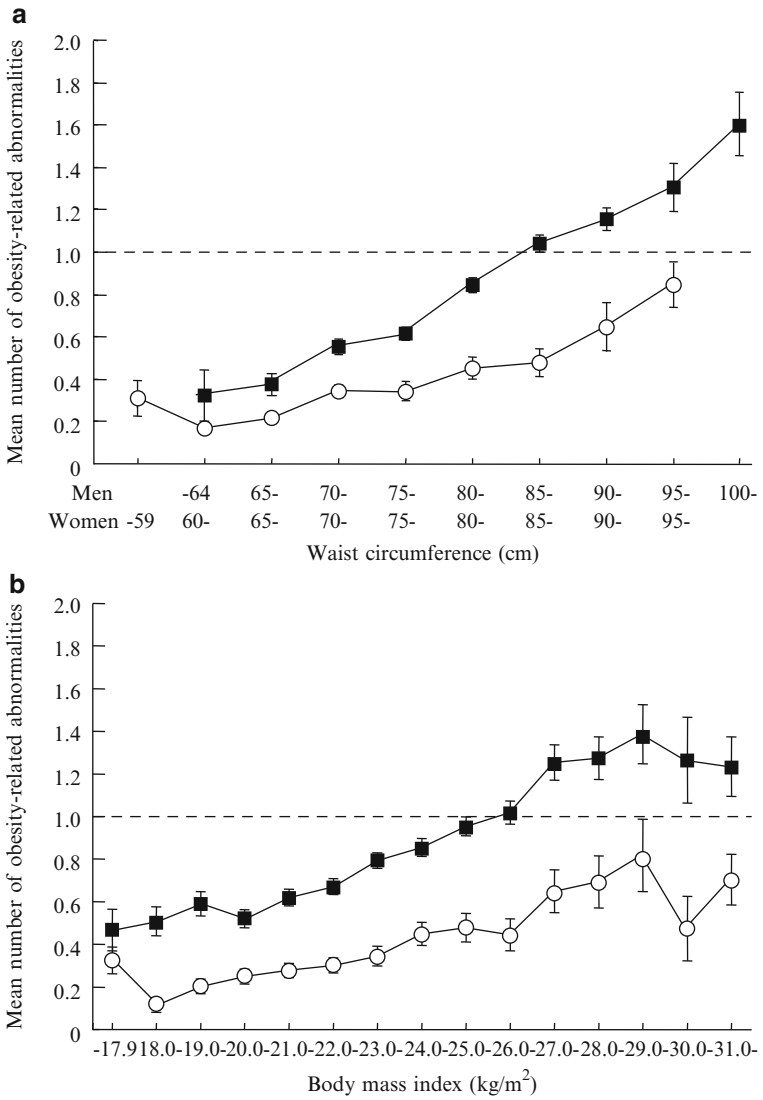

Fig. 121.3 The mean number of obesity-related abnormalities distinguished by waist circumference (**a**) or body mass index (**b**) in men (■) and women (○). Obesity-related abnormalities included hypertension, dyslipidaemia, and glucose intolerance. The horizontal dotted line shows the mean number of obesity-related abnormalities as 1.0. Data are presented as means ± standard errors (Sakurai et al. 2009a)

2006; Nishimura et al. 2007; Lee et al. 2007b; Miyatake et al. 2007; Ohnishi et al. 2008; Kato et al. 2008; Matoba et al. 2008; Narisawa et al. 2008; Oka et al. 2008; Sato et al. 2008; Shimajiri et al. 2008; Kashihara et al. 2009; Sone et al. 2009; Tabata et al. 2009; Yoshida et al. 2009). However, these reports determined the cut-off points only from receiver-operator characteristic (ROC) curves for waist circumference to predict one or more obesity-related metabolic abnormalities, and did not consider the absolute cumulative risk of metabolic abnormalities in Japanese women.

We evaluated the association between waist circumference and accumulation of cardiovascular risk factors in Japanese men and women (Sakurai et al. 2009a) and showed that in women, the mean number of complicated metabolic syndrome components was lower than one even in those with a waist circumference ≥90 cm, which is the abdominal obesity cut-off value for Japanese women (Fig. 121.3). This result suggests that Japanese women are resistant to obesity-related metabolic abnormalities or that waist circumference does not effectively predict the existence of MetS in relatively lean Japanese women.

Hara et al. (2006) and Ohkubo et al. (2006) proposed a waist circumference cutoff point for detecting MetS or insulin resistance in Japanese based on relatively small, older, and a somewhat higher-risk population. Both reports proposed lowering the waist circumference cutoff point for Japanese women to 76 cm because this value provided the highest sensitivity and specificity for detecting MetS. Theoretically, sensitivity and specificity (i.e., ROC curves) are not affected by the prevalence of the detected disease in various populations. For example, in our study, the positive predictive value was as low as 7.1% in a population of middle-aged Japanese women, which means that only 7.1% of women with a waist circumference of 73 cm or greater had metabolic abnormalities (Sakurai et al. 2009a). Therefore, such a cutoff point may not be suitable for a screening test in women. The low positive predictive value was caused by the low prevalence of metabolic abnormalities in middle-aged Japanese women, and possibly by the relatively higher resistance of Japanese women than that of Japanese men to obesity-induced metabolic abnormalities. As proposed in previous reports (Hara et al. 2006; Ohkubo et al. 2006), lower waist circumference cutoff points might detect more people with metabolic abnormalities with a higher sensitivity. However, in a population with a low prevalence of metabolic abnormalities, lower cutoff points would also result in a greater proportion of false positives, with more healthy women, in particular, being judged as at risk. Furthermore, because the mean number of complicated metabolic abnormalities was lower than one even in those with a waist circumference ≥95 cm, and even though the area under the ROC curve was lower in women than in men (Sakurai et al. 2009a), waist circumference would not effectively predict the existence of MetS in Japanese women.

121.4 Gender Differences in Anthropometric Indices Reflecting Obesity-Associated Metabolic Abnormalities in Japanese

Waist circumference is reported to be more closely related to metabolic abnormalities than BMI in many studies from Western countries. Results from urban Japanese men showed that waist-to-hip ratio, but not BMI, was linearly associated with HbA1c, and waist-to-hip ratio was positively associated with serum total cholesterol levels and inversely associated with HDL-cholesterol levels, even after adjusting for BMI (Iso et al. 1991). Similar stronger relationships between the variables associated with abdominal obesity (waist circumference and waist-to-hip ratio) and the prevalence of hypertension, diabetes, and accumulation of metabolic abnormalities have been reported in some cross-sectional studies with Japanese participants (Ito et al. 2003; Hsieh and Muto 2005; Huxley et al. 2008; Kato et al. 2008; Nakamura et al. 2008; Asayama et al. 2009). In contrast, some reports have shown that the association is similar for BMI and waist circumference (Nakamura et al. 2007; Obesity in Asia Collaboration 2008; Kondo et al. 2009), and some reports showed that the relationship to some metabolic abnormalities was stronger for BMI than waist circumference (Sakurai et al. 2006, 2008; Decoda Study Group 2008; Kondo et al. 2009).

We evaluated the gender difference of the association between anthropometric indices and metabolic abnormalities in 2,935 Japanese men and 1,622 Japanese women aged 35–59 years (Sakurai et al. 2006, 2008). As shown in Table 121.1, waist circumference was more strongly associated with high blood pressure, dyslipidaemia, and high fasting plasma glucose (FPG) in men, whereas BMI was more strongly associated with high blood pressure and dyslipidaemia in women. Although waist circumference was more strongly associated with high FPG in women, the association was weaker than the relationship between BMI and high blood pressure or dyslipidaemia. The rate ratio (RR) (95% confidence interval) of having two or more metabolic abnormalities by one standard deviation increment of each anthropometric variable was higher for waist circumference (RR, 1.85;

RR risk ratio; *95% CI* 95% confidence interval

[1.66–2.06]) than for BMI (RR, 1.70; [1.54–1.86]) in men, whereas it was higher for BMI (RR, 1.73; [1.42–2.12]) than for waist circumference (RR, 1.64; [1.33–2.03]) in women. When BMI and waist circumference were included simultaneously in a model, waist circumference showed a stronger association with the presence of metabolic abnormalities in men. However, in women, BMI showed an independent association, whereas waist circumference showed no significant association in women after adjusting for BMI.

At the same BMI, the percentage of body fat in Asians is 3–5% higher than in Caucasians (Deurenberg et al. 2002), and Japanese men have more visceral adipose tissue than do Caucasian men for the same waist circumference (Kadowaki et al. 2006). Thus, these body-fat distribution characteristics in Japanese influence the anthropometric indices of obesity. For example, Oka et al. measured visceral and subcutaneous adipose tissue using CT scans in 2,470 Japanese men and women and showed that the relationship with waist circumference or BMI was greatest for total (visceral plus subcutaneous) adipose tissue and subcutaneous adipose tissue and least for visceral adipose tissue (Oka et al. 2009). These results show that waist circumference does not always reflect visceral adipose tissue. Compared to those in men and women in Western countries and Japanese men, associations between waist circumference and metabolic abnormalities were weaker for Japanese women (Decoda Study Group 2008; Kondo et al. 2009), and these discrepancies may be due to differences in fat distribution. In relatively lean Japanese women, given the stronger influence of subcutaneous fat on waist circumference, BMI may be more appropriate than waist circumference as an index for total and abdominal fat accumulation.

121.5 J-Shaped Relationship Between Waist Circumference and Subsequent Risk for Type 2 Diabetes in Japanese

A linear association between the degree of obesity and the incidence of type 2 diabetes was reported in the Nurses' Health Study (Carey et al. 1997) and other cohort studies from Western populations (Wei et al. 1997; Folsom et al. 2000; Wang et al. 2005; Meisinger et al. 2006). In Western populations, insulin resistance and hyperinsulinemia are observed in subjects with impaired glucose tolerance, and a marked deterioration in insulin secretion precedes the onset of type 2 diabetes (Tripathy et al. 2000) (Fig. 121.4a). However, decreased insulin secretion precedes not only the onset of type 2 diabetes but also the onset of impaired glucose tolerance in Japanese

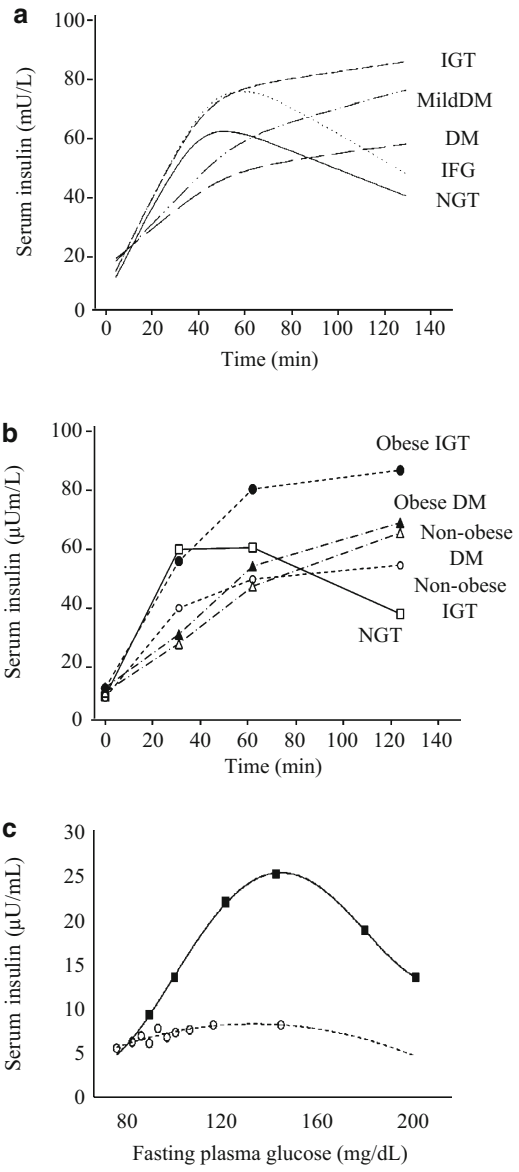

Fig. 121.4 The insulin response during OGTTs in Western and Japanese populations. Comparison of the results from the Botnia study (**a**) with 5,396 Finnish individuals (Tripathy et al. 2000) and our data of 689 Japanese individuals (**b**) (□ normal glucose tolerance, $n = 324$; ○ non-obese impaired glucose tolerance, $n = 86$; ● obese impaired glucose tolerance, $n = 86$; non-obese diabetes mellitus, $n = 73$; ▲ obese diabetes mellitus, $n = 59$. Sakurai and Takamura, unpublished data). Obesity is defined as BMI ≥25 kg/m^2. Fasting plasma insulin levels were compared to fasting plasma glucose levels in Western (■, De Fronzo et al. 1989, 1988) and Japanese populations (○; $n = 689$, Sakurai and Takamura, unpublished data) (**c**). *NGT* normal glucose tolerance; *IFG* impaired fasting glucose; *IGT* impaired glucose tolerance; *DM* diabetes mellitus

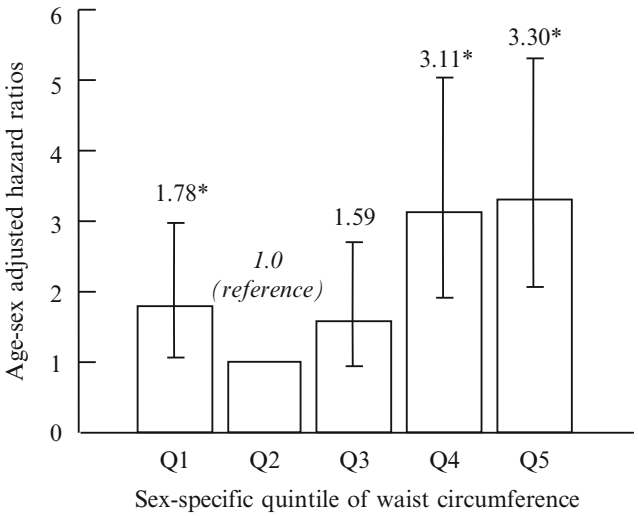

Fig. 121.5 Age- and gender-adjusted hazard ratios for the incidence of type 2 diabetes across the gender-specific quintile for baseline waist circumference. *$p < 0.05$ vs. second quintile (Sakurai et al. 2009b)

(Fukushima et al. 2004). Our data also showed that insulin secretion was reduced in subjects with impaired glucose tolerance compared to those with normal glucose tolerance, at least in non-obese Japanese (Fig. 121.4b), and compensatory higher insulin secretion was not observed in Japanese with higher fasting plasma glucose levels (Fig. 121.4c). Furthermore, the prevalence of type 2 diabetes is similar in Asian and Western populations, although the prevalence of obesity is much lower in Asian countries (Yoon et al. 2006). These findings suggest that the association between obesity and insulin resistance, as well as insulin secretion and the incidence of diabetes may be different in Asian from that in Western countries.

We examined the relationship between waist circumference and the incidence of type 2 diabetes in a Japanese cohort (Sakurai et al. 2009b). The participants were 3,992 employees (2,533 men and 1,459 women, aged 35–55 years) from a metal-products factory in Japan. During an 8-year follow-up, 218 participants developed diabetes. Age- and gender-adjusted hazard ratios (HR) across the waist circumference quintiles were 1.78, 1.00 (reference), 1.59, 3.11, and 3.30 (P for trend, <0.0001) (Fig. 121.5). The HR for the lowest quintile was significantly higher than that for the second quintile. Among participants with a waist circumference in the lowest quintile, the insulin secretion index Homeostatic Model Assessment (HOMA)-B was lower in those who developed diabetes than in those who did not (RR, 33.1; [24.1–45.0] vs. RR, 54.3; [37.9–74.6]) median [interquartile range], $P < 0.0001$), whereas the insulin resistance index HOMA-IR did not differ between the groups (Fig. 121.6). These findings suggest the existence of a J-shaped relationship between waist circumference and subsequent risk for type 2 diabetes in relatively lean Japanese individuals. Not only obesity, but lower pancreatic B-cell function may also increase the risk for diabetes in very lean Japanese.

121.6 Fatty Liver-Associated Metabolic Syndrome

It was recently reported that nonalcoholic fatty liver disease (NAFLD) is related to cardiovascular disease and to most cardiovascular risk factors, including diabetes, hypertension, hyperlipidaemia, and metabolic syndrome (Andre et al. 2007; Lee et al. 2007a; Devers et al. 2008; Adams et al. 2009). Insulin resistance and obesity are the two major risk factors underlying MetS, and they play a pivotal

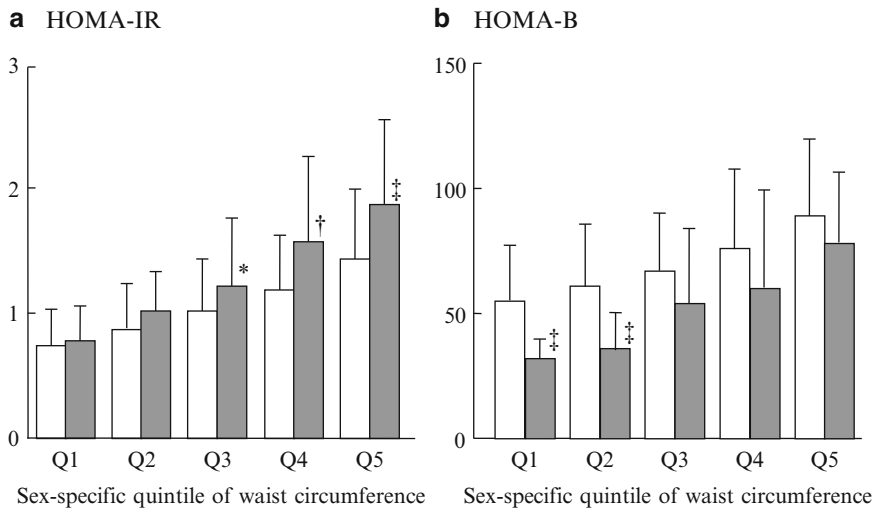

Fig. 121.6 Difference in baseline insulin sensitivity (HOMA-R, **a**) and beta-cell function (HOMA-B, **b**) between subjects who developed type 2 diabetes and those who did not across the gender-specific quintile for baseline waist circumference. *White column*, subjects who did not develop type 2 diabetes; *black column*, subjects who developed type 2 diabetes. Values are geometric means (*column*) and 75th percentiles (*error bar*). * $p < 0.05$, † $p < 0.01$, ‡ $p < 0.001$ vs. those who did not develop type 2 diabetes (Sakurai et al. 2009b)

role in the development of NAFLD and atherosclerosis. These confounding factors should be considered when evaluating the relationships among NAFLD, MetS, and atherosclerosis. We have shown that histological steatosis of the liver is an independent predictor for insulin resistance even after adjusting for BMI (Sakurai et al. 2007), suggesting that not only obesity (abdominal fat), but also fatty liver (hepatic fat deposition) is associated with insulin resistance and insulin resistance-related metabolic abnormalities. Insulin resistance and metabolic abnormalities are observed in the Japanese even with mild degrees of obesity, and one of the reasons for this discrepancy might be explained by the presence of NAFLD in these subjects. In Western people with a high prevalence of obesity, the impact of obesity is so strong on both NAFLD and metabolic abnormalities that it would be difficult to evaluate whether NAFLD itself increases the risk for MetS or cardiovascular disease beyond obesity. Data from lean NAFLD patients in Asia would provide insight into these questions.

NAFLD, especially nonalcoholic steatohepatitis (NASH), is a global issue that will determine the future development of liver cirrhosis, liver failure, and hepatocellular carcinoma. In a prospective evaluation of the histological course of liver pathology, we examined whether metabolic abnormalities were responsible for the histological changes observed in 39 Japanese patients with NAFLD who had undergone serial liver biopsies (Hamaguchi et al. 2010). The median follow-up time was 2.4 years (range, 1.0–8.5 years). Liver fibrosis improved in 12 patients (30.7%), progressed in 11 patients (28.2%), and remained unchanged in 16 patients (41%). In a Cox proportional hazard model, a decrease in HbA1c and insulin use were associated with an improvement in liver fibrosis independent of age, gender, and BMI. However, HbA1c was more strongly associated with the improvement in liver fibrosis than was insulin use after adjusting for each factor (chi-square; 7.97 vs. 4.58, respectively) (Hamaguchi et al. 2010). These findings suggest that tight glycaemic control, rather than weight reduction, may prevent histological progression in Japanese patients with NAFLD. Studies showing that liver fat content, much stronger than visceral fat mass, determines insulin sensitivity in humans (Stefan et al. 2008; Fabbrini et al. 2009), support a direct and major

role of fatty liver in the pathogenesis of insulin resistance. There is now world-wide effort going on in the scientific field aiming at studying the impact of fat accumulation in the liver as a cause for metabolic diseases. One of the links between fatty liver and metabolic abnormalities may be toxic lipids, such as free cholesterol (Matsuzawa et al. 2007) and saturated fatty acid palmitate (Nakamura et al. 2009), that cause inflammation and insulin resistance in the liver. We also hypothesized that in a manner analogous to adipose tissues, the liver may also contribute to the development of diabetes and insulin resistance through the production of secretory proteins, termed hepatokines. Of these, recently identified selenoprotein P, that is over-produced from the liver in face with over-nutrition state, may link over-nutrition and systemic insulin resistance, at least partly, by inactivating an AMP-activated protein kinase (Misu et al. 2010).

121.7 Conclusion

Obesity is an important medical and social problem in Japan, similar to other developed and developing countries. Obesity is closely associated with metabolic abnormalities and MetS in Japanese men and women. However, metabolic abnormalities are not always accompanied by a large waist circumference or high BMI. When we consider the association between obesity indices, such as waist circumference, BMI, and MetS, we should consider the gender/ethnic differences of these associations, insulin deficiency and fatty liver-associated insulin resistance.

Summary Points

- The prevalence of overweight is much lower in Japanese than in Western countries: about 30% for Japanese men and 20% for Japanese women.
- The prevalence of overweight has increased, especially in middle-aged Japanese men, and these trends are similar to trends in other Asian countries.
- Because Asian people, including the Japanese, tend to have a higher risk for cardiovascular disease even with normal body weight, the WHO proposed the BMI cut-off points for pre-obesity as 23 kg/m^2 for the Asian population.
- Abdominal fat accumulation is considered an important etiological factor in the development of MetS, even in relatively lean Japanese. The waist circumference cutoff points for Japanese were proposed as 90 cm for women and 85 cm for men, which correspond to a 100-cm^2 area of visceral fat at the umbilical level on CT imaging.
- Waist circumference does not effectively predict the existence of MetS in relatively lean Japanese women, because it does not strongly related to the prevalence of metabolic abnormalities.
- In relatively lean Japanese women, given the stronger influence of subcutaneous fat on waist circumference, BMI may be more appropriate than waist circumference as an index for total and abdominal fat accumulation.
- J-shaped relationship is observed between waist circumference and subsequent risk for type 2 diabetes in relatively lean Japanese individuals. Not only obesity, but also lower pancreatic B-cell function may also increase the risk for diabetes in very lean Japanese.
- Fatty liver is an independent predictor for insulin resistance even after adjusting for BMI, suggesting that not only abdominal fat, but also hepatic fat deposition is associated with insulin resistance and insulin resistance-related metabolic abnormalities.

Key Features

Table 121.2 Key features of abdominal fat accumulation

1. Body fat distribution contributes to obesity-related disease independent of overall adiposity.
2. The location of body fat has been used to delineate two body shapes; gynecoid versus android.
3. Android obesity is defined as having fat accumulation in the upper body, such as abdomen.
4. Gynecoid obesity is defined as having fat accumulation in subcutaneous area of the lower part of the body, such as hip and thighs.
5. Accumulation of abdominal fat is associated with more adverse metabolic and cardiovascular risk factors than is subcutaneous fat.
6. Abnormal regulation of adipocytokines caused by abundant abdominal fat is one of the important pathogenesis of obesity-related metabolic abnormalities.

Table 121.3 Key facts of Cox proportional hazard model

1. In most clinical situations, many variables act together to produce effects.
2. These variables would relate to each other, and also relate to the outcome of interest. The effect of one might be modified by the presence of others, and the joint effects of two or more may be greater than the sum of their individual effects.
3. "Multivariable analysis" is used to adjust for the effects of many variables to determine the independent effect of one.
4. "Cox proportional hazard model" is a type of multivariable technique used when outcome is the time to an event.

Chapter 122
Anthropometry of Local Fat Reduction

Frank L. Greenway and Susan Pekarovics

Abstract Obesity is growing around the world in epidemic proportions. Diabetes follows obesity by approximately 10 years and the prevalence of diabetes is growing rapidly as well. Not only are diabetes and obesity associated with much suffering and disease, they are also expensive and threaten the economics of public health systems globally. Obesity medications give modest weight loss at best. Diet and lifestyle change are the basis of obesity treatment, and the growing obesity epidemic is testimony to their limitations. Obesity is a stigmatized condition. The fat in obesity is usually concentrated around the waist or at the hips and thighs. Women with lower body obesity become discouraged and may stop dieting, because fat is lost predominantly from their breasts which they often feel are too small, and not from their hips and thighs where they would prefer to lose it. Local fat reduction represents a way that people can direct the area from which fat is lost which gives them control over their own anthropometry. This ability can encourage subjects to remain in weight loss programs for longer periods of time, lose more weight and improve their health to a greater degree. There have been several approaches to local fat reduction. Invasive approaches include plastic surgery and liposuction. Mesotherapy, the injection of lipolytic stimulators or substances that destroy fat cells subcutaneously, is a less invasive method of removing fat locally. The least invasive approaches are low energy laser treatments that release fat from fat cells through the creation of pores in the cell membranes or topical creams containing lipolytic substances that cross the skin into the fat tissue. Although one might be tempted to dismiss all these methods as being cosmetic without any medical benefit, directing the areas from which fat is lost during a weight loss program is encouraging to many obese subjects, improves their self-image and gives them the motivation to continue losing weight for a longer period of time. Longer weight loss programs are associated with greater weight loss and greater health benefits. We hope this chapter allows a risk-benefit assessment of the different methods of local fat reduction. We also hope this chapter makes a case for the benefits of directing the area from which fat is lost during a weight loss program, potentially leading to longer and greater fat loss with a commensurate increase in medical benefits.

122.1 General Consideration

Obesity is one of the most common disorders in medical practice, and among the most frustrating and difficult to manage. Little progress has been made in prevention or treatment, yet major changes have occurred in our understanding of its causes, and its implications for health and beauty.

We have learned that obesity is a chronic disease. Although the NIH consensus conference of 1985 came to that conclusion (1985), the concept did not become widely accepted until the discovery of leptin was made in 1994. The discovery of leptin was a paradigm-shifting discovery, since it identified a hormone that when missing resulted in massive obesity in both man and animals. As is typical with diseases that result from the lack of a hormone, obesity was reversed by leptin replacement therapy (Ravussin et al. 2002).

Thus, obesity is the most recent of the chronic diseases to be recognized as such. This puts obesity therapy at a severe disadvantage compared to hypertension and diabetes for which several effective medication therapies have been developed over the many years they have been recognized as physiologic regulatory disorders. In fact, many of the drugs for diabetes and hypertension can be combined. It is now unusual when hypertension or diabetes cannot be controlled, but doing so often requires a combination of multiple medications.

Obesity is growing at epidemic proportions, and the prevalence of diabetes follows an increase in the prevalence of obesity by about 10 years. Thus, just as the prevalence of obesity began to rise around 1980 in the United States, the prevalence of diabetes began to rise around 1990. Diabetes is a very expensive disease associated with much suffering and disability. In fact, diabetes and obesity each cost the US health care system over $100 billion per year.

122.2 Fat Distribution

Obesity stands apart from the other chronic diseases in that it is easy to diagnose and is stigmatized in our society. Even children point out the “fat man” or “fat woman” to their parents from across the street. This is much different than the case with hypertension or diabetes in which a blood pressure cuff or a laboratory test is needed for diagnosis. Women in particular are stigmatized by being obese.

Although women seem to be more tolerant of heavy men, the intolerance of men toward obese women can be observed on bumper stickers that proclaim "no fat chicks". Thus, it should be no surprise that 80% of people participating in clinical trials of candidate obesity pharmaceuticals are women. This almost certainly has to do with the stigmatization of obesity, since the abdominal fat distribution pattern in men carries greater medical risk than the fat distribution in women which includes fat on the hips and thighs where it carries no medical risk in addition to the accumulation of abdominal fat.

In the context of obesity being a condition that is easily diagnosed visually, is stigmatized particularly in women and has no effective pharmaceutical treatment, the obese person is often blamed for the condition instead of the abnormal physiology that is truly responsible. The obese individual becomes the victim and is accused of gluttony and sloth. Although the medical profession focuses upon the medical implications of obesity, women who suffer from the disease often are concerned about the distribution of their fat as much as its amount.

Many women tell their physicians that they try to lose weight with diet and exercise. They say although they do have some success in losing weight, the fat on their hips and thighs, which are the areas that give them the most concern from a cosmetic perspective, do not seem to get smaller. In fact, women who have heavy hips and thighs usually have small breasts and it is the breast area that seems to account for a disproportionate amount of fat loss. When men and apple-shaped women try to lose weight, their focus is on their waistline and fat that goes away from other areas does not encourage them as much to continue their weight loss program.

Thus, although local fat reduction for cosmetic purposes may not have direct benefits on the medical aspects of obesity, being able to direct the area from which the fat is lost may fulfill the cosmetic goals of obese individuals. Achieving these cosmetic goals can have very positive benefits on the person's self image. Such improvements in self-image can sustain the weight loss efforts causing greater fat loss which results in greater medical benefits. This chapter will be discussing the anthropometry of directed fat reduction in areas with the most cosmetic concern to the individual so afflicted. Although primarily a cosmetic change in anthropometry, the benefits of local fat reduction on self-image should not be underestimated, since this improvement in self-efficacy can result in redoubled efforts at weight loss resulting in a greater reduction in obesity with the accompanying greater improvement in obesity associated medical liabilities.

122.3 Definition and Measurements

Obesity is defined as an excess of adipose tissue. Accurate quantification of body fat requires sophisticated techniques not usually available in clinical practice. Physical examination is usually sufficient to detect excess body fat.

For clinical purposes in people with normal sedentary jobs, a quantitative evaluation of body fat is performed by calculating the Body Mass Index (BMI). Except in people who have an unusual body composition like body builders who have disproportionately large muscles, BMI is closely correlated with more accurate measures of adipose tissue like body densitometry. The BMI is calculated by dividing the body weight in kilograms by the height in meters squared.

Factors other than total fat, however, are medically important. Upper body obesity (excess fat around the waist and flank) is a greater health hazard than lower body obesity (fat in the thighs and buttocks). Obese patients with increased abdominal circumference (>102 cm in men and 88 cm in women) or with high waist-hip ratios (>1 in men and >0.85 in women) have a greater risk of developing diabetes mellitus, stroke, coronary artery disease, and early death than equally obese patients with lower ratios. Further differentiation of the location of the excess fat suggests that visceral fat

within the abdominal cavity is more hazardous to health than subcutaneous fat around and outside of the abdominal cavity.

Current US survey data demonstrate that 65% of Americans are overweight and 30.4% are obese. Women in the US are more apt to be obese than men, and African-American and Mexican-American women are more obese than non-Hispanic whites. The poor are more obese than the rich regardless of race.

Obese individuals often suffer from negative self-image. Many, even those with normal body mass index, resort to pharmacotherapy (lipase inhibitors, appetite suppressants), mesotherapy, and surgery (liposuction, apronectomy or gastric bypass) in order to remove excess adipose tissue. These treatments are associated with significant morbidity, even mortality. Therefore, surgery should be considered seriously before planning the procedure. Aesthetic physicians and plastic surgeons must understand the patient's personal request and ethnic identity as well as any universal ideal of proportions and contour that create the impression of beautiful thighs, waist or buttock. As we learn more about the physiology of obesity we are learning the reasons why fat is distributed in specific patterns. With understanding comes the potential to modify the physiology to change the typical fat distributions. Thus, we will next discuss the lessons we have learned about the physiology of body fat distribution.

122.4 Physiology of Body Fat Distribution

Fat cells give up their fat through a process known as lipolysis. There are two major lipolytic pathways. The traditional pathway involves the adrenergic receptors. Beta adrenergic receptor stimulation in this pathway mediates lipolysis. Activation of the beta adrenergic receptor stimulates adenylate cyclase through a stimulatory g-protein to generate cyclic AMP which activates hormone sensitive lipase through protein kinase A. Hormone sensitive lipase along with perilipins, adipose tissue glyceride lipase and monoglyceride lipase release glycerol and fatty acid from the fat cell (Fig. 122.1).

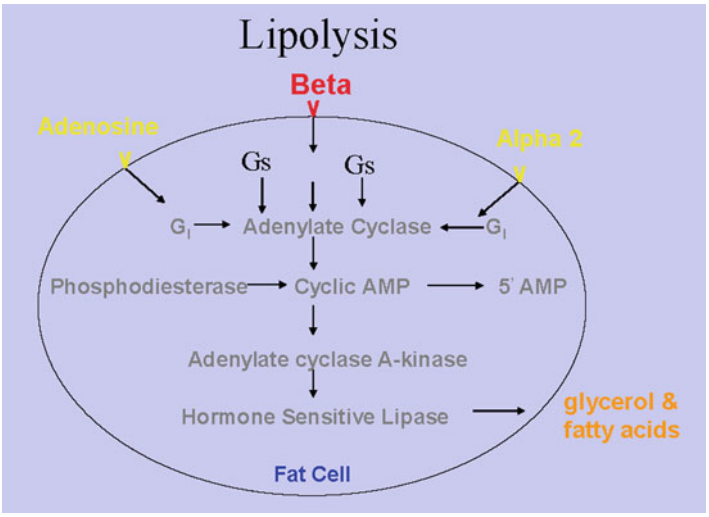

Fig. 122.1 Lipolysis. This illustration summarizes the lipolytic pathway characterized by beta-adrenergic stimulation of the fat cell. Stimulation through the beta receptor is inhibited by activation of the adenosine and alpha-2 receptors. Phosphodiesterase degrades cyclic AMP. Cyclic AMP acts to stimulate lipolysis through hormone sensitive lipase which releases glycerol and free fatty acids from the fat cell. (*AMP* adenosine monophosphate; *Gs* stimulatory G-protein; G_i inhibitory G-protein)

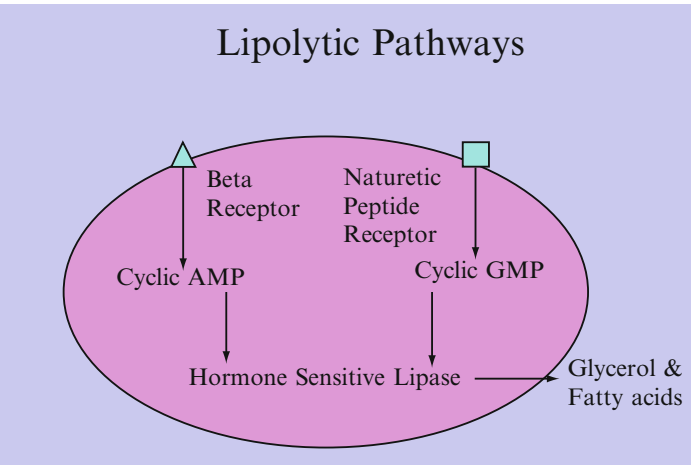

Fig. 122.2 Depiction of both major lipolytic pathway in the fat cell. Beta-adrenergic stimulation induces lipolysis through cyclic AMP while naturetic peptides stimulation does so through cyclic GMP. Both pathways simulate hormone sensitive lipase which results in the release of glycerol and fatty acid from the fat cell. (*AMP* adenosine monophosphate; *GMP* guanine monophosphate)

Cyclic AMP is broken down in the fat cell by phosphodiesterase 3B. Thus, lipolysis can be enhanced by phosphodiesterase inhibitors like xanthenes which also inhibit the adenosine receptor, an inhibitory receptor on the fat cell. The beta adrenergic receptor on the fat cell is inhibited through the stimulation of inhibitory g-proteins like adenosine, alpha-2 adrenergic receptors and other receptors. Thus, lipolysis can also be enhanced by inhibiting these inhibitory receptors. The alpha-2 adrenergic receptors become particularly important in body fat distribution, since they are induced by estrogen and are in higher concentrations in the hips and thighs of women accounting for their characteristic gynoid fat distribution.

The second lipolytic pathway that is quantitatively as important as the beta-adrenergic pathway is activated by naturetic peptides. Atrial naturetic peptide, the most efficient stimulator and this pathway, seems to be important in releasing fatty acids and glycerol during exercise. The naturetic peptide pathway uses cyclic GMP as a mediator, and although this pathway uses phosphodiesterase 5A to breakdown cyclic GMP, inhibiting this phosphodiesterase with sildenafil does not significantly enhance lipolysis in this pathway. Stimulation of this pathway by atrial naturetic peptide causes an intracellular increase of cyclic GMP which activates hormone sensitive lipase to cause lipolysis (Fig. 122.2).

Due to the fact that the naturetic peptides are large molecules that present challenges to transdermal transport and phosphodiesterase inhibitors are unable to achieve significant lipolytic stimulation of this pathway, the naturetic peptide pathway has not been utilized for local fat reduction or body re-contouring. We will, therefore, concentrate our discussion in the remaining part of this chapter on the beta-adrenergic pathway.

122.5 Ablative Topical Fat Reduction

Liposuction has been the gold standard ablative treatment of local fat reduction. Beside its quick and effective result, it carries high risk for general surgical complications (invasive procedures can lead to scarring, etc.) (Table 122.1).

Liposuction can aggravate unfavorable metabolic changes associated with obesity. It has been shown that the recovery of weight lost through these interventions is associated with body fat redistribution toward the visceral cavity, increasing metabolic risk factors for coronary artery disease such

Table 122.1 Local fat reduction

Modality	Risk	Efficacy
Plastic surgery	High	High
Liposuction	High	High
Mesotherapy	Medium	Medium[a]
Phosphatidylcholine-deoxycholate	Medium	Medium[b]
Low energy laser	Low	Medium
Creams	Low	Medium-high

[a]Studies scarce
[b]Inflammation and necrosis
Different modalities used to achieve local fat loss comparing their risks and efficacy

as insulin resistance and increased serum triglyceride level. Adding orlistat to patient's management immediately after surgery for 6 months (Montoya et al. 2009) showed no statistically significant decrease in visceral fat despite weight loss. On the contrary, abdominal liposuction in healthy normal weight or slightly overweight subjects improves the major lipoprotein components of obesity-associated dyslipidemia (Ybarra et al. 2008). This improvement occurs independently of insulin sensitivity.

Fat embolism after liposuction, despite its low incidence, is a life-threatening disorder. Although fat embolism is a multisystem illness, it affects mostly the cerebro- and cardiovascular system, the pulmonary structure and the skin. Many laboratory findings and clinical signs are characteristic but nonspecific, making the diagnosis difficult. There is no specific therapy for the fat embolism syndrome after liposuction so prevention, early detection and supportive therapy are important (Wang et al. 2008).

Combining liposuction with other procedures can increase aesthetic satisfaction and safety in local fat reduction. Circumferential dermo-lipectomy has been an effective means of reducing excess skin fat after massive weight loss; however, regions of residual mid-abdominal and epigastric fat frequently confer a suboptimal contour. Liposuction in association with lower body lift surgery has been regarded with caution, for fear of ischemia or necrosis of the undermined flaps as potential consequences. It has been shown that unlike standard dermolipectomy, the maintenance of a broad subcostal blood supply with selective direct undermining allows for liberal flap contouring with suction and the establishment of lower suture-line position (Kolker and Lampert 2009). With this technique liposuction can be safely used during lower body lift to maximize aesthetic outcomes.

Low-level laser-assisted liposuction (4-L), known as the Neira 4L technique, is an excellent adjuvant tool for the surgeon practicing liposculpture. A low-level laser is used to create a transitory pore in the cell membrane of the adipocyte to move fat from inside the cell to the intersticial space outside without killing the cell. 4-L has been performed successfully in in-vitro human adipose tissue cultures. It protects the patient from the surgical trauma of liposuction by protecting and preparing tissues for the surgery, modulating the inflammatory response to prevent short- and long-term side effects of surgery, improving the quality and quantity of the healing process by accelerating recovery time, diminishing secondary cicatrization, and preventing postoperative neuralgias.

Low level laser treatment without liposuction can be used alone to achieve a cosmetic body recontouring. The low level laser uses light at a wave length of 635–680 nm and uses energy levels that do not heat the tissue. Forty normal weight men and women were randomized to treatment for ten minutes with low energy laser light around the entire waist circumference twice a week for 4 weeks or a placebo condition in which the laser was inactivated. Each individual treatment reduced the waist

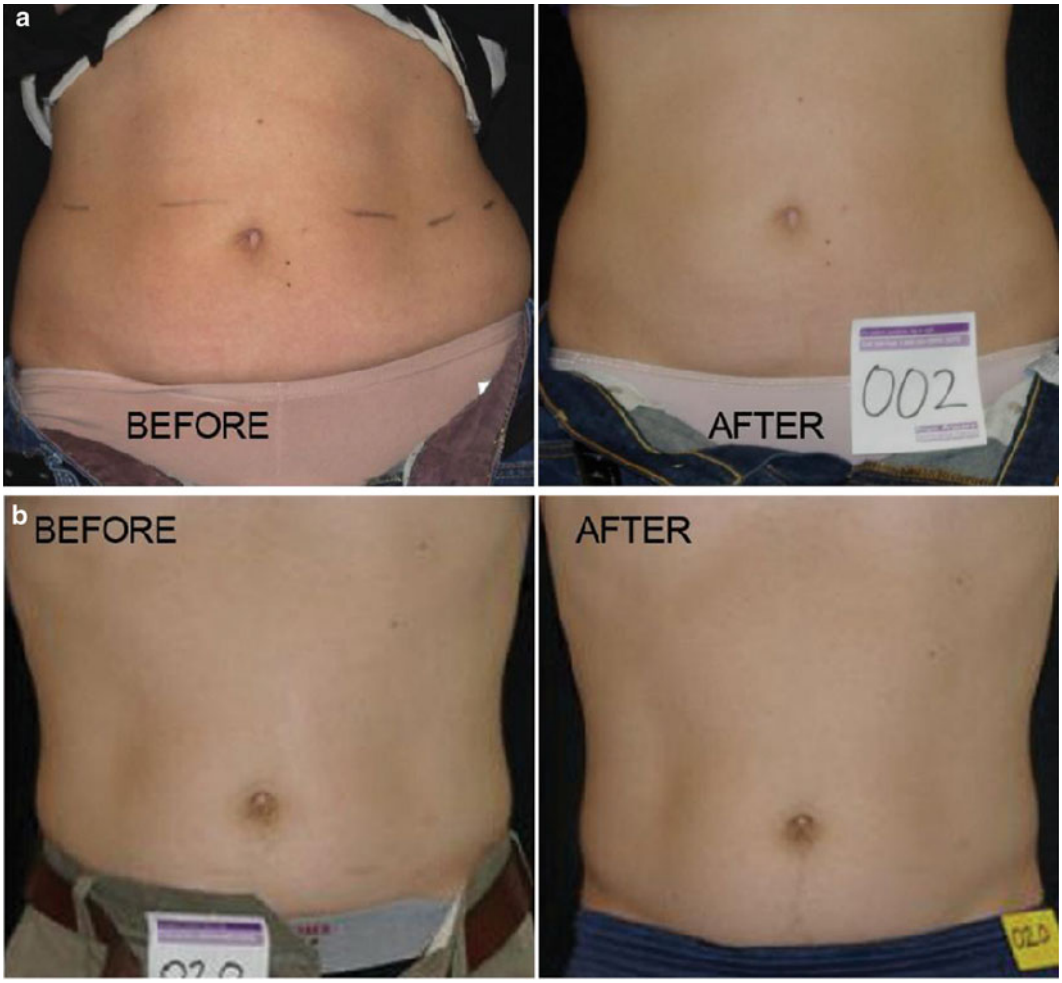

Fig. 122.3 (**a**) Lipolaser treatment to the waist of a female. Two 10-min treatments around the waist using a low energy laser each week for 4 weeks gave a cosmetically significant reduction in waist circumference in excess of 2 cm. (**b**) Lipolaser treatment to the waist of a male. Two 10-min treatments around the waist using a low energy laser each week for 4 weeks gave a cosmetically significant reduction in waist circumference in excess of 2 cm

circumference between 0.4 and 0.5 cm. The treatments were cumulative and those subjects who remained within 1.5 kg of their baseline weight lost an average of 2.2 cm from their waist which was statistically significant. The grading of standardized pictures by blinded observers detected a statistically and cosmetically significant improvement in appearance and body contour (Fig. 122.3a, b).

In-vitro studies to explore the mechanism by which the laser caused local fat reduction demonstrated that in the presence of serum, the laser released fat from the fat cells. It was demonstrated that serum was needed to achieve triglyceride release, that cell lysis was not involved, that the cells were not killed by the treatment, but their metabolism was impaired consistent with the demonstration of pores in the study by Neira et al. (Neira et al. 2002; Caruso-Davis et al. 2008). Thus, it would appear that the fat released from the fat cells returns to the venous circulation via the lymphatics in a similar manner to fat ingested during a meal.

122.6 Transitional Methods

The observation that denervation of adipose tissue results in lipoatrophy led researchers to postulate that chemodenervation using botulinum toxin may achieve the same result, i.e. fat loss (Lim and Seet 2006). Multiple methods were explored leading to potential selective fat loss. It was conceded that removal of subcutaneous fat does not, however, reduce the risk associated with metabolic syndrome, as visceral (intra-abdominal) fat is not reduced by the removal of subcutaneous fat.

The reduction of total adipose depots is considered to be the optimal management to reduce complications with obesity. These anti-obesity strategies are an attempt to achieve an overall weight loss and are unable to target specific adipose depots associated with morbidity. Utilizing localized and sustained delivery of drugs to provide for the selective ablation of adipose tissue offers promising results. This approach demonstrated control over the localization of tumor necrosis factor-alfa by performing blood analysis. It indicates the potential utility of the general tissue ablation approach for treatment of several pathologies (Richardson et al. 2003).

