Chapter 40
Mid-Upper Arm Anthropometric Measurements as a Mortality Predictor for Community-Dwelling Dependent Elderly

Masafumi Kuzuya and Hiromi Enoki

Abstract It remains controversial whether mid-arm anthropometric measurements are reflected with physical impairment or useful predictors of mortality in the elderly. The inconsistency in terms of the relationship between mid-arm anthropometric measurements and physical function and mortality may be due to the difference in study population, i.e., a healthy younger population vs frail/dependent older people. In this article we overviewed the relationships between mid-arm anthropometric measurements and mortality of elderly based on our studies and previous reports targeting older people. Our cohort study, which was composed of cross-sectional and prospective cohort analyses of 957 community-dwelling dependent elderly, demonstrated that significant higher average triceps skinfold (TSF) levels were observed in participants, compared with age-matched (5-year intervals) those of the standard Japanese population. In contrast, the average arm muscle area (AMA) levels at 5-year intervals were significantly lower than the Japanese norm. The AMA levels of the study participants were correlated with activities of daily living (ADL) score after adjusting for gender and age. Whereas TSF levels were not correlated with ADL function after adjusting for gender, age among study participants. Survival analysis of 2-years mortality was conducted using multivariate Cox proportional hazards models. AMA, TSF, and mid-arm circumference (MAC) were independent risk factors for 2-years mortality in the participants. In conclusion among community-dwelling dependent elderly, mid-arm anthropometric measurements were independent predictors of 2-years mortality.

40.1 Introduction

Anthropometric indices of weight, height, body mass index (BMI), skinfold thickness, muscle area, and circumference are simple, easily obtainable, and inexpensive measures of assessing nutritional status. Among them, BMI, the most widely used anthropometric index, has been frequently used as an indicator of nutritional status, and is well known as an important predictor of mortality and activities of daily living (ADL) decline among older people (Liu et al. 2002; Flodin et al. 2000). However, it is not uncommon to find dependent older people who cannot be weighed or measured for height. When subjects living at home have severe functional disabilities, it is essential to have special equipment, such as beds or wheelchair scales, to measure their weight. Frequently, it is difficult to measure the height of older people with postural changes, including muscle and arterial contracture and kyphosis. In fact, we have previously shown in a cohort study of community dwelling dependent elderly that 35.9% and 30.7% had missing data for height and weight, respectively (Izawa et al. 2007).

In addition, measuring height reliably in older individuals is one of the most problematic areas of anthropometry. In old age, there is a decline in sitting and standing height due to vertebral compression, change in the height and shape of vertebral disks, loss of muscle tone, and postural changes. When these height measurements are used in the calculation of BMI, it will tend to be artificially inflated. In addition, it can be difficult to measure the standing height of older people with ADL impairment (Hickson and Frost 2003; Zang et al. 1998).

Anthropometric measurements of the mid-upper arm are often taken for measuring body composition, because they are a quick, inexpensive, and non-invasive method of measuring nutritional status. Triceps skinfold (TSF) thickness reflects subcutaneous fat, whereas mid-upper-arm circumference (MAC) takes into account the humeral diameter as well as the skeletal muscles, and fat covering the limb, therefore reflecting changes in lean body mass and fat. Mid-upper-arm muscular circumference and arm muscle area (AMA), which are derived from MAC and TSF, are also useful indicators of muscle mass.

Although these mid-arm anthropometric measurements may be useful indicators of undernutrition in older adults, it remains controversial whether these measurements are useful predictors of mortality in the elderly or whether physical impairment reflects these measurements in the older population. In this article, we overview the mid-arm anthropometric measurements as a predictor of mortality among older people and their relationships with physical functions.

40.2 Mid-Arm Anthropometric Measurements and Mortality of Elderly-Brief Review

In the general population, it has been believed that low muscle mass and high fat mass are associated with higher mortality (Janssen et al. 2002). In fact, Miller and colleagues demonstrated that among 1,396 community dwelling Australian participants aged 70 years and older, those with a low corrected AMA ($\leq$21.4 cm^2 for men and $\leq$21.6 cm^2 for women) had an increased risk of mortality at 8-year

follow-up. (Miller et al. 2002), whereas no increased risk in 8-year mortality was identified for those with a high or low BMI (Miller et al. 2002). Another study reported that, in a geriatric assessment unit, it was found that an abnormally low AMA (lower than the fifth percentage of age-matched reference data) is strongly associated with increased mortality at 4.5-year follow-up (Muhlethaler et al. 1995). In contrast, over 24 years of follow-up study of random samples of participants aged 65 years and over living in the community revealed that higher AMA was associated with a significantly reduced risk of mortality from all causes only in men, and not in women (Gale et al. 2007).

The relationship between TSF thickness and mortality in the elderly remains controversial. It has been reported that among 408 elderly long-term-care residents aged 60 years and older, TSF was a significant predictor of mortality during 19 months' follow-up in the univariate analysis, but not in the multivariate analysis (Allard et al. 2004). TSF thickness did not show a statistically significant association, with 4.5-year mortality among 219 geriatric patients in a geriatric assessment unit (Muhlethaler et al. 1995). It has been observed that TSF thickness below the 5th percentile was associated with a significant increase in the relative risk of death during 40–46 months' follow-up in a community sample of 758 older people (Campbell et al. 1990).

Another study showed that, during admission in an acute care geriatric ward, MAC had a more negative trend in patients who died than changes in weight, BMI, and subjective nutritional assessment (Antonelli Incalzi et al. 1996).