122.7 Mesotherapy

Mesotherapy was originally initiated in Europe using cutaneous injections of different compounds to treat local medical or cosmetic conditions. Although it was originally designed for pain relief, its aesthetic benefit, particularly its fat and cellulite removal potential, captured increasing attention in the US. Presumably due to its initial use for pain relief, mesotherapy solutions have traditionally included local anesthetics. Local anesthetics have been shown to decrease lipolysis by uncoupling cyclic AMP from hormone sensitive lipase. The lipolytic ingredients used by mesotherapists including isoproterenol, yohimbine, melilotus and aminophylline have been demonstrated to stimulate lipolysis, give greater lipolysis when combined as is done in the practice of mesotherapy, and are presumably effective in causing local fat reduction (Caruso et al. 2008). They should not be used with local anesthetics, however, and clinical trials to demonstrate effectiveness clinically are limited to a small study with injected isoproterenol (Greenway and Bray 1987).

Another treatment for local fat reduction is injectable phosphatidylcholine. Phosphatidylcholine alone has been demonstrated to stimulate lipolysis in vitro (Caruso-Davis et al. 2008) (Fig. 122.4). Phosphatidylcholine is usually combined with the emulsifier, deoxycholate when used clinically and this combination achieves cell lysis rather than lipolysis and has been used to remove small amounts of adipose tissue (Rotunda and Kolodney 2006) (Fig. 122.5). In animal studies (biologic model with rabbits) the phosphadidylcholine-deoxycholate injected group showed marked increase in the tissue necrosis, inflammatory exudation and fibrosis compared to a control group (Rittes et al. 2006).

Studies with human adipose tissue concluded that sodium deoxycholate induces an inflammatory reaction in subcutaneous human fat and dose dependent adipocyte lysis with acute pain and fibrosis. No systemic effect was detected. Further studies are needed to establish the appropriate dose-result ratio, frequency of administration and long-term safety (Yagima Odo et al. 2007).

The medicine Lipostabil-N has been used in Europe since 2002 to achieve reduction in the volume of small fat deposits by subcutaneous fat injections. Although Lipostabil-N was originally thought to stimulate lipolysis, due to the fact that it is combined with deoxycholate, it causes fat necrosis and an inflammatory response. The medicine has been authorized for IV use in the prophylaxis and therapy of fat embolism and liver diseases (Hasengschwandtner 2005).

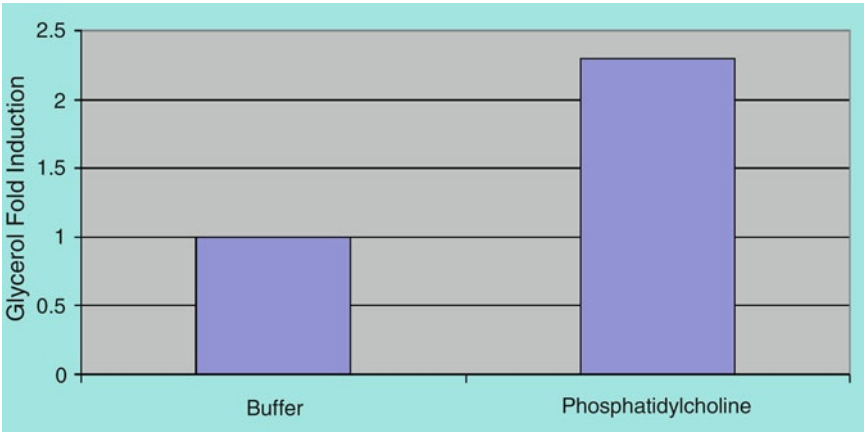

Fig. 122.4 Phophatidylcholine stimulation of lipolysis. Phosphatidylcholine alone stimulates lipolysis in human adipocytes in vitro

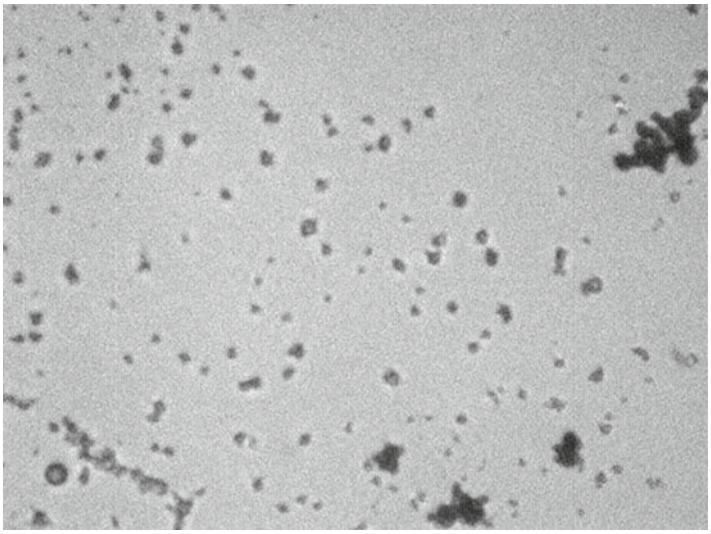

Fig. 122.5 Deooxycholate cell destruction. Deoxycholate, a detergent that is often used to solubilize phosphatidylcholine, causes cell lysis of human fat cells in vitro

Additional studies were conducted on lipomas (benign neoplasms of mature fat cells). Injections of phosphatidylcholine solubilized with deoxycholate have been used to reduce unwanted accumulation of fat. It was concluded that deoxycholate, rather than phosphatidylcholine, was the active ingredient. It was suggested that the low concentration deoxycholate may be a relatively safe and effective injectable treatment for small collections of fat (Rotunda et al. 2005).

A double-blind study was designed (Sasaki et al. 2007) to evaluate the efficacy and safety of a phosphatidylcholine based, cosmeceutical anti-cellulite gel combined with a light-emitting diode (LED) array at the wavelength of red (660 nm) and near infrared (950 nm), designed to treat thigh cellulites. The results of this study affirmed that treatment after 3 months achieved great improvement in cellulite appearance. However, 15 months after their course, a fraction of patients reverted back to their original condition, indicating the need for maintenance therapy.

122.8 Topical Preparations

122.8.1 Reducing Thigh Fat Preferentially: Proof of Concept

Thigh and buttock fat of women is more difficult to mobilize due to increased alpha-2 adrenergic receptor activity induced by estrogen. This fat is thought to be stored in that location to act as a storage site for calories to nourish a baby, since the receptor density changes during pregnancy and lactation to mobilize that fat. The high lipolytic threshold of women's thighs can be reduced to a level below that of fat tissue in other locations by a number of different mechanisms. Lipolysis can be stimulated locally by directly stimulating the beta adrenergic receptor using injectable isoproterenol. This approach was chosen for the proof of concept trial, since the concentration of isoproterenol needed to maximally stimulate lipolysis was known from in-vitro work. In-vitro studies documented that 10^{-5} Molar isoproterenol was well up on the plateau of the dose response curve. Small 0.2 cc injections using an insulin syringe at 4 cm intervals around the thigh circumference 3 times a week for 4 weeks gave a 1.4 cm greater loss of girth in the isoproterenol treated thigh than in the saline treated thigh, and this difference was statistically significant ($p < 0.05$) (Greenway et al. 1995).

122.8.2 Ointment Studies

Since the injection strategy involved the need to inject the back of the thigh which is hard to reach and since injections can be uncomfortable, this approach to local fat reduction was deemed impractical. Other strategies to lower the lipolytic threshold of the thigh include forskolin which directly activates the catalytic subunit of adenylate cyclase and achieves a similar result to stimulating the beta-adrenergic receptor directly with isoproterenol. A second strategy is use of yohimbine to inhibit the alpha-2 adrenergic receptor which inhibits the beta-adrenergic receptor through an inhibitory g-protein. A third strategy is to inhibit phosphodiesterase in the fat cell using a xanthene which will increase cyclic AMP in the cell by inhibiting its breakdown. The first trial combined all three mechanisms by including forskolin, yohimbine and aminophylline in a universal carrier, aquaphor, which has properties similar to vaseline. Applications of this ointment twice a day, 5 days per week for 4 weeks gave a 2 cm greater loss in girth in the thigh treated with the combination ointment compared to the control thigh treated with the ointment base which was statistically significant ($p < 0.05$) (Greenway and Bray 1987).

Since combination medications are more difficult to develop than ones that contain a single ingredient, it was decided to test the individual components of the three-component ointment. The first ointment tested contained yohimbine. The difference in thigh girth between the treated and untreated thighs was not statistically different. This occurred for two reasons. First, one of the subjects dropped out of the trial which left only 4 subjects. Secondly, we learned during this study that to get an accurate and reproducible thigh measurement, the thigh should be measured with the subject's weight on the leg being measured. This was not done in one of the subjects in the yohimbine trial and the lack of uniform muscle tension caused it to appear as if the control thigh lost more girth. Thus, the yohimbine trial was not a valid test, but it did inform future trials that thigh measurements should be done with weight supported on the leg being measured.

The forskolin ointment and the aminophylline ointment both gave more girth loss on the treated thigh compared to the thigh treated with the ointment base ($p < 0.05$) (Table 122.2). Since aminophylline was used at a much higher dose intravenously to treat asthma than the doses used for local

Table 122.2 Thigh girth reductions in excess of placebo using non-invasive local fat reduction (mean ± SEM)

Treatment	Treatment time	Girth loss (cm)	No. subjects
Ointment A+F+Y	4 weeks	2.03 ± 1.36	5
Ointment A	4 weeks	1.5 ± 0.77	5
Ointment F	4 weeks	1.0 ± 0.61	4
Ointment Y	4 weeks	0.75 ± 0.35	4
Ointment A 10%	5 weeks	0.77 ± 0.66	24
Cream A 2%	5 weeks	1.21 ± 0.31	12
Cream A 0.5%	5 weeks	3.08 ± 0.27	12

Girth loss from the thigh greater than placebo for several studies using topical ointment and cream (mean ± SEM)
A Aminophylline; *F* Forskolin; *Y* Yohimbine

fat reduction, and since much more is known about the safety of aminophylline compared to forskolin, a decision was made to limit further trials of topical fat reduction to aminophylline. Aminophylline was the chosen xanthene since it dissolved well in the ointment which was not the case for theophylline or caffeine which are much less soluble. Although the women participating in the trials felt that the ointment was an improvement over the injections, they preferred a cream rather than an ointment which had a tendency to make their clothes greasy.

122.8.3 Cream Studies

Attempts to change from an ointment to a cream used a readily-available cream base. Unfortunately, the aminophylline, which is two theophyllines joined by ethylenediamine, reacted with the cream base, caused the base to turn from white to yellow, did not work to cause fat loss and caused rashes. We discovered that ethylenediamine is a reactive molecule and a skin sensitizer. After going to a dermatologic specialty house to obtain a cream base that would stabilize the aminophylline, we had no further problems with rash or inactive cream.

The first trials we performed to evaluate creams and ointments for local fat reduction put all the subjects on a weight reduction diet to stimulate lipolysis. We performed a trial of a 0.5% aminophylline cream in a stabilizing cream base in which the subjects had the active cream applied to one thigh and the cream base applied to the other 5 days a week for 5 weeks. These subjects were not obese and they were not placed on a diet. At the end of 5 weeks the subjects lost 3 cm more girth on the thigh treated with the active cream compared to the thigh treated with the cream base. This difference was statistically significant ($p < 0.001$) and at 4 weeks the subjects lost approximately 1 in. more girth from the thigh treated with the active cream than from that treated with the cream base. In fact, the thigh treated with the cream base did not change during the trial (Fig. 122.6) (Table 122.2).

The trials done to evaluate the topical ointments and creams for their potential to cause local fat reduction had chemistry panels, complete blood counts and theophylline levels drawn. The laboratory studies did not detect any systemic toxicity and there was no detectable theophylline in the blood stream giving reassurance that the effect was occurring locally in the fat and not systemically. These studies confirmed that topical fat reduction can be achieved safely without diet or exercise in women's thighs (Greenway et al. 1995).

Local fat reduction in other body areas or in men by lowering the local lipolytic threshold was demonstrated in a study using aminophylline cream applied to the waist during a diet and exercise

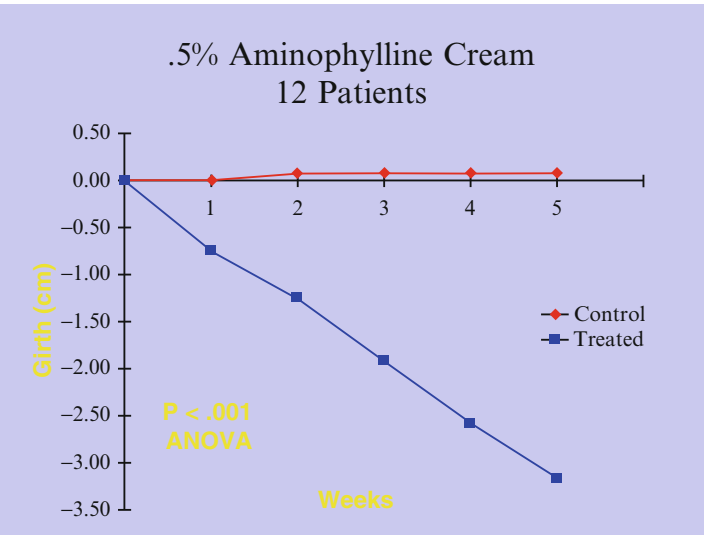

Fig. 122.6 Girth loss of thighs treated with 0.5% aminophylline cream or placebo cream. Women with a stable weight lost 3 cm more girth on the thigh treated with 0.5% aminophylline cream 5 days per week compared to the placebo treated thigh

Table 122.3 Waist girth when treated with 0.5% aminophylline cream compared to a control cream during a weight loss program with equal weight loss in both groups ($N = 50$, mean ± SEM)

Gender	Aminophylline (cm)	Control (cm)
Men	–9.4 ± 0.7	–4.7 ± 0.8
Women	–11.6 ± 0.6	–5.6 ± 0.6
Both	–11 ± 1.0	–5.0 ± 0.6

Girth loss from the waist using 0.5% aminophylline cream or a control cream during a weight loss program in which equal weight was lost in each group ($n = 50$, mean ± SEM)

program. Fifty overweight men and women with an apple shape and a waist to hip ratio of greater than 1 were randomized to treatment around the waist twice a day with 0.5% aminophylline cream or to no cream treatment. All subjects were treated with a 1,200 kcal/day balanced diet, encouraged to walk regularly and seen every 2 weeks in the clinic. At baseline the two groups had BMIs of 28.2 and 28.5 kg/m^2. At the end of the 12-week study the weights were 26.1 and 26.2 kg/m^2, respectively. Thus, there was no difference in weight loss between the two groups. Those treated with the aminophylline cream lost 11 cm from their waist while the group not treated with the cream lost only 5 cm. Thus, during weight loss one can direct the site from which the fat will be preferentially lost, since the weight losses of the two groups were not different while the difference in waist girth lost was more than double in the cream treated group, a change that was highly statistically and cosmetically significant ($p < 0.001$) (Caruso et al. 2007) (Table 122.3).

122.8.4 Botanical Extracts

The reduction of fat depots through the continued use of anti-cellulite botanical products depends on the availability of the active ingredients at the action site, the concentration of the ingredients in the formula and the physiochemical features particular to each ingredient. The botanicals used in topical products must have standardized extracts which insure that each phytomedicine will have the same

effect from batch to batch. Although the regulations are lax in the United States, many other countries have rules in place to ensure that all botanical products are standardized so their effect can be depended upon internationally. Currently, no evidence exists to verify the efficacy or define the ideal concentrations of botanical extracts for the treatment of local fat reduction. Therefore, additional scientific research is necessary before botanical cellulite treatments can be recommended (Hexsel et al. 2005).

122.8.5 Glycyrrhetinic Acid

Clinical observations in patients with Cushing's syndrome have highlighted the link between cortisol and central obesity. The circulating cortisol level is normal or reduced in obesity, but local regeneration of cortisol from inactive cortisone by 11-beta hydroxysteroid dehydrogenase type 1 has been studied as a pathogenic mechanism for visceral fat accumulation and its known association with insulin resistance and the medical problems associated with obesity. Human adipose tissue studies have confirmed that decreased 11-beta hydroxy steroid dehydrogenase type 1 activity can increase insulin sensitivity by reducing tissue-specific cortisol concentrations. Inhibition of 11-beta hydroxy steroid dehydrogenase type 1 may prove to be an important treatment for the metabolic syndrome associated with insulin resistance (Tomlinson et al. 2004).

Glycyrrhetinic acid, the active principle of licorice root, blocks 11-beta hydroxysteroid dehydrogenase type 1, thus reducing the availability of cortisol at the level of the adipocyte. Applying glycylrrhetinic acid cream on a female thigh showed significant reduction in the superficial fat layer. This local reduction in fat was most likely related to a block of 11-beta hydroxysteroid dehydrogenase type 1 at the level of fat cells. Glycyrrhetinic acid could be effectively used in reduction of unwanted local fat accumulation (Armanini et al. 2005).

122.9 Summary and Conclusions

Local fat reduction has been attempted by a number of mechanisms. These have ranged from invasive therapies like liposuction and plastic surgery to less invasive therapies like laser and injection approaches to non-invasive approaches with creams and ointments (Table 122.1). One might be tempted to dismiss such local fat reduction as a cosmetic approach inappropriate for consideration by the medical profession. We contend that this is a short-sighted view. The world is experiencing an obesity epidemic and an epidemic of type 2 diabetes that follows in its wake. Not only does this epidemic of obesity and diabetes carry with it much suffering, it is threatening economic health care systems around the world. Since obesity medications are modest in efficacy and surgery is appropriate for only the most obese, we must concentrate on strategies that will enhance the efficacy of diet and lifestyle change.

Obesity is stigmatized and almost all those that are overweight want to be lean. Most people, however, focus on one aspect of their body fat that disturbs them the most. Often it is the area most difficult to mobilize, like the thigh fat in women. When weight loss results in no change in the "problem thigh area" but causes fat loss in areas like the breast that these same women feel are too small, they become discouraged and give up trying to lose weight. If one could direct the body areas from which the fat would be lost, this might give people much more reinforcement for their efforts and

cause them to continue their weight loss programs over a longer period of time. The more fat that is lost, the greater will be the medical benefits. Thus, using a cream to cause weight loss from around the waist for those who want smaller waists could result in people feeling better about themselves with greater motivation to continue the weight loss program. Anything that will encourage additional fat loss will contribute to the public health of the nation involved.

Thus, anthropometry of local fat reduction is primarily a cosmetic area of research. One must not discount that addressing cosmetic concerns improves one's self image. The ability to direct the areas that fat is lost during a weight loss program could be a powerful motivator to continued fat loss and medical benefits. The most non-invasive of these cosmetic approaches like cream or a low level laser seem to have the best risk to benefit ratio. We hope that this chapter will encourage the medical profession to consider topical fat reduction in a new light and give consideration of its use to motivate weight loss that will lead to greater medical benefits.

122.10 Applications to Other Areas of Research

Topical fat reduction not only motivates obese patients to lose more weight by helping them to lose weight in the body areas that are most troubling to them, but is can be used as a purely cosmetic therapy as well. Many people who may not be obese feel that their thighs or waist are disproportionately large. Although this does not represent a medical problem, reducing fat in these "problem" areas can enhance the person's self-esteem and self-confidence. In fact, plastic surgeons use invasive procedures like liposuction to produce local fat reduction. Non-invasive procedures like low energy laser and topical creams offer reversible alternative treatments for local fat reduction with much lower risks than those carried by invasive techniques.

122.11 Practical Methods

122.11.1 Measuring Thigh Circumference

The thigh is measured two-thirds of the way from the top of the fibular head to the greater trocanter using a tape measure with a tensioning device attached that insures a constant tension on the tape. Once the measurement point on the thigh is located, a measurement from the floor is taken and recorded. Future measures are then taken in a horizontal plane parallel to the floor at the measured distance from the floor on the thigh. Body weight should be supported on the leg being measured, since this insures a reproducible amount of muscle tension and reduces variability of the measure.

122.11.2 Measuring the Waist

The waist is measured according to the recommendation of the United States National Institutes of Health. The waist is measured at the level of the iliac crest in a horizontal plane parallel to the floor using a tape measure with a tensioning device attached that will maintain a constant tension on the tape. The measurement is taken at the end of a normal expiration.

Summary Points

- Obesity is growing at epidemic proportions causing diabetes to increase in prevalence
- Obesity and diabetes are expensive diseases that are straining public health systems
- The mainstay of obesity treatment is diet and lifestyle change, but it is not working well, as evidenced by the growing obesity problem
- Obesity is stigmatized and easily diagnosed visually
- Many obese people want to lose fat in local areas like the waist or thighs
- A method that allows patients to direct the areas of their bodies from which the fat is lost encourages their attempt at weight loss
- By prolonging weight loss programs, more weight is lost and health benefits are commensurately increased
- Local fat reduction can be accomplished invasively by plastic surgery or liposuction
- Mesotherapy represents a minimally invasive method of local fat reduction
- The low energy laser and topical creams are non-invasive methods of local fat reduction
- Non-invasive methods seem to have the greatest cost to benefit ratio
- Local fat reduction gives more than cosmetic benefits
- Local fat reduction increases enthusiasm for the weight loss program and has the potential to prolong weight loss
- Longer weight loss programs result in greater weight loss and greater health benefits
- Local fat reduction is an opportunity to facilitate weight loss and achieve greater medical benefits

Key Facts About Liposuction

Liposuction is a technique in which a cannula is inserted under the skin of the body area from which one desires fat removal. Suction is applied to the cannula through which the fat is removed. This removal of fat changes the contour of the body area and is usually done for a more pleasing cosmetic appearance. There are several techniques through which liposuction can be employed. Dry liposuction is rarely used anymore, but was the original technique that was performed under general anesthesia. Wet liposuction uses a small amount of fluid containing a local anesthetic and a vasoconstrictor to minimize blood loss and can be performed in the office under sedation. Tumescent or super wet liposuction infuses or injects a solution into the fat tissue containing a local anesthetic and a vasoconstrictor. It is used for large volume liposuction under sedation, and is often done in an office setting. The fluid loosens the fat cells and reduces bruising. Laser or ultrasound assisted liposuction uses light or sound energy to lyse the fat cells and make them easier to suck out of the subcutaneous tissue.

Key Facts About Mesotherapy

Mesotherapy is a procedure in which materials are injected under the skin into fat tissue. The practice was initiated in France by Michael Pistor (1924–2003) and became recognized by the French Academy of Medicine as a specialty of medicine in 1987. Mesotherapy came more recently to the United States where it is used primarily as a cosmetic procedure to reduce fat locally. The procedure has been controversial in the United States due to the paucity of well controlled clinical

trials. Part of the controversy, however, may emanate from the plastic surgical community which views this procedure as a competitive business threat. There appear to be two general types of compounds that are injected by those practicing mesotherapy. One class of compounds stimulates lipolysis. Isoproterenol is one such compound, but mesotherapists use other less well-studied compounds as well. The second class of compounds lyse fat cells. Deoxycholine, a detergent, is one such compound.

Chapter 123
Waist-to-Height Ratio and Obesity in Chinese

Che-Yi Chou and Zhiguo Mao

Obesity is defined as a disease by the World Health Organization (WHO) and it increases the risk of chronic diseases such as cardiovascular disease, hypertension, type 2 diabetes, metabolic syndrome, dyslipidemia, chronic kidney disease, and some cancers. China, with a total population that accounts for one-fifth of the global population, is the world's most populous country and the largest developing country. China was once considered to have one of the leanest populations however, it has had an increasing prevalence of obesity over the past two decades because of an increase in family income, availability of food, and changes of lifestyle. In this chapter, we summarised recent researches regarding waist-height ratio and obesity focused on the optimal cut-off for obesity, ethnic differences, gender differences and the correlation to chronic disease.

123.1 Prevalence of Obesity Among Chinese

The prevalence of obesity has increased substantially over the last decades and the trend will continue not only in developed countries, but also in developing countries (Bray 1996; Feinleib 1985). About one-fifth of one billion overweight or obese people are Chinese (Keil and Kuulasmaa 1989) and the incidence of obesity in China has caught up with that of Western countries in the past decade (Wu 2006). It is believed that by 2020 there will be more obese people in China than in the United States, given the increase rates of obesity in past 15 years. The prevalence of obesity among Chinese (Wu 2006; Popkin et al. 1995; Chu 2005; Jia et al. 2002; Gu et al. 2005; Hwang et al. 2006; Ding 2008; Lin 2011) by time is summarized in Fig. 123.1. The prevalence of obesity (defined as BMI >=25) among men increased from 6.4% in 1989 to 26.9% in 2000 and 35% in 2005 and the prevalence of obesity among women increased from 4.3% in 1989 to 36.2% in 2000, kept at 21.4% in 2001, and 26.8% in 2005. The prevalence of obesity in men continuously increased in the past decade, but reached a peak at 2000 and kept stable around 20%. This was also observed to be higher in urban than rural areas (Lin et al. 2003; Ma et al. 2005; Huang 2008; Pan et al. 2008). Based on the survey of nutrition status among Chinese in a study before 2000, a BMI >= 27 or 28 was used to define obesity in later

studies (Ding 2008). It should be noted that in the following studies, the incidence of over-weight (BMI 24–28) and obesity (BMI >=28) that were previous partially classified as obesity increased to 29.9% in individuals older than 18 (Wu 2006). Meanwhile, the change of BMI cutoff also suggested that the average size of the Chinese population has increased in the last few decades.

123.2 Waist-Height Ratio and Obesity

Obesity indicates an excess of body fat. Central distribution of fat, i.e., excessive deposition of intra-abdominal fat, is an important cardiovascular disease risk factor (Bjorntop 1991; Larsson et al. 1984; Kissebah et al. 1982). The distribution of body fat can be measured using dual-energy X-ray absorptiometry (Mazess 1990), neutron activation analysis, electrical conductance, computerized tomography, ultrasound, infrared interactance, and magnetic resonance imaging (Lukaski 1987). Although there are several instruments to measure total body fat and its distribution (Mazess 1990; Lukaski 1987; Friedl et al. 1992), anthropometric measurements are the major measurements used in clinical practice. Body Mass Index (BMI) is one of the most widely used indexes of obesity and is used by WHO for the definition of obesity. The boundary value of BMI in the definition of obesity is different among different ethnic groups such as Asians and Caucasians (Misra 2003; Stevens 2003). The cutoff for Asians, suggested by WHO experts, is BMI = 23 (Choo 2002), but a Chinese working group suggested BMI = 24 (Zhou 2002). As obesity is important for its correlation with disease status including metabolic syndrome, cardiovascular disease, hypertension, diabetes, and total mortality (Gu et al. 2005; Fu et al. 2008; Despres 2001), other indices of obesity such as waist circumference (WC), waist to hip ratio (WHR), and waist to height ratio or waist to stature ratio (WheiR) had been proposed as assessments of obesity.

WheiR is a potential index of central obesity (Chien et al. 2004) and was suggested to be the best index of obesity in its association with chronic diseases such as metabolic syndrome risk factors (Hsieh et al. 2003). The advantages of WheiR are that it is cheaper and easier to measure and calculate and has the same boundary values for men and women (Hsieh et al. 2003; Ho et al. 2003), for different ethnic groups (Ashwell et al. 1996; Hsieh and Yoshinaga 1995), and for children and adults (Savva et al. 2000; Aswell and Hsieh 2005). The measurement of WheiR simply requires the knowledge of height (self-assessment is more stable and reliable than that of weight in the absence

of standard measuring equipment) and of waist circumference, requiring a tape measure rather than weighing scales (Aswell and Hsieh 2005).

123.3 Indices of Obesity and Disease

WheiR is more directly associated with central obesity compared with BMI and WC. Visceral distribution of body fat is an important risk factor for hypertension, diabetes, cardiovascular disease, chronic kidney disease, and cancers. The association between WheiR and disease may be explained by the association between central obesity and disease. We have summarized studies of the indices of obesity and disease among the general Chinese population (Table 123.1).

Ko et al. suggested that higher levels of BMI, WHR, WC, and WheiR are associated with risk of having diabetes mellitus or hypertension in Chinese as in Caucasians (Ko et al. 1999). However, the cutoff values of the anthropometric indices that define obesity are different from those for Caucasians. Zhang et al. studied 67,334 women without prior history of coronary heart disease, stroke, and cancer. BMI, WC, WHR, WHeiR, waist-to-sitting height ratio (WsHtR), and conicity index were positively associated with the risk of coronary heart disease including non-fatal myocardial infarction and fatal coronary heart disease. WHR was positively associated with the risk of coronary heart disease in both younger and older women with a relative risk of 3.2 (1.1–9.1) for the young and 2.9 (1.0–8.4) for the elderly (Zhang et al. 2004). WheiR had the best association with cardiovascular disease risk factors including blood pressure, total cholesterol, high density lipoprotein, low density lipoprotein, triglyceride, fasting glucose, 2-h glucose, fibrinogen, apolipoprotein B, fasting insulin, coronary heart disease, angina, diabetes, dyslipidemia, and stroke (Ho et al. 2003). WheiR as an index of central obesity is also associated with increasing risk of chronic kidney disease. Every 0.1 increase in WheiR is associated with a 2.74 time increase of chronic kidney disease risk (95% confidence interval 1.18–6.72) (Lin et al. 2007). Zhou et al. studied 13,558 men and 15,521 women and found that indices of obesity including BMI, WC, WHR, WheiR, and conicity index were positively correlated with blood pressure and hypertension. After adjusting for age, WheiR in men and BMI in women had the greatest association with hypertension, irrespective of the statistical method used (Zhou et al. 2009).

Table 123.1 Indices of obesity and disease in Chinese population

Indices	Disease	Study population	Major findings	References
WHR, BMI, WC, WheiR	Coronary heart disease risk	Women	WHR for young and old women WheiR, BMI, WC for young women	Zhang et al. (2004)
WHR, BMI, WC, WheiR	Cardiovascular risk factors	Men and women	WheiR is the best indicator	Ho et al. (2003)
WHR, BMI, WC, WheiR	Chronic kidney disease	Men and women	WheiR is the best indicator especially in women	Lin et al. 2007
WHR, BMI, WC, WheiR	Hypertension, diabetes, dyslipidaemia or albuminuria	Men and women	All indices are significant	Ko et al. (1999); Lin (2011)
WheiR, BMI	Hypertension	Men and women	WheiR in men and BMI in women	Zhou et al. (2009)

Table 123.2 Cut-offs of waist to height ratio for obesity related disease

Disease	Cut-off	AUC	Specificity	Sensitivity	References
Chronic kidney disease	0.54	0.612	50.7	72.9	Lin et al. (2007)
Coronary heart disease	0.51	0.66	82.8	60.3	Ho et al. (2003)
Hypertension	0.51	0.82	71.7	64.5	Ho et al. (2003)
Diabetes	0.52	0.78	77.5	64.2	Ho et al. (2003)
Stroke	0.52	0.64	81.8	61.5	Ho et al. (2003)

AUC area under the Receiver Operating Characteristic curve

123.4 Cutoff of Waist to Height Ratio in Association with Disease

The optimal cut-off of WheiR was 0.5 among Caucasians in association with cardiovascular risk (Srinivasan et al. 2009), and Japanese (Hsieh et al. 2003) in association with metabolic syndrome risk factors. The same cut-off can be applied to Chinese in association with disease and is similar to that of Caucasians. The optimal cut-offs for obesity related disease in Chinese population are listed in Table 123.2. The optimal boundary values in different diseases were very close to 0.5, such as 0.54 for chronic kidney disease, 0.51 for coronary heart disease, 0.51 for hypertension, 0.52 for diabetes, and 0.52 for stroke (Ho et al. 2003; Lin et al. 2007). The area under the receiver operating characteristic curve (AUC) indicated the ability of WheiR to discriminate between alternative states of disease over health condition (Zweig and Campbell 1993). Higher AUC values (between 0.5 and 1) indicated better accuracy of WheiR in predicting disease. It should be noted that the cut-off of WheiR determines its specificity and sensitivity in predicting disease. For example, a cut-off of 0.54 in predicting chronic kidney disease results in a sensitivity of 72.9% suggesting that individuals with WheiR less than 0.54 can be used to exclude the risk of chronic kidney disease. A lower cut-off of WheiR such as 0.5 revealed a higher sensitivity (76.5%) and a lower specificity (47%). Therefore, the optimal cut-off of WheiR may be dependent on the purpose of its clinical use. Of interest is that WheiR is more important for Chinese women in predicting chronic kidney disease than men and that the number of metabolic syndrome risk factors is more correlated to the risk of chronic kidney disease (Lin et al. 2007). The cutoff of WheiR is not different between Chinese and Caucasian populations, but the clinical usefulness of WheiR may be different among genders and different age groups.

123.5 Waist to Height Ratio and Obesity in Women

The difference between the measurement of BMI and WheiR is its association to central obesity. Women had a more consistent correlation between waist circumference and abdominal visceral fat than men (Stewart et al. 2003; He et al. 1999). WheiR had a different prognostic value in women such as the presence of proteinuria in diabetic women (Tseng 2005) and the increase of chronic kidney disease risk (Lin et al. 2007). Zhang et al. (2004) studied coronary heart disease risk in 67,334 women aged 40–70 years without prior history of coronary heart disease, stroke, and cancer and found that waist height ratio is associated with coronary heart disease risk among women less than 55. The association between waist to hip ratio and mortality was studied in the ShanghaiWomen's Health Study (Zhang et al. 2007a, b), a population-based, prospective cohort study of Chinese women aged 40–70 years enrolled from December 28, 1996, through May 23, 2000, 95% of whom had a body mass index less than 30. A total of 1,456 deaths occurred in an average follow-up of 5.7 years. The relative risks of total mortality comparing the extreme waist-hip ratio quintiles were 2.36

(95% CI, 1.71–3.27), 1.60 (95% CI, 1.10–2.34), and 1.46 (95% CI, 0.97–2.20) for women with a BMI of less than 22.3, 22.3–25.1, and 25.2 or greater, respectively.

123.6 Waist to Height Ratio and Obesity in Children

The definition of obesity in children is even more complex. The often-used 85th and 95th percentile cut off points for BMI in children were arbitrarily determined and not directly based on evidence linking this level of fatness to adverse health outcomes.

The reason for the devastating obesity increase rate in China is the vast number of Chinese children and youth with obesity. The combined prevalence of overweight and obesity for the 7 to 18 years old Chinese increased from 1.6% to 23.6% for males and from 1.8% to 13.6% for females in the coastal big cities between 1985 and 2000. In 2005, the prevalence of combined overweight and obesity in the northern coastal big cities of China reached 32.5% and 17.6% for male and female youth respectively (Ji and Cheng 2008). Obese children grow up to be obese adults (Cheng 2007). Childhood obesity is becoming one of the public health problems of high priority in China.

General obesity indicator BMI is still one of the most commonly used anthropometric indices in current scientific research and the obesity index of choice according to the World Health Organization (WHO), International Association of the Obesity (IASO) and International Obesity Task Force (IOTF), although controversies exist on the cutoff values in different ethnic populations, the level of understanding is limited among the general public and BMI cannot provide information on fat distribution. Zhang et al. (2008) studied the cardiovascular risk factors in overweight and obese Chinese children, and found that even according to the reference established by the working group on obesity in China (WGOC), BMI underestimated the prevalence of childhood obesity in population-based screening programs, and the overweight children identified by Chinese BMI have presented the metabolic abnormalities like increase levels of TG, LDL-C, apo B, and insulin, lower levels of HDL-C and apo A. As Asian people tend to central obesity at lower levels of BMI than white populations and central obesity in both adults and children is related to cardiovascular risk factors (Han et al. 1995; Kelishadi et al. 2007), more informative anthropometric indicators are of special value when population-based health survey is conducted in Chinese children.

In recent years, as the increasing literature showed the superiority of waist to height ratio (WheiR) as an anthropometric index for obesity and cardiovascular risks prediction when compared with BMI, waist circumference (WC) and waist to hip ratio (WHR) in Chinese adults (Ho et al. 2003), Japanese adults and children (Hsieh et al. 2003; Hara et al. 2002), European adults (Ashwell et al. 1996) and Greek-Cypriot origin children (Savva et al. 2000), research was also performed in Chinese children.

Yan and colleagues (Lin et al. 2006) compared the association of cardiovascular risk factors with WheiR, BMI, and WC in Chinese children including 389 Han and 272 Uygur ethnic children aged 7–18 years, stratified by age, sex, and ethnicity from a school-based cross-sectional study in Xinjiang Uygur Autonomous Region (North-west area of China). After partial correlations (r) and linear regression analysis (R^2) was performed, the authors concluded that in Chinese children, WheiR was a better indicator of lipids and BMI was superior to indicate blood pressure, while WC was the best indicator of fasting glucose. Liao et al. (2008) measured the WheiR, BMI, upper arm circumference, and sitting height of 962 children aged 6–18 years from elementary and middle school in Beijing, and discussed the relationship between anthropometric indices and dyslipidemia in Chinese children. Their data revealed that WheiR together with BMI were the risk factors for dyslipidemia in Chinese children.

Two studies compared WheiR, WC, and BMI in Chinese children to evaluate the accuracy and simplicity of these anthropometric indexes. Weili et al. (2007) enrolled a sample of 2,055 Han and

2,132 Uygur ethnic children aged from 8 to 18 years in Xinjiang Uygur Autonomous Region, with overweight and obesity identified by BMI, aiming to suggest the optimal thresholds of WheiR for overweight and obesity by gender, analyze the correlation between age and WheiR, and make a comparison with that of BMI. As there were minor differences between the two ethnicities shown in this study, the author combined the data of Han and Uygur children. Results showed that the area under curve of WheiR for diagnosing overweight and obesity were both over 0.90 in male and female children, superior to those of WC. Based on their data, the threshold to identify overweight in both genders was 0.445 (with sensitivity and specificity >0.8); the threshold for obesity determination was 0.485 in male and 0.475 in female (with sensitivity and specificity >0.90). Association with age was found as much weaker for WHEIR (r = -0.108 for boys and 0.035 for girls) when compared with BMI (r = 0.413 and 0.39 for boys and girls respectively). Based on their finding, the authors concluded that WheiR is a simple, accurate, and non-age-dependent index to screen overweight and obesity in children and adolescents.

Sung et al. (2008) found that WheiR is a relatively age-independent anthropometric index by analyzing the body measurements of 14,842 Chinese children aged 6–18 years in Hong Kong (south China) in a cross-sectional study. The authors provided age- and sex-specific reference values for WheiR and WC, and found that WC was relatively larger in boys than girls and increased with age, although to a smaller extent after 14 years in girls; meanwhile, WheiR was slightly larger in boys than girls and decreased with age in both genders, particularly up to age 14 and then remained almost constant. For children aged 14–18 years, WheiR 0.5 corresponded to the 95th percentile for boys and the 97th percentile for girls. Their data also showed that WC correlated better with BMI than WheiR (r = 0.93, 0.91 cf. 0.65, 0.59 for boys and girls respectively). As the public health tool, WheiR failed to offer major advantages over WC for Chinese children in this study in that WheiR cannot avoid the need for age-related reference range. Considering its better correlation with BMI and it being easy-to-use, the authors recommended WC as a more convenient parameter for central fat estimation rather than WheiR in Chinese children.

WheiR has been shown as correlated with CV risk markers among children in studies concerning several ethnic populations, a few of which suggested that WheiR was an anthropometric index independent of age and sex. Based on these advantages, WheiR was proposed as a convenient alternative anthropometric index to assess central obesity in children as it was normalized for growth and obviated the need for age reference charts during application. Moreover, "Keep your waist circumference to less than half your height" (WheiR cutoff value 0.5) seems to be an attractive simple health target for the public.

Considering the dramatic differences of climates, life style, and ethnic composition between regions of this vast country, the conflicts between the conclusions of two major surveys with relatively large sample sizes among Chinese children might be the results of variability between regions and ethnic factors, suggesting further direct confirmatory evidence from comparative correlations with central obesity and cardiovascular risk factors in children of different age and ethnic origins will be mandatory before the WheiR cutoff of 0.5 is universally accepted as the alternative screening tool for population-based health survey.

123.7 Waist to Height Ratio and Obesity in Chinese Elderly

To date, there are few studies designed specifically for Chinese elderly population to discuss the value of WheiR in obesity measurement and cardiovascular risk prediction. Some studies incorporated the data of elderly people into the major results to evaluate WheiR in adults of all ages.

As a result, it is difficult to get a full-spectrum view of WheiR in elderly population from the current published data.

Huang et al. (2002) studied the relationship between anthropometric measurements and cardiovascular risk factors in 38,556 Chinese people of Taiwan, 1,013 of which, including 528 male and 485 female, were 65 years old or above. The authors measured BMI, WheiR, WC, and WHR, and assessed their relationships with blood pressure, glucose, and lipid profiles. Surprisingly, this study failed to find significant trends by different WheiR groups in hypertension, hypercholesterolemia, and LDL cholesterol elevation in elderly women, nor hypercholesterolemia and LDL cholesterol elevation in elderly men. Similarly, the relationships with other anthropometric indices were also statistically inconsistent for lipid profiles. Meanwhile, the four anthropometric indices were found to be closely related to cardiovascular risk factors in adults of both genders below 65 years.

This difference of WheiR's role in cardiovascular risk prediction among different age groups might imply that the value of anthropometric indices in elderly Chinese deserve further demonstration. Or more likely, the discrepancy was due to the relatively small sample size of senior subjects in that study, as was discussed by the authors.

In summary, further evidence is urgently needed before the importance of WheiR in the Chinese elderly is established, considering the lack of specific data concerning this population.

123.8 Conclusion

Waist to height ratio can be an important indicator of central obesity in Chinese and is associated with chronic diseases such as hypertension, cardiovascular disease, diabetes, metabolic syndrome, and chronic kidney disease. The optimal cutoff of WheiR is 0.5 for general population and children. However, small differences exist in genders and age groups in the optimal cut-off. The optimal cut-off of WheiR may be slightly different in cardiovascular disease, diabetes, hypertension and chronic kidney disease. More interventional studies are needed to determine if treatment of central obesity decreases risks of chronic disease.

Chapter 124
Diagnosis of Obesity Using Anthropometric Indices in Urban Populations: Brazilian Perspectives

Cláudia Aparecida Marlière, Silvia Nascimento de Freitas, Silvia Eloíza Priore, and Sylvia do Carmo Castro Franceschini

Abstract There is a consensus in the literature that the etiology of obesity is multifactorial, caused by interaction of several factors. The parameter used for diagnosis is established by the WHO and defined by the body mass index (BMI), obtained by calculating the ratio between body weight (kg) and square of the height (m^2). An adult is considered obese when for BMI greater than or equal to 30 kg/m^2. In Brazil, an increase in obesity has been observed in all regions, especially in the South and Southeast regions, and more in urban than rural areas. This evolution is concomitant to a nutritional transition process, showing great change in the Brazilian diet pattern. Decrease in malnutrition and increase in obesity in adults were identified when two national surveys were compared: The National Study on Family Expenses [*Estudo Nacional sobre Despesas Familiares*] (1974/1975) and the National Health and Nutrition Survey [*Pesquisa Nacional de Saúde e Nutrição*] (1989). The evolution of obesity in Brazil took place in a relatively short time, and controlling it became a priority in the country public health policies. Among the several factors that determine obesity, are urbanization, which has changed diet patterns; sedentary lifestyle, which has contributed to weight excess; and a change in nutritional indicators. Hence changes in diet patterns indicate urgency in directing health and nutrition policies towards minimizing the problem of obesity in adults in Brazil.

124.1 Introduction

The morbidity and mortality patterns in the Brazilian population have undergone changes since the 1960s (Monteiro et al. 2000), and understanding of their behavior is based on concepts from the epidemiological transition, nutritional transition, and demographic transition.

With regard to the epidemiologic transition, changes in the population morbidity and mortality patterns were observed, with reduction of infectious diseases and rapid increase of chronic non-communicable diseases (CNCDs), which stand out as causes of death. Increase in life expectancy and aging of population in developing societies further raise the likelihood of the onset of CNCD.

Regarding nutrition disorders and diet- and nutrition-related diseases, an important drop in the prevalence of malnutrition/low weight has been observed in all age groups and regions. This is especially true in children aged 0–5 years, during the past decades, which was followed by an increase in the overweight and obesity rates in all regions and age groups, with special focus on women from lower social and economic levels.

The demographic transition resulted in changes in the trends of morbidity and mortality and fecundity patterns. These caused changes in the population structure in which there was a decrease in high morbidity and mortality due to infectious diseases, but a high predominance of chronic non-communicable diseases, which was observed to alter how a population falls prey to disease and how it dies.

The nutritional transition, following the same logic of the previously mentioned transitions, is also a process of sequential change associated with diet and nutrition patterns. It is influenced by economic, social, and demographic change, modifying the diet and nutrition profile in the context of the population's health–disease process (Monteiro et al. 2000).

In Brazil, there were two national nutrition surveys, conducted in the 1970s and 1980s: the National Study on Family Expenses (ENDEF) and the National Health and Nutrition Survey (PNSN). The former was carried out during 12 months between 1974 and 1975 and comprised a sample of 55,000 households. This study assessed the nutrition conditions, establishing diet consumption and family expenses (Brazil 1975). The PNSN was conducted in 1989 by the former National Institute of Diet and Nutrition [*Instituto Nacional de Alimentação e Nutrição*] (INAN), in partnership with the Brazilian Institute of Geography and Statistics [*Instituto Brasileiro de Geografia e Estatística*] (INAN 1990). It was a household-based transversal study, with a stratified and probabilistic-type sampling of approximately 63 million Brazilians, encompassing 14,455 households. Its main objective was to assess the population nutrition condition, in addition to obtaining information on the

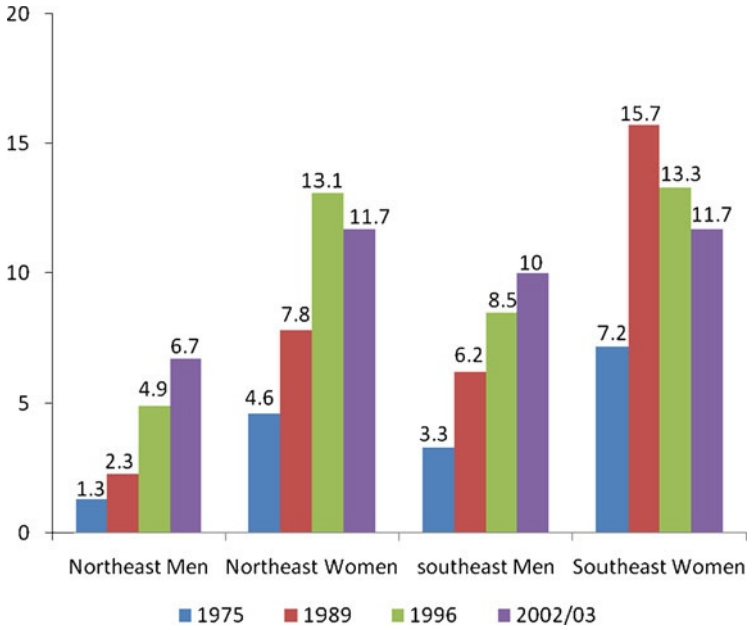

Fig. 124.1 Temporal evolution of obesity prevalence (BMI ≥ 30 kg/m^2) in northeast and southeast of Brazil (1974/1975, 1989, 1996, and 2002/2003) (Source: IBGE, National Study on Family Expenses (ENDEF) 1974–1975; National Institute of Food and Nutrition, National Health and Nutrition Survey (PSNS) 1989; Sociedade Civil Bem-Estar Familiar no Brasil, National Survey on Demographics and Health (PNDS) 1996 and 2006; and IBGE, Department of Surveys, Coordination of Work and Income, Family Budget Survey (POF) 2002–2003 (Based on Batista Filho and Rissin 2003; IBGE/MP/MS 2004))

household health condition, income, occupation, and participation in government-sponsored diet and nutrition programs.

An inversion in the nutrition indicators that evaluate the Brazilian population nutrition profile was found in these surveys. According to the ENDEF, the weight deficit in the adult Brazilian population was 24% for men and 26% for women, and obesity was 2% for men and approximately 7% for women (Brazil 1975).

The PNSN also showed changes in nutrition indicators, with a reduction of 15% in low weight for men and of 16% for women, and obesity rates were 5% among men and 12% among women during the same period. A significant reduction of low weight was identified in the 15-year interval between both surveys.

Still, according to these studies, there was a 50% drop in weight deficit for both genders. This is contrary to what was observed regarding overweight, which affected approximately 32% of 27 million Brazilian adults, corresponding to 27% of 11 million men and 38% of 16 million women.

The National Survey on Standard of Living [*Pesquisa Nacional sobre Padrões de Vida*] (PPV), conducted between 1996 and 1997, revealed an increase of obesity in all educational levels for the male population. For females, the ratio was similar to that of the male population during the period between 1974/1975 and 1989. Between 1974/1975 and 1995/1996, a continuous trend of increase in obesity was observed only among women in the low educational level and also stabilization, or even reduction in obesity, among women in the high educational level.

According to data from the Familiar Budget Survey [*Pesquisa de Orçamento Familiar*] (POF), from 2002 to 2003, overweight was diagnosed in 41.1% of men and in 40% of women, and, of this group, 8.9% of men and 13.1% of adult women were obese (Fig. 124.1).

124.2 Distribution of Obesity in Brazilian Regions

According to Coitinho et al. (1991), the country's several geographic regions show social differentiations in distribution of obesity. These authors found higher prevalence of overweight in the more economically developed regions of the country and in the higher income levels, but an increased trend of obesity is already observed in the poorer regions and lower income levels.

To better understand the obesity distribution in Brazil, which is 8.5 million km^2, it is necessary to know some of the country's characteristics and the Human Development Index (HDI). The HDI is an index created by the United Nations Development Program (UNDP) and calculated for several countries since 1990. Originally intended to measure the differences between countries, it was adapted also to be applied to states and cities (Table 124.1). The index ranges from 0 to 1. The closer the index is to 1, the better is the quality of human life. The most recent HDI ranking of the Brazilian states shows a country divided in half. Figure 124.2 reveals that, in 2005, the highest HDIs are from 11 states in the South, Southeast, and Midwest regions, with the Federal District ranked first.

On the other hand, the lowest values of HDI are in the nine states in the Northeast region. No state in this region has a HDI higher than that of any other part of the country, according to the report *Employment, Human Development and Decent Work – Recent Brazilian Experience*, recently launched by three United Nations agencies: the Economic Commission for Latin America and the Caribbean (ECLAC), International Labor Organization (ILO), and the United Nations Development Program (UNDP) Programa de las Naciones Unidas para el Desarrolo (PNUD 2004).

Between 1991 and 2005, the HDIs of all states in the country improved. The Northeast region, which registers the lowest values since the last decade, was however, the region with the highest increase (16.3%) of the index. The Southeast and the Midwest had HDIs increased by 10.9%. The South, which maintained its three states among the six highest HDIs since the past decade, showed the lowest increase in the index (8.5%). Of the ten states with the highest variation in the HDI, nine are from the Northeast region.

This situation, showing a country in which the HDI is lower in the North/Northeast regions and higher in the Southeast, South, and Midwest regions, can be explained by the economic geography of Brazil, in which production, economic activity, and income are still much more concentrated in these regions. The recent increases in the HDI were attributed to education according to the report (PNUD 2004), and education is one of the three HDI dimensions (income, education, and longevity). In all states, the education dimension showed the highest increase between 1991 and 2005. The HDI–education evolution – and, less noticeably, that of the HDI–longevity – contributed to considerably reducing the difference in development levels between the Brazilian regions (Fig. 124.2).

According to Coitinho et al. (1991), the highest percentage of overweight was in the South region. This region is the smallest in area, comprising 7% of Brazil and 15% of the population. Five million adults are overweight, with higher prevalence in urban areas. This difference is more noticeable in males, with 4% in rural areas and 8.6% in urban areas. Among women, the indices are practically the same for both rural and urban areas, with 15% and 14.6%, respectively.

In absolute terms, the Southeast region occupies 11% of Brazil and has 45% of population, which is the most populated in the country. It has ten million overweight adults and roughly 3.5 million obese individuals, making up the critical picture of the country. In this region, the obesity is more frequent in females (13%) than in males (5%). The indices are higher for female population in urban areas (13.7%) as compared to rural areas (11.4%). However, decreased obesity rate is a trend observed among higher-income women in this region (Monteiro & Conde 2000).

Table 124.1 Criteria to classification of Human Development Index (HDI)

Criteria	Classification
≥0.90	Human developing higher
0.80–0.89	Human developing high
≥0.50–0.79	Human developing medium
<0.50	Human developing low

Fig. 124.2 Distribution of Human Development Index in Brazilian regions in 2005. (Source: IBGE 2009)

The North region comprises the largest area and occupies 45% of Brazil, with only 7% of population. The lowest economic development is found in this region, and the number of adults with excess weight reaches 34% of total population, with differences between sexes, and it is higher in women (10%) than in men (6%).

The Midwest region corresponds to 18% of Brazil, and excess weight affects 31% of adult population: 10% of females and 4% of males. Unlike other regions, the highest frequency is observed in women residing in rural areas (10.5%) and in men in urban areas (5.6%), as compared to rural areas (1.8%) (Cointinho et al. 1991).

The Northeast region occupies 18% of Brazil and has the largest number of states. Twenty-four percent of the adult population in the region has excess weight (Cointinho et al. 1991). The highest incidence is found in the female group (7%) as compared to males (2%), and it is an urban problem for both men and women.

Hence, it could be concluded that obesity in Brazil is more present in the urban context, and the rates are slightly higher in urban than in rural areas throughout all regions. In urban areas, the problem of excess weight is more significant in females (12%) than in males (6%).

124.3 Factors that determine obesity in Brazil

According to Peña and Bacallo (2006), determining obesity may be different among the poorest and wealthiest people in the same country, or in developed and developing countries. Therefore, these differences must be taken into account since there are some factors that contribute to this condition.

Genetics, although not fully elucidated, seems to have a mechanism of metabolic adjustment in poor obese individuals. Thus, people exposed to inappropriate or fluctuating food consumption, in whom food intake alternates with no intake, seem to be able to efficiently use the energy and fat when the food supply is regular and available, which could lead to increased prevalence of overweight and type II diabetes mellitus – non-insulin dependent diabetes mellitus (NIDDM) (Peña and Bacallo 2006).

Some factors, such as living and environmental conditions (political, economic, social, cultural and physical) are considered as important influence in determining urban obesity in Brazil. The sociocultural factors as violence, lack of infrastructure and education for health as determinants, in addition to lack of physical activities. A negative effect in economic growth, observed in the 1980s, in Brazil, led to poor income distribution, and together with stabilization measures of economic plans, contributed to increase poverty and to intensify its extreme forms in the Brazilian population. Social inequality among these population groups and rural exodus to large metropoles, besides sedentary lifestyle, aggravated even more this situation (Gigante et al. 2006).

Distant acculturation influenced by the food industry, induces people to take habits and lifestyles that are not adequate for their region and style, making the low-income groups having conflicts between their real life and that projected they identify with, thus assuming Western food habits. In general, they comprise groups with less cultural and social opportunities, living in violent and unsafe environments and who suffer from micronutrient deficiency and overweight, and pose a higher risk of developing infectious and chronic diseases.

In regard to the factor sex, women are more vulnerable for having fewer opportunities, taking more social responsibilities and underestimating their body image. Some factors related to the female reproductive cycle, such as age at menarche, gestational weight gain, number of children, interval between deliveries, duration of breastfeeding and menopause are also considered as determinants of female obesity (Ministério da Saúde 2006).

In addition to other factors, the newest challenge is to face the dynamic relation between poverty and obesity in Latin America and the Caribbean as observed by the United States Agency for International Development (USAID) and also reported in Brazil.

124.4 Applications to Other Health and Disease Areas

The metabolic syndrome (MS), also known as syndrome X, insulin-resistance syndrome, deadly quartet, or plurimetabolic syndrome, is characterized by a group of risk factors related to insulin resistance and abdominal obesity (Gomes 2006).

Although there is no consensus in the national and international literature in the diagnosis of MS, it is assumed that the individuals who meet three or four of the following criteria are considered as suffering from this syndrome: (1) abdominal obesity, (2) hypertriglyceridemia, HDL cholesterol <40 mg/dL in males and <50 mg/dL in females, (3) blood pressure 130/85 mmHg, and (4) fasting glucose ≥110 mg/dL.

It is estimated that 24% of the adult population in the USA and 50–60% of population aged over 50 have metabolic syndrome. The projection for 2010 is that 50–70 million or more Americans will have some manifestation of this syndrome.

However, there is scarce information about this syndrome in the adult population in Brazil. However, there are some studies in specific populations using centralized obesity indicators, such as waist and hip circumferences, waist circumference, BMI, and percentage of fat (%F), to predict the presence of metabolic syndrome in adults.

A study conducted by Pontes et al. (2008), with women aged 27–29 years, showed mean values above the normal nutritional standards in BMI, percentage of body fat and presence of MS.

Another study performed by Gomes et al. (2006) demonstrated that BMI ≥ 25.0 kg/m^2 was the best predictor of altered abdominal circumferences in females, when assessing the area under the ROC curve. In males, a BMI ≥ 25.0 kg/m^2 was the best predictor in presence of abdominal circumference for cardiovascular risk, whereas the circumference of metabolic syndrome occurred in those with a BMI ≥ 30.0 kg/m^2.

A third study used the waist-to-hip ratio (WHR) and the waist circumference (WC) and showed that the WHR, with alteration, has a significant association with metabolic syndrome, such as hypertension and low HDL-cholesterol levels, but the WC had significant association only with isolated arterial hypertension. However, both indicators present a strong association with concomitant presence of two or more changes related to MS (Martins & Marinho 2003).

The literature reports that the most accurate cutoff points are sometimes greater or smaller than those established by the World Health Organization, thus hindering interpretation of results in other populations. Very often, these indicators present low sensitivity and low specificity, when compared to American reference measures, mainly for cardiovascular risk, although validation of these indicators is reported in specific studies.

124.5 Practical Methods and Techniques

According to Himes (2006), the anthropometric indicator to assess obesity demands answers to three questions, as follows:

- What is the specific purpose of identifying those overweight or obese?
- Which anthropometric indicator meets this purpose?
- Which is the best cutoff point for the indicator?

The indicator to use should be one that maximizes both sensibility (proportion of those who become ill and are correctly identified by the indicator) and specificity (proportion of those who are not ill and are correctly identified by the indicator) relative to a specific result, that is, the risk of being ill subsequently. This method produces an indicator with the best general efficiency, or the correct classification of individuals in relation to expected result (Himes 2006).

Practice related to implementation of anthropometric assessments in public health units is a decisive factor in selection of the most appropriate anthropometric indicator. Location, facilities, and team have important implications on the demands of equipment, training, quality control, and reliability of the measurements.

Cultural acceptance of measurements, frequency of visits required, and transport may bring some limitations to the target groups, but anthropometric indicators are considered more feasible (Himes 2006).

Different cutoff points of the same indicator are associated with diverse sensibility and specificity points. Theoretically, there may be many claims to select a cutoff point based on maximum sensibility, maximum specificity, or maximum efficiency of an indicator or screening, depending on the purpose.

In practice, the variety of probable purposes for the anthropometric indicators of overweight or obesity in public healthcare facilities suggests that, in most cases, the indicators should be selected based on maximum specificity.

Although it seems to be controversial, using specificity rather than sensibility corresponds to identifying who could be ill through calculation of the predictive positive value (PPV) or the proportion of individuals considered at risk by the indicator (Himes 2006).

Among the several indicators are used to evaluate body fat, the WHO recommends, from 1995, the body mass index (BMI) in kg/m^2, as the anthropometric indicator for adults aged under 60 years. The main reasons for such a recommendation include the fact that: (1) they are measures routinely collected; (2) they have good reliability; (3) pieces of equipment used to measure are easily acquired; (4) there is no need for ideal weight reference specific for that population; (5) it is valid in relation to morbidity and mortality; and (6) the standard report categories and the tables and normograms for calculations are provided by the World Health Organization.

The several cutoff point levels for overweight, based on the BMI, are for grade I: 25–29.99); for grade II: 30–39.99; and for grade III: over 40; moreover, they have not been assessed for other purposes apart from determining the total subsequent mortality (WHO 1995).

There are other indicators to evaluate body fat that can be used to consider total fat and its distribution. Such indicators are: (1) circumference of the arm, waist, and hip; (2) proportion of the circumferences (waist-to-hip); (3) tricipital, bicipital, subscapular, and suprailiac skinfold thickness; (4) sum of skinfold measurements; (5) proportion of skinfolds (tricipital and subscapular); and (6) equations to predict total body fat.

The circumferences are influenced by fat mass, muscle mass, and size of bones. It is possible to measure several body circumferences, including the main ones, as follows: mid-upper-arm circumference and its combination with the tricipital skinfold thickness enables calculating, by means of formulas, the arm muscle circumference (AMC), the arm muscle area (AMA), and bone-free arm muscle area, which correlate with total muscle mass, thus assessing the protein nutritional status.

Some studies analyzed the association of diet and development of central adiposity (Koh-Banerjee et al. 2003), and others showed gain in waist circumference (WC).

The association of food patterns with excess weight has been the object of several studies, indicating a positive association between these food patterns and global and central obesity (Sichieri et al. 2003). For other authors, this relation is not clear (Quatromoni et al. 2002; Togo et al. 2004).

Waist circumference (WC) is used due to its low cost and relatively simple measurement, and it is one of the indicators to assess composition of total body fat and its relation with chronic diseases. It classifies adiposity and has been recently used to evaluate cardiovascular risk for predicting visceral fat, which is responsible for metabolic and cardiovascular alterations (Freitas et al. 2007).

In a study conducted by Freitas et al. (2007) the use of BMI and WC was very precise in evaluating obesity in the urban mixed-race population, except for men aged under 40 years. These two indicators have a good discriminatory power according to the ROC curve, independent of age and sex (Fig. 124.3), and the lower estimates of BMI cutoff points compared to the international standards were observed in this study, according to sex and sex/age.

Similar results were reported by other authors in studies of specific population groups, in whom the cutoff points varied according to sex and age (Stanforth et al. 2004; Movsesyan et al. 2003; Aronne and Segal 2002; Pitanga and Lessa 2005; Sánches-Castillo et al. 2003). When the values

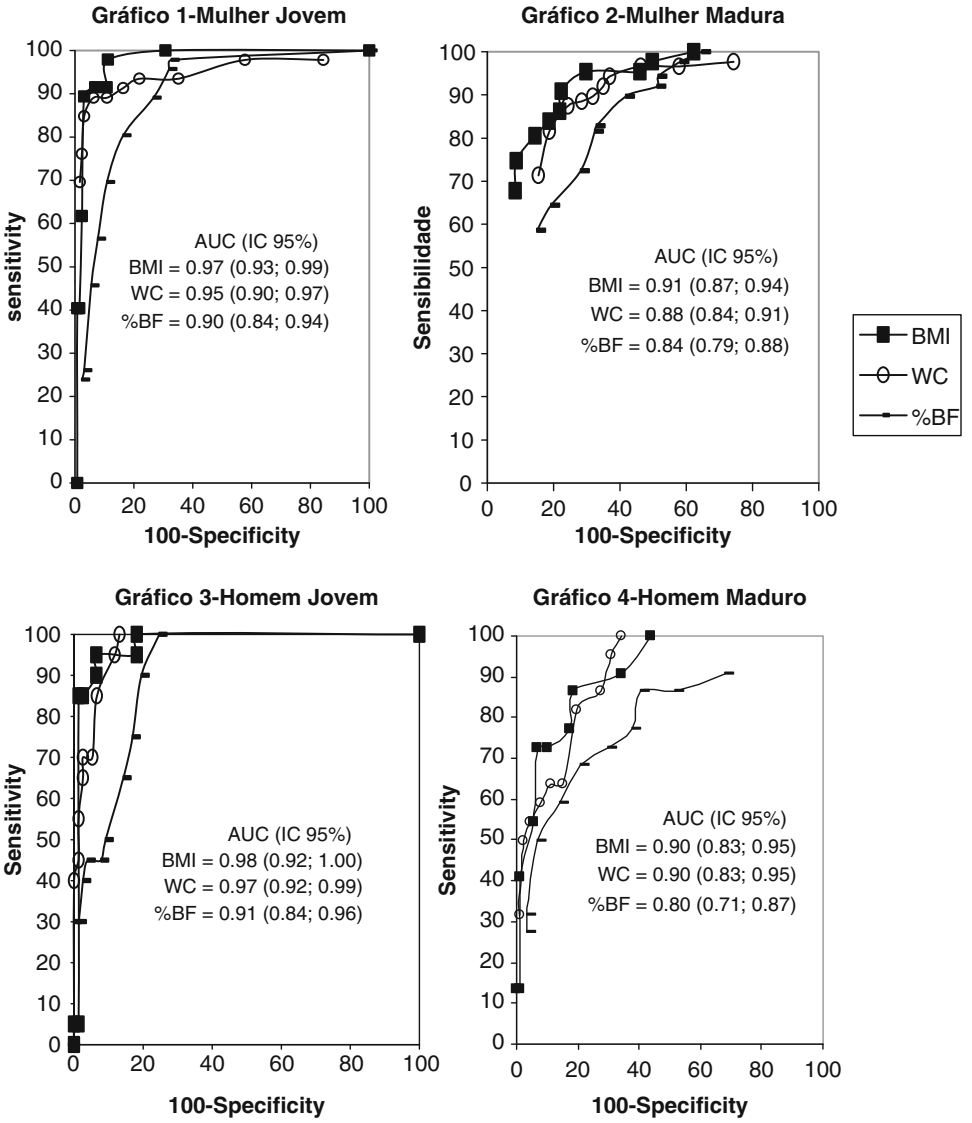

Fig. 124.3 Receiver operating characteristic curves of anthropometric predictors in the urban population of Ouro Preto City, Brazil aged 20–79 years, by sex and age (*AUC* area under the curve, *CI* confidence interval, *BMI* body mass index, *WC* waist circumference, *%BF Siri* percentage total body fat estimated with Siri's equation)

recommended by the NIH and WHO (National Institutes of Health 2000) were used to define obesity, an increase in specificity for men and women (98.8% and 94.2%, respectively) and a significant drop in sensibility (33.3% and 60.4%, respectively) was observed.

The rise in the number of false-negatives, that is, obese individuals who were not considered as such, led to an underestimated rate of obesity of 57.2% and 29.9% for men and women, respectively, regardless of age. Similar under-reporting estimates were reported by Frankenfield et al. (2001), using the same cutoff points recommended by the WHO to estimate obesity in white individuals (Table 124.2).

According to Rezende et al. (2007), the WC is widely used to differentiate gynecoid and android fat distribution, and, like the BMI, it is able to predict the incidence of diabetes. Moreover, the waist–

hip ratio is able to predict diabetes with other indices, BMI and WC, and it has better inverse association with low HDL-cholesterol levels than waist circumference.

There are more than 100 equations to estimate body fat based on skinfolds, and some studies, such as that performed by Durnin and Wormersley (1974) and Jackson et al. (1980) in population groups, verified the validity of equations. Nonetheless, Rezende et al. (2007) demonstrated the existence of low accuracy due to ethnicity, level of physical activities, and amount of body fat, when these equations are used in other population groups.

The studies on the Brazilian population to validate these equations and that were cited by Rezende et al. (2007) showed that the samples were often small and with a very specific population group. For this reason, the equations of Durnin and Wormersley (1974) and of Jackson et al. (1980) are still used, even though the specific and general equations of Durnin and Wormersley underestimate the percentage of fat measured by hydrostatic weighting. Hence, one must bear in mind that the equations found in the literature have gone through a validation process for specific groups and should not be generalized, which hinders their use in other populations, unless they are proven.

Other indicators to assess body composition, such as hydrostatic weighing and dual-energy X-ray absorptiometry (DEXA), are considered gold standards and have the disadvantage of low applicability and high cost for population studies.

Bioelectrical impedance (BIA) has been used to assess body composition through two techniques – bipolar measurement in lower and upper limbs or tetrapolar, measuring the whole body. These techniques are based on conduction of a low-intensity electrical current, applied by cables connected to electrodes or conducting surfaces that are in contact with the skin.

Although easy to be used and presenting high reproducibility, they provide less precise data depending on the body's hydroelectrolytic balance, which alter due to intense physical activity, use of alcohol, and edema or fluid retention.

Another disadvantage is that these devices provide values of fat mass, lean mass, and body water by means of predictive equations adjusted by sex, age, weight, and height. For each device, there are prediction equations that vary and are valid only for the study population, thus making it necessary to validate them for other population groups.

Although this technique is not invasive, inexpensive, and highly reproducible, the studies showed that validation of the equations presented body composition values that were very different from those found according to the standard methods (Sun et al. 2005), both with bipolar and tetrapolar techniques. On the other hand, when compared to anthropometric equations, there were fewer errors in tetrapolar bioelectric impedance than in Durnin and Wormersley (1974) and Jackson et al. (1980) equations.

In three studies performed in Brazil (Carvalho & Pires-Neto 1999; Marques et al. 2000; Glaner 2005), the difficulty to validate the tetrapolar BIA for the Brazilian population is evident due to diverse characteristics of the groups evaluated and the use of different equations, in addition to scarcity of studies with this approach.

Rezende et al. (2007) reported that some studies with bipolar or tetrapolar BIA showed no differences in fat percentage obtained by hydrostatic weighing or by some BIA models. However, the same authors demonstrated that superior and inferior bipolar BIA models were not adequate to assess fat body as compared to DEXA. Since there are data still unclear, further epidemiological investigations on the use of BIA are necessary.

124.6 Conclusion

In Brazil, the studies show that obesity affects urban area populations more, followed by high-income- and low-income groups in rural areas. There is an urgent need for studies to validate indicators that can provide early detection of possible harm to health, primarily obesity, and to be preventatively used in individuals and collectivities. The literature is scarce in this type of studies in Brazil; it is necessary to define possible indicators to determinate factors that contribute to the onset of chronic non-communicable diseases.

Nowadays, in developing countries, the same agenda is shared with both excess and deficiency, obesity and malnutrition; thus, it is necessary to establish more efficient programs to change the predominant idea that conditions related to malnutrition have more impact in developing countries than obesity.

Summary Points

- *Introduction*: In Brazil, a decrease in prevalence of malnutrition/low weight has been observed in all age groups and regions, followed by a rise in overweight and obesity rates in all regions and age groups, with special focus on women from lower social and economic levels.
- *Obesity distribution in Brazilian regions*: The distribution of obesity in the country shows social differentiations in several geographic regions. A higher prevalence of overweight was found in the more economically developed regions and in the higher income levels, but a trend of obesity increase is already observed in the poorer regions and lower income levels.
- *Factors that determine obesity in Brazil*: Several factors determine obesity in developed and developing countries, and there are differences between poor and wealthy peoples in the same country.
- *Applications to other health and disease areas*: Metabolic syndrome (MS), also known as syndrome X, insulin-resistance syndrome, deadly quartet, or plurimetabolic syndrome, is character-

ized by a group of risk factors related to insulin resistance and abdominal obesity and is generally a consequence of obesity.
- *Practical methods and techniques*: Among the several indicators used to evaluate body fat, the WHO recommends the body mass index (BMI), in kg/m^2, as the anthropometric indicator for adults aged under 60 years.
- *Conclusion*: In Brazil, the studies show that obesity affects primarily urban-area populations followed by high-income groups in rural areas and low-income brackets in rural areas.

Key Points

Key features of prevalence of obesity in adults in northeast and southeast of Brazil (Fig. 124.1).

- BMI of 18.5–25 may indicate optimal weight, a BMI lower than 18.5 suggests the person is underweight, while a number above 25 may indicate the person is overweight; a BMI below 17.5 may indicate the person has anorexia nervosa or a related disorder; a number above 30 suggests the person is obese (over 40, morbidly obese).
- Figure lists the key facts of evolution of obesity prevalence (BMI ≥ 30 kg/m^2) in northeast and southeast of Brazil through surveys conducted in 1974/1975, 1989, 1996, and 2002/2003.

Key features of Human Development Index in the Brazilian regions (Fig. 124.2).

- HDI is defined as a measure to compare the characteristics as richness, education, and life of expectancy of the population of a country. This is a pattern of assessing the welfare of a population. It is used to identify if the country is developed, is developing or subdeveloped and also to assess the impact of economic politics on the quality of life.
- Figure shows that, in 2005, the 11 states with the highest HDI in Brazil are from states in the South, Southeast, and Midwest regions, with the Federal District ranked first.

Chapter 125
Presurgical Assessment of Intra-abdominal Visceral Fat in Obese Patients

Angela Falbo and Stefano Palomba

Abstract To date, obesity is simply defined as body mass index (BMI) higher or equal to 30 kg/m2 (National Heart, Lung, and Blood Institute/National Institutes of Diabetes and Digestive and Kidney diseases 1998). Although BMI is widely accepted as a marker of adiposity in population-based studies, and is recognized as an instrument to diagnose obesity for all age groups, it should be more properly seen as an index of weight excess, rather than body fatness.

Abbreviations

AFI	Abdominal wall fat index
BMI	Body mass index
CT	Computed tomography
DXA	Dual-energy X-ray absorptiometry
LADG	Laparoscopy-assisted distal gastrectomy
MRI	Magnetic resonance imaging
P	Preperitoneal fat layer
RCT	Randomized controlled trial
RR	Relative risk
S	Subcutaneous fat layer
SC	Subcutaneous
SF	Subcutaneous fat
SPAIR	Spectral attenuation with inversion recovery
THRIVE	3D T1-high-resolution isotropic volume examination
VF	Visceral fat
WC	Circumference of the waist
WHO	World Health Organization
WHR	Waist-to-hip ratio

125.1 Introduction

To date, obesity is simply defined as body mass index (BMI) higher or equal to 30 kg/m^2 (National Heart, Lung, and Blood Institute/National Institutes of Diabetes and Digestive and Kidney diseases 1998). Although BMI is widely accepted as a marker of adiposity in population-based studies, and is recognized as an instrument to diagnose obesity for all age groups, it should be more properly seen as an index of weight excess, rather than body fatness. In fact, BMI measurement does not provide information on body composition or distinguish between fat and fat-free mass or between deep and subcutaneous abdominal fat.

The deep abdominal fat, also known as organ fat or intra-abdominal fat or, more simply, visceral fat (VF), is located inside the abdominal cavity, packed in between internal organs and torso, as opposed to subcutaneous fat, which is found underneath the skin, and intramuscular fat, which is found interspersed in skeletal muscle (Fig. 125.1). Fat in the lower body, as in thighs and buttocks, is subcutaneous, whereas fat in the abdomen is mostly visceral. This is composed of several adipose depots including mesenteric, epididymal white adipose tissue and perirenal depots. An excess of visceral fat is known as central obesity, or "belly fat," in which the abdomen protrudes excessively.

According to the National Institutes of Health, the number of overweight and obese has continued to increase since 1960, a trend that is not slowing down. Today, obesity affects nearly one-third of the adult American population, about 30.5% of adult Americans, with a prevalence slowly

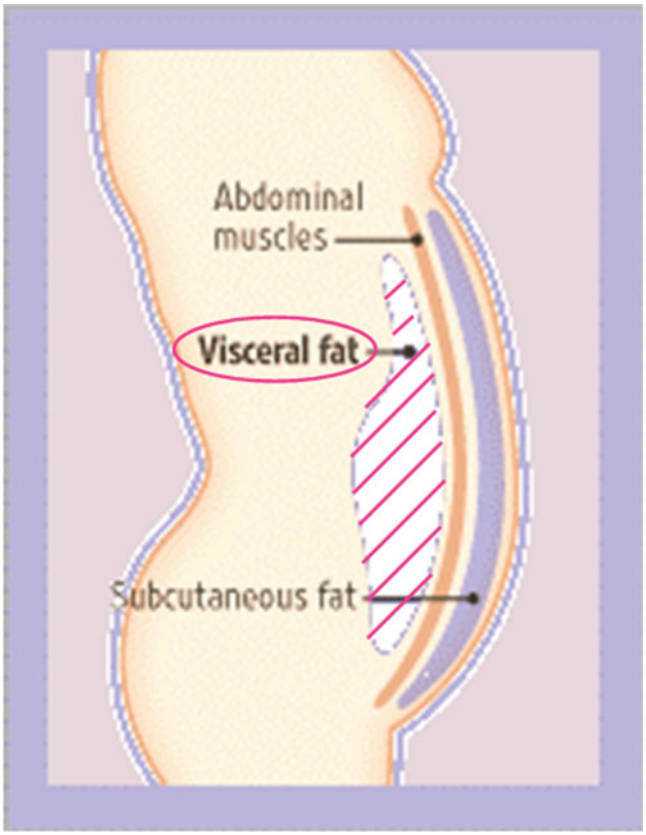

Fig. 125.1 Localization of intra-abdominal visceral fat

growing also in European countries, where the figure is 15–20% (Fig. 125.2). The latest figures published in 2005 state that 22% of men and 24% of women are now obese and projected figures expect those numbers to rise to 60% of men and 50% of women, with a diagnosis of clinical obesity by 2050.

At the present, obesity, and in particular abdominal obesity, represents a very expensive condition due to direct and indirect costs. In fact, each year, obesity causes at least 300,000 excess deaths in USA, and the healthcare costs of American adults with obesity amount to approximately $100 billion (Andreyeva et al. 2010).

There is substantial evidence supporting the notion that a great amount of VF is predictive of insulin resistance and of the presence of related metabolic abnormalities, commonly referred to as the metabolic syndrome (Wajchenberg 2000; Despres and Lemieux 2006; Schneider et al. 2007). Moreover, regardless of BMI, patients with increased VF usually have an atherogenic lipid profile, high fasting serum glucose and insulin levels, and high blood pressure, all metabolic factors participating in the atherosclerotic process. These factors, in turn, contribute to the occurrence of coronary heart disease, stroke, as well as peripheral vascular diseases (Wajchenberg 2000; Despres and Lemieux 2006; Schneider et al. 2007).

Other than medical diseases, patients with visceral obesity undergo more frequently surgery due to: (1) the effectiveness of bariatric surgery in weight loss and complete resolution or improvement of obesity-related risks (Buchwald et al. 2004) and comorbidities and (2) risk of some common adult cancers (Renehan et al. 2008). In this regard, a recent meta-analysis (Renehan et al. 2008) showed that, in men, a 5 kg/m^2 increase in BMI was strongly associated with esophageal adenocarcinoma [relative risk (RR) 1.52, $p < 0.0001$] and with thyroid (RR 1.33, $p = 0.02$), colon (RR 1.24, $p < 0.0001$), and renal (RR 1.24, $p < 0.0001$) cancers, whereas, in women, close associations between a 5 kg/m^2 increase in BMI and endometrial (RR 1.59, $p < 0.0001$), gallbladder (RR 1.59, $p = 0.04$), and esophageal adenocarcinoma (RR 1.51, $p < 0.0001$), and renal (RR 1.34, $p < 0.0001$) cancers were observed.

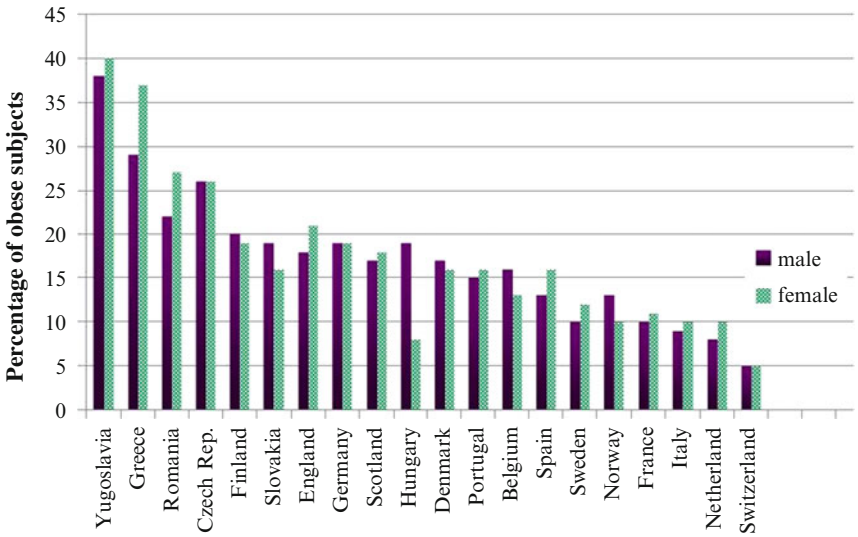

Fig. 125.2 Distribution of obesity in several European countries

125.2 Obesity and Surgical Risk

In each surgical procedure, anesthesia is the first step to be safely overcome. Obesity can present significant problems for anesthesiologists, including difficult airway management, intravascular access, pulmonary aspiration, monitoring, and choosing appropriate medications (Adams and Murphy 2000).

The main organ systems impaired, concerning anesthesia, in obese patients are the cardiovascular and respiratory systems. In fact, because of the restrictive ventilatory effects of obesity, these patients show an overall decrease in total lung capacity due to both decreased functional residual capacity and decreased expiratory reserve volume. Consequently, arterial hypoxemia, ventilation–perfusion mismatch and right-to-left shunting are often shown in these patients. In addition, obese patients require increased cardiac output to maintain pulmonary and systemic circulations. Since increased left-ventricular blood volume and systemic hypertension are common in these patients, complications of chronic, increased afterload, which translates into increased cardiac work and increased oxygen demands often occur (Adams and Murphy 2000; Tantawy 2008).

Apart from cardiovascular and pulmonary issues, several perioperative and postoperative complications, such as renal diseases, atelectasis, pneumonia, wound infections, sleep apnea-related problems, and thrombo-embolic events, are more common in obese patients (Candiotti et al. 2009).

125.3 Surgical Approach in Obese Patients

The choice of a specific surgical approach in obese patients is crucial. Specifically, in women, more and more data have demonstrated that the vaginal approach is superior to others in terms of intra- and postoperative complications (Sheth 2010). Moreover, the abdominal access in several diseases is needed.

In the early development of laparoscopic techniques in surgery, obesity was considered a relative contraindication. In fact, there are technical challenges specific to laparoscopy and which are particularly important for obese patients. They include adequate insufflation of the peritoneal cavity, trocar insertion, maintenance and physiologic complications of the pneumoperitoneum, and reduced pelvis visualization due to limited exposure.

Anesthesiologic complications are more common in obese patients during laparoscopic surgery because CO_2 insufflation of the peritoneal cavity causes cephalad displacement of the diaphragm, increased peak inspiratory pressure, decreased functional residual and vital capacity, and increased intrathoracic pressure. As a result of these pulmonary changes, patients who undergo laparoscopy are at risk of atelectasis and of decreased arterial oxygenation.

At the moment, techniques, instrumentation, and knowledge of physiology associated with laparoscopic procedures have improved and some contemporary series have shown that obese patients can undergo laparoscopic procedures safely with reduced patient morbidity compared with open surgery (Lamvu et al. 2004). In particular, although minor technical modifications (i.e., proper trocar-site selection and greater insufflation pressures) were necessary, the benefits of the minimally invasive laparoscopic approach were preserved in the obese population undergoing laparoscopic radical nephrectomy (Fugita et al. 2004). Other data show that laparoscopic surgery can be safely applied to obese patients with colorectal diseases requiring colectomy. Recent data indicate that, although obesity is associated with a high conversion rate, laparoscopic colorectal surgery is feasible and effective in both obese and non-obese patients and that obese patients, who are thought to be at increased risk of postoperative morbidity, have the similar benefit of laparoscopic surgery as non-obese patients with colorectal disease (Schwandner et al. 2004; Leroy et al. 2005).

During the past 10 years, we contributed to increasing use of the laparoscopy also for treating gynecological malignancies, especially for early stage endometrial cancer, which typically occurs in

obese women. Safety data have demonstrated that the laparoscopic approach to this cancer is a well-standardized procedure with the same indications and limits of the laparotomic one. No difference between the laparotomic and the laparoscopic approach was observed in terms of feasibility, safety, recurrence and survival rate and several advantages over the traditional open approach was noted in patients who received laparoscopy. Complications rate, postoperative pain, duration of hospital stay and length of time needed to return to full activity and/or work, and quality of life resulted in significantly improved after laparoscopic surgery (Palomba et al. 2007).

Notwithstanding these benefits of the laparoscopic approach over the laparotomic one, a significant proportion of laparoscopies are commonly converted to abdominal surgery. The laparotomic conversion rate, in obese subjects, in fact, is higher when compared with normal-weight or overweight patients, even if the morbidity and length of hospitalization associated with the procedure seem to be similar to those among women with lower BMI (Palomba et al. 2007).

Also in patients undergoing coronary artery bypass surgery, obesity does not affect the risk of perioperative death and other adverse surgical outcomes compared to normal-weight, even if obese patients appear less likely to be selected for surgery than normal-weight patients (Reeves et al. 2003).

A recent study demonstrated that obesity, and particularly VF, was strongly, and significantly, correlated with both operation time and operative blood loss in subjects who received laparoscopy-assisted distal gastrectomy (LADG) for early gastric cancer, even if there was no significant difference in the rate of postoperative complications or conversions to open laparotomy between the approaches. According to their results, authors concluded that VF was significantly correlated with operative difficulties during LADG, and that it appears to be a possible risk factor in laparoscopy that should be considered when making a decision about treating early gastric cancer with LADG (Ueda et al. 2009).

Finally, concerning the gynecologic oncology field, although several studies (Kadar 1995; Eltabbakh et al. 1999, 2000; Holub et al. 2000, 2001; Scribner et al. 2001; Bai et al. 2002; Obermair et al. 2005) demonstrated that the laparoscopic approach to gynecological malignancies is feasible and has many advantages, the laparotomic conversion rate in obese subjects seems to be higher when compared with normal-weight or overweight patients (Kadar 1995; Eltabbakh et al. 1999, 2000; Holub et al. 2000, 2001; Scribner et al. 2001; Bai et al. 2002; Obermair et al. 2005). In particular, in a recent randomized controlled trial (RCT) comparing the laparoscopic and laparotomic approach to early stage endometrial cancer, we observed a 12.5% of laparotomic conversions, of which 7.5% were early laparotomic conversion due to anesthesiologic indication. A subanalysis of these data (Palomba et al. 2006) showed that all patients who were early converted to laparotomy were obese, even if their BMI was similar to those measured in obese patients who successfully completed the laparoscopic interventions. Furthermore, patients converted to laparotomy had significantly higher VF amount (Palomba et al. 2006). In a successive study (Palomba et al. 2007), it was confirmed that the only one discriminating parameter that was related to early laparotomic conversion in women with early stage endometrial cancer was the VF.

125.4 Presurgical Assessment of Obesity

125.4.1 Anthropometric Measurements

Body weight and BMI can be easily measured and therefore are frequently used in large-scale epidemiologic studies and in the clinical practice. BMI is measured as the ratio between the weight and the square of the height, where weight is measured at a standard balance beam scale to the nearest

0.1 kg with patients wearing light clothing and height is measured barefoot using a statiometer to the nearest 0.1 cm.

All anthropometric measurements are always obtained with the patients in a standing position with relaxed abdomen, arms at their sides, and joined feet (Yanovski 1993).

According to this widely used measurement, normal-weight patients are defined as subjects with a BMI ranging from 20 to 25, whereas a BMI > 25 ≤ 30 identifies overweight subjects, BMI > 30 ≤ 40 means obesity, and BMI values >40 are synonymous of morbid or severe obesity (National Heart, Lung, and Blood Institute/National Institutes of Diabetes and Digestive and Kidney diseases 1998).

Major limitations of this measure are that the BMI does not distinguish between fat mass and muscle (lean) mass, both weight and height are surrogate measures of body size, and the body weight and the BMI provide no information regarding the nature of body fat distribution (Chen et al. 1993).

On the other hand, the World Health Organization (WHO) (World Health Organization 2000) has agreed on an international standard for identifying overweight and obesity in adult populations using the BMI, but, increased risk of cardiovascular disease has been found in individuals presenting with a distribution of excess fat in the abdominal region, leading to an insulin resistance state.

Among the anthropometric indices usable to obtain a measurement of body composition, the waist-to-hip ratio (WHR) is the most reliable to reflect the regional distribution of adipose tissue in the body. WHR is calculated as the ratio between the circumference of the waist (WC) and the circumference of the hip (considered as the maximal extension of the buttocks). A WHR of 0.8 for women and 1.0 for men correlates strongly with general health and fertility. Women with values within 0.8 have optimal levels of estrogen and are less susceptible to major diseases, such as diabetes, cardiovascular disorders and ovarian cancers. Men with WHR around 1.0, similarly, are more healthy and fertile with less prostate cancer and testicular cancer. Even if not universally recognized (Taylor et al. 2010), WHR, rather than BMI, seems to be the more appropriate yardstick for overall mortality risk stratification of older adults (Srikanthan et al. 2009). Furthermore, that indicator of VF does not distinguish between subcutaneous (SC) and VF volume, thus is s poor predictor of changes in VF.

WC alone is another parameter widely used to evaluate obesity, with particular regard to abdominal obesity. On the basis of WC measurement, WHO (World Health Organization 2000) identifies two levels of abdominal obesity in Europids, depending on risk for metabolic complications: increased risk, that is, WC >94 cm in men and >80 cm in women, and substantially higher risk, that is, >102 cm in men and >88 cm in women. More recently, the WC was also introduced as one of the criteria for clinical diagnosis of the metabolic syndrome (Alberti et al. 2005). However, gender and ethnic variations have been proposed for identifying cutoff values (Alberti et al. 2005).

WC is considered as the smallest circumference of torso, measured at the end of a normal expiration, with the measuring tape positioned at the level of noticeable waist narrowing (Fig. 125.3). When narrowing cannot be determined, the circumference is measured at the level of the lower floating rib. For hip circumference, the tape would be positioned around the hips at the level of the symphysis pubis and the greatest gluteal protuberance (Dobbelsteyn et al. 2001). Tips for accurately measuring WC are to ensure that the tape is snug but does not push tightly into the skin, and to measure waist circumference after breathing out normally, without "sucking in" the stomach.

Several data (Balkau et al. 2007) showed the implications of WC in impairing the long-term cardiometabolic risks. WC was also indicated as possible marker of surgical complications in patients undergoing laparoscopic colorectal surgery (Nitori et al. 2009). Moreover, in a recent crossover study (Wei et al. 2010), WC was demonstrated to have the greatest impact on pulmonary function in obese patients undergoing bariatric surgery. These findings confirmed the repercussion of central obesity on the postoperative complication rate and the need of more intensive post-operative care. That result was also found in normal-weight and overweight subjects (Chen et al. 2007).

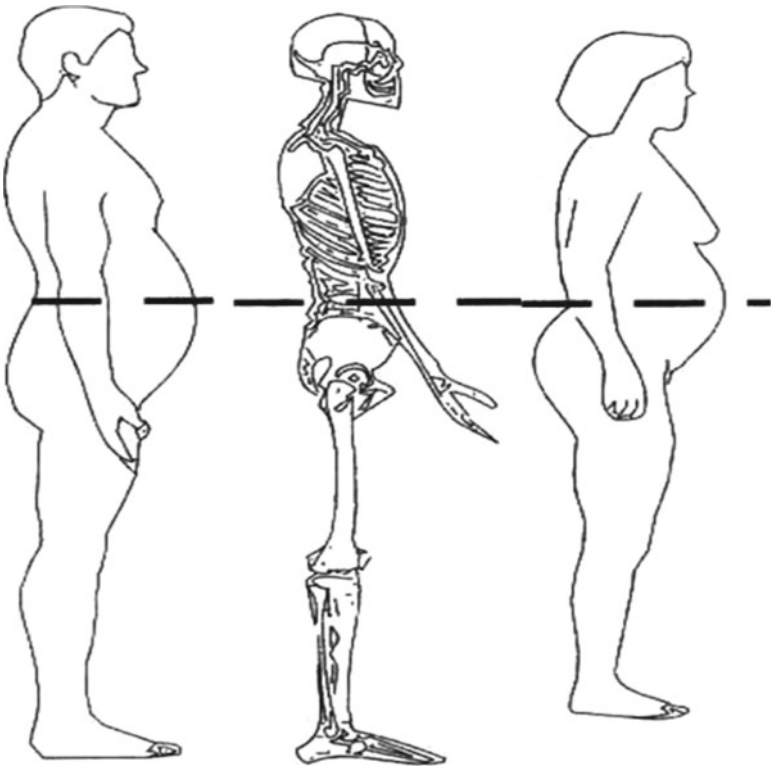

Fig. 125.3 Method for measuring waist circumference

In a recent study (Dobbelsteyn et al. 2001) designed to determine and comparatively evaluate cutoff points of WC, BMI, and WHR with respect to their ability to individually or collectively predict a number of cardiovascular risk factors at different ages, including multiple risk factors, the authors concluded that WC is probably the best single anthropometric measure for identifying individuals with cardiovascular disease risk factors, with many advantages over both BMI and WHR, that is, the simplicity by which it may be used in a clinical setting, and the ease of interpretation. In fact, WC assessment requires only the use of a tape measure, reducing the expense of the equipment needed to measure height and weight and, thanks to requiring a single measurement as opposed to the ratio of two measures, it is less susceptible to measurement and calculation errors (Dobbelsteyn et al. 2001).

Regarding surgical risk, several studies used anthropometric measurements for stratifying population on the basis of increased risks. To our experience, these indices have a weak value in predicting complications and conversion (Palomba et al. 2006, 2007). In particular, in a recent study aimed to evaluate any relationship between preoperative assessments and early laparotomic conversions in obese patients who receive laparoscopic surgery for clinical early stage endometrial cancer, we confirmed that a significant percentage subjects were converted to laparotomy for anesthesiologic reasons (Palomba et al. 2007). Furthermore, neither BMI nor other anthropometric measurements, such as WC or WHR, were predictors for anesthesiologic complications during laparoscopy in our sample (Palomba et al. 2007). In fact, no difference in any anthropometric evaluation was detected between patients who stopped the surgical intervention laparoscopically and those who had an early laparotomic conversion for anesthesiologic reasons.

125.4.2 Imaging

Numerous imaging techniques have been developed to assess VF, even if more of them are used only in experimental settings and do not have any application in the clinical practice.

Computed tomography (CT) and magnetic resonance imaging (MRI) was used as excellent tools for quantifying fat-tissue areas. However, these imaging techniques are expensive, MRI is time consuming and CT exposes patients to ionizing radiation. On the other hand, ultrasonography was also proposed as a simple procedure for estimation of the amount of VF, showing its effectiveness in both clinical and research settings.

125.4.2.1 Ultrasonography

During the years, several methods were proposed for assessing the distribution of fat tissue by ultrasonography.

In 1993, a study was conducted to establish a new index of regional fat distribution using ultrasound examination. The thicknesses of the preperitoneal fat layer (P) and subcutaneous fat layer (S) in the abdomen were measured by ultrasonography and the P/S ratio was calculated. The ratio of the maximum thickness of preperitoneal fat to the minimum thickness of subcutaneous fat was termed the abdominal wall fat index (AFI). AFI was shown to be positively correlated with metabolic impairment, suggesting that it may be a new indicator of VF deposition and may reflect lipid metabolism and glucose metabolism disorders (Suzuki et al. 1993).

Unfortunately, the first proposals failed to have a wide clinical application due to the trouble and complexity required to obtain these values.

More recently, Armellini et al. (1997) proposed the use of the sonographic intra-abdominal depth as a useful and simple indicator of VF amount. In particular, the probe is located 1 cm from the umbilicus in a transverse plane and measurements of VF and SF are taken and expressed in centimeters. SF is defined as the distance between the skin and the abdominal fascia, whereas VF is defined as the distance between the internal face of the rectus abdominis muscle and the anterior wall of the aorta (Fig. 125.4a). The VF to SF ratio (VF/SF) can be also calculated as an adjunctive parameter. However, the main difficulty of the Armellini method consists in the problem to have always a clear view of the aorta.

For these reasons, variants to that method have been successively proposed (Koda et al. 2007). Other authors (Koda et al. 2007) measured the distance from the internal face of the rectus abdominis and the anterior wall of the vertebra since it is more easily visible (Fig. 125.4b) and standardized ultrasound intra-abdominal thickness by height.

In clinical use, ultrasonographic fat indices result cheaper and easier than MRI or CT when used for assessing of fat distribution. In fact, sonographic intra-abdominal thickness seems to correlate well with abdominal fat area. In addition, the ultrasonographic measurements of the intra-abdominal muscle–vertebra distance seem to be a valid method in assessing the amount of VF as compared to L4–L5 adipose tissue area considered as a gold standard.

The high concordance of ultrasonography with CT was confirmed in a recent study (Palomba et al. 2007) showing also important clinical implications of that inexpensive, quick, and safe tool. In particular, in obese patients with endometrial cancer undergoing laparoscopy, we demonstrated that both ultrasonographic and CT procedures for assessing VF are useful in giving an estimation of the conversion risk. In fact, VF assessment by ultrasound and CT are strongly related (Fig. 125.5).

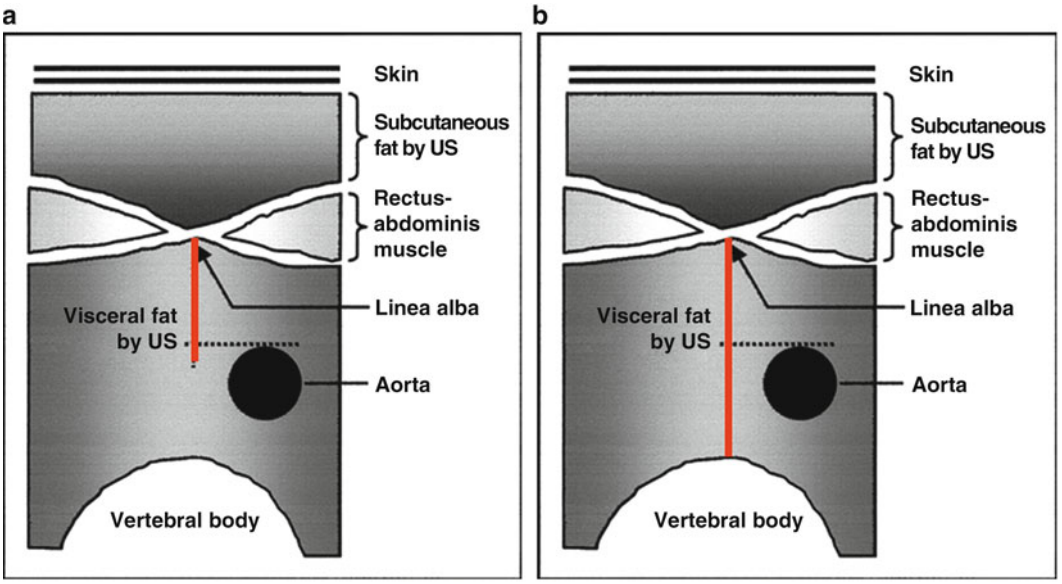

Fig. 125.4 Sonographic intra-abdominal depth by using two different indices for visceral fat amount (**a**) Classic Armellini method (**b**) Variant for sonografic visceral fat measurement

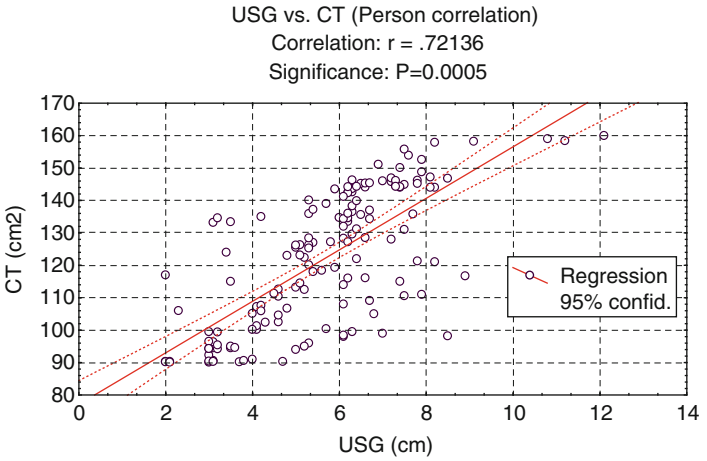

Fig. 125.5 Relationship between ultrasound and computerized tomography indices for visceral fat measurement

125.4.2.2 Computerized Tomography

CT is the most accurate and reproducible technique for assessing body fat and for quantifying the abdominal adiposity. It has been demonstrated to be an accurate and precise technique for measuring soft-tissue composition and for differentiating between visceral and subcutaneous fat in a cross section of the body.

Subjects are placed in the supine position with their arms above their head and legs elevated with a cushion to reduce the curve in the back and at the end of a normal exhalation. VF amount is evaluated using a single tomographic slice with a thickness of 0.5 mm at the L4–L5 level just before the appearance of the common iliac arteries. Specifically, the fields of interest consist of complete intra-abdominal

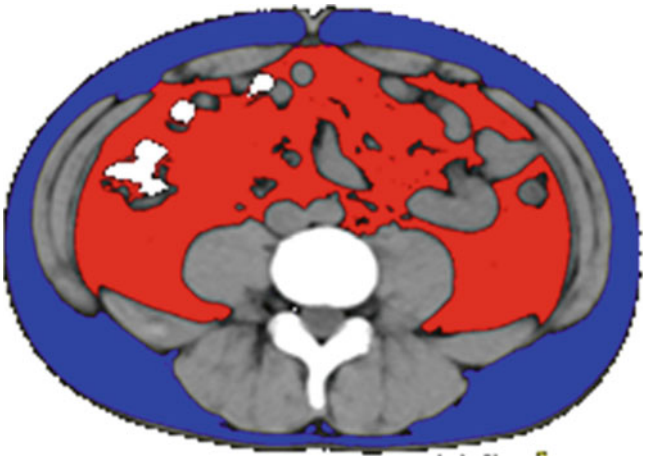

Fig. 125.6 Estimation of visceral fat by computerized tomography

region, and the extension of this area is considered as estimation of the VF (VF-CT) (Fig. 125.6). The intra-abdominal region is defined using the visceral surface of the following structures: rectus abdominis muscles with the linea alba on the midline, internal oblique muscles, psoas major muscles, quadratus lumborum muscles, inferior vena cava, and abdominal aorta (Lamvu et al. 2004).

Binary logistic regression analysis examining the relationship between VF, as an independent variable, and a laparoscopy successfully completed or early converted, as a dependent variable, showed the closest correlation ($r = 0.781$, $p = 0.008$) by using the VF-CT with an RR of 2.2 (Palomba et al. 2007). However, no cutoff value was calculated in order to give any suggestion in the clinical practice for reducing the laparotomic conversions in obese patients (Palomba et al. 2007).

Therefore, CT should be proposed to subjects scheduled for imaging evaluations before surgery, without adjunctive costs and risks.

125.4.2.3 Dual-Energy X-Ray Absorptiometry

An alternative method for measuring total body soft-tissue composition is dual-energy X-ray absorptiometry (DXA), based on the exponential attenuation of X-rays at two energies as they pass through body tissues. DXA provides accurate and precise measurements of fat, bone mineral content and fat-free soft tissue in the total body and in specific regions.

Because DXA is able to provide measurements at two dimensions, it is not possible to differentiate directly between VF and SF. Furthermore, VF is evaluated with that method either by using the standard trunk region or by manually defining a subregion at the abdomen. These subregions correlate with VF with small intra- and inter-operator variation (Snijder et al. 2002).

A recent study (Snijder et al. 2002) showed that DXA is useful in measuring total abdominal fat in elderly men and women when a single-slice CT is used as a gold standard, although it seems to underestimate total abdominal fat, in particular, when it is less. Furthermore, DXA is not superior to anthropometric measurements in prediction of visceral fat by CT (Snijder et al. 2002).

125.4.2.4 Magnetic Resonance Imaging

MRI compares well with CT-measured fat and both techniques have a similar accuracy in comparison with chemical analysis. Compared to CT, the risk of radiation exposure is really reduced by MRI

using a single planimetric evaluation obtained at the umbilical level with a successive process of 3D images. With the spectral attenuation with inversion recovery (SPAIR) water-suppression THRIVE (3D T1-high-resolution isotropic volume examination) technique, water can be selectively inverted, and when the T1-relaxation of the water signal reaches the null point, only the fat signal is excited by impression of the excitation pulse. Thus, MRI allows the estimation of adipose tissue, skeletal muscle, and other internal tissues and organs. In particular, MRI allows the quantification of the distribution of adipose tissue into visceral, subcutaneous, and more recently intermuscular depots.

The main limitation of MRI is the high costs in scan acquisition and processing of data. Claustrophobic persons cannot be scanned, and large individuals cannot fit within field of view. In addition, neither MRI nor CT is capable of accommodating very large persons, as the field of view for most MRI scanners is limited to 48 × 48 cm.

125.5 Conclusions

A presurgical assessment of VF should always be done in obese patients to estimate the risk of complication and to assess the risk of laparotomic conversion in patients scheduled for laparoscopic surgery (Table 125.1).

Anthropometric measurements are cheap and easy to perform but have a low value in the prediction of these surgical risks. On the other hand, imaging assessment of VF is useful, with significant relationship with surgical complications and, in particular, early laparotomic conversion for patients undergoing laparoscopic surgery.

An increased VF in obese and overweight patients should be considered as an adjunctive risk factor to identify a subgroup of patients with high risk conditions. In these patients, more accurate cardiopulmonary and anesthesiologic evaluations should be done in order to reduce the incidence not only of surgical complications but also of critical care during the postoperative period.

Summary Points

- Obesity, and, specifically, visceral obesity, is closely related to metabolic, cardiovascular and respiratory abnormalities, an increased risk for surgical intervention and of adult cancers.
- An increased visceral fat correlates with higher risks for both surgery and anesthesiology managements.
- In obese subjects, laparoscopic procedures seem to improve patient morbidity, even if an increased visceral fat is related to a higher laparotomic conversion rate.
- The body mass index is an accurate measure for obesity, even if it does not give any information regarding the body percentage of fat and lean mass. Similarly, no distinction between visceral and subcutaneous fat can be obtained by using this index.
- Waist-to-hip ratio and waist circumference are both indices of regional distribution of adipose tissue in the body.
- Neither body mass index nor waist-to-hip ratio nor waist circumference is an accurate predictor for anesthesiologic complications during laparoscopy.
- Ultrasonography is a cheap and simple tool for the assessment of fat distribution.
- Computerized tomography is the most accurate and reproducible technique for assessing body fat and for quantifying abdominal adiposity.

- Visceral fat assessment by using computerized tomography should be proposed to subjects scheduled for presurgical imaging evaluation without adjunctive costs and risks.
- In obese women undergoing laparoscopic treatment of early stage endometrial cancer, visceral fat, assessed with ultrasonography and with computerized tomography, is an accurate predictor for the laparotomic conversion risk.

Key Features

Table 125.1 Key features of the presurgical assessment of intra-abdominal visceral fat

1. In obese patients, a preliminary assessment of visceral fat is needed in order to prevent intra- and post-operative complications.
2. Visceral fat is the main factor related to early laparotomic conversion due to anesthesiology complications in patients undergoing laparoscopy.
3. Anthropometric measurements are reproducible, cheap and easy to perform, but they have a poor predictive value for anesthesiology complications.
4. Ultrasonography and computerized tomography are two noninvasive and accurate methods for evaluating visceral fat. Thus, they can be used for predicting an increased risk of surgical complications, including laparotomic conversion.
5. Other imaging techniques, as well as dual-energy X-ray absorptiometry and magnetic resonance imaging, do not have a favorable cost–efficacy ratio when compared to ultrasonography and computerized tomography.

This table lists the key points of the presurgical evaluation of intra-abdominal visceral fat in obese patients

Anthropometry in Diabetes

Chapter 126
Maternal Anthropometric Indices and Gestational Diabetes

Edwina Yeung, Yiqing Song, and Cuilin Zhang

Abstract The prevalence of gestational diabetes (GDM) has been on the rise worldwide. GDM is glucose intolerance first detected in pregnancy and heightens the risk of caesarian section, prematurity and neonatal mortality, to name a few of its consequences. Greater prepregnancy BMI is a strong risk factor for GDM with evidence that overweight doubles its risk and obesity triples it. Other anthropometric risk factors of GDM reviewed in this chapter include low birth weight, short stature or leg length, increased abdominal adiposity (by waist circumference or waist-to-hip ratio), excessive total adiposity by skinfolds, greater gestational weight gain, and postpartum weight retention. Due to the strong association between prepregnancy BMI and the risk of GDM, these other anthropometric risk factors were also evaluated for whether there is evidence that they can delineate risks apart from that related to BMI; that is, whether they have clinical relevance independent of pregravid BMI. Scarce evidence was given that measures of total adiposity by skinfolds add to discriminating participants at risk for GDM that may not have been determined by prepregnancy BMI. Measures of central adiposity by waist and hip circumferences may have added information. Difficulties in measurement may preclude their use in clinical practice as they require some technical training to obtain valid and reliable values. Short stature or leg length and low birth weight, were factors that remained associated with increased risk of GDM independent of BMI but these associations were weak. Investigations of these associations, however, support the developmental origins of human disease hypothesis and generate evidence that early life risk factors may be important for future health. Gestational weight gain has been regarded as not to be a determinant of GDM by the Institute of Medicine, and review of the studies to date supports their conclusion, although there is some evidence that it is still relevant for development of less severe forms of hyperglycemia in pregnancy. Lastly, post-partum weight retention may increase the risk of GDM in subsequent pregnancies but this is through the mechanism of BMI. In conclusion, anthropometry does play a significant role in the development of GDM and investigations of its measures may bring about greater understanding of the etiology of the disease, even if not all measures are suitable for clinical use.

126.1 Introduction

Gestational diabetes mellitus (GDM) is glucose intolerance with first onset or diagnosis during pregnancy (ADA 2009) (Table 126.1). Failure to resolve the condition postpartum may be an indication of undiagnosed preexisting type 2 diabetes (T2D) in the mother, rather than GDM. The pathology of

Table 126.1 Key facts of gestational diabetes mellitus

- Gestational diabetes mellitus is high blood sugar that starts or is first diagnosed during pregnancy
- Pregnant women with GDM usually do not have any severe symptoms prior to their diagnosis and their sugar levels return to normal after the delivery
- American Diabetes Association and American Society of Obstetrics and Gynecology recommend screening pregnant women at low risk for GDM between the 24th and 28th week of pregnancy, which involves blood taken and measured for glucose after fasting overnight and at an hour after the woman ingests a glucose dose (usually 50 g of sugar)
- Depending on the blood sugar levels, women then may go on to be tested with a lengthy diagnostic test (i.e., oral glucose tolerance test). Different doctors will screen and diagnose GDM using different cut-points for what is regarded as "high" glucose levels and with different glucose doses (see Table 126.2 for various diagnostic criteria)
- GDM affects about 3–7% of all pregnancies. It has been found to occur more among women who are ethnic minorities have a parent with type 2 diabetes, are older than 25 years when pregnant, or are overweight
- It leads to greater risk of the baby being born very large (i.e., macrosomia), which creates difficulties at birth including physical injury to the baby and increased need to have a C-section for the mother (see Table 126.3)
- There is some evidence that GDM has longer lasting effects, with increased risk to both the mother and child to have type 2 diabetes in the future
- Prevention or early detection of GDM is vital to avoid pregnancy complications and future risk of type 2 diabetes

This table lists some key facts regarding the characteristics and epidemiology of gestational diabetes mellitus

Table 126.2 Criteria for diagnosis of gestational diabetes mellitus

Measure	WHO	ADA	Carpenter & Coustan	NDDG
OGTT dose (g)	75	75 (or 100)	100	100
Fasting glucose (mg/d)	126	95	95	105
1-h glucose (mg/dl)	–	180	180	190
2-h glucose (mg/dl)	140	155	155	165
3-h glucose (mg/dl)	–	n/a (140)[a]	140	145
Diagnostic criteria	*1 of 2*	*2 of 3*	*2 of 4*	*2 of 4*

This table provides the multiple diagnostic criteria for GDM used worldwide. Although the WHO criterion requires only one measurement of glucose to be above the cut-point listed, the other criteria require at least two measurements to be above the values indicated (NDDG 1979; Carpenter and Coustan 1982; WHO/IDF 2006; ADA 2009)
OGTT oral glucose tolerance test, *WHO* World Health Organization, *ADA* American Diabetes Association, *NDDG* National Diabetes Data Group
[a]ADA criteria either by 75- or 100-g OGTT with 3-hr cutoff only applicable for the 100-g test

GDM has been discussed extensively in other works (Buchanan and Xiang 2005; Metzger et al. 2007; Reece et al. 2009) and is reviewed briefly here. Pregnancy naturally increases insulin resistance. This increase is hypothesized due to both increased maternal adiposity and placental hormones, (Buchanan and Xiang 2005) and functions to provide necessary nutrients to the fetus. Failure to compensate for this increase in insulin resistance through increased insulin secretion by expansion of β-cells of the pancreas leads to abnormally high glucose levels in the blood which marks GDM (Buchanan 2001). It is believed that women who develop GDM already have decreased β-cell capacity for insulin secretion prior to pregnancy and that the pregnancy unmasked this defect (Buchanan 2001). Multiple factors may contribute to β-cell dysfunction, including mutations in genes involved in insulin secretion.

GDM is commonly diagnosed at the third trimester of pregnancy (i.e., 24–32 weeks' gestation) by oral glucose tolerance test. The diagnostic criterion used varies in different areas of the world (Table 126.2). It has been estimated that GDM affects 3–7% of pregnancies in the USA and occurs more frequently among ethnic minorities (Dabelea et al. 2005). Similarly, it is estimated to affect

Table 126.3 Maternal and perinatal/neonatal complications from GDM

◦ Hyperbilirubinemia
◦ Hypocalcemia
◦ Erythremia
• Polycythemia
• Prematurity
• Respiratory distress syndrome
• Mortality
• Increased risk of obesity and type 2 diabetes later in life

This table lists the complications that occur to both the mother and the baby from GDM (2004)

3–5% of pregnancies in the UK (Ben-Haroush et al. 2004). Worldwide estimates of GDM prevalence are unclear, as screening and diagnostic practices affect estimates. Nevertheless, even at the lowest estimate of 3%, the burden of GDM is considerable, as it is associated with increased risk of complications to both mother and fetus (Table 126.3) including cesarean section, preeclampsia, prematurity, macrosomia, shoulder dystocia, and perinatal mortality. Using US National Hospital Discharge Survey data, which included information on 27,000 maternal–child pairs, Chen et al (2009) estimated that GDM increased mean health-related expenditures by $3,305 per pregnancy and, additionally, $209 for the first year of life for the infant born to the GDM mother. Extrapolating this information to the 180,000 GDM pregnancies that occurred in 2007, the authors concluded that over $600 million was spent in additional medical care due to GDM. These costs, however, do not incorporate the increased costs at later life of both the mother and child. For example, after the index pregnancy complicated by GDM, the cumulative incidence of diabetes ranged from 2.6% to over 70% in studies that examined women 6 weeks postpartum to 28 years postpartum (Kim et al. 2002). This increase in diabetes risk associated with GDM is similar, regardless of ethnic subgroups or maternal age, although body mass index (BMI) at GDM diagnosis and subsequently at T2D diagnosis does play a role (Bellamy et al. 2009).

Anthropometry, especially body mass index (BMI), is a predominating risk factor for GDM. Other maternal anthropometric measures have also been investigated in relation to GDM development including maternal birth weight, central adiposity (e.g., waist and hip circumferences), skinfold thickness, height, leg length, pregnancy weight gain, and postpartum weight retention. Conversely, GDM may also affect changes in anthropometry after pregnancy including increased postpartum weight retention. The following chapter will review the evidence of these anthropometric measures as risk factors for GDM.

126.2 Maternal Anthropometry and GDM

126.2.1 Practical Methods and Techniques for Measurement of Anthropometry in Pregnant Women

Some methods to measure anthropometry may not be feasible in pregnant women due to safety concerns. In general, most methods are similar to those used in non-pregnant individuals (McCarthy et al. 2004). Pre-pregnancy measures of anthropometry may be more ideal markers of risk, as they are less likely to be misclassified due to pregnancy (e.g., waist circumference due to fetal growth vs. maternal growth). However, most women come for their clinical visit after the onset of pregnancy, which makes it a more convenient window for evaluation. Measures taken during pregnancy need to take into consideration the length of pregnancy at the time of measurement to correctly account for anthropometric changes that occur due to pregnancy. Anthropometric changes could also independently be a risk factor for GDM, in addition to static measures at any one time point (e.g., pregnancy weight gain).

126.2.2 Body Mass Index

Obesity is a top global concern in the twenty-first century. Pregnancy is not an exception, with an alarmingly high proportion of women beginning their pregnancy overweight or obese. In USA, this has been estimated to be 45% of all pregnant women (Gunderson. 2009). Pregravid BMI is a major risk factor for GDM, and determines risk much more strongly than even maternal age, ethnicity, birth weight, or diet (Radesky et al. 2008). Table 126.4 highlights the key points on BMI and GDM risk.

BMI is defined as weight (in kilograms) divided by height (in meters) squared. It has been used by the World Health Organization (WHO) to categorize individuals as normal (20–24.9 kg/m^2), overweight (25–29.9 kg/m^2), stage 1 obese (30–34.9 kg/m^2), stage 2 obese (35–39.9 kg/m^2), or stage 3 obese (≥40 kg/m^2). BMI remains an important risk factor for GDM, both because of its increase in prevalence over recent years and as it is a modifiable risk factor compared to other established risk factors (e.g., family history).

A meta-analysis of 70 studies (published between 1977 and 2007), which included 671,945 women, found that the prevalence of GDM increased in a dose-dependent manner by BMI (Fig. 126.1) (Torloni et al. 2009). Compared to normal-weight women, the combined odds ratio

Table 126.4 Key points of BMI and GDM Risk

1.	BMI, which accounts for weight and height, is a fairly good marker of total adiposity except among individuals who have high lean muscle mass. These individuals tend to be heavier even though they are lean. Its measurement, however, is simple and reliable, with the use of a standard scale and stadiometer
2.	The causal evidence between BMI and the development of GDM is fairly strong and consistent across many observational studies. Compared to women with normal pre-pregnancy BMI (BMI<25 kg/m^2), women at greater BMI who are overweight (BMI 25–30) or obese (≥30) can have two to six times greater risk of GDM during pregnancy. Studies of bariatric surgery have demonstrated that weight loss can decrease the risk of GDM, which further supports causality
3.	Excess adiposity is tied to development of GDM through affecting insulin resistance and pancreatic beta-cell function through multiple pathways including dysregulation in production of adipokines (e.g., adiponectin and leptin) and inflammatory cytokines (e.g., C-reactive protein and tumor necrosis factor-alpha)

This table lists the key points that highlight the findings on maternal BMI and GDM risk

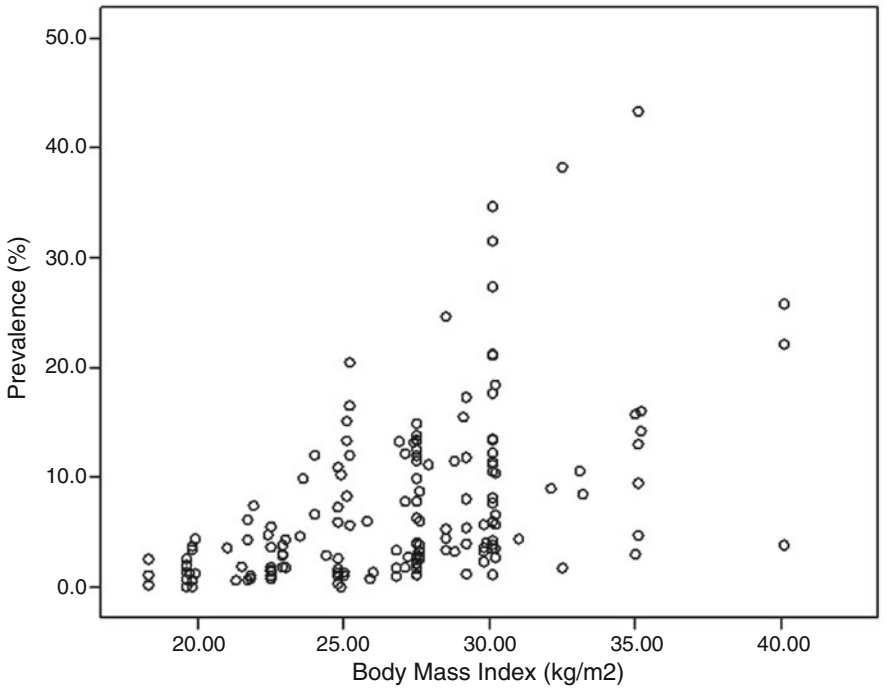

Fig. 126.1 Prevalence of GDM according to initial maternal BMI. Prevalence of GDM by pre-pregnancy BMI using information from 56 cohort studies (165 comparisons) that provided raw data with information from a total of 631,763 women. Estimating the risk of GDM in a linear fashion, each one unit increase in BMI increased the risk of GDM by 0.92% (95% CI 0.73–1.10). Extrapolating this to one category increase in BMI (i.e., 5 units) would result in 4.6% increase in GDM (Reproduced with permission from Obesity Reviews. Copyright 2009, Blackwell Publishing, Torloni et al. 2009)

(OR) and 95% confidence interval (CI) for GDM was 1.97 (95%CI: 1.77–2.19) among overweight women, 3.01 (95%CI: 2.34–3.87) among obese women, and 5.55 (95%CI: 4.27–7.21) among morbidly obese women (Torloni et al. 2009). Figure 126.2 shows all the studies and the pooled odds ratio of non-obese versus obese women for risk of GDM. No significant heterogeneity in associations was found for studies by method of assessing BMI (i.e., self-report vs. measured), region of study (i.e., North America, Western Europe, or Latin America/Middle East), prevalence of GDM (i.e., <5% or >5%), and study sample size. However, a difference was found by diagnostic criteria used ($p = 0.02$ for heterogeneity), with a stronger association found for studies which diagnosed GDM based on the 100-g OGTT (pooled OR: 4.19 (95%CI: 3.46–5.08)) compared to the 75-g OGTT (pooled OR 2.86 (95%CI: 2.25–3.62)).

Obesity is implicated in the pathogenesis of GDM via multiple mechanisms. As mentioned earlier, insulin resistance increases naturally during pregnancy. Overweight or obesity also increases insulin resistance through obstructing the insulin signaling pathway. For individuals with insulin resistance, the binding of insulin secreted from pancreatic β-cells to glucose transporters in muscle and liver cells does not trigger the adequate response required for glucose transport. Thus, glucose levels in the bloodstream remain high, which leads to negative effects for the mother and for the fetus exposed.

Adipose tissue, until recently, has been viewed as only storage units for excess lipids. However, recent breakthroughs have demonstrated that they are highly active endocrine tissues, secreting hormones called adipokines that have wide-ranging effects including those on appetite and insulin resistance (Berg and Scherer 2005). Excess adiposity, however, leads to dysregulation of these hormones,

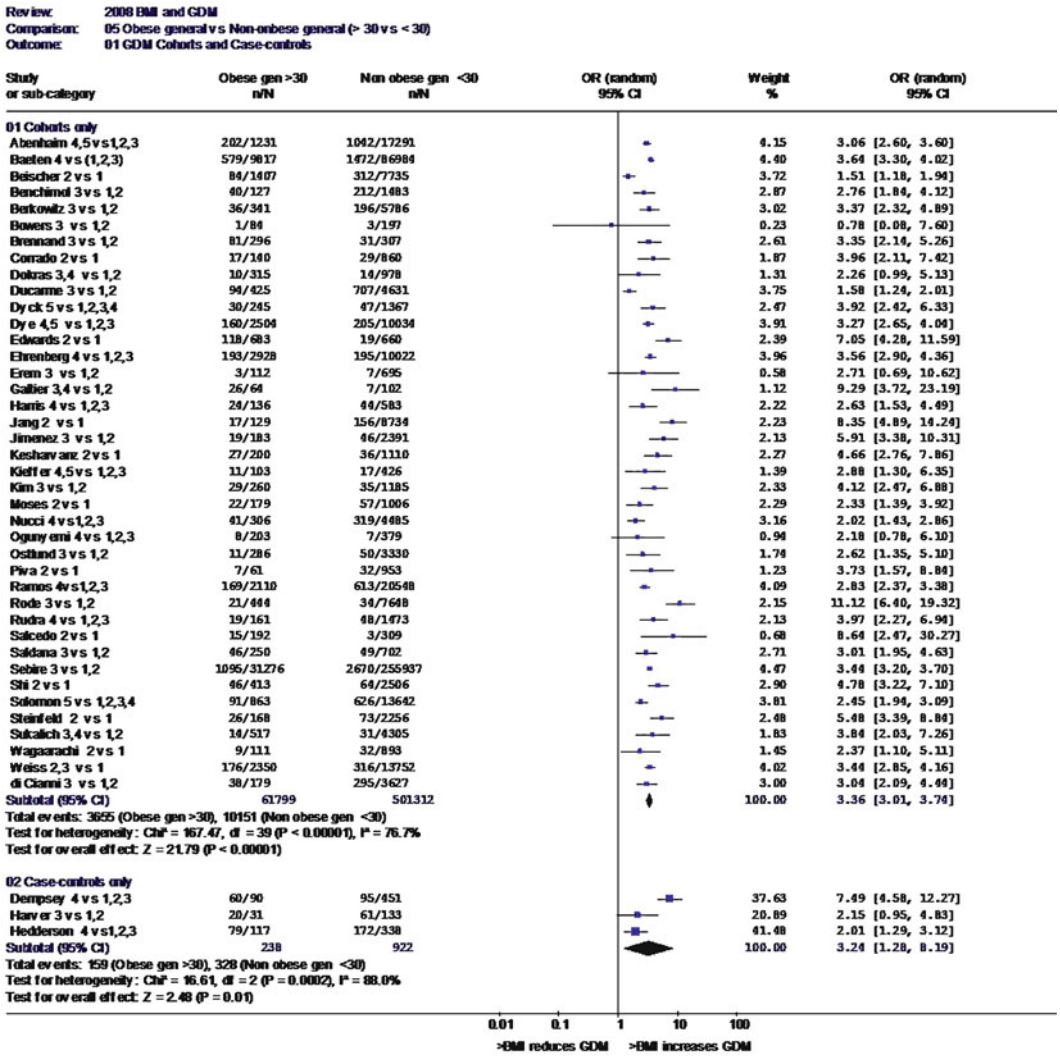

Fig. 126.2 Risk of GDM in obese and non-obese women in a meta-analysis. Meta-analysis of 40 cohort and three case-control studies on risk of GDM by pre-pregnancy obesity status (BMI>30 kg/m^2). Studies published between 1977 and 2007 were located from four databases (MEDLINE, EMBASE, CINAHL, and LILACS) (Reproduced with permission from Obesity Reviews. Copyright 2009, Blackwell Publishing, Torloni et al. 2009)

which subsequently generates metabolic imbalances stemming from lack of satiety in response to meals or to increasing inflammation. Levels of cytokines involved in inflammation, such as C-reactive protein, have been linked to increased risk of GDM (Wolf et al. 2003). As the understanding of these different molecular pathways becomes clear, interventions targeted at specific pathways may arise.

However, weight loss prior to pregnancy will likely remain the most important intervention in preventing GDM among overweight and obese women. Obese women who conceived post-bariatric surgery have a decreased risk of GDM (Guelinckx et al. 2009). Weight loss by less drastic methods between pregnancies of women who weighed over 200 lbs in their first pregnancy has also shown to significantly decrease the risk of GDM (Glazer et al. 2004). Of 4,102 women captured in the

Washington State Longitudinal Birth Database, women who lost at least 10 lbs of weight before their second pregnancy had 37% less risk of GDM compared to women who remained at the same weight (±10 lbs) (Glazer et al. 2004).

126.2.3 Central Adiposity and Its Measurement

Body fat distribution has been demonstrated to be more closely related to metabolic disorder than total adiposity (Ibrahim 2009). Upper body or android (i.e., "apple" shape) obesity leads to greater risk of CVD and T2D than peripheral or gynoid (i.e., "pear" shape) obesity (Ibrahim 2009). Individuals with android obesity have more visceral adipose tissue (VAT) than those with peripheral adiposity who store excess energy to a greater extent in their subcutaneous depots (SCAT). Anatomical, structural, and molecular differences between visceral and subcutaneous adiposity help to explain how the two depots affect metabolic risk (Ibrahim 2009). Specific measurements of VAT and SCAT require computed tomography (CT) or magnetic resonance imaging (MRI) to differentiate between the two adipose depots in the abdominal region. However, anthropometric measurements of central adiposity have been found to be effective alternatives to measures by CT or MRI, which are prohibited in pregnant women and thus impossible for studies of GDM.

Central adiposity can be assessed via measurements of waist (WC) and the ratio of waist to hip circumferences (WHR). These circumferences are typically measured by tape measure and may be more subject to measurement error than measures of height and weight. Moreover, it would be ideal to have pre-pregnancy measurements to ensure that measures are not due to fetal or placental mass. Various methods for measurement of WC have been used in research, from taking the narrowest waist to use of anatomical landmarks for its measurement (Ross et al. 2008). The National Health and Nutrition Examination Survey (NHANES), for example, measures WC at the uppermost lateral border of the right ilium (IC) and its protocol has been adopted by various organizations for defining abdominal adiposity. Even though as a continuous measure, methods of measurement do not seem to affect its association with mortality or morbidity including diabetes risk, it may be important to note the method of measurement for comparison between study means (Ross et al. 2008). For hip girth, the tape measure is placed at the level of the symphysis pubis and is run down to determine the site of the maximal protrusion of the gluteal muscles. The WHR additionally provides information on the distribution of adiposity (i.e., upper vs. lower). Despite being more technically involved, previous studies have shown that trained personnel could conduct these measurements with high reliability. Among a large group of women, measurements of waist, hip, and WHR had intraclass correlation coefficients (ICC) of 0.89, 0.81, and 0.74, respectively (Sonnenschein et al. 1993).

Despite the concern that measurement of waist after pregnancy onset is biased by fetal growth, the first trimester visit remains an important access point for clinicians. Thus, of note is that Branchtein et al. (1997) investigated the longitudinal changes in waist by uterine height and concluded that measurements conducted before the 26th week of gestation should reflect mainly central fat deposition rather than fetal growth. Valid measurements of WC can therefore be conducted early in pregnancy.

126.2.4 Evidence for Central Adiposity and GDM Risk

Given the strong association between BMI and GDM as discussed above, it would be important to determine whether waist or WHR is an independent predictor of GDM after accounting for BMI. However, the findings seem to be conflicting on the subject. Table 126.5 reviews the evidence of the

Table 126.5 Studies of the association between central adiposity and GDM

Table 126.5 (continued)

Author (year)	Study design	Study period	GDM diagnostic criteria	Controls/cases	Assessment	Mean (SD) age; BMI; WHR	Covariates adjusted for in statistical models	Associations with risk of GDM
Wendland et al. (2007)	Expanded above for six sites (Brazilian Study of GDM)	1991–1995	WHO	4735/354	Measured in duplicate – waist (minimal abdominal girth)	27.6 (5) yrs; 23.2 (4) kg/m^2 pre-pregnancy; waist = 81.7 (8) cm	Unadjusted ORs (calculated from authors' prevalences)	Quintiles of WC: Q5 vs. Q1: 2.91 (95% CI: 2.07–4.08); Q4 vs. Q1: 1.54 (1.07–2.23); Q3 vs. Q1: 1.04 (0.70–1.55), Q2 vs. Q1: 0.90 (0.59–1.35); ROC AUCs: pregravid BMI = 0.615 WC = 0.621
Madhavan et al. (2008)	Consecutive patients from gynecology unit at ≤12 weeks gestation in India	2005–2006	ADA	106/8	Measured waist (midpoint between iliac crest and lowest rib) and hip (widest area)	26 (4) yrs; 21.6 (4) kg/m^2; 0.85 (0.03)	Stratified by both BMI and WHR in subgroup analyses	WHR >0.85: OR = 12.05 (1.82–77.43); BMI > 23: OR = 7.5 (1.61–34.31). Subgroup: WHR more strongly a risk factor among heavier women (BMI > 23); By ROC, BMI a better determinant of GDM than waist or WHR

Yeung et al. (2009)	Prospective US cohort study (NHSII) with pre-pregnancy data	1989–2001	Self-report	4981/264	Self-reported waist (measured at navel) and hip circumferences (maximal protrusion)	30 (3) yrs; 23.0 (4) kg/m^2; 0.78 (0.08)	age, race, BMI, smoking, parental history T2D, age of first birth, parity and physical activity	Quintiles of WHR: Q5 vs. Q1: 2.12 (95% CI: 1.38–3.26); Q4 vs. Q1: 2.03 (1.30–3.17); Q3 vs. Q1: 1.51 (0.94–2.42), Q2 vs. Q1: 1.50 (0.94–2.39); Quintiles of WC Q5 vs. Q1: 1.88 (95% CI: 1.14–3.09); Q4 vs. Q1: 1.90 (1.20–3.00); Q3 vs. Q1: 1.47 (0.84–2.56), Q2 vs. Q1: 1.05 (0.64–1.79)

This table describes the study characteristics and summarizes the findings from literature on maternal central adiposity and GDM risk. The articles were located by a MEDLINE search conducted in September 2009. Mean (standard deviation) are noted where authors made information available

ADA American Diabetes Association, *CARDIA* Coronary Artery Risk Development in Young Adults, *BMI* body mass index, *CI* confidence interval, *GDM* gestational diabetes mellitus, *mmol/l* millimoles per liter, *NHSII* Nurses' Health Study II, *SD* standard deviation; *WC* waist circumference, *WHO* World Health Organization, *yrs* years

five studies published to date that have investigated central adiposity and development of GDM (Zhang et al. 1995; Branchtein et al. 1997; Wendland et al. 2007; Madhavan et al. 2008; Yeung et al. 2009). Of these studies, the CARDIA and NHSII studies investigated these associations using pre-pregnancy measurements and found that larger waist and WHR were significantly associated with increased risk of GDM (Zhang et al. 1995; Yeung et al. 2009). In CARDIA, compared to women in the lowest tertile (WHR 0.629–0.705), women in the highest tertile (WHR 0.743–1.02) had four times the risk of GDM even after adjusting for BMI, leading the investigators to conclude that WHR may be a better marker for GDM risk than BMI (Zhang et al. 1995). Significant associations with GDM risk were seen for both WC and WHR in NHSII after adjusting for BMI (Yeung et al. 2009). Findings from Branchtein et al. (1997) using 2-hr glucose levels among pregnant women undergoing OGTT as outcome demonstrated that women with higher WHR or WC had higher glucose levels, even after accounting for adiposity by skinfold thickness. However, a follow-up study in the same Brazilian cohort by Wendland et al. (2007) did not give sufficient evidence for these associations with GDM. Although crude ORs for GDM increased by increasing quintiles of WC, the investigators did not provide results from a BMI-adjusted model or results by WHR due to the lack of information on hip circumference. However, area under ROC curves were virtually the same (AUC ~0.6) by WC or BMI for discriminating women with GDM, leading the authors to conclude that both measures carry similar clinical information (Wendland et al. 2007). Lastly, a pilot study in India found an interaction between WHR and BMI, with WHR being a stronger risk factor among women who are heavier (Madhavan et al. 2008). From their analyses using ROC curves, BMI was found to be better than WHR or WC at predicting GDM case status (Madhavan et al. 2008). These findings, however, were based on only eight GDM cases. Taken together, these five studies suggest that WC and WHR are determinants of GDM though how much information they may add to clinical practice, in addition to BMI, remains unclear.

The CARDIA study showed results by hip circumference, with greater risk by increasing tertiles (Zhang et al. 1995). This finding, however, is in contradiction with what was observed in NHSII which found no association and in type 2 diabetes literature, where larger hip circumference has generally been found to be associated with decreased risk of T2D after accounting for total adiposity (Parker et al. 2009; Yeung et al. 2009). Biologically, hip circumference, as a surrogate measure of SCAT, should be protective after accounting for total adiposity. Clearly, more research is need for understanding how these anthropometric variables of central adiposity relate to development of GDM.

126.2.5 Maternal Body Composition

Measurement of skinfolds is one method by which investigators have assessed body composition without the use of tests, such as dual energy X-ray absorptiometry (DXA) or bioelectrical impedance analysis (BIA), that are potentially harmful for the fetus in pregnant women. Multiple measurements of skinfolds need to be conducted and care taken that the pressure exerted on the calipers was consistent for all measurements. There are undoubtedly a number of limitations to use of skinfolds, including low reliability and unavailability of some sites that would be difficult to measure in later pregnancy. However, given the lack of other safe methods to estimate total body fat during pregnancy, these measures remain important to consider for investigation of GDM.

Fat accretion and rates of subcutaneous fat accumulation during normal pregnancy by skinfolds have been documented extensively (Taggart et al. 1967; Forsum et al. 1989; Sidebottom et al. 2001). Taggart et al. measured multiple skinfolds throughout pregnancy in 84 pregnant women (Taggart et al. 1967). Measurements were made in triplicate by the first author for the whole study at seven

sites (coefficient of variation, CV), including the triceps (4%), biceps (12%), scapula (4%), costal (6%), suprailiac (11%), mid-thigh (3%), and knee-cap (5%) (Taggart et al. 1967). Analyses were conducted standardized to weeks 10, 20, 30, and 38 weeks of gestation. Total skinfolds (TSF) increased to a greater extent in nulliparous than multiparous women (Taggart et al. 1967). Skinfolds did not increase as greatly among women who were obese (Taggart et al. 1967).

The relationship between body fat by skinfolds and GDM has been explored in several studies (Ehrenberg et al. 2003; Kale et al. 2005; Yilmaz et al. 2009). Of these, two were cross-sectional, with measurements of skinfolds by GDM status only conducted at one point in time (Kale et al. 2005; Yilmaz et al. 2009). Yilmaz et al. (2009) found that women with GDM (n = 56) had greater total body fat by sum of skinfolds compared to women with normal pregnancy (n = 42) at 26–36 weeks' gestation (22.0% vs. 20.8%, p = 0.007). Kale et al (2005) measured maternal skinfolds within 24 h of delivery and similarly found that the sum of skinfolds was greatly increased among GDM mothers (98.4 vs. 61.4 mm, $p < 0.001$) and that this difference was true even among lean women (BMI < 25 kg/m^2), though no data were shown. The only longitudinal study conducted (n = 19 GDM, 33 NGT) with measurements taken at 12–14 and at 33–36 weeks concluded that pre-pregnancy body fat had a greater influence on accumulation of body fat than GDM status (Ehrenberg et al. 2003). Findings from these studies suggest that subcutaneous fat by skinfolds' measures is increased in women with GDM. However, no strong evidence has been given that this information is advantageous in predicting risk of GDM over risks associated with pre-pregnancy BMI.

126.2.6 Maternal Height

Eight of ten studies have found that maternal height is inversely related to the risk of GDM even after accounting for pre-pregnancy weight and other GDM risk factors (Table 126.6) (Jang et al. 1998; Anastasiou et al. 1998; Kousta et al. 2000; Branchtein et al. 2000; Innes et al. 2002; Tabak et al. 2002; Yang et al. 2002; Di et al. 2003; Kale et al. 2005; Rudra et al. 2007; Yeung et al. 2009). The two studies which did not find a significant association may have been influenced by methodological problems regarding the selection of cases and controls from different hospitals and time periods (Tabak et al. 2002; Kale et al. 2005). One early study that looked at this association explicitly was conducted in a cohort of Korean women (n = 8863, 1.9% GDM) and found that women in the lowest quartile of height (≤157 cm) had twice the risk of GDM as women in the highest quartile (≥163 cm), even after adjusting for age and BMI (Jang et al. 1998). Despite differences in mean height by race, the magnitude of association was similar in Brazilian (adjusted OR = 1.60, p = 0.005) and American (adjusted OR = 1.76, p = 0.002) women, when comparing highest to lowest cohort-specific quartiles of height (Branchtein et al. 2000; Innes et al. 2002). In absolute differences, women with GDM were, on average, 1–3 cm shorter than women who did not develop GDM.

One factor of note that might not have been adequately addressed by most of the studies, however, was a birth cohort effect. To capture enough GDM cases for the studies, periods of 5–6 years of screening were used, which introduces the possibility of birth cohort effects that considering for maternal age may not properly account for. For example, a 25-year-old woman screened in 1995 would be born in an earlier birth cohort than a 25-year-old woman screened in 2000. In fact, the woman screened in 1995, born in 1960, may be shorter due to the increasing trend in height over time (Jang et al. 1998). Nevertheless, two studies that investigated the birth cohort effect on these associations found that the inverse height association remained significant even after stratifying the sample by birth cohort, despite taller height being found in women born in more recent times (Jang et al. 1998; Anastasiou et al. 1998).

Table 126.6 Studies of the association between height and GDM

Author (year)	Study design	Study period	GDM diagnostic criteria	Race/Ethnicity	Sample size (controls/cases)	Age; BMI; height	Covariates adjusted for in statistical models	Associations with risk of GDM or difference in height by GDM status
Jang et al. (1998)	Cross-sectional at 24–28 weeks' gestation from single hospital with universal screening	1991–1994	NDDG	Korean	8863/168	28.5 (3) yrs; 20.1 (2) kg/m^2; 160.0 (4) cm	age, pre-pregnancy weight, pre-pregnancy BMI, parental history, parity, and weight gain	GDM vs NGT: OR by height quartiles: Q4 vs. Q1: 2.04 (95% CI: 1.37–3.03) Q3 vs. Q1: 1.50 (0.91–2.46) Q2 vs. Q1: 1.15 (0.66–2.03)
Anastasiou et al. (1998)	Cross-sectional at 24–32 weeks' gestation from single hospital with women referred to for screening	1990–1996	NDDG	Greek	2087/685	29.5 (6) yrs; 24.8 (5) kg/m^2; 161.0 (6) cm	age, weight, education, and one abnormal glucose value	GDM vs. NGT: −2.52 cm (95% CI: −3.06 to −1.98)
Kousta et al. (2000)	Case-control at median 22 months postpartum; ten hospitals for cases; one hospital with universal screening for controls	1997–1999	WHO	European (W), South Asian (SA), Afro-Caribbean (B)	470/346 (W: 282/169, SA: 94/102; B: 94/75)	29–40 yrs; 23–30 kg/m^2 postpartum; 155–165 cm	stratified by ethnicity	GDM vs. NGT: W: −2.4 cm (162.9 vs. 165.3, $p < 0.0001$) SA: −3.0 cm (155.2 vs. 158.2, $p < 0.0001$) B: −1.5 cm (162.2 vs. 163.7, $p = 0.10$)

Tabak et al. (2000)	Cross-sectional analysis of two cohorts; one case only (n = 186)	1999–2000 & 1985–1990	WHO	Hungarian	517/280	27.2 (5) yrs; 23.4 (4)kg/m^2; 165.1 (6) cm	year of birth	GDM vs. NGT: unadjusted difference = –3.2 cm ($p < 0.0001$); adjusted difference = 0.3, $p = 0.70$
Branchtein et al. (2000)	Cross-sectional at 21–28 weeks' gestation from multiple general prenatal care units	1991–1995	WHO	Brazilian (white, black or mixed)	4973/ not given	27.8 (6) yrs; 23.4 (4) kg/m^2; 155.7 (7) cm	age, obesity, family history, race, education, gestational age, parity, referral, waist, and ambient temperature	Adjusted OR by height quartiles: Q4 vs. Q1: OR = 1.60 ($p = 0.005$) Q3 vs. Q1: OR = 1.12 ($p = 0.52$) Q2 vs. Q1: OR = 1.02 ($p = 0.91$)
Innes et al. (2002)	Case-control of women with first pregnancy using New York State Department of Health registry data	1994–1998	ICD-9 (648.0)	81% White, 12% Black, 5% Hispanic, 2% Other	22955/440	21.1 (4) yrs; median: 22.9 kg/m^2; median: 165 cm	age, race, and education, employment, maternal diabetes, pre-pregnancy weight, alcohol, and smoking	Adjusted OR by height quartiles: Q4 vs. Q1: OR = 1.76 (95%CI: 1.25–2.46) Q3 vs. Q1: OR = 1.15 (0.82–1.61) Q2 vs. Q1: OR = 1.53 (1.11–2.10)
Yang et al. (2002)	Cross-sectional at 26–30 weeks' gestation of all women screened from six Tianjin districts	1998–1999	WHO	Chinese	9109/174	26.8 (3) yrs; 21.2 (3) kg/m^2; 161.7 (5) cm	age, pre-pregnancy BMI, weight gain, family history, and smoking	Adjusted OR per cm increase in stature = 0.96 (95% CI: 0.93–0.99)

(continued)

Table 126.6 (continued)

Author (year)	Study design	Study period	GDM diagnostic criteria	Race/Ethnicity	Sample size (controls/cases)	Age; BMI; height	Covariates adjusted for in statistical models	Associations with risk of GDM or difference in height by GDM status
Di et al. (2003)	Cross-sectional at 24–28 weeks' gestation from single site with universal screening	1995–2001	Carpenter & Coustan	Italian	3473/333	31.1 (5) yrs; 22.5 (4) kg/m^2; 164 (6) cm	age, parity, family history, pre-pregnancy BMI, and weight gain	GDM vs. NGT: adjusted difference = −2.60 (p = 0.02)
Kale et al. (2005)	Retrospective case control from two hospitals (all controls from second hospital in 1998)	1998–2003	WHO	Asian Indian	315/268	25.6 (4) yrs; median: 21.9 kg/m^2; 153.0 (6) cm	age, parity and gestation at delivery	Height of GDM women vs. non-GDM women: 154.4 vs. 153.0 (p>0.05 after adjustment)
Rudra 2006	Orospective Omega Study cohort with two site hospitals in Washington, USA	1996–2002	NDDG	85% White, 2% Black, 3% Hispanic, 7% Asian, 3% Other	1644/67	71% between 20–34 yrs; 66% with BMI 19.8–26.0 kg/m^2; and unknown height	age, race, education, pre-pregnancy BMI	RR by categories of height with ≤160 cm as reference: vs. 161–165 cm: 0.54 (95% CI: 0.30–0.97) vs. 166–170 cm: 0.43 (0.23–0.82) vs. >170: 0.26 (0.11–0.59)

This table describes the studies on maternal height and GDM risk identified from MEDLINE in September 2009. Mean (SD) are given where authors made information available for age, BMI, and height

BMI body mass index, *GDM* gestational diabetes mellitus, *ICD-9* International Classification of Diseases, 9th edition, *NDDG* National Diabetes Data Group, *NGT* normal glucose tolerance, *OR* odds ratio, *p* p-value, *RR* relative risk, *SD* standard deviation, *WHO* World Health Organization, *yrs* years

A few hypotheses have been proposed as to the mechanism explaining the relationship between height and GDM. Insulin secretion impairment prior to puberty could have affected growth directly or indirectly via growth hormone and related factors (i.e., GH/IGF-1 axis) (Anastasiou et al. 1998). Puberty is known to be a time of increased insulin resistance (Goran and Gower 2001), thus underlying the fact that insulin secretion impairment may have resulted in short stature. Another mechanism hypothesized is that reduced fetal growth affected both pancreatic development and height potential. Evidence for this hypothesis comes from findings that socioeconomic status is associated with both factors. Branchtein et al. (2000) found that the inverse association of height with GDM risk was significant only among women with greater fat mass as determined by skinfold thickness, suggesting that early fetal or childhood malnutrition was at work to decrease height but led to more weight gain in later life. Lastly, common pleiotropic genes regulating both height and glucose intolerance may also play a role in this association. These hypotheses suggest that the relationship is not causal, but rather that height is a proxy of insulin secretion impairment due to either the direct effect of that impairment on height or factors which influence both insulin secretion and height.

126.2.7 Maternal Leg Length

Height may be a reflection of shorter leg length. It is generally accepted that shorter leg length is the result of growth delay in childhood due to a suboptimal early life environment which could arise from socioeconomic deprivation (Kim et al. 2008). A birth cohort of 2,879 British adults followed since childhood has demonstrated that breastfeeding and energy intake at 4 years of age were significant determinants of leg length (Wadsworth et al. 2002). In terms of measurements of leg length (i.e., femur and tibia length), most studies have taken the difference between standing (head to toe) and sitting heights (head to buttocks). Others have also looked at relative leg length, including leg to height ratio or leg to trunk length ratio.

Three studies have investigated the association between leg length and GDM development. In one study from Wollongong, Australia ($n = 161$ controls, 61 cases), the association between shorter stature and GDM was specifically attributed to shorter leg length (−3.2 cm), with no difference in trunk length ($p = 0.36$). (Moses and Mackay 2004) Findings were similar from a study of 831 healthy women from Kunming, China (163 cases), where GDM was associated with shorter leg length (−0.80 cm), leg to height ratio (−0.3%), and leg to trunk ratio (−0.4%) (Ma et al. 2007). A cross-sectional study using the National Health and Nutrition Examination Survey (NHANES) III cohort found that leg length tended to be 1 cm shorter among women who reported a history of GDM, although this difference did not reach significance ($p = 0.18$) due to the few number of cases ($n = 85$) (Kim et al. 2008). In summary, shorter height and leg length are both significantly, albeit weakly, associated with risk of GDM. Further studies are needed to tease apart the exact mechanisms. Although it is unlikely that such data would be used in clinical practice due to their weak associations with GDM, these observations have led to a greater emphasis on life-course risk factors of GDM and highlight the significant role of childhood environment on future risk of chronic conditions.

126.2.8 Birth Weight

Other markers of developmental inadequacy may also play a role in GDM. Low birth weight has been established as a risk factor for many conditions including type 2 diabetes as another chapter in

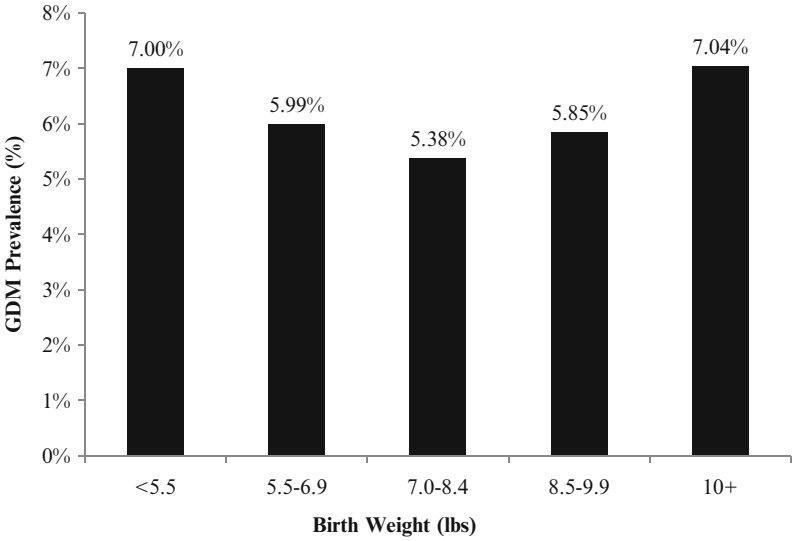

Fig. 126.3 Prevalence of GDM by birth weight among 19,018 women from the Nurses' Health Study II (unpublished results). A U-shaped association was observed between maternal birth weight and GDM prevalence using unpublished data in the Nurses' Health Study II (1991–2001). The prevalence is estimated from women who reported having a singleton birth with no previous history of diabetes (type 1 or 2 or gestational), CVD, or cancer

this book also addresses. The prevalence of GDM by maternal birth-weight categories from a US cohort of women from the Nurses' Health Study II exhibits a similar pattern (Fig. 126.3). A systematic review of eight studies assessing the association between maternal birth weight and GDM have demonstrated that the association is either linear inverse or J-shaped, with increased risk at both low and high birth weights (Pettitt and Jovanovic 2007).

One study conducted using New York state birth registry data ($n = 23{,}314$) found that the J-shape disappears after adjusting for family history of diabetes and that high birth weight was no longer significantly associated with increased risk of GDM (Innes et al. 2002) (Refer to Table 126.3 on height and GDM for more details of the study.). This finding is consistent with what is known about maternal hyperglycemia leading to greater risk of macrosomia in the offspring. Adjusting for parental diabetes then took into account those infants born to women who may have had diabetes during their pregnancy and therefore had children who were larger (i.e., macrosomic). The risk among women born 10 lbs or greater also became non-significant after adjustment for various risk factors including parental T2D history, in the NHSII (Yeung et al. 2009). Nevertheless, high birth weight remains a strong predictor of future GDM risk that women should take note of, regardless of whether it is due to shared genetic cause or previous exposure to maternal hyperglycemia.

Associations between birth weight and GDM are weaker when compared to other anthropometric risk factors, such as adulthood BMI or central adiposity. They are, however, independent of adulthood BMI, suggesting that low birth weight functions on a separate pathway. Innes et al. (2002) also found that the association with birth weight and GDM risk significantly differed (p-interaction = 0.007) when participants were stratified by BMI, such that women who were overweight/obese (BMI ≥25 kg/m^2) did not have increased risk of GDM due to low birth weight, whereas the inverse linear trend remained significant ($p < 0.001$) among leaner women

(BMI <25 kg/m^2). Nevertheless, this interaction remains to be replicated and it is widely accepted that low birth weight is a risk factor of GDM for all women.

The suggested mechanisms in explaining the association between low birth weight and risk of GDM are similar to those for height and leg length; that is, the increased risk arises from fetal programming or shared genetic risk (Innes et al. 2002). Individuals born during famine conditions have increased risk of cardiovascular disease and type 2 diabetes hypothesized to be due to fetal programming. Fetal programming involves metabolic adaptations made for the efficient use of energy in face of reduced caloric or protein intake. It is generally believed that these metabolic adaptations lead to dysfunction later in life, when, in childhood or in adulthood, the same individual faces caloric excess (Barker. 2005). The programming may occur by epigenetic changes (i.e., to DNA or histone proteins) modifying the expression of certain genes. Support for the change in caloric accessibility as being a putative cause has been found from studies of type 2 diabetes, which have shown that individuals, who are born at low birth weight and then undergo rapid catch-up growth as children, are at greatest risk of insulin resistance and metabolic dysfunction than their peers, due to being put on an early trajectory of increased weight gain (Eriksson et al. 2003).

126.2.9 Weight Cycling and Weight Gain Since Age 18 Years

Few studies have looked at weight cycling in the context of pregnancy outcomes. Here, we refer to weight cycling as the gaining and losing of weight prior to pregnancy. The Omega study, as previously discussed for height and GDM, also investigated weight cycling and found no association independent of pre-pregnancy BMI (Rudra et al. 2007). No other studies, to our knowledge, have been published on this association.

Conversely, longer-term changes in weight have been investigated (Solomon et al. 1997; Rudra et al. 2007). In a prospective study of 1,644 pregnant women, weight gain since adolescence (i.e., difference in weight at age 18 years and pre-pregnancy weight) was strongly associated with GDM risk even after adjusting for BMI with over twice the risk of GDM observed for women who gained 5–10 lbs (RR 2.19, 95%CI: 0.96–5.05) (Rudra et al. 2007). Weight gain of 10 or more lbs resulted in over three times the risk of GDM (Rudra et al. 2007). Similarly, among 14,613 women (722 GDM cases) in NHSII, a low weight gain of 5–10 lbs since age 18 was associated with a relative risk of GDM of 1.67 (95%CI: 1.37–2.05). Greater weight gain of 20 lbs or more increased the relative risk to 3.56 (95%CI: 2.70–4.69) (Solomon et al. 1997).

126.2.10 Gestational Weight Gain

Gestational weight gain (GWG) must optimize neonatal weight, while concurrently minimizing maternal overweight. Approximately 30–40% of weight gained during pregnancy is fat (Stevens-Simon et al. 1997; Gunderson et al. 2008), which leads it to be suspected as a contributor of GDM risk. Nevertheless, only a handful of studies have looked specifically at whether GWG or rates of weight gain are associated with increased risk of GDM and these investigations have not produced strong evidence (Ratner et al. 1991; Kieffer et al. 2001; Brennand et al. 2005; Saldana et al. 2006; Wolff et al. 2008; Herring et al. 2009; Tovar et al. 2009).

Table 126.7 IOM gestational weight gain and rate of weight gain recommendations by pre-pregnancy BMI

Pre-pregnancy BMI	BMI (kg/m^2) (WHO)	Total weight gain range (lbs)	Rates of weight gain second and third trimester (Mean range in lbs/wk)
Underweight	<18.5	28–40	1 (1–1.3)
Normal weight	18.5–24.9	25–35	1 (0.8–1.0)
Overweight	25.0–29.9	15–25	0.6 (0.5–0.7)
Obese	≥30.0	11–20	0.5 (0.4–0.6)

This table consists of the IOM guidelines on gestational weight gain as reproduced with permission from The National Academies Press. Women who are overweight or obese prior to their pregnancy are recommended to gain less weight during pregnancy. Copyright 2009, National Academies of Sciences. Originally in IOM 2009s Weight Gain During Pregnancy: Reexamining the Guidelines Table 126.1. *New Recommendations for total and rate of weight gain during pregnancy, by prepregnancy BMI* (IOM (Institute of Medicine) 2009)
BMI body mass index, *IOM* Institute of Medicine, *WHO* World Health Organization

126.2.11 Guidelines on Gestational Weight Gain

In 2009, the Institute of Medicine (IOM) issued new gestational/pregnancy weight gain guidelines that were revised from guidelines previously issued in 1990 (Table 126.7). The guidelines were provided stratified on pre-pregnancy BMI, which remains the strongest predictor of GWG. The recommendations span a rather large range (~10 lbs). The guidelines draw from evidence among many studies based on maternal and neonatal outcomes. However, due to lack of evidence, GDM has been removed from the guidelines as a definitive complication of GWG. Studies of the adherence to the former IOM guidelines issued in 1990 have shown that many pregnant women do not adhere to the guidelines and frequently gain weight above the recommended levels (Saldana et al. 2006).

126.2.12 Gestational Weight Gain and GDM

Studies investigating GWG with the risk of GDM have made comparisons based on mean GWG, rates of GWG, and the ratio of GWG to the target weight participants should have gained according to the 1990 IOM guidelines. There are methodological difficulties in measuring the causal association between pregnancy weight gain and risk of GDM. Studies that calculated mean GWG as the difference between postpartum weight and pre-pregnancy weight may be affected by GDM treatment and so have found that women with GDM gain less or the same amount of weight as other women (Brennand et al. 2005; Nohr et al. 2008). It is most likely that this observation is due to reverse causality of women being told to restrict their dietary intake after the OGTT in the third trimester.

On the other hand, studies defining GWG by the difference between pre-pregnancy weight and weight prior to or at glucose testing in the third trimester does not capture maternal weight alone but also includes weight from the fetus, placenta, and water retained. Studies of the latter kind have argued that water retention is greatest during the third trimester and that weight prior to 28 weeks remains predominantly maternal weight (Herring et al. 2009). Despite this latter argument, the evidence remains mixed. Among those studies, two found no associations with glucose tolerance (Saldana et al. 2006; Tovar et al. 2009); one found a significant association of higher GWG with increasing risks of impaired glucose tolerance (IGT), a state of intermediate hyperglycemia prior to

overt GDM, but not with GDM itself (Herring et al. 2009); and only one study found a linear relationship with an increased odds ratio for GDM of 1.02 (95% CI: 1.004–1.042) per pound of weight gained (Kieffer et al. 2001). The evidence using rate of GWG and the ratio of GWG compared to target weight by IOM guidelines is equally as mixed, with some suggestion that a greater rate of GWG is more detrimental only among women with a pre-pregnancy BMI in the overweight or obese categories (Saldana et al. 2006; Herring et al. 2009; Tovar et al. 2009).

126.2.13 Weight Retention

Abrupt and dramatic decreases in skinfolds have been observed after delivery, with total measures decreasing by 6.5 mm in 2–3 days postpartum, indicating great anthropometric changes after pregnancy (Taggart et al. 1967). However, weight retention has been observed for many women. From the 1988 National Maternal and Infant Health Survey data, 44% white and 63% black women retain 4 or more lbs after pregnancy (Keppel and Taffel 1993). A more recent review of the data from five pregnancy cohort studies showed that 13–20% of women experienced postpartum weight retention of 5 lbs or more at 1 year after pregnancy (Gunderson 2009).

Pregravid body size, excessive GWG, race, higher parity, and not breastfeeding are some risk factors associated with greater postpartum weight retention (Gunderson 2009). Not many studies have investigated whether specific conditions during pregnancy may also affect weight retention. One study found that women with GDM or preeclampsia are more likely to retain more weight after pregnancy than women with normal births (Suntio et al. 2009). However, the direction of causality remains uncertain. Greater pre-pregnancy BMI and excessive pregnancy weight gain may have led to the development of these conditions and simultaneously to greater weight retention.

Weight retention may lead to risk of GDM in subsequent pregnancies. Childbearing has been shown to particularly increase visceral adiposity (Gunderson et al. 2008), which predisposes women to increased metabolic dysfunction. Parity has been shown to be associated with increased risk of GDM (Egeland et al. 2000). However, it is difficult to tease apart the effects of older maternal age with children born subsequently to the same mother. Parity has also been shown to be associated with increased risk of type 2 diabetes independent of weight, although only grand multiparity (having five or more children) was significantly associated with increased risk (Nicholson et al. 2006).

126.3 Applications to Other Areas of Health and Disease

As mentioned throughout the chapter, many of the findings reported for GDM were observed for type 2 diabetes, as they share some common features of pathology and women with a history of GDM are at substantially increased risk for type 2 diabetes later in life. Women who develop GDM are recommended to lose weight to lower their future risk for developing type 2 diabetes. A larger amount of evidence has been published for short stature, low birth weight, and central adiposity as being risk factors for T2D as well. The associations do not differ for T2D risk among men, suggesting that the etiology is not gender specific. It only remains that pregnancy is likely a stress test that unmasks a woman's risk of metabolic disorders earlier in life. Gestational weight gain may not be as relevant to T2D except as a marker for greater postpartum weight retention, which, in turn, may put a woman on the trajectory of greater BMI as she ages.

126.4 Conclusion

Pre-pregnancy BMI remains the strongest risk factor for GDM risk. Maternal birth weight, height, waist circumference, and gestational weight gain, all play minor roles in comparison to pregravid BMI. The high prevalence of overweight/obesity in women of reproductive age in USA and in some other countries foreshadows a continuing increase in GDM that requires many efforts to be made for weight loss both before and after pregnancy.

Summary Points

- Pre-pregnancy BMI is the strongest anthropometric predictor of GDM risk.
- There is some evidence that supports measurement of waist circumference or waist-to-hip ratio for discriminating risk of GDM in addition to BMI.
- Skinfold measurements remain difficult to perform, especially among pregnant women and there is scarce evidence suggestive that they would be helpful in discriminating who would be at increased risk of GDM.
- Birth weight, height, and leg length are weakly inversely associated with GDM risk and reflect underlying developmental challenges in the women.
- IOM guidelines recommend lower pregnancy weight gain among women of higher pre-pregnancy BMI, although the ranges for these recommendations remain wide. There is a lack of evidence demonstrating that gestational weight gain is associated with increased risk of GDM. It should also be noted that studies on such an association are limited.
- Postpartum weight retention is a concern, as it contributes to increasing BMI as women age, increasing their future risk of GDM in subsequent pregnancies and their future risk of T2D.

Key Terms Used in This Chapter on Maternal Anthropometry and Gestational Diabetes

Coefficient of variation	A statistical measurement of the reliability of a technique. The lower the number, the more reliable the test
Covariates	This term refers to risk factors that are adjusted for in statistical models to ensure that the association between exposure to disease is not due to these factors but rather the primary exposure of interest
Cross-sectional	A study that is conducted at one time point with estimates of risk made on prevalent (i.e., preexisting) conditions rather than incident (i.e., new) conditions
Epigenetic	Changes to the way that a gene functions due not to changes in the DNA sequence (i.e., mutations) but to changes that lead to genes not being expressed through blocking promoter binding or by stopping its translation. Some epigenetic mechanisms include DNA methylation, histone acetylation, and interfering RNA
Gestation	The state of being pregnant which includes time from conception to birth
Hyperglycemia	This medical term refers to when a person has blood glucose levels above normal
Insulin	A hormone the body makes in the pancreas that helps regulate the blood glucose (sugar) level in the body
Insulin resistance	The state in which a person's body no longer responds to insulin so that blood glucose levels are not lowered in response to insulin, leading to higher amounts of insulin being produced to compensate for the loss of effect
Insulin secretion	The ability of the pancreas to produce insulin

Meta-analysis	The process of collecting and quantitatively synthesizing findings from studies on the same topic
Neonatal	The newborn period that corresponds to 1–4 weeks after delivery
Obesity	This is medically defined as a BMI > 30 kg/m^2
Odds ratio	A measure of association which literally conveys the odds of disease in one group compared to the odds of disease in another group. An odds ratio approximates relative risk when the occurrence of the condition is small, which is true for GDM. Thus, it can be thought to be the same as a relative risk estimate
Oral glucose tolerance test	This test is used to diagnose GDM in the third trimester of pregnancy and involves measuring blood glucose levels after the ingestion of a certain dose of glucose (either 75 or 100 g)
Parity	Number of children a woman conceived and delivered
Pleiotropy	This genetic term refers to genes having multiple functions and related to multiple consequences or effects
Pregravid	This term refers to measures taken prior to pregnancy and is synonymous to pre-pregnancy
Perinatal	The duration of pregnancy and after pregnancy that spans approximately from the 20–28th week of gestation to 1–4 weeks after birth
Relative risk	The mathematical calculation of the probability that an event (i.e., GDM) will occur in one group compared to the probability that it occurs in another group. Usually the two groups differ by what they were exposed to (i.e., obese vs. non-obese)
Reliability	The repeatability of a measure; that the value of the first measurement is close to the value of the subsequent measurements
Screening	A medical test that is the first step in identifying who may have a certain condition. This is not the same as a diagnostic test which is necessary to confirm whether the person truly has the condition, in this case GDM
Subcutaneous adiposity	Adiposity that is located just beneath the skin
Type 2 diabetes	This term refers to the chronic medical condition of having persistent high blood glucose levels. The condition is associated with damage to nerves, kidneys, heart, and other organs, which together lead to increased risk of death
Visceral adiposity	Adiposity that is located near the organs and the inner parts of the body rather than near the skin
Weight retention	This refers to the amount of weight that a pregnant woman weighs after delivery that is above the amount they weighed prior to pregnancy

Chapter 127
Body Size at Birth and Risk of Type 2 Diabetes in Adult Life

Yiqing Song, Lu Wang, Edwina Yeung, and Cuilin Zhang

Abstract A large body of evidence supports the hypothesis that the risk of developing chronic diseases including type 2 diabetes (T2D) in adulthood is related to body size at birth. Birth weight may reflect fetal adaptation to an adverse intrauterine environment due to both genetic and environmental factors. Epidemiologic studies, primarily from prospective cohorts, have consistently shown that birth weight in the 2,500–4,000 g range is inversely associated with T2D risk in adulthood, while increased risk has been found at both extremes of low (<2,500g) and high (>4,000g) birth weight. The association between birth weight and risk of T2D can be modified by postnatal growth. Recent evidence appears to support that low birth weight may be related to rapid postnatal weight gain, which has been associated with increased risk for central obesity and T2D in adult life. Several mechanisms have been proposed to explain the robust association between birth weight and T2D. The "fetal origins hypothesis" remains the most popular one and has been revised based on recent evidence. This review aims to summarize both epidemiological and experimental observations relating birth weight and rapid postnatal weight gain to T2D risk in adulthood. This article will also highlight recent evidence on the mechanisms of fetal programming of diabetes due to maternal and fetal genetic factors as well as fetal epigenetic changes.

Abbreviations

ACE	Angiotensin-converting enzyme
BMI	Body mass index
CDKAL1	Cyclin-dependent kinase 5 regulatory subunit associated protein 1-like 1
CDKN2A/CDKN2B	Cyclin-dependent kinase inhibitor 2A/2B
CI	Confidence interval
CVD	Cardiovascular disease
FTO	Fat mass and obesity-associated gene
GCK	Glucokinase gene

T2D	Type 2 diabetes mellitus
UK	United Kingdom

127.1 Introduction

Type 2 diabetes (T2D) is considered "the epidemic of the twenty-first century," affecting more than 170 million individuals worldwide (Table 127.1). Overall, it is estimated that the prevalence of diabetes will increase by 42% among adults living in developed countries and by 170% among adults in developing countries by 2025 (Stumvoll et al. 2005). Given the rising global burden of T2D and its devastating complications, there is a great urgency to develop effective strategies to curb the epidemic by prevention and early treatment. In addition, the increasing prevalence of obesity in children has also become a growing threat to public health because it will also further fuel the increase in future prevalence of T2D.

Table 127.1 Key features of type 2 diabetes (T2D)

1. Diabetes mellitus is a group of metabolic diseases characterized by high blood glucose levels that result from impairments in insulin action and/or secretion
2. T2D is the most common form of diabetes. About 90–95% of all diabetes cases are T2D. Historically, it affects adults rather than children, but age of onset has become younger more recently
3. T2D is considered "the epidemic of the twenty-first century," affecting approximately 24 million individuals in USA alone and more than 170 million individuals worldwide. It is estimated that, by the year 2030, these numbers will double
4. It places patients at high risk for serious complications in the eyes, nerves, kidneys, and cardiovascular system
5. Diabetic angiopathy is a major cause of morbidity and mortality in diabetes mellitus. Cardiovascular complications are the leading cause of death in diabetes
6. T2D is a multifactorial disease that involves interactions between many genetic and environmental factors
7. There is an urgent need for early detection and prevention strategies to lessen the burden placed on individuals and society by T2D

This table lists some basic facts of T2D concerning its epidemiology and health effects

T2D is a multifactorial disease that involves interactions between many genetic and environmental factors. In addition to established diabetes risk factors, anthropometric measures at birth, especially birth weight, as surrogates of intrauterine malnutrition, have long been implicated as important predictors for risk of T2D. It has been hypothesized that fetal adaptation to an adverse intrauterine environment during critical periods may have lasting or lifelong effects on the development of metabolic syndrome and its associated chronic diseases, such as T2D, hypertension, and cardiovascular diseases, in adulthood (Hales et al. 1991; Hales and Barker 1992; Barker et al. 1993). Numerous studies have specifically tested this "fetal origins hypothesis" for the etiology of T2D in diverse populations. Majority of epidemiologic studies have focused on birth weight and shown consistent associations with subsequent risk of glucose intolerance and T2D in adult life (Harder et al. 2007; Whincup et al. 2008). Low birth weight is often followed by accelerated postnatal growth, which may be important for risk of T2D in adult life. Emerging evidence has shown that people who had low birth weight are more likely to have rapid weight gain in early life and thereby have higher risk for central obesity, T2D, and cardiovascular disease in later life (Colle et al. 1976; Eriksson et al. 2003; Singhal et al. 2003; Ekelund et al. 2007).

This chapter aims to summarize epidemiologic data on the relation between birth weight and T2D and interpret these data in the context of emerging biological evidence. Given the epidemic of obesity and T2D and trends for increasing birth weight in the general population, it becomes very important to address the public health issue of birth weight from the perspective of T2D prevention. Information regarding environmental and genetic determinants of birth weight and their roles in the development of T2D in adulthood will have major public health implications, from which specific intervention strategies can be better conceived and tailored for primary prevention of T2D in the general population.

127.2 Epidemiologic Evidence on Birth Weight and T2D

Over the last two decades, many observational studies have reported associations between birth weight and subsequent risk of T2D. In 1991, Hales and Barker and their colleagues first reported an inverse association between birth weight and T2D risk, with the highest risk at the lowest levels of birth weight (Hales et al. 1991; Hales and Barker 1992). Subsequently, numerous observational studies have tested the fetal origins hypothesis for T2D in diverse populations. The associations of both low birth weight (<2,500 g) and high birth weight (>4,000 g) with impaired glucose tolerance and increased risk of T2D appeared to be consistent and robust (Harder et al. 2007; Whincup et al. 2008).

127.2.1 The Strength of the Birth Weight–T2D Association

Differences in the study population and participants' basic characteristics may account for some discrepancies in the strength of the association found from the literature. Meta-analysis has been used to combine evidence across various studies and thus reduce sampling error and increase statistical power. A meta-analysis involving a total of 132,180 participants with 6,901 cases found that, as compared with a birth weight of ≥2,500 g, both low birth weight (<2,500 g) and high birth weight (>4,000 g) were associated with increased risk of T2D (odds ratio [OR] = 1.47, 95% confidence interval [CI] = 1.26–1.72 for low birth weight and OR = 1.36, 95% CI = 1.07–1.73 for high birth

weight) (Harder et al. 2007). This finding indicated a U-shaped relation between birth weight and later-life risk of T2D. Another recent meta-analysis, which included more studies (152,084 individuals and 6,090 diabetes cases), reported approximately 20–25% lower risk of T2D associated with each 1,000 g increase in birth weight, indicating a linear inverse relation between birth weight and T2D (Whincup et al. 2008). Because birth weight is closely correlated with many established risk factors for T2D, including parental socioeconomic status, it is very important to adjust for diabetes risk factors and socioeconomic indicators in observational studies including meta-analyses. Birth weight has been independently associated with T2D, even after adjusting for adulthood BMI, physical activity, smoking, dietary habits, and other lifestyle confounders, as well as socioeconomic status (Harder et al. 2007; Whincup et al. 2008). Overall, adjustment for adult socioeconomic status had no apparent effect on the strength of the birth weight–T2D association. It should be noted that approximately 58% of T2D globally could be attributable to overweight and obesity and 90% of T2D cases in Western countries is attributable to weight gain; however, birth weight appears to be associated with T2D independent of BMI at adulthood. In general, the inverse association tended to be slightly attenuated but remained significant after further controlling for adult BMI.

It is worth mentioning that both previous meta-analyses included retrospective studies (in which information was collected after the onset of disease) and therefore were limited by recall and selection bias. In observational studies, the prospective study design allows us to minimize bias due to recall or sample selection. Individual prospective studies with basic cohort characteristics are shown in Table 127.2. Discrepancies in the association between birth weight and T2D risk among these studies cannot clearly tell us the sufficiency or consistency of the evidence over time. To better track how the body of evidence has shifted over time, we performed a cumulative meta-analysis, which calculates the cumulated relative risk estimates over time of studies (Fig. 127.1). We first sorted the data by publication year and then ran a cumulative analysis to see how the combined effect shifted as each individual study was added one after the other. In the plot of the cumulative meta-analysis of 23 prospective cohort studies, we observed a consistent trend toward lower risk of T2D per 1,000 g increase in birth weight that became statistically significant and stabilized by 1999 (Fig. 127.1). With the increasing number of studies included, the influence of a single study on the final summary estimate tended to be minimal. Our summary estimate of RR of 0.78 (95% CI: 0.71–0.85) represents a reliable magnitude of the linear inverse relation between birth weight and T2D, particularly at birth weights of 4,000 g or less.

127.2.2 The Shape of the Birth Weight and T2D Association

Given significant heterogeneity in previous studies, epidemiologic evidence on the strength and shape of the association has been inconsistent. Of the two meta-analyses, one study has found a U-shaped association (Harder et al. 2007), whereas the other reported an inverse linear association (Whincup et al. 2008). Despite this discrepancy in the shape of the association, both studies consistently indicated an increased risk of T2D associated with both low birth weight (<2,500 g) and high birth weights (>4,000 g) (Harder et al. 2007; Whincup et al. 2008). Of note, there is strong evidence of heterogeneity among the published studies in both meta-analyses. For example, two large studies of native North Americans in Arizona and one study in young adults from the Saskatchewan population showed positive associations between birth weight and T2D (Whincup et al. 2008). For higher birth weight, maternal diabetes (including both prepregnancy T2D and gestational diabetes) may be an important factor. Maternal hyperglycemia due to prepregnancy T2D or gestational diabetes could result in fetal and neonatal macrosomia and thus explain most of the excess risk of T2D in individuals

Table 127.2 Prospective cohort studies quantifying the linear relation of birth weight with T2D risk

Author, (publication year)	Country	Year of birth	Mean age (years)	Total number of participants	Total number of T2D cases	RR per 1-kg increase in birth weight[a]

T2D type 2 diabetes, *RR* relative risk, *UK* United Kingdom

[a]Multivariate-adjusted relative risk from each individual study; with the exception of three studies by Curhan, Lithell, and McCance et al., all other studies adjusted for age, sex, and BMI, excluding participants with birth weights of more than 4,000 g or maternal diabetes

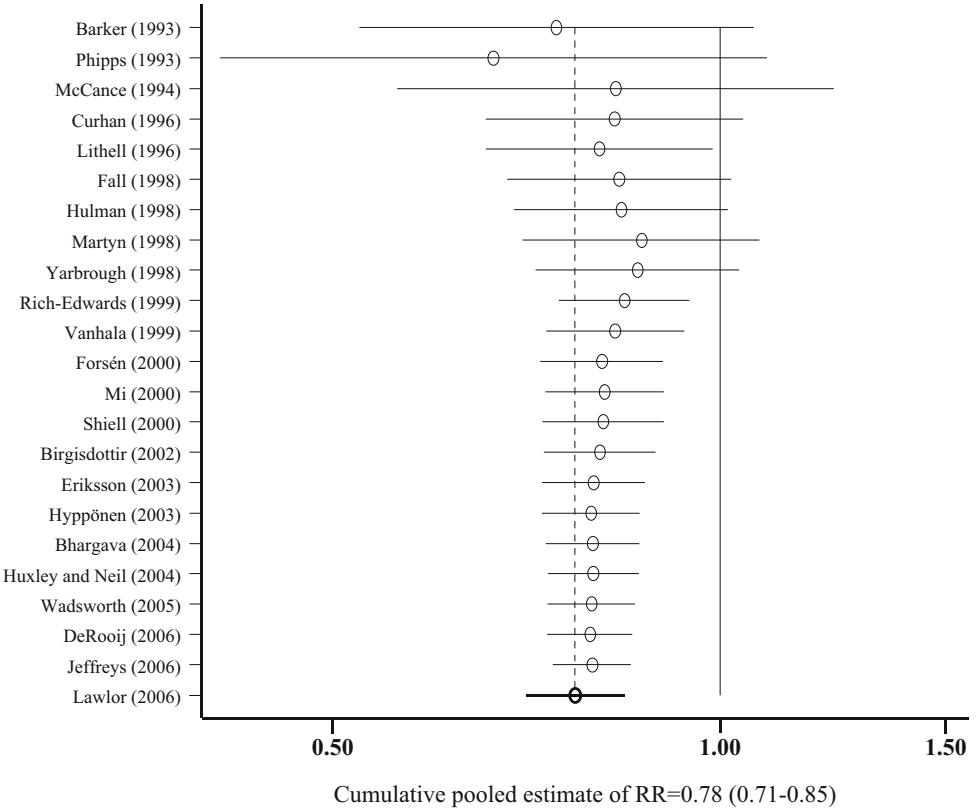

Fig. 127.1 Cumulative meta-analysis plot of relative risk (*RR*) and 95% confidence interval (*CI*) of T2D per 1-kg increase in birth weight based on prospective data (This plot of the cumulative meta-analysis of 23 prospective cohort studies showed a consistent trend toward lower risk of T2D per 1,000-g increase in birth weight that became statistically significant and stabilized after 1999. Source: unpublished meta-analysis results)

who had birth weights of 4,000 g or more. In fact, all three studies showed marked increase in T2D risk among participants with birth weights of more than 4,000 g and thereby showed strong U-shaped associations (Whincup et al. 2008). As a result, the ORs of T2D per 1,000-g increase in birth weight (assuming a linear relation) appeared to be positive, significantly deviating from the findings reported in other studies. Removal of these three studies greatly reduced the heterogeneity. Among 11 studies that had sufficient information, further exclusion of participants with macrosomia or maternal diabetes strengthened the inverse association between birth weight and T2D, lowering the pooled OR from 0.81 (95% CI, 0.77–0.86) to 0.67 (95% CI, 0.61–0.73). As shown in Fig. 127.2, a meta-analysis involving a total of 14 studies provided a suggestive evidence for a U-shaped curve for the relation between birth weight and T2D, with both low and high birth weights related to increased risk of T2D. Compared with the lowest birth weight category (≤ 2,000 g), birth weight within the range from 2,000 to 4,000 g was inversely related to T2D risk. In the birth weight categories of >4,000 g, there was an increasing trend, although the OR in the highest category (>4,500 g) was not statistically significant due to limited data. Taken together, it becomes evident that birth weight is related to T2D in adult life in a U-shaped manner. Both high birth weight (>4,000 g) and low birth weight (<2,500 g) were associated with increased risk of T2D.

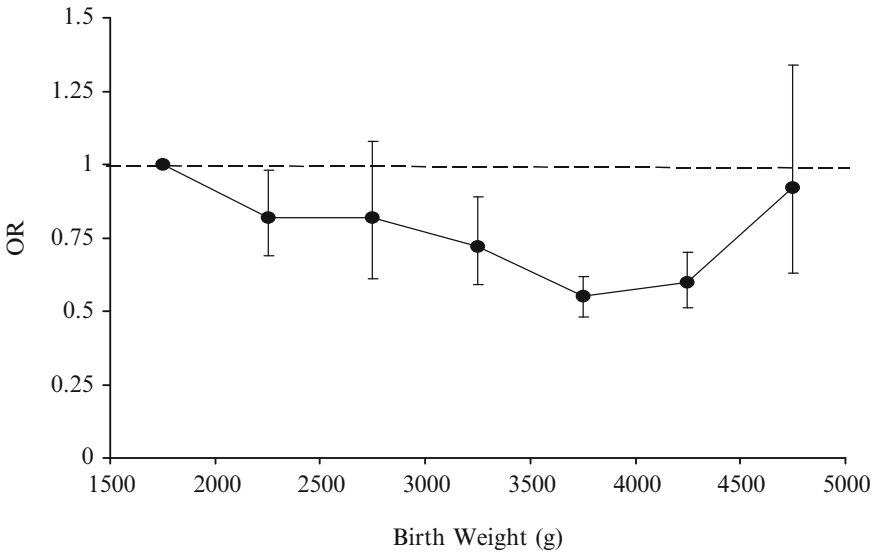

Fig. 127.2 Odds ratios for T2D risk stratified by category of birth weight in a meta-analysis of prospective studies (This figure was created based on the values from Table 3 published in the article by Harder et al. (2007). Based on a total of 14 studies, there was a suggestive evidence for a U-shaped curve for the relation between birth weight and T2D, with both low and high birth weights related to increased risk of T2D. The lowest category of birth weight was used as the reference category in each study. Source: unpublished figure)

127.3 Relations of Postnatal Weight Gain and T2D

Infants born with low birth weights are more likely to develop rapid growth during infancy and childhood. Such rapid postnatal weight gain may play an important role in the development of T2D associated with low birth weight. The largest variation in weight gain after birth occurs in the first 2 years of life, when infants born small for gestational age (SGA) show a rapid early weight gain (Holzhauer et al. 2009). Their fast growth rates are thought to be compensatory responses for the restraint on intrauterine fetal growth (Albertsson-Wikland and Karlberg 1994). A number of studies have shown that rapid postnatal weight gain, irrespective of birth weight, may have adverse effects on metabolic health in later childhood and adulthood (Colle et al. 1976; Eriksson et al. 2002a; Singhal et al. 2003; Ekelund et al. 2007).

127.3.1 Plausible Explanations for Adverse Effect of Rapid Postnatal Weight Gain

Proposed mechanisms for the harmful effect of rapid postnatal weight gain involve endocrine and metabolic changes in response to undernutrition in utero. It is hypothesized that the intrauterine exposure to insufficient nutrient supply during critical periods of fetal life affects the development of skeletal muscle, and results in a lower proportion of lean mass in SGA infants (Hediger et al. 1998). Because there is little muscle cell replication after birth (Widdowson. 1972), rapid postnatal weight

gain would lead to a disproportionately high fat mass relative to lean body mass (Hediger et al. 1998). The accumulation of fat mass in childhood would tend to induce an early onset of persistent obesity and the development of insulin resistance (Barker et al. 1993; Bavdekar et al. 1999; Eriksson et al. 2002a). This interpretation has been supported by several observational studies that linked rapid early weight gain to obesity in later life (Eid 1970; Stettler et al. 2002; Monteiro et al. 2003; Stettler et al. 2005). Another postulation that explains the adverse effect of rapid early weight gain is that when the tissues that are chronically depleted of insulin and insulin-like growth factor-I (IGF-I) during fetal life are exposed to increased concentrations of both hormones shortly after birth, insulin resistance develops as a metabolic defense mechanism to counteract the excessive insulin-like actions of the hormones and protect the organism from hypoglycemia (Cianfarani et al. 1999). Thus, the infants who experience slow fetal growth but early and quick postnatal recovery would have higher risk for insulin resistance and T2D compared to those with no fast postnatal weight gain (Cianfarani et al. 1999). Consistent with this hypothesis, a previous study of 15 full-term infants born with SGA have found a positive correlation between their glucose-induced insulin release and growth velocity during the first 6 months of life (Colle et al. 1976).

127.3.2 Timing Issue for Adverse Effects of Postnatal Growth

It remains unclear what time in the postnatal period with accelerated growth may be disadvantageous. Infants with intrauterine growth retardation usually show a rearrangement of the endocrine system after birth. Normalization of the endocrine parameters occurs during the first trimester of postnatal life (Leger et al. 1996; Cianfarani et al. 1998). Therefore, early infancy is considered a critical time for the development of long-term metabolic disorders (Karlberg and Albertsson-Wikland 1995). There have been several lines of evidence showing association of rapid weight gain in early postnatal period with the adverse metabolic profiles in later life. One intervention study randomized infants born preterm to receive a nutrient-enriched diet or a reference diet at birth and followed them to age 13–16 years (Singhal et al. 2003). The study found higher fasting proinsulin concentration in children given a nutrient-enriched diet than in those given the lower-nutrient diet and weight gain during the first 2 weeks of life was positively associated with insulin resistance in adolescence, irrespective of birth weight (Singhal et al. 2003). Another prospective cohort study reported that rapid weight gain during infancy (0–6 months) but not during early childhood (3–6 years) was positively associated with metabolic risk at age 17 years, independent of birth weight (Ekelund et al. 2007). One potential caveat in many previous studies is the correlation between rapid postnatal weight gain and low birth weight per se. The undernourishment state in SGA infants at the time of birth may facilitate a more efficient nutrient uptake and metabolism that results in a faster postnatal growth rate (Vaag 2009). Furthermore, the statistical "regression toward the mean" may explain the rapid weight gain in early life among SGA infants (Vaag 2009).

Although most infants born SGA show rapid weight gain in the first 2 years, some may have accelerated growth throughout childhood, adolescence, and into adulthood (Karlberg and Albertsson-Wikland 1995), which would further increase the risk of insulin resistance and T2D (Eriksson et al. 2003). Among young children, the degree of obesity as measured by BMI decreases after the age of 2 years, and achieves a minimum around 6 years before BMI increases again; the phenomenon is called adiposity rebound. Early age at adiposity rebound has been related to increased risk of obesity in childhood and adult life (Rolland-Cachera et al. 1987; Whitaker et al. 1998). A longitudinal study of 8,760 subjects born in Helsinki during 1934–1944 had found that the cumulative incidence of T2D decreased progressively from 8.6% in persons whose adiposity rebound occurred before the

age of 5 years to 1.8% in those where it occurred after 7 years (Eriksson et al.2003). Another prospective cohort study of 7,086 men and women in Finland found that the OR of developing T2D was 1.39 (95% CI: 1.21–1.61) for each standard deviation increase in weight between 7 and 15 years of age. The corresponding OR reached 1.83 (95% CI: 1.37–2.45) when the analysis was restricted to persons whose birth weights were below 3,000 g (Forsen et al. 2000).

127.4 Fetal Origins of Adult Onset of T2D

127.4.1 The Original "Thrifty Phenotype Hypothesis"

The development and growth of the fetus are likely determined by a complex interplay between environmental factors (e.g., maternal nutrition and metabolic state) and fetal genetic susceptibility. Several biological mechanisms have been proposed to explain the relation between altered programming in the uterus and birth weight. Hales and Barker first put forth the "thrifty phenotype hypothesis," also known as "the developmental origins of adult disease hypothesis" or the "fetal origins hypothesis" (Hales et al. 1991; Hales and Barker 1992; Barker et al. 1993). On the basis of this hypothesis, irreversible adaptations in tissue and organ growth and development in the fetus in response to prenatal malnutrition increase the predisposition to adult chronic diseases, including T2D and cardiovascular disease.

127.4.2 The "Fetal Insulin Hypothesis" Based on Genetic Evidence

Based on the growing evidence linking low birth weight and measures of insulin resistance, Hattersley and Tooke proposed an extension of the fetal origins hypothesis, called the "fetal insulin hypothesis," to explain the consistent association between low birth weight with diabetes and vascular disease (Hattersley and Tooke 1999). Insulin resistance and progressive pancreatic β-cell dysfunction are two fundamental features in the pathogenesis of T2D. Insulin is also a critical growth factor during fetal life. The central theme of the hypothesis focuses on the genetic basis for insulin-mediated fetal growth (shown in Fig. 127.3). It is hypothesized that fetal genetic factors affect both fetal insulin secretion and insulin sensitivity in peripheral tissues and thereby determine insulin-mediated fetal growth in utero, which may explain the development of insulin resistance in childhood and adulthood that is associated with birth weight.

This hypothesis is supported by the findings from familial genetic studies that have identified several mutations in the genes that affect fetal insulin secretion and insulin resistance, such as glucokinase, insulin receptor, sulfonylurea receptor, and insulin promoter factor 1 (Hattersley and Tooke 1999). The rare monogenic disorders caused by these mutations have significant effects on birth weight. In the general population, however, much remains unknown about the contribution of common genetic variation to birth weight and susceptibility to T2D. Some available genetic evidence is summarized in Table 127.3. Recently, this "fetal insulin hypothesis" is further supported by accumulating data from genome-wide association studies (GWAS) for T2D. In the past 3 years, GWAS has emerged as a comprehensive and powerful approach to identify genetic variants of complex chronic diseases without a priori hypothesis. Preponderance of evidence has led to the identification of more than 20 important genetic loci with robust associations with T2D (Groop and Lyssenko 2008).

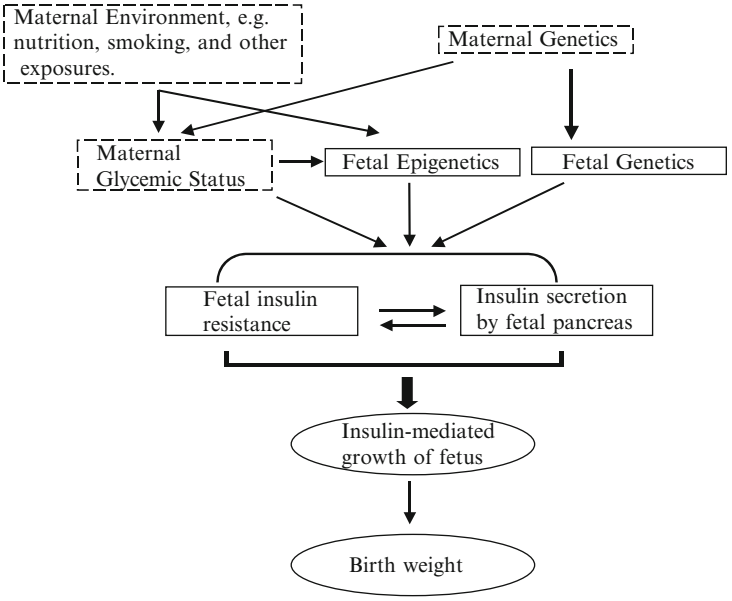

Fig. 127.3 Scheme showing the "fetal insulin hypothesis" for the pathogenesis of fetal growth (The central theme of the hypothesis focuses on the genetic basis for insulin-mediated fetal growth. It is hypothesized that fetal genetic factors affect both fetal insulin secretion and insulin sensitivity in peripheral tissues and thereby determine insulin-mediated fetal growth in utero. Source: unpublished figure)

Table 127.3 A list of potential candidate genes for both birth weight and T2D based on the available data

Source	Susceptibility genes	Main function
Maternal genotype	*TCF7L2*	Insulin secretion
	GCK	Insulin sensitivity
	INS	Insulin production
	H19; IGF1	Growth modulation
Fetal genotype	*HHEX/IDE; CDKAL1; CDKN2A/2B*	Insulin secretion
	FTO; MC4R	Postnatal growth and obesity
	ACE	Obesity and insulin sensitivity
	Leptin and leptin receptor	Appetite and energy balance
	IGF1; IGFR1	Growth modulation
	INS	Insulin production
	PPARG	Insulin sensitivity
	HFE	Iron metabolisms and T2D
	JAZF1	Unknown function

The evidence was summarized from the results from published genetic association studies up to August 2009

TF7L2 transcription factor 7-like 2 gene, *GCK* glucokinase gene, *INS* insulin gene, *H19* adult skeletal muscle gene, *IGF1* insulin-like growth factor 1, *HHEX/IDE* hematopoietically expressed homeobox/insulin-degrading enzyme, *CDKAL1* cyclin-dependent kinase 5 regulatory subunit associated protein 1-like 1, *CDKN2A/CDKN2B* cyclin-dependent kinase inhibitor 2A /2B, *KCNJ11* potassium inwardly rectifying channel, subfamily 1, member 11, *FTO* fat mass and obesity-associated, *MC4R* melanocortin 4 receptor, *ACE* angiotensin-converting enzyme gene, *IGFR1* insulin-like growth factor type 1 receptor, *PPARG* peroxisome proliferator-activated receptor gamma gene, *HFE* Human hemochromatosis gene, *JAZF1* juxtaposed with another zinc finger gene 1

Overall, there are several novel findings that may provide new insights into the "fetal insulin hypothesis." First, many genetic variants newly identified by GWAS appear to influence insulin secretion (Pulizzi et al. 2009) but, there is no strong evidence that any of these loci primarily alter insulin resistance. These findings have indicated the key role of genetically determined beta cell dysfunction

in the pathogenesis of T2D. Second, several genetic association studies in white Europeans have investigated the associations between birth weight and maternal or fetal genotype at several recently identified T2D susceptibility loci. Maternal inheritance of common risk alleles in some, but not in all T2D loci, appeared to be associated with higher offspring birth weight (Freathy et al. 2009). These results suggest that maternal risk alleles may determine maternal insulin secretion during pregnancy, which could in turn affect birth weight. Third, fetal inheritance of the risk alleles at *CDKAL1* (*cyclin-dependent kinase 5 regulatory subunit associated protein 1-like 1* gene) and *HHEX-IDE* (*hematopoietically expressed homeobox/insulin-degrading enzyme* gene) was also associated with reduced birth weight in four studies of 7,986 mothers and 19,200 offspring (Freathy et al. 2009). Finally, it remains to be defined whether obesity-susceptibility variants contribute to fetal programming, as no strong evidence to date has been shown. The common form of obesity-associated T2D in adults is polygenic and multifactorial in nature. GWAS has identified common variants in the FTO (*the fat mass and obesity associated*) (Freathy et al. 2009) and MC4R (*melanocortin 4 receptor*) genes (Zobel et al. 2009) that are reproducibly associated with T2D through their correlations with fat mass and obesity. However, *FTO* and *MC4R* risk variants appeared to contribute to weight gain during childhood, but not to birth weight (Lopez-Bermejo et al. 2008; Zobel et al. 2009). Taken together, the overall evidence from these findings, though limited, seems to support the "fetal insulin hypothesis" and further suggest that genetically determined beta-cell dysfunction, independent of insulin resistance, may congruently reduce birth weight and predispose individuals to the development of T2D.

127.4.3 Gene–Environment Interactions

It has become increasingly apparent that both birth weight and T2D are determined by a complex interplay between intrauterine environmental factors (e.g., diet and physical activity) and genetic susceptibility. The Helsinki Birth Cohort Study reported significant interactions between common risk variants of three T2D susceptibility genes (*HHEX, CDKN2A/2B*, and *JAZF1*) and birth weight on T2D risk among 2,003 participants with 311 T2D patients. The genetic association with T2D appeared to be more pronounced in individuals with a low birth weight (P for interaction = 0.03 for the most high-risk genotypes) (Pulizzi et al. 2009). Polymorphisms in *PPAR gamma* (*peroxisome proliferator-activated receptor-gamma*), a gene involved in the regulation of both adipogenesis and insulin sensitivity, have been associated with increased T2D risk only among those born with low birth weight (Eriksson et al. 2002b). It seems plausible that rapid weight gain during infancy also reflects a combination of genetically determined rapid weight gain in early life and postnatal environmental factors, but the data are scarce.

127.4.4 Epigenetic Mechanisms

Besides genetic effects, epigenetic modification of the fetal genome triggered by an adverse intrauterine environment has been proposed as part of fetal programming. Changes in intrauterine environment could act as epigenetic stimuli, but epigenetic changes of the genome seem more likely to reflect gene–environment interactions. In the past two decades, the role of epigenetics in human diseases involving regulation of gene expression has drawn widespread interest. Histone post-translational modifications and DNA methylation represent two major epigenetic mechanisms that modulate gene activities in response to environmental changes during development. So far, evidence for an important role of

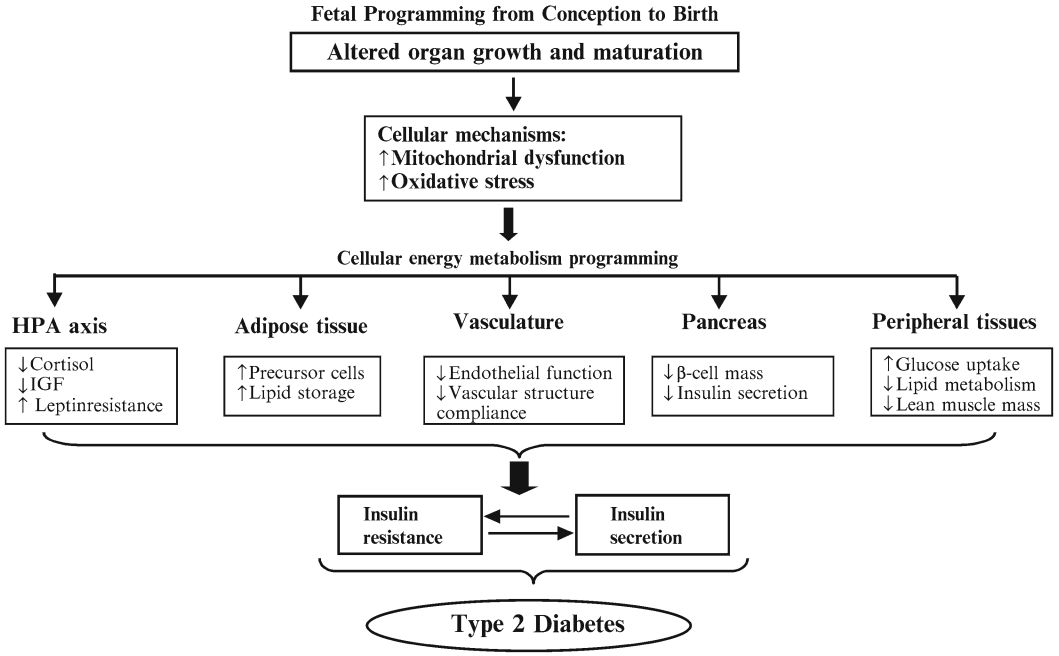

Fig. 127.4 Hypothetic pathways linking birth weight to the development of T2D (It is hypothesized that changes in neuroendocrine balance and cellular energy metabolism may be fundamental to the developmental programming response to intrauterine environments. Insulin resistance and progressive pancreatic β-cell dysfunction are two fundamental features in the pathogenesis of T2D. Abbreviations: HPA, hypothalamic–pituitary–adrenal axis; IGF, insulin-like growth factor. Source: unpublished figure)

epigenetics in the development of T2D predominantly comes from animal studies. For example, a gene (*pancreatic and duodenal homeobox 1*, *Pdx1*) critical for beta cell function and development was found to undergo distinct epigenetic changes in a rat model of intrauterine growth retardation, with its expression reduced by more than 50% (Park et al. 2008). Low levels of *Pdx1* expression persisted after birth and progressively deteriorated in response to dynamic epigenetic processes, finally leading to overt T2D in the IUGR animal. Such epigenetic adaptations in pancreatic gene silencing could induce beta-cell dysfunction in the human fetus, who underwent intrauterine growth retardation. Further investigation of the epigenetic basis of fetal programming holds the promise for unraveling the complex molecular events leading to T2D.

127.4.5 Molecular and Cellular Mechanisms

The development and growth of a fetus depends upon its genotype, intrauterine environments, and gene–environment interactions. The precise molecular and cellular mechanisms underlying the causal link between fetal development and later diseases have yet to be fully elucidated. There is growing evidence indicating that changes in neuroendocrine balance and cellular energy metabolism may be fundamental to the developmental programming response to maternal malnutrition. As shown in Fig. 127.4, proposed mechanisms include altered activation of the hypothalamic–pituitary–adrenal (HPA) axis,

increased tissue glucocorticoid and endocrine sensitivity, leptin resistance, impairment of tissue sensitivity to the insulin and the IGF systems, impaired mitochondrial function and reduced oxidative capacity, and increased number of adipocyte precursor cells. Consequently, these permanent developmental changes in cellular energy metabolism in response to suboptimal intrauterine environments have the potential to ensure short-term survival of the fetus during gestation but increase the risk of a variety of metabolic disorders in later life. It should be noted that fetal development in adipose tissue abundance and function might be critical for an individual's lifetime risk of obesity and T2D. A cohort of infants has been found born with reduced subcutaneous fat but with preserved visceral fat depots (Modi et al. 2006). An increased number of adipocytes may be one of the main determinants of postnatal growth and childhood obesity as well as T2D in later life.

127.5 Implications and Future Research

There is growing evidence supporting the "fetal origins hypothesis" for the development of diabetes in adult life. However, many important questions remain to be answered before we can incorporate measures of birth weight into diabetes risk prediction and treatment. First, fetal development is a multifaceted process, and anthropometric measurements, such as birth weight, may not fully reflect the extent to which body composition has been permanently altered by fetal malnutrition. For example, there is evidence suggesting that size proportions, abdominal circumference, head circumferences, and body length are associated with dyslipidemia in later life. Data for other anthropometric indices at birth in relation to subsequent risk of T2D are limited. Second, additional research is needed to elucidate the causal role of genetically determined insulin secretion in the development of diabetes mellitus during adult life. It is difficult to assess the interaction between maternal glycemia and fetal genetic factors on birth weight. Furthermore, the precise mechanisms that regulate fetal pancreas' development and glucose metabolism remain poorly defined and are likely to vary by different maternal nutrition status. It is also uncertain which period during gestation represents the key window linking fetal growth to risk of T2D in adulthood. Third, the epigenetic mechanisms for fetal programming remain largely uncharacterized. With advance of technology, global epigenetic profiling has recently emerged from basic laboratory exploration to practical applications in clinical research. Mapping and characterizing specific patterns of post-translational epigenetic modifications will transform our understanding of diabetes' pathogenesis and enhance our ability to diagnose and treat this disease. Fourth, most importantly, whether birth weight has a direct causal impact on the multifactorial etiology of T2D requires further evaluation. If birth weight is a genuine causal factor, the public health implication will be substantial. Finally, there is a notable lack of data from prospective studies regarding the clinical and public health significance of birth weight measurement in diabetes prevention, diagnosis, and treatment. Specifically, it is important to decide appropriate clinical cut points of birth weight for T2D risk prediction since its association with T2D is linear at birth weight <4,000 g. More research and careful consideration is needed to evaluate the predictive value of birth weight for risk of T2D.

127.6 Applications to Other Areas of Health and Disease

In addition to T2D, birth weight and postnatal rapid weight gain have been associated with hypertension, cardiovascular disease (CVD), and certain types of cancer, which may share common pathophysiological traits that also underlie T2D (such as insulin resistance and/or compensatory hyperinsulinemia).

Despite inconsistent findings in diverse populations, both birth weight and weight gain in children seemed to correlate significantly with all features of the metabolic syndrome (also known as insulin resistance syndrome) in adulthood including adiposity, hyperinsulinemia, insulin resistance, hypertriglyceridemia, low high-density lipoprotein cholesterol, and hypertension. There is growing recognition that, as a cluster of metabolic abnormalities, the metabolic syndrome is a common antecedent for the initiation of T2D, CVD, colorectal cancer, and prostate cancer. Birth weight measure could also influence the timing of puberty via a pathway related to intrauterine hormones. Low birth weight or rapid growth in infancy has been associated with early age at puberty onset, which may predispose an individual to many hormone-related cancers, including breast and testicular cancer (Michos et al. 2007; Xue and Michels 2007). The etiology of cancer is a multistage process that results from a complex interaction of multiple factors. Although biological mechanisms remain to be elucidated, intrauterine and early postnatal growth hormones may contribute to puberty onset and explain, at least in part, the associations between anthropometric measures at birth and hormone-related cancer risk. For example, high birth weight may result from high levels of growth factors in utero, especially insulin and IGFs, which have potential carcinogenic effects. Some studies have identified that high birth weight and preterm birth were associated with early age at menarche in girls (Terry et al. 2009), although the available evidence has been limited and inconsistent. Early age at menarche (less than 12 years of age) is a well-established risk factor for breast cancer through elevated cumulative exposure to endogenous sex-steroid hormones. There is need for further epidemiologic as well as mechanistic studies to elucidate the underlying biology of the fetal origins of certain types of cancer.

127.7 Conclusions

In summary, epidemiologic evidence from prospective studies for a relation between birth weight, postnatal weight gain, and T2D is accumulating, indicating that anthropometric measures at birth and in childhood may add significant value for clinical risk stratification and prognosis of T2D. Such findings, coupled with a large body of experimental work, advance our understanding of the pathophysiological role of fetal growth and development in the pathogenesis of adult diabetes mellitus. Further investigation is warranted to help decipher the mechanisms underlying the birth weight–T2D association, optimize anthropometric measures for infants and children, identify population at high risk for diabetes, and tailor prediction and intervention strategies in diabetes research.

Summary Points

- An infant's body weight at birth may reflect the degree of fetal growth as a result of maternal environment and fetal genetics.
- Accumulating evidence indicated an increased risk of T2D associated with both low birth weight (<2,500 g) and high birth weight (>4,000 g).
- Prospective data suggest that there is a linear and inverse association between birth weight and T2D in the range of 4,000 g or less and risk of T2D in adulthood.
- Infants with low birth weights are more likely to develop rapid growth during infancy and childhood, and this rapid early weight gain is significantly associated with obesity and T2D in adulthood.
- Genetic defects for insulin production from pancreas may play a critical role in fetal growth and determine future risk of T2D in adults.

- Body size at birth and rapid weight gain during infancy may result from a combination of genetic and environmental factors.
- The clinical utility of anthropometric assessment at birth and during postnatal growth for diabetes risk prediction deserves further investigation.

Terms Used in This Chapter on Body Size at Birth and T2D in Adulthood

Fetal growth	The process in which an embryo or fetus grows in mass during pregnancy, between conception and birth
Postnatal growth	The growth of an infant occurring after birth, especially during the period immediately after birth, with reference to the newborn
Intrauterine growth restriction (IUGR)	The growth of the fetus is abnormally slow. When born, the baby appears too small (fetal size is less than expected for gestational age). IUGR is often associated with increased risk of medical illness and death in the newborn
Birth weight	The measured heaviness of a baby when born, the average of which is about 3,500 g, or 7.5 lb. A baby weighing less than 2,500 g (5.5 lb) is consider small for gestational age and weighing more than 4,500 g (10 lb) is considered as large for gestational age
Macrosomia	The mass of a baby at its birth is above a defined limit at any gestational age
Small for gestational age (SGA)	Infants whose weight is below the 10th percentile at gestational age for all children born after the same number of weeks of pregnancy. A baby could have experienced some IUGR but not necessarily be SGA
Insulin resistance	A condition in which the body is unable to use available insulin effectively
Insulin secretion	The capability of the beta cells of the pancreas to regulate the production and release of mature insulin
Genome-wide association studies (GWAS)	Any study of genetic variation across the entire human genome that is designed to identify genetic associations with observable traits (such as birth weight or glycemia), or the presence or absence of a disease or condition
Prospective study	A study in which the subjects are identified and then followed forward in time
Cumulative meta-analysis	The repeated performance of conventional meta-analysis whenever a new study becomes available for inclusion. Such cumulative meta-analysis can retrospectively identify the point in time when an effect estimate first reached conventional levels of significance

Chapter 128
Waist-Circumference Phenotype and Risk of Type 2 Diabetes

Ike S. Okosun and Tandeih A. Ghogomu

Abstract Waist phenotypes (waist circumference, waist-to-hip ratio and waist-to-height ratio) are associated with type 2 diabetes as demonstrated in many studies and confirmed in meta-analyses of prospective studies from various studies. Evidence for the association is stronger for waist circumference and waist-to hip ratio. A verdict is yet to be made with respect to the nature of the association of waist-to-height ratio with type 2 diabetes. The clinical and epidemiologic appeal for the use of waist phenotypes is irrefutable. Waist measurement is simple and requires only a measuring tape and a weighing scale. Effective translation of the use of waist phenotype into clinical practice to predict type 2 diabetes may help in reversing the increasing trend of type 2 diabetes.

128.1 Introduction

Awareness of the association between upper-body adiposity and cardiovascular diseases was first recognized over 50 years ago (Vague 1956). Vague observed that upper-body obesity was a better correlate of cardiovascular diseases than excess body weight, as determined by body mass index. He used the terms "android adiposity" to describe the accumulation of fat around the abdomen

and "gynoid adiposity" to depict the accumulation of fat found in the hips and thigh regions (Vague 1956). These adiposities were later described as upper- and lower-body fat accumulation (Kissebah et al. 1982). However, the term "abdominal or "central obesity" has replaced android and gynoid forms of obesity. In abdominal or central obesity (also called apple-shape body fat distribution), abdominal fat predominates (Rimm et al. 1988). This form of fat buildup is thought to pose greater health risks than fat accumulation in the hip area (also called pear-shape body fat accumulation). Epidemiologic evidence now suggests that abdominal obesity and not generalized obesity is the most potent form of adiposity that is associated with visceral adiposity. Visceral fat (deep abdominal fats) is the culprit for obesity-associated sequelae (Fox et al. 2007). This chapter will review data from prospective studies that indicated independent association of anthropometric surrogates of abdominal adiposity – waist phenotypes (waist circumference, waist-to-hip ratio, and waist-to-height ratio) with the risk of type 2 diabetes.

128.2 Determination of Abdominal Adiposity

There are various techniques for measuring abdominal obesity. These methods include magnetic resonance imaging, computed tomography, hydrodensitometry, and dual energy X-ray absorptiometry. However, these methods are difficult to use in large-scale epidemiologic settings. The cost, discomfort, and risk associated with these methods can be prohibitive. Also, some of the methods, including X-ray absorptiometry, magnetic resonance imaging, and computed tomography carry added risk of radiation. Hence, anthropometric indices, such as waist circumference, waist-to-hip ratio, and waist-to-height ratio are used as surrogates for abdominal obesity. The diagnostic performance or accuracy of waist circumference, waist-to-hip ratio, and waist-to-height ratio to discriminate cardiovascular risk factors, such as type-2 diabetes, is commonly evaluated using receiver operating characteristic curve analysis.

These anthropometric indices differ with respect to correlation with metabolic abnormalities and have markedly different values in different populations. Correlations between waist phenotypes and body mass index vary across populations. For example, in the Atherosclerosis Risk in Communities (ARIC) study, waist circumference was much highly correlated with body mass index as shown by a correlation coefficient value of 0.90 in African-American and white men and women (Harris et al. 2000). In the same study, the correction coefficient value for the waist-to-hip ratio with body mass index was ~0.60 for men and between 0.40 and 0.50 for women (Harris et al. 2000). The degree of correlation between waist circumference and waist-to-height ratio and between waist circumference and waist-to-hip ratio was high, with values of 0.90 and 0.70, respectively, in men and women (Harris et al. 2000). These differences in correlation may indicate that each waist phenotype measures different aspects of abdominal adiposity.

A meta-analysis of published work from 1966 to 2006 by Lee et al. (2008) indicates that measures of abdominal obesity tend to give a higher *Area under the curve* (AUC) value compared to body mass index, in both sexes, with the highest pooled AUC found for waist-to-height ratio, with values of 0.73 and 0.76, for males and females, respectively. The lowest pooled AUC values were for BMI with values of 0.67 and 0.69 for males and females, respectively (Lee et al. 2008). The tests for heterogeneity between each of the waist phenotypes with BMI showed statistically significant differences between BMI and waist-to-height ratio in males only (AUC for BMI was 0.67 vs AUC for waist-to-height ratio of 0.73) (Lee et al. 2008). The combinations of BMI and waist circumference, waist-to-hip ratio, or waist-to-height ratio did not significantly increase the discriminatory capability of BMI for type-2 diabetes (Lee et al. 2008).

128.3 Waist Variables of Abdominal Obesity

128.3.1 Waist Circumference

Waist circumference is an aggregate measure of the actual amount of total and abdominal fat accumulation (Kissebah et al. 1982). It is a crucial correlate of abnormal metabolic syndromes found among obese and overweight subjects. Waist measurement is simple, requires only a flexible tape, and, with appropriate training, measurement error is low due to the large circumference. Although waist circumference is a simple measure of abdominal obesity, it assumes that people with the same waist circumference would have the same cardiovascular risk, regardless of their height. This assumption is, however, invalid because the percentage body fat is higher for shorter subjects compared to taller individuals of the same body mass index. Waist circumference is highly linked to visceral adipose tissue accumulation (Molarius and Seidell 1998). Visceral adiposity is the component of body composition that is most highly associated with many metabolic abnormalities, such as type 2 diabetes, hypertension, hyperinsulinemia, hypercholesterolemia, hypertriglyceridemia, and high levels of low-density lipoprotein cholesterol (Lemieux et al. 1996; Haffner et al. 1992). Also, waist circumference has the best predictive value for visceral adipose tissue over many of the commonly used anthropometric indices of central body fatness, including triceps and subscapular skinfold thicknesses (Wei et al. 1997). In agreement with the increasing trends in body mass index often seen in many parts of the world, waist circumference is also increasing. An analysis (Okosun et al. 2004) of the US nationally representative sample of adults (20–79 years of age) using the 1960–1962, 1988–1994, and 1999–2000 National Health and Nutrition Examination Surveys showed that the distribution of waist circumference shifted to the right (higher values) in 1988–1994 and in 1999–2000 in both men and women (Fig. 128.1). The right shift suggests increasing prevalence of abdominal obesity.

128.3.2 Waist-to-Hip Ratio

Waist-to-hip measurement is a ratio and as a consequence suffers from statistical limitations in terms of analysis and interpretation (Kronmal 1993; Allison et al. 1995). As a ratio, waist-to-hip is fundamentally difficult to interpret in the public health context because lean and obese individuals can have equivalent values of waist-to-hip ratio. From a statistical viewpoint, ratio indices have shortcomings in modeling because their use can introduce spurious correlation with other ratio indices and variables (Kronmal 1993; Allison et al. 1995). Waist-to-hip ratio can remain unchanged even when there is a change in body size because waist circumference and hip circumference can increase or decrease proportionately. This ratio is associated with multiple disease outcomes as well as all-cause mortality (Zhang et al. 2008). Some investigators suggest that waist-to-hip ratio represents an aspect of body composition and distribution of fat which includes muscle that is not reflected in body mass index or waist circumference. The predictive value of waist-to-hip ratio for all-cause mortality and ischemic heart disease is greater than that of body mass index (Björntorp 1988).

128.3.3 Waist-to-Height Ratio

The waist-to-height ratio is less known compared to waist circumference, waist-to-hip ratio, and body mass index. Like waist-to-hip ratio, it has limitations in statistical analyses and interpretation (Kronmal 1993; Allison et al. 1995). The waist-to-height ratio will change only when there is a

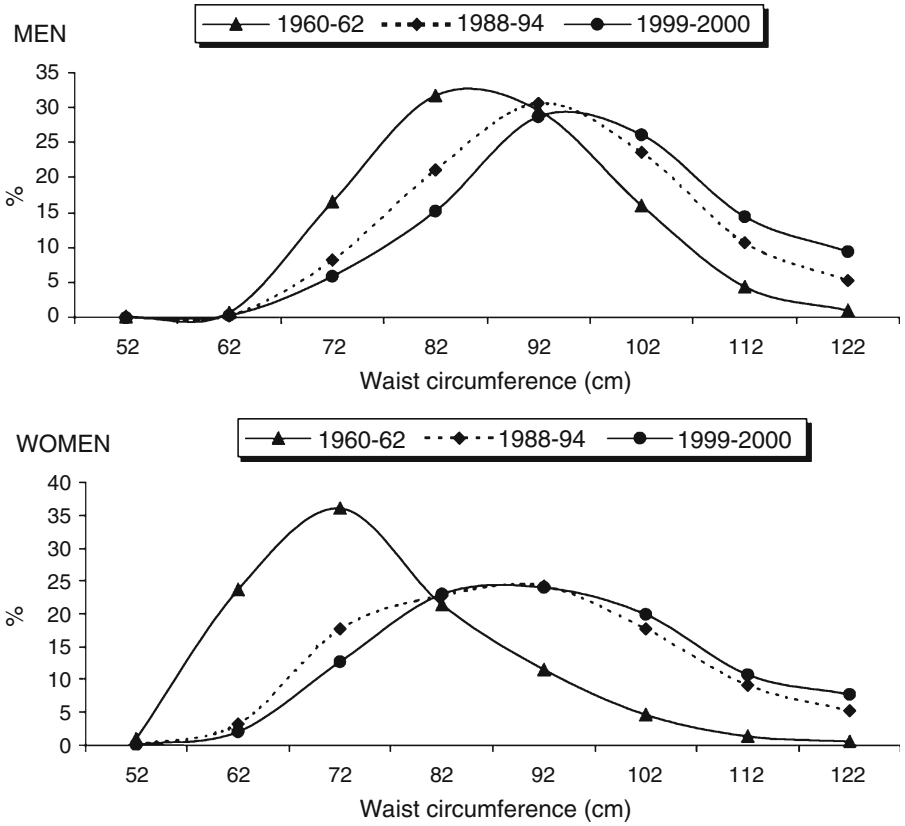

Fig. 128.1 Distribution of waist circumference in US adults from 1960 to 2000. In both men and women, the distribution of waist circumference shifted to the right (higher values) in 1988–1994 and 1999–2000 (Adapted from Okosun et al. 2004)

change in waist, given that height often remains constant in adults. Recent findings suggest that the waist-to-height ratio is more accurately descriptive of the distribution of body fat compared to body mass index, including abdominal fat distributions. Cohort studies have shown that the waist-to-height ratio is better than body mass index at predicting mortality from coronary heart disease and all-cause mortality (Lu et al. 2006; Chei et al. 2008). The waist-to-height ratio is, also to some extent, a better predictor of mortality than waist circumference (Ashwell 2009).

128.4 Cut-Points for Waist Circumference, Waist-to-Hip Ratio, and Waist-to-Height Ratio

The currently used waist phenotype cut-points are recommended by different agencies, including the United States National Heart, Lung, and Blood Institute (NHLBI), the International Diabetes Federation (IDF), and the National Cholesterol Education Program-Adult Treatment Panel III (NCEP-ATPIII). The NHLBI- and NCEP-ATPIII-recommended waist-circumference thresholds are based on studies in whites relating waist circumference to body mass index. A waist circumference value of ≥94 cm in men and ≥80 cm in women predicts overweight (BMI ≥ 25 kg/m²) (NIH/NHLBI

Table 128.1 Sex-specific waist circumference values that denote "increased risk" and "significantly increased risk" of cardiometabolic risks

	Risk of obesity-related cardiometabolic risks	
	Increased risk	Significantly increased risk
Men	≥94 cm (~37 in.)	≥102 cm (~40 in.)
Women	≥80 cm (~32 in.)	≥88 cm (~35 in.)

Waist cut-points differ by gender and risk of obesity-related cardiometabolic risks

1998), whereas a waist circumference of ≥102 cm in men and ≥88 cm in women predicts the presence of obesity (BMI ≥ 30 kg/m²) (NIH/NHLBI 1998) (Table 128.1). These waist circumference cut-points were proposed originally by Han et al. (1995), to assist professionals in managing subjects with obesity-related comorbidities. However, unlike the NCEP-ATPIII and NHLBI, the IDF advocates waist cut-points along national and racial/ethnic lines.

Waist-to-hip ratios have been arbitrarily recommended as 0.95 for men and 0.80 for women, and vary by race/ethnicity and national origin (Misra et al. 2005). A waist-to-height ratio of 0.5 has been proposed as the cut-point at which individuals should keep waist circumference to less than half their height, whereas the value of 0.6 has been suggested as the value for which adults should take action (Ashwell 2009). In agreement with the IDF and the NCEP-ATPIII, the United States National Institute of Health Clinical Guidelines recommends measurement of waist as a screening instrument for health-risk assessment.

A comparative analysis of studies of waist circumference and waist-to-hip ratio for assessing risk of type 2 diabetes was recently published (Qiao and Nyamdorj 2009). Both prospective and cross-sectional studies were reviewed. Tongans were found to have the highest waist circumference cut-points (103 cm for both men and women), followed by Americans and Europeans (Qiao and Nyamdorj 2009). The waist circumference cut-points were higher for all races in the USA and the UK studies compared to their counterparts in their original countries (Qiao and Nyamdorj 2009). The optimal waist-to-hip ratio cut-points were 0.95 for white men and 0.83–0.85 for white women living outside the USA and the UK, compared to 0.90 for Asian men and 0.79–0.85 for Asian women (Qiao and Nyamdorj 2009). The authors concluded that "there is no universal cutoff value that can be applied worldwide, and a country-specific value should be considered taking into account the purposes and resources."

128.5 Association of Waist Variables to Risk for Type 2 Diabetes

Studies linking waist variables to type 2 diabetes date back to 1956 when Schmidt et al. 1992, used a case-control study nested within a community-based survey. The aim of the study was to determine the relative importance of waist-to-hip ratio in type 2 diabetes. In that study, increased waist-to-hip ratios were 4.72 (95% CI: 2.39–9.34) and 2.17 (95% CI: 1.03–4.58) for women and men, respectively (Schmidt et al. 1992). Subsequently, many case-control and cross-sectional studies linking waist phenotypes to type 2 diabetes were published. The majority of these studies are based on waist circumference and waist-to-hip ratio, and not waist-to-height ratio.

This section provides an overview of the current evidence-based findings linking waist phenotypes with type 2 diabetes from prospective studies. Although numerous cross-sectional and case-control studies have associated waist phenotypes to increased risks for type 2 diabetes, they are excluded in this analysis because of their obvious inability to establish definite directionality between

waist phenotypes and type 2 diabetes. The public health significance of waist phenotypes for type 2 diabetes and the potential mechanism linking these variables to type 2 diabetes are also discussed.

Several prospective studies indicate that waist phenotypes, including waist circumference, waist-hip ratio, and waist-to-height ratio, are associated with the risk of type 2 diabetes. However, findings have been contradictory as to which of the phenotypes are most associated with type 2 diabetes. There is also ambiguity about how these measures perform across diverse ethnic/racial population groups. The majority of the evidence regarding the relationships between these obesity phenotypes and risks has been derived mainly from Caucasian populations. Hence, it remains unclear whether the relationships are consistent in non-Caucasian populations. The lack of consistencies across populations may be driven by varying methodology, sample size, type of study design, as well as cut-points for waist phenotype.

To the best of our knowledge, only a few meta-analyses of the association of waist circumference and waist-to-hip ratio with type 2 diabetes have been published. To compare the association of the incidence of type 2 diabetes with general and central obesity indicators, Vazquez et al. 2007, conducted a meta-analysis based on studies published from 1985 to 2004, retrieved from PubMed searches. The analysis was performed with 32 studies out of 432 publications that were identified (Vazquez et al.2007).

The result of the analysis, as summarized using forest plots, is shown in Fig. 128.2. The pooled relative rate estimate of waist circumference (SD: 11.6) was 1.87 (95% CI: 1.62–2.15), whereas that of waist-to-hip ratio (SD: 0.84) was 1.82 (95% CI: 1.55–2.13). Comparison of body mass index and waist circumference ($p = 0.50$) or body mass index and waist-to-hip ratio ($p = 0.73$) did not show any significant difference in the magnitude of association. The proportion of total variation ($I^2 > 0.90$) among study specific estimates was high, indicating that heterogeneity was present for all obesity indicators that were studied (Vazquez et al. 2007).

The pooled relative risks for waist circumference and waist-to-hip ratio stratified by study-level variables, as published by Vazquez et al. 2007, are shown in Fig. 128.3. Differences in relative risks for type 2 diabetes due to waist phenotypes are evident between groups based on the definition of type 2 diabetes, region, gender, and age. Studies that were restricted to a sample of subjects with a higher diabetes rate or with impaired glucose tolerance had lower relative risks for diabetes (Vazquez et al. 2007). When pooled relative risks between waist phenotypes were compared, some modest differences were also observed by region and age.

The pooled relative risks for waist circumference for Asia, USA, and Europe were 2.4 (95% CI: 1.5–4.0), 1.9 (95% CI: 1.4–2.5), and 2.1 (95% CI: 1.7–2.6), respectively. Pooled relative risks for waist-to-hip ratio were similar for the three regions, but was smaller in Asia at 1.4 (95% CI: 1.1–1.7) compared to Europe at 2.1 (95% CI: 1.7–2.6) and USA at 1.8 (95% CI: 1.4–2.2) (Vazquez et al. 2007). Where analysis was stratified by age, pooled relative risks for type 2 diabetes due to waist circumference was 2.0 (95% CI: 1.6–2.3) for those who were 50 years of age and older, and 1.6 (95% CI 1.4–1.9) for those who were <50 years of age. For studies where the mean age was ≥50 years, pooled risk for type 2 diabetes due to waist-to-hip ratio was 1.8 (95% CI: 1.5–2.2) and 2.1 (95% CI: 1.8–2.4), when mean age was <50 years (Vazquez et al. 2007).

We carried out a review through comprehensive PubMed searches of published prospective studies in English from 1985 to 2009 that investigated the relationship between waist phenotypes and incidence of type 2 diabetes in men and women. The waist phenotypes that were considered in the review were waist circumference, waist-to-hip ratio, and waist-to-height ratio. Table 128.2 summarizes the characteristics of the studies used for this review. All studies showed a positive association of waist circumference, waist-to-hip ratio, and waist-to-height ratio with incidence of type 2 diabetes.

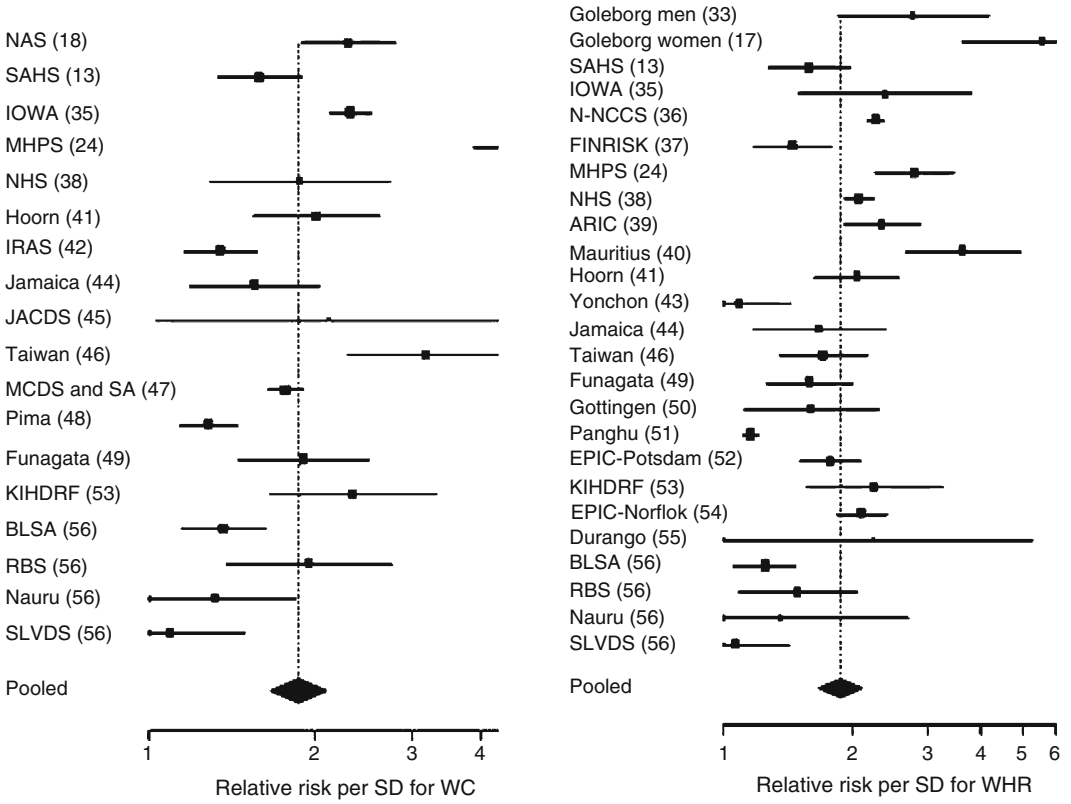

Fig. 128.2 Forest plot of the association of waist circumference and waist-to-hip ratio, with incident diabetes (95% confidence interval) for publications between 1985 and 2004) (*NAS* Normative Aging Study, *SAHS* San Antonio Heart Study, *IOWA* Iowa Women's Health Study, *MHPS* Male Health Professionals Study, *NHS* Nurses' Health Study, *IRAS* Insulin Resistance Atherosclerosis Study, *JACDS* Japanese-American Community Diabetes Study, *MCDS* Mexico City Diabetes Study, *SA* San Antonio, *KIHDRF* Kuopio Ischemic Heart Disease Risk Factor Study, *BLSA* Baltimore Longitudinal Study of Aging, *RBS* Rancho Bernardo Study, *SLVDS* San Luis Valley Diabetes Study, *N-NCCS* Northern Native Canadian Cohort Study, *MHPS* Male Health Professionals Study, *ARIC* Atherosclerosis Risk in Communities Study, *EPIC* European Prospective Investigation into Cancer and Nutrition). The pooled relative rate estimate of waist circumference (SD: 11.6) was 1.87 (95% CI: 1.62–2.15), whereas that of waist-to-hip ratio (SD: 0.84) was 1.82 (95% CI: 1.55–2.13). Comparison of body mass index and waist circumference ($p = 0.50$) or body mass index and waist-to-hip ratio ($p = 0.73$) did not show any significant difference in the magnitude of association. The proportion of total variation ($I^2 > 0.90$) among study specific estimates was high, indicating that heterogeneity was present for all obesity indicators that were studied (Adapted from Vazquez et al. 2007)

Kaye et al. (1991), Carey et al. (1997), and Meisinger et al. (2006) used participant self-report or medical record information to define diabetes. Kaye et al. (1991) examined a cohort of 41,837 women aged 55–69 years for an association between waist-to-hip ratio and 2 years' incidence of type 2 diabetes. After adjustment for body mass index, age, and education level using multivariate logistic regression, waist-to-hip ratio was a significant independent predictor of type 2 diabetes in a dose–response fashion. Subjects with diabetes were 4.6 times (95% CI = 3.8–5.6) more likely than those without diabetes to be in the upper tertile of waist-to-hip ratio and 2.2 times (95% CI = 1.8–2.7) more likely to be in the middle tertile. Women in the highest tertiles of waist-to-hip ratio had a 14.4-fold (95% CI = 9.5–21.9) higher risk of type 2 diabetes than women in the lowest tertiles (Kaye et al. 1991).

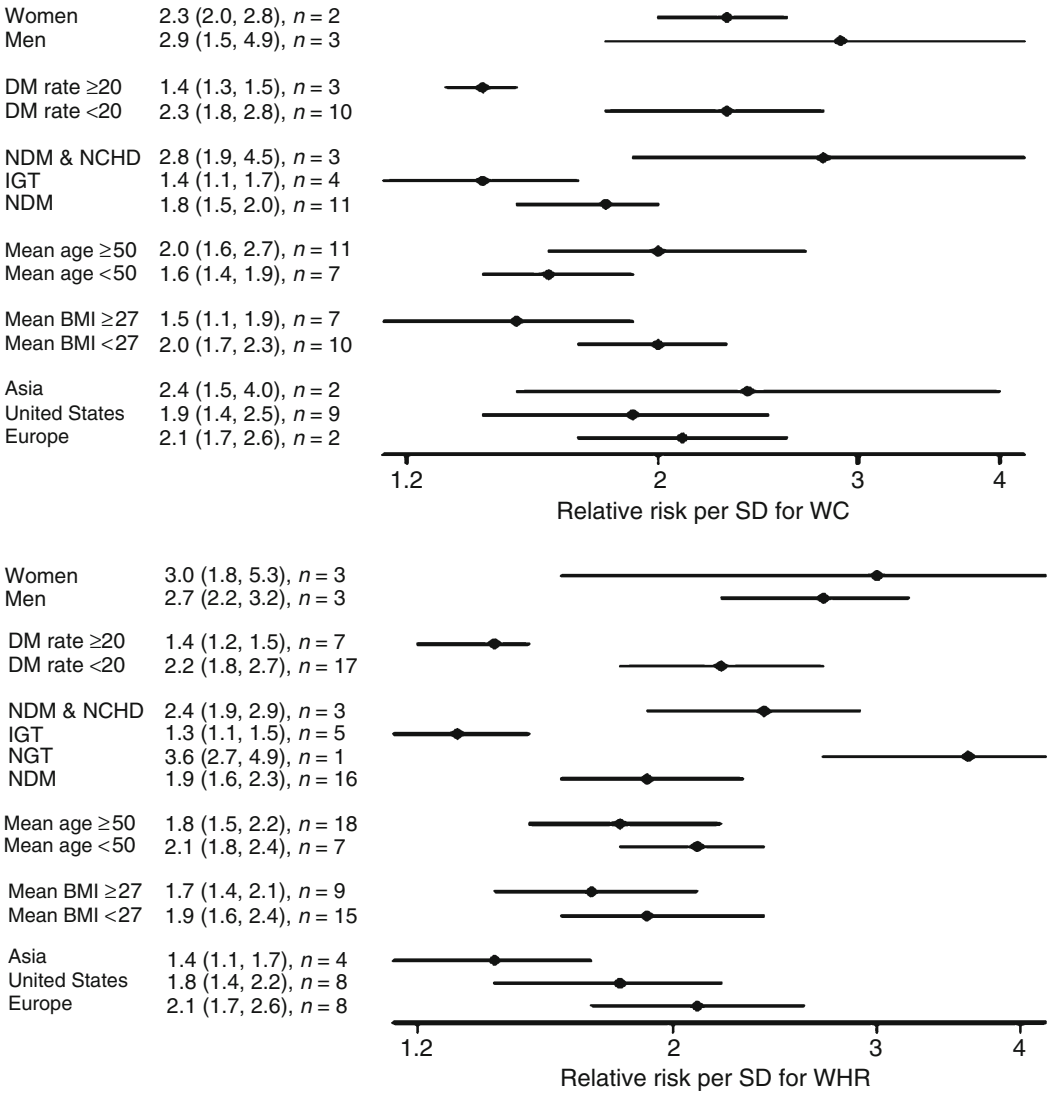

Fig. 128.3 Pooled relative risk (95% confidence interval) for waist circumference and waist-to-hip ratio with incident diabetes from the meta-analysis of studies published between 1985 and 2004, stratified by study-level population characteristics: gender, diabetes rate, inclusion criteria, age, general obesity, and region (*DM* diabetes mellitus, *NDM* non-diabetes mellitus, *NCHD* non-coronary heart disease, *IGT* impaired glucose tolerance, *BMI* body mass index, *SD* standard deviation). The pooled relative risks for waist circumference for Asia, USA, and Europe were 2.4 (95% CI: 1.5–4.0), 1.9 (95% CI: 1.4–2.5), and 2.1 (95% CI: 1.7–2.6), respectively. Pooled relative risks for waist-to-hip ratio were similar for the three regions, but was smaller in Asia at 1.4 (95% CI: 1.1–1.7) compared to Europe at 2.1 (95% CI: 1.7–2.6) and USA at 1.8 (95% CI: 1.4–2.2). Where analysis was stratified by age, pooled relative risk for type 2 diabetes due to waist circumference was 2.0 (95% CI: 1.6–2.3) for those who were 50 years of age and older, and 1.6 (95% CI 1.4–1.9) for those who were less than 50 years of age. For studies where the mean age was ≥50 years, pooled risk for type 2 diabetes due to waist-to-hip ratio was 1.8 (95% CI: 1.5–2.2) and was 2.1 (95% CI: 1.8–2.4) when mean age was less than 50 years (Adapted from Vazquez et al. 2007)

Table 128.2 Summary of studies linking waist phenotype to type 2 diabetes (*WC* waist circumference, *WHR* waist-to-hip ratio, *WthR* waist-to-height ratio)

Study	Waist variable	Sample size	Follow-up	Race/ethnicity	Gender	Age	Adjustment factors
Diabetes defined by self-report or medical record information							
Kaye et al. (1991)	WHR	41,837	2 years	USA	Female	55–69	Age, education, BMI
Carey et al. (1997)	WC, WHR	42,492	8 years	USA	Female	30–55	Age, family history, BMI, smoking, diet, exercise
Meisinger et al. (2005)	WC, WHR	6,012	9.2 years	Germany	Male/Female	35–74	Age, survey, education, Parental history of diabetes, hypertension, dyslipidemia, smoking, alcohol intake, and physical activity
Diabetes defined using fasting blood glucose and glucose tolerance tests							
Cassano et al. (1992)	WHR	1,972	18 years	Mainly Whites (98%)	Male	42	Age, smoking, BMI
Snijder et al. (2003)	WC, WHR	738	6 years	Whites	Female	60	Age, BMI, hip, thigh
Snijder et al. (2003)	WC, WHR	619	6 years	Whites	Male	60	Age, BMI, hip, thigh
Wang et al. (2005)	WC, WHR	22,270	13 years	USA	Male	40–75	Age, BMI, physical activity, smoking, alcohol, diet, fat intake
Wei et al. (1997)	WC, WHR	451	7.2 years	Mexican-American	Female	42	Age
Wei et al. (1997)	WC, WHR	270	7.2 years	Mexican-American	Male	42	Age
McNeely et al. (2001)	WC	466	5 years	Japanese American	Male/Female	52	Age, gender, family history, Smoking
Hadaegh et al. (2006)	WC, WHR	1,852	3.6 years	Iranian	Male	20+	Age, smoking, hypertension, family history
Diabetes defined using insulin and glucose concentration							
Wang et al. (1997)	WC, WHR	1,195	3.3 years	Chinese	Female	52	Age
Wang et al. (1997)	WC, WHR	995	3.3 years	Chinese	Male	54	Age
Sakurai et al. (2009)	WC	3,992	8 years	Japanese	Male/Female	35–55	Age, gender
Gruson et al. (2009)	WC, WHR, WthR	10,602	10 years	French and Irish	Male	50–59	Education, physical activity, Tobacco and alcohol

All the studies showed a positive association of waist phenotypes ((WC, waist circumference; WHR, waist-to-hip ratio; WthR, waist-to-height ratio) with the incidence of type 2 diabetes.

Using the US Nurses' Health Study, and after 8 years' follow-up, Carey et al. (1997), reported a positive association between waist-to-hip ratio and type 2 diabetes. After adjustment for BMI and other potential confounding factors, the relative risk for the 90th percentile of waist-to-hip ratio versus the 10th percentile was 3.1 (95% CI 2.3–4.1) and that for the 90th percentile of waist circumference versus the 10th percentile was 5.1 (95% CI 2.9–8.9) (Carey et al. 1997).

In a prospective population-based cohort study of 3,055 men and 2,957 women aged 35–74 years who participated in the MONICA (Monitoring Trends and Determinants on Cardiovascular Diseases) study and followed up for about 9.2 years, Meisinger et al. (2006) found a positive association of waist circumference and waist-to-hip ratio with type 2 diabetes. In the study, multivariable-adjusted hazard ratios for type 2 diabetes estimated from Cox proportional hazards models across quartiles of waist circumference were 1.0, 1.15, 1.57, and 3.40 in men and 1.0, 3.21, 3.98, and 10.70 in women. Those for waist-to-hip ratio were 1.0, 1.14, 1.80, and 2.84 in men and 1.0, 0.82, 2.06, and 3.51 in women (Meisinger et al. 2006).

We found eight cohort studies that defined diabetes using fasting blood glucose and glucose-tolerance tests. All the studies observed positive independent associations of waist circumference or waist-to-hip ratio for diabetes risks. Cassano et al. (1992) used a proportional hazards model based on a prospective evaluation of male participants in the Department of Veterans Affairs Normative Aging Study cohort. Adjusting for age, body mass index, and cigarette smoking, men in the top tertile for waist-hip ratio had a 2.4-fold (95% CI 1.7–3.7) greater risk of diabetes than men in the lowest tertile (Cassano et al. 1992).

Snijder et al. (2003) reported data from the Hoorn study to prospectively determine the association of hip and thigh circumferences, independent of waist circumference, with the incidence of type 2 diabetes. Glucose tolerance was assessed by the use of a 75-g oral-glucose-tolerance test. When adjusted for hip circumference and BMI or thigh circumference and BMI, the ORs for WC were higher in both men and women, the highest being 2.66 per one SD larger waist for the latter adjustment in women (Snijder et al. 2003).

Wang et al. (2005) compared waist circumference and waist-to-hip ratio in predicting type 2 diabetes using a prospective cohort study (Health Professionals Follow-Up Study) of 27,270 men. During 13 years of follow-up, 884 incident type 2 diabetes cases were found. Age-adjusted relative risks across quintiles of waist circumference were 1.0, 2.0, 2.7, 5.0, and 12.0 and those of waist-to-hip ratio were 1.0, 2.1, 2.7, and 3.6 (p for trend < 0.0001 for all). Statistical adjustment for diabetes risk factors only slightly attenuated these relative risks (Wang et al. 2005).

In a study of 721 Mexican Americans aged 25–64 years who were followed for an average of 7.2 years, Wei et al. (1997) found that waist circumference was the best obesity-related predictor for type 2 diabetes. The risk for type 2 diabetes for those in the highest quartile of waist circumference was 11 (95% CI: 4.2–28.8) times greater than for those in the lowest quartile. The authors argue that abdominal fat localization was a more important determinant than the total amount of body fat in this population of mean age of 42 years and 43 years for men and women, respectively (Wei et al. 1997).

In a prospective, cohort study of Japanese Americans, McNeely et al. (2001) found that, in their younger subgroup aged 55 years or less (n = 240), waist circumference greater than or equal to the third tertile was associated (adjusted RR: 5.4; 95% CI: 1.7–17.0) with type 2 diabetes (McNeely et al. 2001).

To investigate whether central obesity variables are more important than general obesity variables in predicting the incidence of type 2 diabetes in Iranians, Hadaegh et al. (2006) investigated a representative sample of 1,852 males aged 20 years and older. After 3.6 years of follow-up, waist circumference was significantly associated with type 2 diabetes, adjusting for age, smoking, hypertension, and family history of diabetes.

Some studies, including those of Wang et al. (1997), Sakurai et al. (2009), and Gruson et al. (2009), also investigated the association of waist phenotype with type 2 diabetes by defining diabetes on the

Table 128.3 The association between waist phenotypes and the incidence of type 2 diabetes

Author	RR	95% CI	RR	95% CI
	Waist circumference

Wang 2005	–	–	2.80	(2.10, 3.80)

Point and interval estimates for type 2 diabetes due to waist circumference and waist-to-hip ratio from reviewed published articles are here summarized. In studies where waist circumference was used as a measure for abdominal obesity, relative risk for type 2 diabetes ranged from 1.8 to 5.1 for women and ranged from 1.23 to 4.50 for men. Using waist-to-hip ratio, relative risk ranged from 1.72 to 4.6 and 1.8 to 3.4 for women and men, respectively.

basis of insulin and glucose concentration. In Chinese men and women, Wang et al. (1997) found a stronger relationship between diabetes incidences in women than in men and indicated that waist circumference was a better predictor than waist-to-hip ratio. During an 8-year follow-up, Sakurai et al. (2009), calculated age- and sex-adjusted hazard ratios according to the sex-specific quintile of waist circumference at baseline. Age- and sex-adjusted hazard ratios across the quintiles of waist circumference were 1.78, 1.00, 1.59, 3.11, and 3.30, respectively (p for trend < 0.0001) (Wang et al. 1997).

Gruson et al. (2009) compared the associations of waist circumference, waist-to-hip ratio, and waist-to-height ratio with the incidence of coronary events, including type 2 diabetes in a prospective study of 10,602 men aged 50–59 years, recruited between 1991 and 1993 in three centers in France and one center in Northern Ireland. Waist circumference, waist-to-hip ratio, and waist-to-height ratios were positively associated with diabetes ($p < 0.0001$). The authors concluded that, in middle-aged European men, the waist-to-height ratio identifies coronary risk more strongly than waist circumference and waist-to-hip ratio (Gruson et al. 2009).

Table 128.3 summarizes point and interval estimates for type 2 diabetes due to waist circumference and waist-to-hip ratio from reviewed published articles. In studies where waist circumference was used as a measure for abdominal obesity, relative risk for type 2 diabetes ranged from 1.8 to 5.1 for women and from 1.23 to 4.50 for men. Using waist-to-hip ratio, relative risk ranged from 1.72 to 4.6 and 1.8 to 3.4 for women and men, respectively.

128.6 Mechanism of Waist Variables for Type 2 Diabetes

The mechanism linking waist phenotype to cardiometabolic risk factors including type 2 diabetes is not clear. Two likely mechanisms may be involved in the association of waist phenotypes with type 2 diabetes. One, through the preponderance of the highly sensitive lipolytic hypertrophied visceral

adipose tissues, elevated free fatty acids are suggested to incite insulin resistance (Bjorntorp 1990). Two, elevated free testosterone and reduced sex-hormone-binding globulin may be associated with the promotion of increased fat deposits in the waist region and reduced fractional hepatic extraction of insulin (Salans et al. 1968). Thus, the association of waist phenotypes with type 2 diabetes may be due to an enlarged visceral fat depot discharging free fatty acids into the portal and systemic circulation.

It has also been suggested that the connection between waist phenotype and cardiovascular diseases may be due to an overflow of chemical energy to intra-abdominal fat tissue and liver (Seppala-Lindroos et al. 2002). Intra-hepatic fat accumulation is associated with dyslipidemia and hepatic insulin resistance leading to type 2 diabetes (Seppala-Lindroos et al. 2002). Since intra-abdominal fat tissue is a marker for the degree of overflow of fatty acids from subcutaneous depots, waist phenotype may be a true marker of the overall impairment in energy storage regulation, in which an increase in intra-abdominal fat tissue signifies an altered capacity for energy storage in other adipose tissues (Seppala-Lindroos et al. 2002).

128.7 Public Health and Clinical Significance of Waist Phenotypes

As a correlate of type 2 diabetes, waist phenotype has both public health and clinical significance. From a public health perspective, waist circumference is a powerful indicator of body fat distribution, which can identify patients who are at increased risk of obesity-related cardiometabolic disease, above and beyond what is indicated by body mass index. Waist circumference is easy to measure, subject to little error, and requires an inexpensive apparatus. Given the increasing epidemics of obesity and the association between obesity and type 2 diabetes, advocating the use of waist phenotype for obesity surveillance could help in the early identification of those at risk for type 2 diabetes. Weight reduction programs or other interventions targeted specifically at abdominal regions may help to alleviate the risk of obesity-related sequelae. From a clinical point of view, measuring waist phenotypes could provide additional information above and beyond what is provided by body mass index. Prescribing abdominal obesity reduction in morbidly obese subjects may add to the clinical relevance of waist phenotypes in risk populations.

128.8 Applications to Other Areas of Health and Disease

The association of waist phenotypes with type 2 diabetes has been demonstrated in many studies and confirmed in our analysis of prospective studies and pooled estimates of the relative risks from various studies, including three studies that performed meta-analyses. Despite the largely unexplained heterogeneity of relative risk, studies have demonstrated consistent strong associations of increased waist circumference and waist-to-hip ratio with the risks for type 2 diabetes. The verdict is yet to be given with respect to the nature of the association of waist-to-height ratio with type 2 diabetes.

The clinical and epidemiologic appeal for the use of waist phenotypes is undeniable. Waist measurement is simple and requires only a measuring tape and a weighing scale. The statistical appeal is that waist circumference is highly correlated with adiposity measured with more precise techniques, including magnetic resonance imaging, computed tomography, hydrodensitometry (underwater weighing), and dual energy X-ray absorptiometry. Waist-hip ratio, despite lower correlation with body mass index, appears to have the same ability to predict diabetes as waist circumference.

However, the role of waist-to-height ratio in diabetes is poorly understood, and additional research is needed to define its predictive utility. The association of waist phenotypes with other diseases and components of metabolic syndrome needs to be investigated. Effective translation of the use of waist phenotypes into clinical practice to predict obesity-related diseases may help in reversing the increasing trend of components of the metabolic syndrome.

Summary Points

- The three most important waist phenotypes are waist circumference, waist-to-hip ratio, and waist-to-height ratio.
- Waist circumference, waist-to-hip ratio, and waist-to-height ratio are surrogate measures of abdominal obesity.
- Abdominal obesity is the most potent form of adiposity and is the culprit for obesity-associated diseases.
- Studies indicate that waist phenotypes of waist circumference, waist-hip ratio, and waist-to-height ratio are associated with the risk of type 2 diabetes.
- Routine assessment of waist phenotypes in clinical practice to predict obesity-related disorders may help in reversing the increasing trend of type 2 diabetes.

Key Features

Table 128.4 Key features of waist phenotypes

1. The three most widely used waist phenotypes for predicting obesity-related disorders are waist circumference, waist-to-hip, ratio and waist-to height ratio
2. Many studies showed a positive association of waist circumference, waist-to-hip ratio, and waist-to-height ratio with incidence of type 2 diabetes.
3. Waist phenotype cut-points for predicting type 2 diabetes vary by gender, race, and nationality.
4. Increased values of waist phenotypes are associated with increased risk for type 2 diabetes.
5. The connection between waist phenotype and cardiovascular diseases may be due to an overflow of chemical energy to intra-abdominal fat tissue and liver.
6. Weight-reduction programs or other interventions targeted specifically at abdominal regions may help to alleviate the risk of obesity-related sequelae, including type 2 diabetes.
7. Effective translation of waist phenotypes into clinical practice may be critical in reversing the increasing prevalence of obesity-related disorders.

This table lists the key facts of waist phenotypes, including potential mechanism and impact of its effective translation into medical practice

Chapter 129
The Use of Skinfolds in Anthropometric Measures and Their Applications to Diabetes

Marie-Eve Mathieu and Louise Béliveau

Abstract Worldwide, the last few decades have been marked by a concomitant rise in adiposity and metabolic disorders. Based on current projections, it is expected that this situation will continue. To assess adiposity and not solely weight, various techniques have been used. The measurement of skinfold thickness has received a great deal of attention as early as the 1980s. In this chapter, we present the extent to which skinfold thickness is associated with metabolic impairments, in both cross-sectional and longitudinal studies. Gender, age-group and ethnicity specificities are brought forward when such information is known. Issues of gestational diabetes and familial diabetes history are also addressed. Moreover, the skinfolds, skinfold ratios or body fat percentage formulas based on skinfolds that have a better association with metabolic impairments are presented. Advantages, as well as limitations, versus other measurement techniques are discussed. As new technologies are now available to measure adiposity, it is important to understand the role of the simple technique that enables the measurement of subcutaneous adiposity. It was among the first to be used in large-scale studies, at a moment corresponding to the beginning of a drastic rise in obesity and diabetes. Revisiting the link between the skinfold technique and metabolic impairments will enable a good understanding of adiposity and diabetes studies that ground today's current state of knowledge.

T2D Type 2 diabetes

129.1 Introduction

Identified as early as circa 1500 BC, diabetes is a disease that can take many forms. Type 1 diabetes is characterized by the absence of insulin, whereas resistance to insulin is the primary characteristic of type 2 diabetes (T2D). During pregnancy, women can develop a transitory diabetes (i.e., gestational diabetes). Common features of these conditions are a rise in glycemia and the potential development

of complications, such as metabolic, cardiovascular, and kidney diseases, as well as neurological complications. To work toward the prevention of this disease and to better treat individuals who have developed it, a better understanding of the characteristics of these individuals is important. The anthropometric profile is one parameter that has received a great deal of attention. Among all of the techniques used, skinfold thickness is one that stands out because of its use in large cohort studies for many years and in various populations.

Among the numerous studies that have addressed the issue of skinfolds in line with diabetes, the skinfolds selected have varied considerably, including abdomen, biceps, calf (lateral and medial), chest, midaxillary, subscapular, suprailiac, thigh, and triceps. The two most commonly measured skinfolds are the subscapular and the triceps. The subscapular-to-triceps ratio is also frequently used as an indicator of centralized adiposity, with a higher ratio indicating higher adiposity in the central portion of the body. Some authors have also used various combinations of skinfolds. For example, Chandalia et al. (1999) computed the sum of subscapular, midaxillary, chest, abdomen, and suprailiac skinfolds to reflect truncal adiposity and the sum of triceps, biceps, thigh, and calf skinfolds for peripheral adiposity. How do all of these adiposity indicators relate to glucose metabolism impairments? What is the adiposity profile of individuals who will develop the disease or who already have it? Do children with mothers who had gestational diabetes have a particular adiposity status? The present chapter aims at answering these questions and presents ethnic and gender specificities when such information is known. Although type 1 and gestational diabetes will be discussed when possible, most available data come from studies on T2D. Finally, the usefulness of skinfolds versus other anthropometric measurements in the assessment of the anthropometric characteristics of individuals at risk or with diabetes will be addressed.

129.2 Total Adiposity Assessed Using Skinfolds and Diabetes

129.2.1 Cross-Sectional Studies

Various groups of researchers have conducted cross-sectional studies aiming to better understand the relationship between glucose metabolism and total adiposity, as measured with skinfolds. Among them, Menke et al. (2007) reported, for a diverse ethnic sample (non-Hispanic black, Mexican-American, and non-Hispanic white individuals), that the age-adjusted prevalence of diabetes was higher for men and women having higher skinfold thicknesses (subscapular, suprailiac, thigh, and triceps). In men, the age-adjusted prevalence of T2D was 5.0 for individuals with a sum of skinfolds under 83.7 mm, versus 10.4 for those with values equal to or above 83.7 mm. In women, the age-adjusted prevalence was 3.4 if the sum of skinfolds was under 120.3 mm and 7.7 if equal to or above 120.3 mm. Globally, the prevalence was about double for individuals in the group with the highest adiposity. Similar findings have been reported with Algonquin individuals in Canada, in whom glucose tolerance abnormalities (impaired glucose tolerance and T2D) were significantly associated with the sum of triceps and subscapular skinfold thicknesses (Delisle and Ekoé 1993). Even in pregnant women, the presence of glucose metabolism impairments (gestational diabetes) is associated with a higher body fat percentage derived from skinfolds and higher skinfold thicknesses (subscapular, triceps, and biceps) (Yilmaz et al. 2009). Looking at the incidence of impaired glucose tolerance, impaired fasting glucose and T2D in women with gestational diabetes, Krishnaveni et al. (2007) measured the sum of skinfolds (biceps, subscapular, suprailiac, and triceps) and glucose metabolism for five years post pregnancy. As depicted in Fig. 129.1, women who had gestational diabetes tended

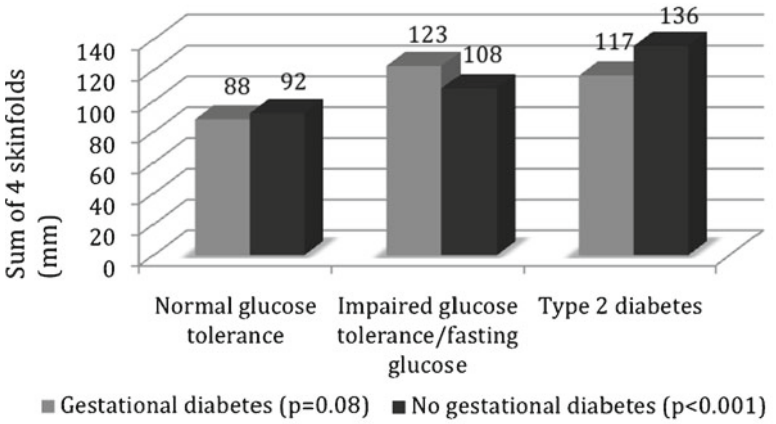

Fig. 129.1 Adiposity of women with and without gestational diabetes five years after giving birth, according to their metabolic status (Adapted from Krishaveni et al. 2007)

to have thicker skinfolds at follow-up if they developed glucose metabolism impairments. That trend was revealed to be significant in women who did not have glycemic impairments during gestation. Control of body fat thus appears to be important in order for both women who had or did not have gestational diabetes to remain free of diabetes and glycemic disorders post pregnancy.

In opposition to these studies, Misra et al. (2001) showed that fasting blood glucose was not associated with percent body fat calculated from skinfolds (subscapular, suprailiac, biceps, and triceps) in a sample of 424 Asian Indian individuals, of whom about 10% had T2D. This is in line with the study by Chandalia et al. (1999). In their study, the rate of glucose disposal was significantly correlated to total body fat, measured with underwater weighing, in Caucasian but not in Asian Indian individuals. However, the authors showed that, for a given amount of overall adipose tissue, Asian Indian individuals have lower insulin sensitivity, as assessed with the euglycemic hyperinsulinemic clamp technique. Therefore, concluding only on the basis of fasting blood glucose that there is no association between overall adiposity and glucose metabolism in Asian Indian individuals could be a mistake. In fact, insulin sensitivity is a key feature of T2D pathophysiology. Another study conducted with newborn babies also reinforces the link between adiposity and insulin defects among Asian Indians individuals. Insulin concentration at birth was directly related to subscapular thickness in Asian Indian, but not in Caucasian, individuals (Yajnik et al. 2002). Therefore, the available data from cross-sectional studies suggest that an association between high overall adiposity, as assessed with skinfolds, and glucose metabolism impairments could exist in non-Hispanic blacks, Mexican American, non-Hispanic whites, Algonquin, and Asian Indian individuals, as well as in women during and after pregnancy.

129.2.2 Longitudinal Studies

Cross-sectional studies are an interesting option for identifying associations. However, is the conclusion presented in the previous section supported by longitudinal studies? This appears to be the case for all but one study. In adult Mexican-American individuals who were T2D-free at baseline, Haffner et al. (1991) reported that those who developed the disease over the course of an eight-year period were the ones who had higher skinfold thicknesses at baseline (Table 129.1). A study by the same

Table 129.1 Eight-year incidence (%) of T2D by gender, according to anthropometric characteristics (Adapted from Haffner et al. 1991)

		Men	Women
Subscapular skinfold (mm)	Low (men: <17.5; women: <18.9)	2.4	0.8
	Moderate (men: 17.5–22.0; women: 18.9–27.0)	9.3	7.4
	High (men: >22.0; women: >27.0)	7.1	13.9
	p value	0.996	<0.001
Triceps skinfold (mm)	Low (men: <12.1; women: <20.5)	5.9	4.1
	Moderate (men: 12.1–17.8; women: 20.5–26.7)	6.0	5.7
	High (men: >27.0; women: >26.7)	>27.0	> 26.7
	p value	0.73	0.021
Body mass index (kg/m^2)	Low (men and women: <24.6)	2.4	2.5
	Medium (men and women: 24.6–28.2)	7.1	5.7
	High (men and women: >28.2)	9.5	13.9
	p value	0.21	<0.001
Centrality index (ratio of subscapular-to-triceps skinfolds)	Low (Men: <1.19; women: <0.85)	4.7	0.8
	Moderate (Men: 1.19–1.52; women: 0.85–1.11)	6.0	8.2
	High (men: >1.52; women: >1.11)	8.2	13.1
	p value	0.552	<0.001

group showed that age-adjusted odds ratios for developing T2D were 1.46 for women and 1.78 for men, for an increase of 0.98 mm in subscapular and 1.42 in triceps skinfold thicknesses in women and 1.82 and 0.87 mm, respectively, in men (Wei et al. 1997). A similar conclusion was reached in a representative sample of the Canadian population that was composed of more than 1,500 adult individuals. According to the authors, the incidence of diabetes over a 15.5-year period was associated with the sum of five skinfolds (biceps, triceps, subscapular, suprailiac, and calf) (Katzmarzyk et al. 2007). These findings are in line with results from Wang et al. (1997), who showed in a sample of 2,190 Chinese individuals that those who developed T2D over a 3.3-year period had, on average, a significantly higher subscapular skinfold thickness at baseline (men: 18.2 vs. 16.0 mm, $p = 0.016$; women: 26.4 vs. 18.9 mm, $p < 0.001$). In addition, the difference between those who developed the disease and those who did not was significant for triceps thicknesses in women (22.0 vs. 19.4 mm, $p = 0.020$).

As mentioned previously, only one study does not support the association between adiposity and the development of glucose metabolism impairment. In that study, which was conducted to investigate glucose metabolism in the first eight years of age, it was reported that insulin resistance at 8 years, as assessed with the homeostatic model, was neither associated with neonatal subscapular nor with triceps skinfold thicknesses (Ponsonby et al. 2008). However, skinfold thicknesses at age 8, as well as the gain in skinfold thicknesses from neonatal to childhood periods (adjusted for neonatal skinfold thicknesses), were associated with a higher insulin resistance. Consequently, it would not be the profile at birth, but the evolution thereafter that matters.

129.2.3 Gender Differences

Skinfold measurements, as well as T2D criteria, are the same in men and women, but the association between different parameters appears to vary. In their longitudinal study, Haffner et al. (1991) showed that the difference in subscapular and triceps skinfold thicknesses between individuals who developed T2D and those who did not was more marked in women than men (Table 129.1). For the

subscapular skinfold, the difference was 2.2 mm in men and 10.0 mm in women, whereas the difference was 0.8 mm in men and 4.0 mm in women for the triceps skinfolds. This gender difference was significant for the subscapular skinfold. The finding that suggests adiposity is more closely linked to T2D incidence in women is further supported by the interventional study of The Diabetes Prevention Program Research Group (2006). In their study, men and women were allocated to one of three groups: placebo, metformin (an anti-diabetic drug), and lifestyle (nutrition and physical activity). Subsequently, the incidence of T2D was followed over an average of 3.2 years. In men, they reported that only the calf skinfold thickness at baseline was a significant predictor of the development of the disease in the lifestyle group. In women, the subscapular skinfold and the sum of triceps and subscapular skinfolds were significant predictors of T2D development in the placebo and lifestyle groups. Furthermore, the suprailiac skinfold and sum of skinfolds (triceps, subscapular, suprailiac, and abdomen), including or excluding the calf skinfold, had a predictive value for women in the placebo group. It should also be noted that two skinfolds (subscapular and triceps) were higher in women that were developing T2D, whereas this was the case for only one skinfold type (subscapular) in men, as reported by Wang et al. (1997). Taken together, the available data from both cross-sectional and longitudinal studies suggest that the association between adiposity and T2D is stronger in women than in men.

129.3 Family History of Type 2 Diabetes and Adiposity Assessed with Skinfolds

If higher adiposity is associated with a higher prevalence and incidence of T2D and glucose metabolism impairments, then the adiposity status of individuals with a family history of T2D should be examined. In one large study ($n = 869$) conducted in Italy, it was reported that 10-year-old children had a larger sum of subscapular, bicep, triceps, and suprailiac skinfolds if they had a family history of diabetes (10.2 vs. 11.0 mm; $p < 0.05$) (Giampietro et al. 2002). Amini et al. (1997) also addressed the question of adiposity and family history of diabetes in 66 children with an average age of 9 in Papua New Guinea. While they reported that children having a family history of the disease were heavier, the difference in triceps skinfold thicknesses was not statistically different (7.7 vs. 6.6 mm; $p = 0.13$). In a longitudinal study by Srinivasan et al. (2003), a total of 1,439 children aged 4–17 years were evaluated at entry during childhood, adolescence, and adulthood to better understand the association between parental diabetes and adiposity, as assessed using subscapular skinfold measurements. A positive association between parental diabetes and adiposity was present in childhood and persisted through adolescence and adulthood. The authors also reported that the rate of increase in skinfold thickness was significantly higher in the offspring of parents with T2D (0.70 mm per year vs. 0.57 mm per year; $p = 0.02$). Based on these studies, it appears that children having diabetic parents tend to be fatter and that they also gain more fat every year.

The issue of ethnicity, adiposity, and familial history of diabetes has been addressed by two groups of researchers. Srinivasan et al. (1998) have identified that triceps and subscapular skinfold thicknesses were significantly higher in the offspring of diabetic parents, but this was only true for white individuals, not for black individuals. The difference between offspring of diabetic and non-diabetic parents was 5.9 mm in white individuals, compared to 3.5 mm in black individuals, for triceps skinfolds. The difference was 7.8 mm in white individuals, compared to –0.7 mm in black individuals, for subscapular skinfolds. Whereas this study was conducted in 53 individuals aged 7–25 years, a larger study ($n = 1,338$) in slightly older individuals (19–37 years of age) showed

different results (McClain et al. 2000). Body fat, also assessed with triceps and subscapular skinfolds, was higher in individuals with a parental history of diabetes, whether they were black or white. The authors also showed that the magnitude of differences in skinfold thicknesses between the offspring of diabetic and non-diabetic parents was greater among black individuals and that this ethnic difference was significant for the subscapular skinfold. More research will be needed to identify if the association is stronger in black or white individuals.

Another issue that should raise awareness is that the offspring of diabetic parents not only present more subcutaneous fat in most cases, but also have metabolic complications associated with a disadvantageous adiposity profile. In the study by McClain et al. (2000), the offspring of both black and white diabetic parents had, in addition to higher adiposity, higher cholesterol, triglycerides, very low density lipoprotein, glucose and insulin levels, insulin resistance, as well as lower high-density lipoprotein. Similarly, higher insulin, glucose, and insulin resistance was reported in adolescents and adults whose parents had diabetes, in the study by Srinivasan et al. (2003). Only during childhood was the metabolic profile similar between children whose parents had diabetes or not. Based on these studies, it can be concluded that adiposity is higher in individuals with parents having diabetes. A difference can be seen as early as childhood, and metabolic complications associated with an adverse adiposity profile and family history of the disease can appear in adolescence.

129.4 Gestational Diabetes and Adiposity Assessed with Skinfolds

In the previous sections, we addressed adiposity in individuals with diabetes or a family history of the disease. In the first case, the body has to deal with glucose metabolism impairments. In the second case, genetic susceptibility to the disease is present without impairments necessarily existing. Mid-way between these conditions is the case of individuals who are exposed to a milieu where glycemic control is not optimal but whose bodies are free of glucose metabolism impairments. This is the case of babies of women who had gestational diabetes.

How are the anthropometric characteristics of these babies? At birth, the group of Krishnaveni et al. (2005a, b) showed that a larger neonatal subscapular skinfold was positively associated with maternal glucose concentration. They also showed that babies of mothers with gestational diabetes had larger skinfold thicknesses than babies of mothers free from the disease. As illustrated in Fig 129.2, the authors reported small but significant differences. At 1 year of age, however, the difference was no longer significant (Krishnaveni et al. 2005a). This is similar to the findings of Wright et al. (2009), who showed that the children of mothers who had gestational diabetes or impaired glucose tolerance were not significantly fatter at 3 years of age. However, the authors found a significant 1.31-mm difference in the sum of subscapular and triceps skinfolds between the groups, when they took into account various factors including maternal age, education, race/ethnicity, smoking history, body mass index (BMI), pregnancy weight gain, parity, paternal BMI, and fetal growth. Differences between these studies could thus be attributable to different adjustment techniques, considering that Krishnaveni et al. (2005a) only adjusted for gestational age and sex.

Whereas no difference was noted at one year of age, Krishnaveni et al. (2005a) reported that, by the age of five, daughters of mothers who had gestational diabetes have significantly higher adiposity. They demonstrated 8.5 mm vs. 7.7 mm for triceps skinfolds ($p = 0.01$) and 6.6 mm vs. 5.9 mm for subscapular skinfolds ($p = 0.01$) (Fig. 129.2). This could indicate a larger adiposity rebound in children of mothers who had gestational diabetes, at least in girls. This is in line with findings from the same group, which showed that maternal insulin concentrations, along with neonatal skinfold thicknesses, were significant predictors of skinfold thickness at four years of age. However, it should

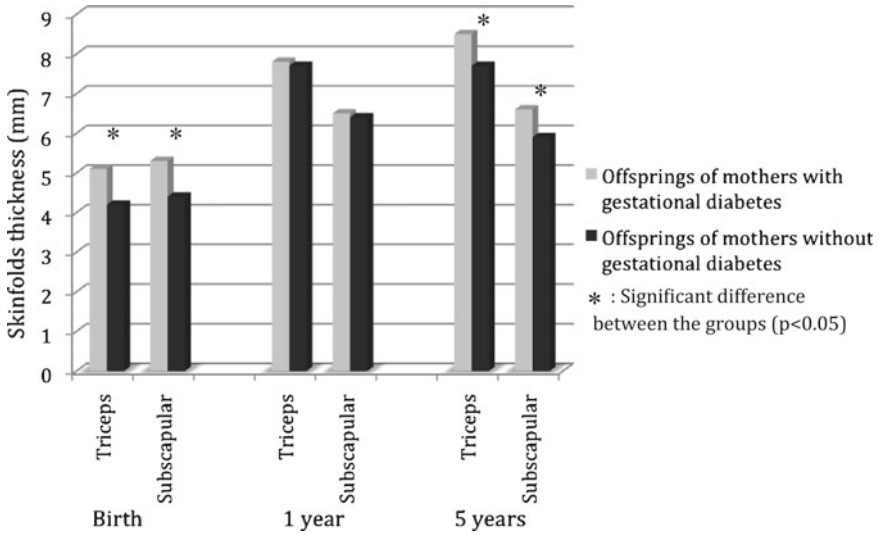

Fig. 129.2 Skinfold thicknesses of the offspring of mothers with gestational diabetes and control children (Adapted from Krishnaveni et al. 2005a)

be noted that differences between the groups are always quite small (less than 1 mm per skinfold), when they are present. In fact, factors such as maternal insulin levels and neonatal skinfold thicknesses explained less than 1% of the variability in skinfold thickness at four years of age, according to Krishnaveni et al. (2005b). Thus, it appears that gestational diabetes could, in some cases, be detrimental to the adiposity status of a child, but only to a very small extent.

129.5 Adiposity Localization as Assessed with Skinfolds and Diabetes

Skinfolds are a useful tool to document overall adiposity based on the amount of fat present under the skin. Most authors use the absolute thickness of each skinfold or the sum of various skinfold thicknesses, whereas others compute the percent body fat according to formulas. Potentially even more interesting is the comparison between various skinfolds, to better appreciate fat localization. The case of fat localization documented with skinfolds and diabetes deserves special attention considering that a growing body of research tends to indicate that fat present in the central portion of the body is associated with metabolic abnormalities.

129.5.1 Comparison of Various Skinfolds and T2D

Where fat is localized in relation to T2D presence and incidence has been addressed by several research groups for various ethnic groups. In a large cohort of 1,155 Mexican-American individuals aged 10 years and over, Mueller et al. (1984) showed that diabetic individuals have more fat in the upper portion of the body (subscapular skinfold) than age- and sex-matched non-diabetic individuals. On the other hand, diabetic individuals had less fat in the lower portion of the body, as assessed by calf skinfolds. This appears to suggest a preferential deposition of fat in the central portion of the

Table 129.2 Standardized relative risk of type 2 diabetes incidence for skinfolds – adjusted for age (Adapted from Wang et al. 1997)

	Men		Women	
	Standardized relative risk	95% confidence interval	Standardized relative risk	95% confidence interval
Subscapular	1.62	1.12–2.32	3.07	2.12–4.55
Triceps	1.37	0.97–1.87	1.57	1.11–2.20

body in T2D individuals. These cross-sectional findings were further supported by longitudinal studies. For example, Wang et al. (1997) reported that the incidence of T2D was more associated to indices of trunk adiposity (i.e., subscapular skinfold) than indices of fat in the extremities (i.e., triceps skinfolds) in Chinese individuals. In men, the standardized relative risk of developing the disease was 1.62 for the subscapular and 1.37 for the triceps skinfolds. In women, the difference in the standardized relative risk was about two times higher for the subscapular skinfold than for the triceps skinfolds (3.07 vs. 1.57, respectively). These findings are in line with those of Haffner et al. (1991), who showed that the incidence of the disease was more strongly linked to subscapular skinfolds, compared to triceps skinfolds, in Mexican-American women (Table 129.1). As in the study by Wang et al. (1997), it was also reported that, in men, the subscapular skinfold was better than the triceps skinfolds at predicting disease incidence. However, this was only the case to a smaller extent in women (Table 129.2). Therefore, cross-sectional, as well as longitudinal, studies indicate that, among various ethnic groups, the subscapular skinfold was more closely linked to the disease than peripheral skinfolds, such as the triceps and calf. Researchers who addressed the question of gender differences indicated that this association was even stronger in women.

129.5.2 Centrality Index and T2D

Apart from documenting the association of the disease with various skinfolds distributed throughout the body, the link between glucose metabolism impairments and the centrality index has been addressed. This index, which refers to the ratio of subscapular-to-triceps skinfolds, is a good indicator of fat localization. The higher the ratio, the more fat is present in the central portion of the body. For First Nation individuals in Canada, the centrality index was not associated with glucose intolerance abnormalities (Delisle and Ekoé 1993). On the other hand, the sum of skinfolds was associated with glucose metabolism impairments in this population, suggesting that, for First Nation individuals, the adiposity per se, but not its distribution, is associated with the disease. In Mexican-American individuals, Wei et al. (1997) also reported that the risk of T2D was associated with skinfold thicknesses (subscapular and triceps), but not with the centrality index. These findings are in opposition to what was reported for Asian Indian individuals, in whom the centrality index was significantly associated with the presence of T2D (Menon et al. 2006). Moreover, Marshall et al. (1993) identified a positive association between the risk of T2D and centrality index, for both non-Hispanic white and Hispanic individuals. However, they identified that, for each increase of 0.2 units in the centrality index, the odds ratios associated with the risk of T2D were higher in non-Hispanic whites than in Hispanic individuals (1.4 vs. 1.2, respectively). The association between central adiposity and T2D was also stronger among women, in whom an increase in 0.2 units corresponded to an odds ratio of 1.5, versus an odds ratio of 1.2 in men. Based on available cross-sectional studies, it is thus difficult to determine if the centrality index is linked to T2D. If so, it could be linked to a larger extent in non-Hispanic whites and Asian Indian individuals, compared with Mexican-American and First Nation individuals.

It could also be more detrimental for glucose metabolism in women. These conclusions, which were based on cross-sectional studies, are partly confirmed by the longitudinal study of Haffner et al. (1991), as they showed that the incidence of T2D was more closely linked to the centrality index in women than in men (Table 129.1). Considering also that this study was conducted in Mexican-American individuals, the conclusion indicating that the centrality index was not linked to the presence of T2D in Mexican-American individuals could be questioned. Based on the current state of knowledge, we can only affirm that the centrality index could potentially allow for the identification of non-diabetic individuals who are at a higher risk of developing the disease.

129.5.3 Type 1 Versus Type 2 Diabetes

Whereas the pathophysiology of the two main types of diabetes (type 1 and type 2) differs, very little information is available regarding the morphologic profile of individuals having type 1 diabetes. In fact, the only study that has addressed this is the one by Lev-Ran and Hill (1987). In a comparative study between anthropometric characteristics of individuals with type 1 and type 2 diabetes, they showed that, for similar BMI, men with T2D have a higher centrality index than men with type 1 diabetes (2.48 vs. 1.95, $p = 0.049$). On the other hand, women with either types of diabetes have a similar centrality index (1.18 for T2D and 1.09 for type 1 diabetes, $p = 0.284$). This is despite a larger BMI in T2D women. The limited data do not however allow for a firm conclusion.

129.6 Comparison of Skinfolds with Other Anthropometric Measures

In large cohort studies addressing the topic of the anthropometric characteristics of individuals presenting or at risk of developing diabetes, various measurement techniques other than skinfolds are used. The present section aims to compare the usefulness of skinfold thickness versus other anthropometric measures, such as BMI, waist circumference, hip circumference, and waist-to-hip ratio. Unfortunately, more recent techniques, such as electrical bioimpedance and dual energy X-ray absorptiometry, have not been compared to skinfold measurements in the assessment of the anthropometric characteristics of individuals with or at risk of developing diabetes. Therefore, the next sections will focus on the comparison of skinfolds to BMI and various body circumferences.

129.6.1 Skinfolds Versus Weight and Body Mass Index

In the only study on anthropometric differences between type 1 and type 2 diabetic individuals, no distinction was made based on their BMI or centrality index (subscapular-to-triceps ratio) (Lev-Ran and Hill 1987). This is similar to the study conducted with Mexican-American individuals who were free of diabetes at baseline, in whom the odds of developing the disease were similar for individuals based on their BMI, subscapular skinfold, triceps skinfolds, and the sum of seven skinfolds. In fact, sex- and age-adjusted odds ratios were 1.51, 1.55, 1.49, and 1.52, respectively (Wei et al. 1997). These studies suggest that there is no advantage in using the absolute skinfold value over BMI. The latter even appears to have a better predictive capacity than the centrality index, which has an odds ratio of only 1.26 in the study by Wei et al. (1997). Other groups have also indicated that weight or

BMI could be better than skinfolds at predicting the presence and incidence of T2D. Misra et al. (2001) reported that, in Asian Indian individuals, BMI was a predictor of fasting blood glucose in both men and women, whereas the sum of four skinfolds (biceps, triceps, subscapular, and suprailiac) was not. In the lifestyle group of The Diabetes Prevention Program, the incidence of T2D was predicted by the weight, but not by the adiposity per se, as assessed by skinfolds (The Diabetes Prevention Program Research Group 2006). On the other hand, Haffner et al. (1991) reported that the effect of BMI on T2D incidence was present, although less important than the effect of the centrality index (Table 129.1). Also supporting the use of skinfolds, the study of Katzmarzyk et al. (2007) showed that the odds of developing the disease were slightly higher for individuals presenting high adiposity (sum of five skinfolds) versus high BMI (odds ratios of 2.09 vs. 1.99, respectively).

What emerges from these studies is that discrepancies exist when trying to determine if skinfolds are more closely linked to the prevalence and incidence of diabetes than body weight and BMI. These differences could be partly explained by the choice of skinfolds. Indeed, Wang et al. (1997) identified that indices measured at the trunk, such as the subscapular skinfold, and measurements representing overall adiposity, such as BMI, are more closely linked to T2D incidence than indices from the extremities, such as the triceps skinfolds. Pooling indices from the center and extremities of the body could thus reduce the usefulness of skinfolds. Also, Yilmez et al. (2009) documented no relation between BMI, sum of skinfolds, and insulin resistance. However, skinfolds were linked to insulin resistance when the percent of body fat based on skinfolds was computed. In all other studies that compared anthropometric measurements, skinfolds were always summed and the percent body fat was not calculated. Based on these findings, we recommend that further studies make a distinction between central and peripheral skinfolds, as well as make use of percent body fat in addition to the sum of skinfold thicknesses. Until then, the choice between skinfolds, body weight, and BMI in the assessment of anthropometric characteristics of individuals presenting or at risk of developing the disease remains to be established.

129.6.2 Skinfolds Versus Waist Circumference, Hip Circumference, Waist-to-Hip Ratio, and Waist-to-Thigh Ratio

The study by Lev-Ran and Hill (1987), which was conducted with type 1 and type 2 diabetic individuals, used different anthropometric measures to try to differentiate both types of the disease. The BMI, waist-to-hip, waist-to-thigh, arms-to-thigh, and subscapular-to-triceps ratios were assessed in both men and women. Of all these parameters, only the waist-to-thigh ratio was independently correlated with diabetes type. Individuals having T2D presented higher waist-to-thigh ratio, suggesting more fat in the trunk than in the extremities.

Compared to the waist-to-thigh ratio, the waist-to-hip ratio is more commonly used. In a recent study, it was identified as the anthropometric parameter more closely linked to the incidence of T2D. The odds ratios for the incidence of the disease were 2.94 for the waist-to-hip ratio, 2.53 for waist circumference, and 2.09 for the sum of five skinfolds (Katzmarzyk et al. 2007). Furthermore, this ratio was identified as the best predictor of T2D development in men for the lifestyle group of The Diabetes Prevention Program, when compared to a wide spectrum of skinfold measures (triceps, abdomen, subscapular, and suprailiac skinfolds, the sum of these skinfolds, and the sum of abdomen and suprailiac skinfolds) (The Diabetes Prevention Program Research Group 2006). Waist circumference was also a good predictor in this study. For women in the placebo group, waist circumference was in fact the best predictor of disease development. The importance of waist circumference over skinfold thicknesses also applies to women who had glucose metabolism impairments during pregnancy (impaired glucose tolerance, impaired fasting glucose, or gestational diabetes). In this

population, waist circumference stands as a better predictor of the development of subsequent glucose metabolism impairments, superseding skinfold thicknesses and BMI (Krishnaveni et al. 2007). Whereas some studies indicate that waist circumference is linked to T2D in both men and women (Menke et al. 2007; The Diabetes Prevention Program Research Group 2006; Katzmarzyk et al. 2007), Wang et al. (1997) suggest that the association would be even stronger in women.

Overall, it appears that other parameters, such as the waist-to-thigh ratio, waist-to-hip ratio, and waist circumference, could present more interest. This is despite the utility of skinfold measurements at discriminating the anthropometric characteristics of individuals presenting or being at risk of developing diabetes. Compared to weight and BMI, the conclusion is somehow less clear, given contradictory findings among studies that compared methods. In the future, it would be important to rely on studies that compared these anthropometric techniques to new ones, such as electrical bioimpedance and dual energy X-ray absorptiometry, in the assessment of morphologic characteristics of individuals having or at risk of developing the disease.

129.7 Applications to Other Areas of Health and Disease

Skinfold thickness assessment is a technique that has been used in many health areas where adiposity is part of the pathophysiology. Metabolic impairments, such as impaired glucose tolerance, impaired fasting glucose, type 1 and type 2 diabetes, gestational diabetes, and familial history of type 2 diabetes have been discussed thoroughly in this chapter. However, cardiovascular health is another area in which skinfolds have been used to better understand the association between anthropometric characteristics and diseases. In the case of coronary heart diseases, for example, it is interesting to note that the association with the condition is similar to that reported for metabolic diseases: (i) BMI and skinfolds appear to be similar in their association with coronary heart diseases; (ii) skinfolds in the trunk are linked to a greater extent to coronary heart diseases than those in the periphery; and (iii) the waist-to-hip ratio is more associated to these diseases than skinfold thicknesses (Williams et al. 1997). Cancer is another pathology that was studied in relation to adiposity. In agreement with what was presented for the other diseases, a higher adiposity was associated with the presence of endometrial cancer, as assessed with subscapular skinfold thickness and a higher deposition of fat in the central portion of the body, which was measured with the subscapular-to-thigh ratio (Pischon et al. 2008). However, in opposition to what was reported for metabolic and cardiovascular diseases, subscapular skinfold thickness could better predict the risk of having this type of cancer than the waist-to-hip ratio. Consequently, each disease appears to have a specific association with skinfold thicknesses, supporting the importance of not generalizing findings from one condition to the other.

129.8 Conclusion

Skinfold thickness assessment is among the first techniques that have been used to document the adiposity of healthy individuals and those presenting health impairments. The association of skinfold thicknesses with metabolic impairments has been reported in various ethnic groups, from birth to adulthood and in both men and women, with a better association in the latter group when gender differences exist. Specifically, skinfolds in the central portion of the body, which are indicative of abdominal adiposity, appear to have a better association with the disease in most cases. This is probably why other measurements of abdominal adiposity (i.e., waist-to-hip ratio and waist circumference) that are not restricted to subcutaneous fat, but are estimates of the overall amount of fat present in the abdomen (subcutaneous and visceral), have a better association with metabolic impairments.

With the introduction of other techniques, such as dual energy X-ray absorptiometry and bioimpedance, which allow for overall adiposity measurements and not only those located subcutaneously, it is important to compare their association with metabolic impairments to those obtained with skinfold thicknesses. Presently, no study has compared the adiposity status obtained using skinfold assessment with more recent techniques. This would enable the documentation of whether skinfolds are still useful and would facilitate links with studies conducted before the end of the last century, when skinfold thickness assessment was largely used. Also, for studies where more advanced techniques cannot be used, skinfold thickness assessment could be an alternative, along with body weight and circumference measurements. Recently, we published changes in BMI, waist circumference, and skinfold thicknesses for individuals with or at-risk of T2D who were taking part in the DiabetAction program (Mathieu et al. 2008, 2009). The choice of skinfold measurements was supported by the fact that the implementation study was taking place in clinical settings, where other measurements of adiposity were not possible. Skinfold thickness assessments are also widely used in clinical settings for physical evaluation prior to and following lifestyle interventions. Therefore, it would be important to not create a gap between research, where skinfolds appear to be less used, and the clinic, where they are an important tool for adiposity assessment of individuals who, in a large proportion, have cardiometabolic conditions or are at risk of developing them.

Summary Points

- The higher the skinfold thickness, the higher the prevalence and incidence of metabolic impairments.
- In some cases, the association between skinfolds and metabolism appears to be stronger in women.
- Skinfolds in the central portion of the body are more associated to metabolic impairments than those at the periphery, in most cases.
- Measuring skinfolds does not appear to yield better results than body mass index.
- Circumferences appear to be more useful than skinfolds to document the association and development of metabolic impairments, such as type 2 diabetes.

Key Features

Table 129.3 Key facts on skinfold thickness and glucose and/or insulin metabolism

Metabolic impairments	Based on cross-sectional studies, a positive association between adiposity assessed with skinfolds and metabolic impairments has been shown in – Diverse ethnic groups (non-Hispanic black, non-Hispanic white, Mexican-American, Asian, and First Nation individuals); – Men, women, and pregnant women; – Individuals from birth to adulthood. Based on longitudinal studies, a positive association between baseline adiposity assessed with skinfolds and the incidence of type 2 diabetes is – Reported in Mexican-American, Canadian, and Chinese individuals; – Applicable for periods of three to 15.5 years; – Stronger in women, when gender differences in the association exist; – Not shown in children, although a gain in adiposity is associated with the incidence of metabolic impairments.

Adiposity localization	The association with metabolic impairments – Is stronger for skinfolds in the central portion of the body than at the periphery, according to cross-sectional and longitudinal studies, and in women, when a gender difference is present; – Is positive with the centrality index in non-Hispanic white and Hispanic individuals; – Is better for skinfold thicknesses than the centrality index in First Nation and Mexican-American individuals in cross-sectional studies, but not in longitudinal studies with Mexican Americans; – Is stronger for the centrality index in type 2 than in type 1 diabetic individuals for men, whereas no difference is present in women.
Skinfolds vs. other measurements	The advantage of skinfold measurements over body mass index is not clearly supported. – Waist-to-hip ratio and/or waist circumference are more linked to metabolic impairments (e.g., the incidence of type 2 diabetes and impaired glucose metabolism during pregnancy) than skinfold thicknesses in both men and women, with a stronger association in women when a gender difference exists.

Part XX
Anthropometry in Cardiovascular Disease

Chapter 130
Altered Bone Geometry of the Radius and Tibia Among Stroke Survivors

Marco Y.C. Pang and Ricky W.K. Lau

Abstract Stroke is a major cause of disability, with muscle weakness, balance deficits, spasticity, and sensory loss being some of the most common physical impairments observed in stroke survivors. The skeleton also undergoes considerable change after stroke, which includes secondary bone loss. This not only leads to changes in bone mineral density but also causes substantial alterations in long bone cross-sectional geometry. Bone geometry is an important determinant of bone strength and fracture risk. It is thus highly relevant to study bone geometry among individuals living with stroke, as this population has a much higher risk of fragility fractures than age-matched reference populations. Peripheral quantitative computed tomography (pQCT), a relatively new bone imaging technology, enables researchers to evaluate bone geometric properties at different skeletal sites. Recent pQCT studies of chronic stroke patients revealed that both the radius and tibia on the hemiparetic side had significantly altered geometric properties, which resulted in lower estimated bone strength than on the unaffected side. These studies also showed that muscle strength, degree of functional recovery, and severity of spasticity were closely associated with long bone geometry. Further research is required to determine the temporal changes in geometric properties at different skeletal sites and their determinants among stroke survivors. Such information is essential for developing effective intervention strategies that enhance bone geometry, and hence reduce fracture risk in this vulnerable population.

130.1 Introduction

Stroke is one of the most common chronic conditions among older adults (Feigin et al. 2003). The prevalence of stroke in USA currently stands at approximately 5.5 million cases, with a reported incidence of 700,000 cases per annum (American Heart Association Statistics Committee and Stroke Statistics Committee 2006). Stroke is a major cause of disability. It is well documented that stroke often causes physical impairments, such as hemiparesis, balance problems, spasticity, and deficits in sensory functioning. Less well known, however, is that the skeletal system also undergoes significant change following a stroke event. Mounting evidence demonstrates that secondary bone loss is prevalent after stroke, particularly on the side of the body affected (Ramnemark et al. 1999; Jorgensen and Jacobsen 2001). Loss of bone material not only has a detrimental impact on bone mineral density (BMD), but also causes unfavorable changes in the geometric properties of bone (Ashe et al. 2006; Pang et al. 2007, 2008, 2009). Bone geometry is an important determinant of bone strength (Burr and Turner 2003; Bouxsein and Karasik 2006). It has been shown that the geometric properties of bone are closely related to fracture risk (Ahlborg et al. 2003 and Peacock et al. 1995). Given the high rate of fragility fractures among stroke survivors (Kanis et al. 2001; Dennis et al. 2002), studying bone geometry among stroke patients is highly clinically relevant. Research into bone geometry post stroke has only recently started to emerge. In this chapter, the relevant research findings in this important area are reviewed and discussed.

130.2 Why Study Bone Geometry?

As mentioned, bone geometry has strong clinical relevance, as it influences bone strength. Bone strength is strongly dependent on BMD and the distribution of bone mass. Resistance to bending and torsional loading requires bone material to be distributed far from the neutral axis of bending or torsion, which is typically close to the center of the bone (Burr and Turner 2003; Bouxsein and Karasik 2006). This distribution of bone mass about the bending or torsional axis is referred to as the area moment of inertia and is directly proportional to the resistance to bending and torsional forces (Bouxsein and Karasik 2006). An example is illustrated in Fig. 130.1. Both bones shown in the figure have exactly the same BMD as measured by dual-energy X-ray absorptiometry (DXA). However, if the bone mass is distributed further away from the neutral bending or torsional axis, then the area moment of inertia increases, leading to greater bending or torsional strength. Moreover, this bone mass distribution also increases the total cross-sectional area of the bone, which is directly proportional to the resistance of the bone to compressive forces. Both bending and compressive strength are thus highly influenced by bone geometry (Bouxsein and Karasik 2006). Indeed, a reduced cross-sectional area of the radius is associated with increased wrist fracture risk in postmenopausal women (Ahlborg et al. 2003).

The importance of bone geometry has been illustrated in several studies of changes in bone geometry associated with the aging process (Riggs et al. 2004; Lauretani et al. 2008). In a cross-sectional population-based study using peripheral computed quantitative tomography (pQCT), Riggs et al. (2004) reported that, at the distal radial site, older adults had a significantly greater total bone cross-sectional area and total marrow area than had younger adults (Riggs et al. 2004). They suggested that periosteal apposition (the addition of bone to the periosteal surface) may explain the expansion of the total cross-sectional area, whereas endosteal resorption (bone resorption on the endosteal surface) may account for the expansion of the marrow area. As the addition of bone to the periosteal surface increases the area moment of inertia, they postulated that periosteal apposition is a compensatory

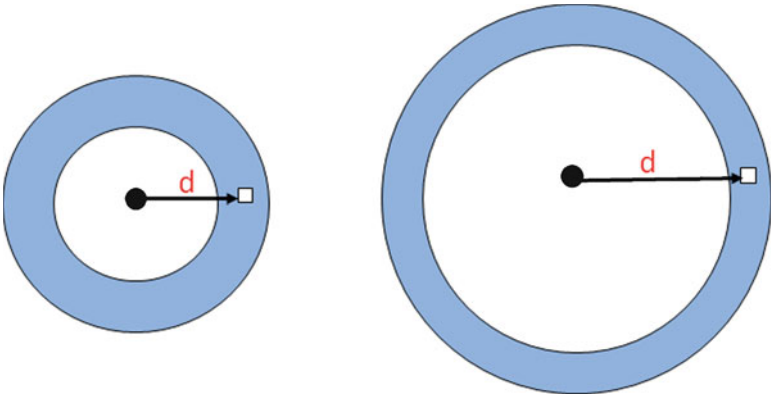

Fig. 130.1 Effect of bone geometry on bone strength. The *shaded areas* represent the cross-sectional view of the cortical shell of a long bone. Both bones have identical bone mineral density as measured by dual energy X-ray absorptiometry (DXA). However, the bone mass is distributed further away from the center of the neutral torsional axis in the bone on the right (distance *d*, illustrated by the *arrow*). This increases the total cross-sectional area and the area moment of inertia, which increases the compressive and bending or torsional bone strength

adaptation to maintain bone strength in response to age-related decline in bone mass (Riggs et al. 2004). A recent longitudinal study found that the rate of age-related medullary expansion due to endosteal resorption was significantly higher among women than among men (Lauretani et al. 2008). This indicates that accelerated endosteal resorption is insufficiently offset by periosteal apposition in elderly women, leading to cortical thinning and a reduction in the area moment of inertia. These differential changes in bone geometry between men and women may partly explain why fragility fractures are more prevalent among elderly women than among elderly men (Riggs et al. 2004; Lauretani et al. 2008).

As bone geometry is a major contributor to bone strength, it is clinically important to study bone geometry among stroke survivors, as these individuals are highly susceptible to fragility fractures. For example, within the first year of hospitalization for stroke, the relative risk of fractures is more than seven times greater among survivors than among age-and gender-matched reference populations (Kanis et al. 2001). Fractures in the stroke population are associated with adverse consequences including increased mortality and morbidity (Ramnemark et al. 2000). The medical cost associated with the treatment of fractures also imposes a financial strain on the healthcare sector. Although it is well documented that stroke survivors sustain a decline in BMD at various skeletal sites (Ramnemark et al. 1999), it is essential to gain a better understanding of the changes in bone geometry that occur after stroke and the factors associated with these changes so that proper therapeutic strategies can be devised to enhance bone geometry and reduce the fracture risk of this compromised population.

130.3 Measuring Bone Geometry

The method most commonly used to diagnose osteoporosis is dual-energy X-ray absorptiometry (DXA). However, because of its planar nature, DXA provides only a two-dimensional BMD measurement (areal BMD in g/cm^2) of a three-dimensional bone structure. Thus, bone-geometry parameters must be estimated indirectly using equations derived from areal BMD measurements and projections of the area of the region of interest (Szulc et al. 2004). For example, the endocortical

Fig. 130.2 A peripheral quantitative computed tomography (pQCT) device. A pQCT device can be used to measure bone geometry

diameter can be estimated from the bone mineral content and external diameter of the bone (Szulc et al. 2006). Cortical thickness can then be calculated based on the external and estimated endocortical diameters (Szulc et al. 2006). However, this technique has many limitations, not the least of which is that the estimation of the endocortical diameter is indirect. This technique also assumes a perfectly circular bone shape and constant cortical porosity (Boivin et al. 2002; Beck et al. 2003). Nevertheless, for certain skeletal regions, such as the diaphyseal sites of long bones (e.g., the radius), this technique may provide a reasonable estimate of bone geometric properties, as the bone at such sites is nearly circular in shape and the bone material is almost entirely cortical (Boivin et al. 2002; Szulc et al. 2006).

Peripheral quantitative computed tomography (pQCT), by contrast, is a relatively new technique that is capable of providing a volumetric bone density measure (in mg/cm^3; see Fig. 130.2). In addition, pQCT analyzes the cortical and trabecular compartments separately, and provides valuable information on bone geometry, including parameters, such as the total cross-sectional area, total cortical bone area, and cortical thickness. Figures 130.3 and 130.4 show the pQCT images of the tibia and radius, respectively. The effective radiation dose is also very small (<0.5 μV per slice) compared with that of DXA (1–10 μV), making pQCT a very safe imaging technique.

The precision of pQCT measurements of bone structure is comparable to that of peripheral DXA, with a precision error of just 1–2% and trueness error of 2–8% (Genant et al. 1996; Boutroy et al. 2005). Various estimates of bone strength can be computed using the densitometric and geometric parameters generated by pQCT. Several bone strength indices derived in this way have been validated in human cadaver studies, indicating that pQCT is a useful and noninvasive means of estimating bone strength. For example, the stress–strain index (SSI), which is the product of section modulus

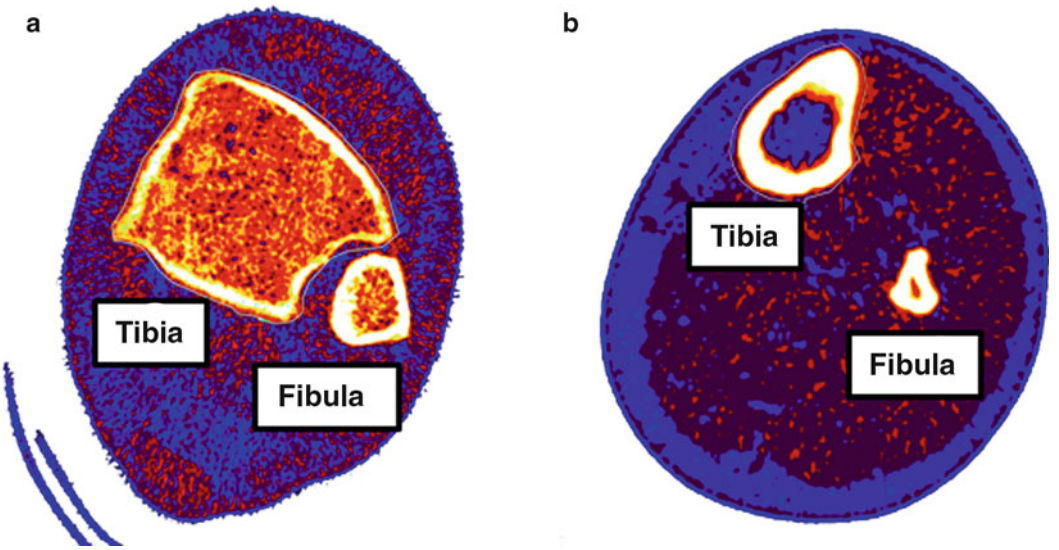

Fig. 130.3 A peripheral quantitative computed tomography (pQCT) image of the tibia. (**a**) A pQCT image of the epiphyseal site of the tibia (mostly trabecular bone). The white area represents the cortical bone shell. (**b**) A pQCT image of the diaphyseal site of the tibia (mostly cortical bone)

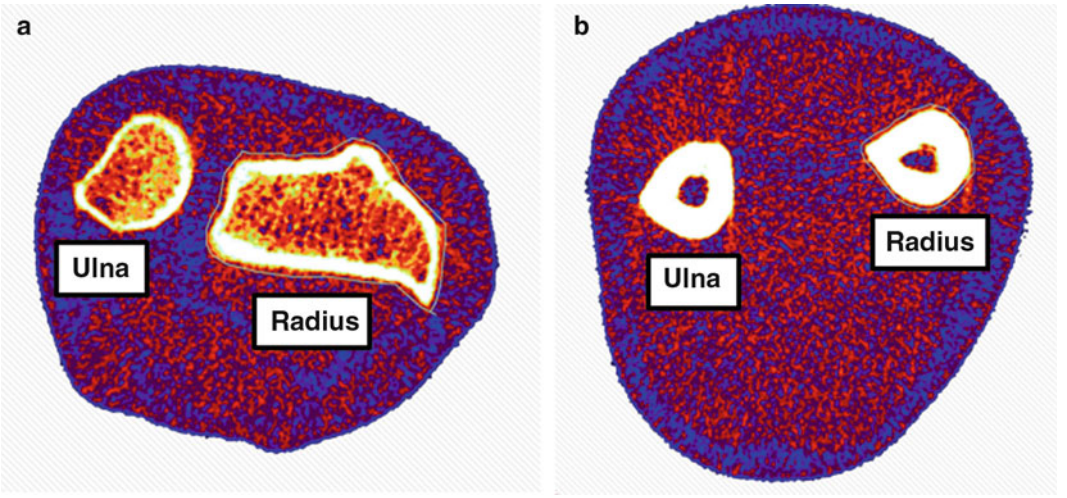

Fig. 130.4 A peripheral quantitative computed tomography (pQCT) image of the radius. (**a**) A pQCT image of the epiphyseal site of the radius (mostly trabecular bone). (**b**) A pQCT image of the diaphyseal site of the radius (mostly cortical bone)

measurements (i.e., the maximum distance from the periosteal surface to a particular bending or torsional axis) and the ratio of measured cortical BMD to physiological BMD (1,200 mg/cm^3) (Fig. 130.5), has been shown to be strongly associated with the bending failure load at the epiphyseal and diaphyseal sites of the radius and tibia (Lochmuller et al. 2002; Kontulainen et al. 2008). Another bone strength index, the bone strength index for compression (BSIc), which is the product of the

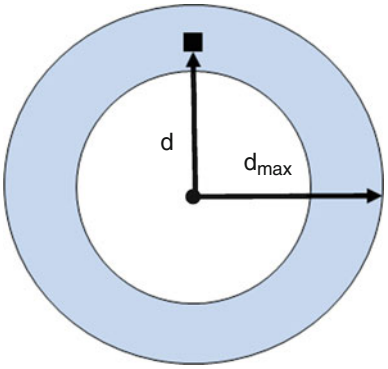

Fig. 130.5 Stress–strain index (SSI). SSI is computed from densitometric and geometric parameters derived from peripheral quantitative computed tomography (pQCT). It reflects the resistance of the bone to bending and torsional loads. The filled square represents the area of one voxel and the filled circle represents the center of gravity (C of G). [a = area of one voxel (mm^2); d = distance of one voxel to the C of G (mm); d_{max} = maximum distance to the C of G (mm); CD = volumetric cortical bone mineral density in one voxel (mg/cm^3); ND = normal physiological bone mineral density (1,200 mg/cm^3)]

Table 130.1 Key features of the stress–strain index (SSI)

1. Data generated by peripheral quantitative computed tomography (pQCT) can be used to compute a bone strength index called the stress–strain index (SSI).
2. The calculation of the SSI takes into account both the geometric and densitometric properties of the bone.
3. The SSI reflects the ability of the bone to withstand bending or torsional forces.
4. It is usually used for the cortical sites of long bones, where bending and torsional loading predominate.
5. The calculation of the SSI requires the accurate measurement of cortical parameters. Therefore, this index may not be appropriate for the epiphyseal sites of long bones, where the cortical shell can be very thin, and pQCT may not have adequate resolution to assess the cortical compartments at these sites.

This table lists the key features of the stress–strain index, including its properties and potential use

Table 130.2 Key features of the bone strength index for compression (BSIc)

Data generated by peripheral quantitative computed tomography (pQCT) can be used to compute the bone strength index for compression (BSIc).
BSIc = (total cross-sectional area) × (total bone mineral density)^2.
The calculation of the BSIc takes into account both the geometric and densitometric properties of the bone.
The BSIc reflects the ability of the bone to withstand compressive forces.
It is usually used for the distal end of long bones, which is subjected primarily to axial compression.

This table lists the key features of the bone strength index for compression (BSIc), including its computation, properties, and potential use.

measurements of the total bone cross-sectional area and the square of the total BMD, has been shown to account for 85% of the compressive failure load and 57% of the stiffness at epiphyseal sites of the tibia (Kontulainen et al. 2008). Tables 130.1 and 130.2 summarize the key features of the SSI and BSIc, respectively.

130.4 Practical Guidelines

Stroke patients often demonstrate impaired motor control. Therefore, it is important that the scanned limb segment be stabilized when performing pQCT measurements among these patients, as any movement will cause image artifacts. The subject should sit comfortably on a chair in front of the device (Fig. 130.6). Ideally, the limb segment to be scanned should be supported by a holder of a suitable size.

The length of the limb segment concerned should be measured before scanning. Next, a scout view of the radius/tibia should be obtained to ensure correct positioning of the limb segment, and to determine the reference line. For a radial scan, the cortical end plate of the radius should be used as an anatomical landmark. For a tibial scan, the middle of the distal end of the tibia is where the reference line should be placed (XCT 3000 Manual, Stratec 2007).

After the reference line has been determined, the measurement line can be defined. The distance between the reference line and measurement line is usually expressed as a percentage of the total length of the limb segment. For example, scanning the tibia at the 4% site means that the measurement line is 4% of the lower leg length proximal to the reference line (XCT 3000 Manual, Stratec 2007).

The voxel size needs to be specified. For more accurate measurements, a smaller voxel size should be chosen (i.e., better resolution). However, the achievement of better resolution necessitates a slower scanning speed. As mentioned previously, stroke patients may demonstrate spasticity or tremor, which may induce movement artifacts. In addition, they may not tolerate staying in a static position for an extended period of time because of fatigue or balance problems. There needs to be a balance between the resolution of images and scanning speed when performing pQCT scans on these individuals. In previous studies of stroke, a scan speed of 25 mm/s and voxel sizes ranging from 300 to 500 μm were used (Ashe et al. 2006; Pang et al. 2007, 2008, 2010).

To assess the trabecular bone compartments of the tibia and radius, the most common measurement site is the 4% one (Russo et al. 2003; Lauretani et al. 2008; Pang et al. 2010). To assess the cortical bone sites of the radius, the 30% site is commonly used (Uusi-Rasi et al. 2002; Pang et al. 2007).

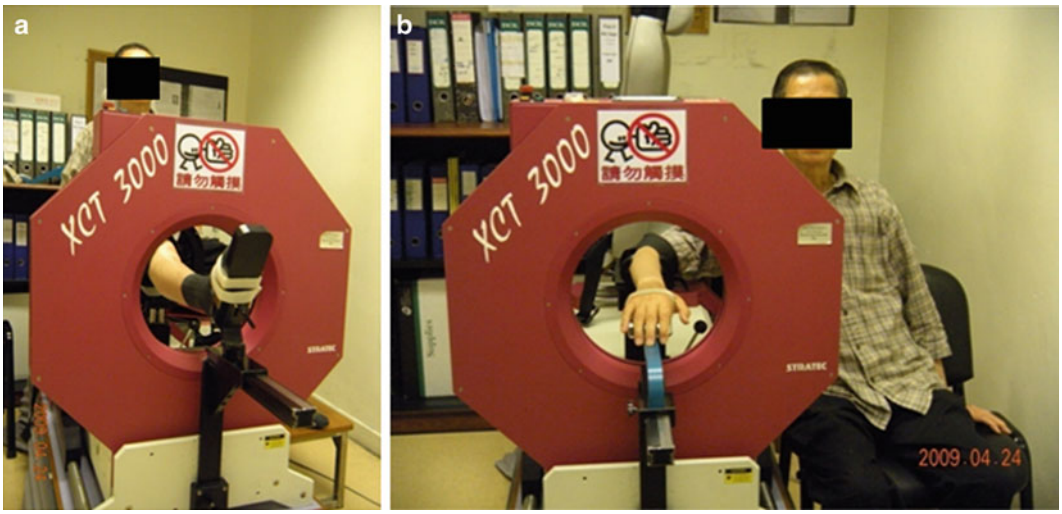

Fig. 130.6 Bone scanning using peripheral quantitative computed tomography (pQCT). (**a**) A stroke patient is undergoing pQCT scanning of the tibia. (**b**) The same individual is undergoing scanning of the radius

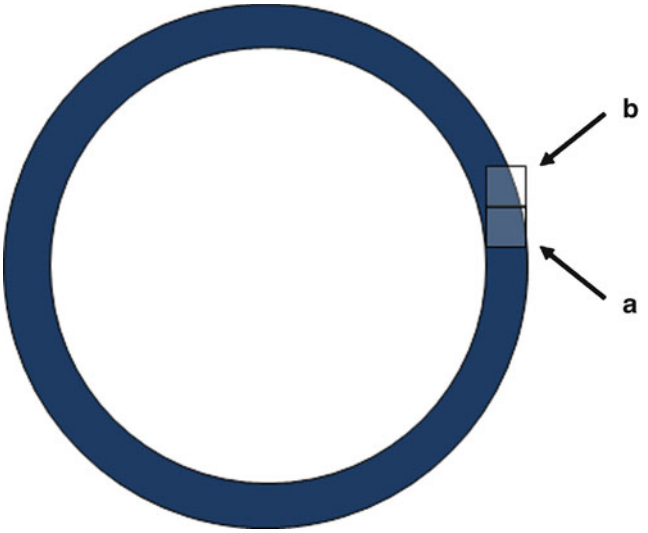

Fig. 130.7 Illustration of the partial volume effect. When a low resolution is used and the cortical shell is thin (<2 mm), the partial volume effect may occur. Voxel (**a**) contains mostly bone material, and the computed bone mineral density value is thus an accurate reflection of the true density of the bone material contained within the voxel. However, a substantial proportion of the area covered by voxel (**b**) contains non-bone material. Thus, the calculated bone mineral density value will be much lower than the true density of the bone material contained within the voxel. If a large number of voxels behave similarly to voxel (**b**), then the bone mineral density may be grossly underestimated

For the tibia, the 30%, 38%, and 50% sites have been used in previous studies (Uusi-Rasi et al. 2002; Lauretani et al. 2008; Pang et al. 2008).

As mentioned, a relatively fast scanning speed (e.g., 25 mm/s) may be used to keep the scanning time short to avoid movement artifacts, particularly among patients who are susceptible to involuntary movements or tremors, such as those with stroke (Ashe et al. 2006). However, this means that a lower-resolution/larger voxel size (e.g., 800 μm) has to be used to improve the signal-to-noise ratio (XCT 3000 Manual, Stratec 2007). With a lower image resolution, the accurate measurement of the cortical thickness at the distal sites of long bones can be difficult, particularly for bones with a thin cortical shell (<2 mm), as observed among patients with osteoporosis (Hangartner et al. 1996). The combination of a lower resolution and thin cortical bone shell may also lead to the "partial volume effect," which occurs when there is heterogeneous material within a single voxel. In areas where cortical bone is thin, the voxels are only partially filled by bone material. These partially filled voxels will yield falsely lower densities because of the surrounding soft tissues, which have significantly lower densities (Hangartner et al. 1996; Leonard and Shore 2003) (Fig. 130.7). Recently, a high-resolution pQCT system has become available that is capable of measuring bone parameters at high resolutions of up to 80 μm (Boutroy et al. 2006).

130.5 Geometric Changes in the Tibia After Stroke

As yet, no prospective studies have been conducted to examine the specific changes in bone geometry that occur after stroke. Alterations in the geometric properties of bone post stroke are generally inferred by comparing the differences between the paretic and non-paretic sides among stroke survivors. However, these comparisons do not reveal temporal changes in bone geometry as recovery progresses.

Table 130.3 Peripheral quantitative computed tomography (pQCT) parameters at the 30% tibial site (Reproduced from J. Bone. Miner. Res. 2008; 23; 1023–1030 with the permission of the American Society for Bone and Mineral Research)

A negative % difference denotes a lower value on the non-paretic than the paretic side
*indicates a significant difference between the paretic and non-paretic sides ($P < 0.05$)
†A positive % difference denotes a higher value on the non-paretic than the paretic side
‡Indicates a significant difference between men and women ($p < 0.05$)

Further, it is possible that the affected and unaffected extremities may undergo different changes in bone geometry after the onset of stroke.

The tibia, a major weight-bearing bone in the lower extremity, may undergo substantial geometric changes after stroke. In a study of Pang et al (2008), 55 individuals with chronic stroke underwent pQCT scans of the diaphyseal site (30% site, mostly cortical bone) of the tibia. Both male and female stroke subjects had a significantly lower cortical bone mineral content and smaller cortical area on the paretic than the non-paretic side, indicating a loss of bone mineral (Table 130.3). Other geometric changes seemed to be gender specific. In men, the marrow cavity area was significantly larger on the paretic side, with no significant difference between sides in the total cross-sectional area (Fig. 130.8a). By contrast, in women, the total area on the paretic side was significantly smaller than that on the non-paretic side, but no significant difference in the marrow cavity area was identified between sides (Fig. 130.8b). These findings indicate that, in male stroke survivors, endosteal resorption may occur, whereas in women, periosteal resorption may predominate. Losing bone from the periosteal surface compromises bone strength more than does endosteal resorption, as it reduces the total cross-sectional area and area moment of inertia. The reasons for such gender-specific differences in bone geometry after stroke are currently unknown. It is possible that lifestyle factors, genetics, and endogenous sex hormones may play a role (Pang et al. 2008).

At the tibia epiphysis (4% site, mostly trabecular bone), the bone changes are different. Based on a sample of 45 individuals with chronic stroke, Pang et al. (2010) found that although there was a significantly lower trabecular BMD on the paretic side, there was no significant difference in the total cross-sectional area. However, despite the apparent preservation of the total cross-sectional area, the lower trabecular BMD on the paretic side contributed to a lower compressive bone strength index (BSIc) than that on the non-paretic side.

Researchers have also attempted to identify the correlates of the bone geometry of the tibia. It has been demonstrated that cardiovascular function and muscle atrophy/weakness are independently associated with the estimated bone strength of the tibia measured at both the epiphyseal and diaphyseal sites in stroke patients (Pang et al. 2008, 2010). These findings indicate the possibility that tibial

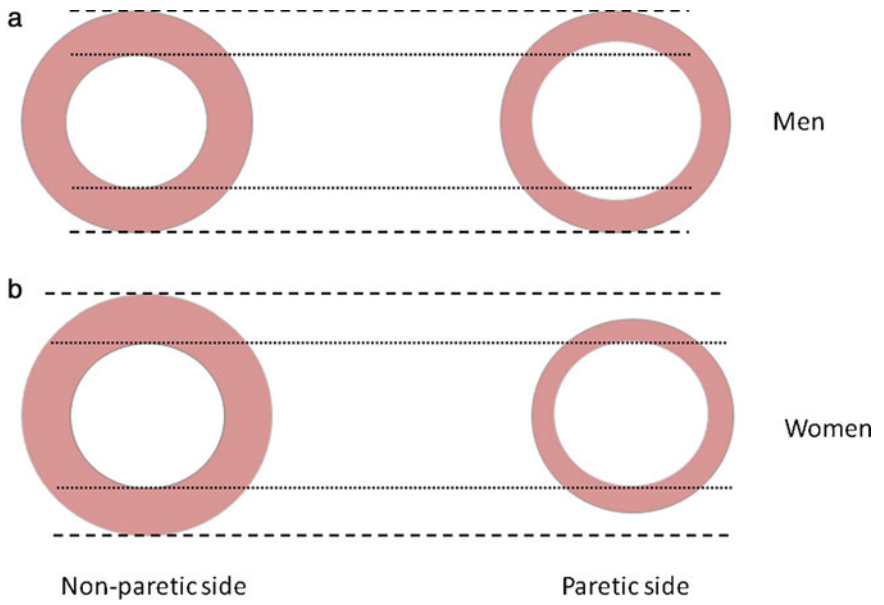

Fig. 130.8 Geometric properties of the tibia measured at the 30% (cortical) site in chronic stroke patients. (**a**) In men, the cortical shell is significantly thinner on the paretic than the non-paretic side. However, there is no significant difference in the total cross-sectional area between the two sides. This suggests that endosteal resorption may have occurred in the tibia on the paretic side (Pang et al. 2008). (**b**) In women, the cortical shell is significantly thinner on the paretic than the non-paretic side. However, the total cross-sectional area is also significantly smaller on the paretic side. This suggests that periosteal resorption may have occurred in the tibia on the paretic side (Pang et al. 2008) (Illustration adapted from Pang 2010)

bone geometry could be enhanced by improvement in cardiovascular fitness, muscle strength, mobility, and spasticity levels, but further investigation is required.

130.6 Geometric Changes in the Radius After Stroke

Only two studies have examined the geometric properties of the radius among stroke patients. Ashe et al. (2006) conducted a small study of 15 chronic stroke patients, all of whom had substantial muscle weakness in the affected upper extremity. Using pQCT, it was found that, at the diaphyseal site of the radius (30% of bone length as measured from the distal end of the radius; mostly cortical bone), the paretic side had a significantly lower cortical bone mineral content and cortical BMD than the non-paretic side by 8% and 3%, respectively, indicating possible secondary bone loss on the paretic side post-stroke. Interestingly, there was no difference in the total bone cross-sectional area between sides, indicating that bone material on the periosteal surface of the hemiparetic radius may be spared (Ashe et al. 2006).

Pang et al. (2007) conducted a larger study of 47 individuals with chronic stroke, all of whom underwent pQCT scanning of the same 30% site of the radius (Pang et al. 2007). Similar to the findings of Ashe et al. (2006), significantly lower cortical bone mineral content (8%) and cortical BMD (2%) were found on the paretic side compared with the non-paretic side. A more interesting finding is that there was no significant difference in the total cross-sectional area between the paretic and non-paretic sides, whereas the cortical bone area and cortical thickness values were significantly lower on the paretic side (Table 130.4). This indicates that bone loss occurred primarily on

[a] Paired *t*-test to compare the paretic and non-paretic sides

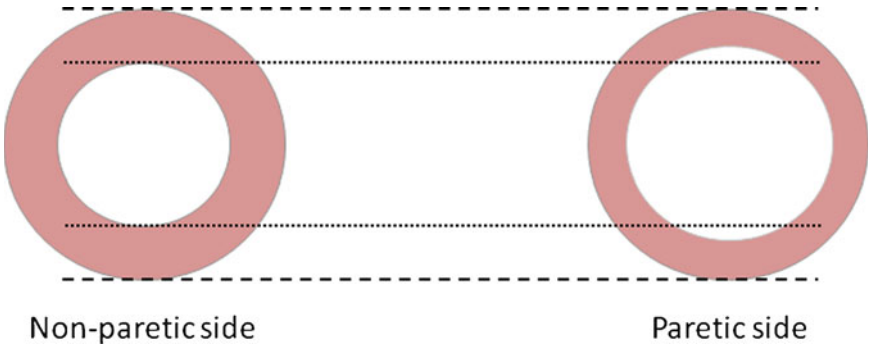

Fig. 130.9 Geometric properties of the radius measured at the 30% (cortical) site in chronic stroke patients. This diagram shows a cross-sectional view of the midshaft site (30% site) on both sides of the radius. The shaded area represents the cortical bone shell. The cortical bone area and cortical thickness are significantly reduced on the paretic side as compared with the non-paretic side, but there is no difference in the total cross-sectional area between the two sides. This suggests that endosteal resorption may have occurred in the radius on the paretic side (Pang et al. 2007) (Illustration adapted from Pang 2010)

the endosteal surface (i.e., there was endosteal resorption) of the hemiparetic radius (Fig. 130.9). Despite the relative preservation of bone on the periosteal surface, the overall decrease in cortical thickness due to endosteal resorption contributed to the significantly lower SSI on the paretic side (Pang et al. 2007).

Studying the bone geometry of the distal epiphysis of the radius is particularly relevant, as this is a common site of wrist fracture and the second most common site of fracture among stroke patients (Dennis et al. 2002). Ashe et al. (2006) found a trend toward a lower trabecular BMD on the paretic side at the epiphyseal site of the radius (at 4% of the total bone length as measured from the distal end), suggesting possible loss of trabecular elements. Similar to the findings for the cortical bone

Table 130.5 Key differences in the bone geometry of the tibia and radius at the cortical sites

Mid-shaft of the tibia on the paretic side (compared with the non-paretic side)	
Men	Women
Smaller cortical bone area	Smaller cortical bone area
Larger marrow cavity area	Similar marrow cavity area
Thinner cortical shell	Thinner cortical shell
Similar total cross-sectional area	Smaller total cross-sectional area
Lower estimated compressive bone strength	Lower estimated compressive bone strength
Mid-shaft of the radius on the paretic side (compared with the non-paretic side)	
Smaller cortical bone area	
Thinner cortical shell	
Similar total cross-sectional area	
Lower estimated torsional bone strength	

This table summarizes the main differences in bone geometry at the cortical sites of the tibia and radius between the paretic and non-paretic sides in chronic stroke survivors. The findings are based on the studies of Ashe et al. (2006), Pang et al. (2007), and Pang et al. (2008)

site, no difference was found in the total cross-sectional area between the paretic and non-paretic sides. However, further study is required to fully determine the changes in the geometric properties at the epiphyseal site of the radius after stroke (Table 130.5).

There is also evidence that the geometric properties of the radius are associated with the severity of stroke impairment. Pang et al. (2007) showed that a greater difference in cortical thickness at the 30% radial site between the affected and unaffected sides was correlated with poorer functional recovery of the upper extremity, more severe spasticity, greater disuse, and greater deficits in muscle strength (Pang et al. 2007). It would be interesting to determine whether modifying these factors through various means (e.g., upper extremity muscle strengthening or functional training, anti-spastic agents) could improve the bone geometry of the radius and thus reduce the risk of wrist fracture among the stroke population.

130.7 Applications to Other Health Areas and Disease Groups

As mentioned, alterations to bone geometry can affect fracture risk. Thus, measuring bone geometry is an important aspect in the study of bone health. pQCT provides a safe way to evaluate the geometric properties of bone, and has been used among healthy subjects of various age groups, including children (McDonald et al. 2006) and the elderly (Riggs et al. 2004; Lauretani et al. 2008). The evaluation of bone geometry is particularly applicable among certain disease groups in which bone health and fracture risk are of major concern. For example, patients living with chronic conditions may benefit from the measurement of bone geometry, as these individuals are often subject to an elevated risk of falls or fractures because of factors, such as secondary bone loss, muscle atrophy, cardiovascular deconditioning, visual impairment, and depression. In addition to stroke, bone geometry has been studied among patients with other chronic conditions, such as spinal cord injury (Eser et al. 2004) and arthritis (Burnham et al. 2008). Using pQCT to evaluate bone geometry may also be of value for those with chronic diseases, such as Parkinson's disease, which is known to be associated with compromised BMD and an elevated fracture risk (Di Monaco et al. 2006). It may also be worth evaluating the bone geometry of individuals at risk of glucocorticoid-induced osteoporosis, as observed among some patients with chronic obstructive pulmonary disease (Nuti et al. 2009).

130.8 Conclusion

In summary, among chronic stroke survivors, the radius and tibia have significantly different geometric properties on the affected side as compared with the unaffected side, leading to reduced bone strength and hence increased fracture risk. The stroke-related alterations in radial and tibial bone geometry are drastically different from those observed to result from general aging (i.e., endosteal resorption with concomitant periosteal apposition) (Riggs et al. 2004; Lauretani et al. 2008). There is therefore a need for longitudinal studies that examine the temporal changes in bone geometry after the onset of stroke and their determinants. Such information could be instrumental in the development of effective interventions to improve bone geometry and reduce fracture risk in this vulnerable population.

Summary Points

- Bone geometry plays an important role in bone strength.
- Peripheral quantitative computed tomography (pQCT) can be used to measure cross-sectional long-bone geometry.
- There is a significant difference in radial and tibial geometry between the affected and non-affected sides in stroke survivors.
- Endosteal resorption may predominate in the radial diaphysis on the hemiparetic side.
- In men, endosteal resorption may predominate in the tibial diaphysis on the hemiparetic side.
- In women, periosteal resorption may predominate in the tibial diaphysis on the hemiparetic side.
- Both the radius and tibia on the affected side demonstrate a lower estimated bone strength than on the unaffected side in stroke survivors.