40.3 Japanese Cohort Study

40.3.1 Study Design and Aim

We examined whether anthropometric measurements of mid-upper arm may be a good predictor of mortality among disabled community-dwelling older people (Enoki et al. 2007). In the present study targeting dependent community dwelling elderly persons, using the baseline and 2-year follow-up data of the Nagoya Longitudinal Study of Frail Elderly (NLS-FE), the following hypotheses were tested: (1) in community-dwelling elderly persons, who are disabled or dependent and receiving some assistances using the long-term care insurance (LTCI) program, MAC, TSF, and AMA levels are lower than those of not-frail, independent elderly persons living in the community; (2) these lower levels of measurements are associated with physical function impairment and comorbidity status; and (3) lower levels of MAC, TSF, or AMA are independent predictors of relative short-term (2-year) mortality.

40.3.2 Study Participants

This analysis was conducted using a total of 957 subjects (men, 355; women, 602) extracted from the NLS-FE data set. The study population of NLS-FE consisted of 1,875 (men, 632; women, 1,243) community-dwelling elderly (aged 65 years or older) eligible for the LTCI, who lived in Nagoya city (Central Japan) and were provided various home care services from the Nagoya City Health Care Service Foundation for Older People, which is comprised of 17 visiting nursing stations accompanying care-managing centers (Kuzuya et al. 2006, 2008). The LTCI system provides care for the

elderly aged 65 years and older. Under the LTCI program, care levels (levels 0–5) are determined according to eligibility criteria (Izawa et al. 2006). The elderly in the community, who are eligible for LTCI, are disabled and chronically ill, have physical and mental problems, and easy to admit to the acute hospital or institute care setting. A total of 957 (men, 355; women, 602) using visiting nurse services under LTCI were enrolled for the anthropometric measurements.

40.3.3 Data Collection

Anthropometric measurements were conducted by trained nurses at the clients' home. Measurement of TSF (to the nearest 2 mm) was made using caliper and MAC (to the nearest 0.1 cm) using a flexible measuring tape, on the right side of the participant's body, unless affected by disability or disease. These measurements were taken at least twice, by one trained nurse, according to the instruction sheet, and reported values were the means of the repeated measurements. Arm muscle circumference (AMC = MAC (cm) – $\pi \times$ TSF (mm)/10) and AMA were calculated using a standard formula: AMA cm^2 = (AMC (cm))$^2/4\pi$. BMI was defined as weight in kilogram divided by height squared.

The mean scores of anthropometric measurements of patients grouped by age and gender were compared with the JARD 2001, anthropometric norms for healthy men and women without physical function impairment in each 5-year age bracket, including subjects over age 65 years (Japanese Anthropometric Reference Data 2002). In JARD 2001, a mean value, a central value, standard deviation, maximum value, minimum value, and percentile (5th, 10th, 25th, 75th, 90th, and 95th) were determined according to the age division. Therefore, it was possible to compare the obtained measurement values and these reference values.

40.3.4 Sample Description

Characteristics of subjects in the present study are given in Table 40.1. The mean (SD) age of 957 patients studied was 80.4 (7.9) years, with a range of 65–102 years. Among those, 318 patients (33.2% of total) were 85 years or older. Most were capable of oral food intake (91.5% of total). The physical function of the participants (basic ADL, score range: 0–20) was markedly impaired with a mean (SD) score of 10.3 (6.9). A history of cerebrovascular disease was the most frequent diagnosis observed in this cohort (334 patients, 34.9% of total).

40.3.5 Comparison of Anthropometry Between Study Participants and Japanese Norms

BMI is the anthropometric measurement most widely used for assessing nutrition status. However, it is often difficult for older people with impaired physical function to be measured for height and weight at their homes. In fact, in our cohort, BMI data were not available for 437 out of 957 participants, even though we asked visiting nurses and caregivers to measure weight and height as far as possible. It should be noted that there were no differences in BMI levels between the participants and Japanese norms for any age group in either gender (Enoki et al. 2007) (Tables 40.2 and 40.3).

JARD Japanese Anthropometric Reference Data

Anthropometric measurements of the mid-upper arm including TSF and MAC can be introduced easily in the community-dwelling elderly, as it is a quick, handy, inexpensive and non-invasive method. AMA, as an index for muscle mass, can easily be calculated from TSF and MAC. As shown in Table 40.2, the MAC levels of male participants of the 75–84 years age group were significantly lower than the Japanese norm. In female participants, MAC levels in the 80–84 years and 85 years and older age groups were lower than the Japanese norms (Table 40.3). There were significantly higher TSF levels in male participants of all age groups except for 70–74 years and higher TSF levels in female participants of the 75–79 years and 85 years and older age groups, compared with Japanese norms. The AMA of male participants was significantly lower than the Japanese norm in all age groups. In female participants, lower AMA levels were observed in the 75–79 years, 80–84 years, and 85 years and older age groups. We observed that AMA or TSF levels were lower and higher, respectively, in participants of NLS-FE than those of the standard Japanese population. The lack of differences in BMI levels for each 5-year-interval, gendered age group between our cohorts with some disabilities and the Japanese norm suggested that though there were clear differences in body composition between Japanese subjects with or without physical impairment, total body mass did not reflect those differences.

40.3.6 Anthropometry and ADL

The correlation between anthropometric measurements and ADL function was evaluated using the partial rank correlation coefficients, after adjusting for gender and age. ADL score was significantly correlated with BMI (correlation coefficient (r) = 0.191, $p < 0.01$), MAC ($r = 0.288$, $p < 0.01$), and AMA ($r = 0.298$, $p < 0.01$), but not with TSF ($r = 0.019$, $p = 0.749$). It has been reported in cross-sectional observations that physical disability is associated with increases in percentage body fat as well as a decrease of fat-free mass (Liou et al. 2005; Broadwin et al. 2001; Davison et al. 2002). In cross-sectional analyses from the Rancho Bernardo Cohort Study,

a significant positive association was shown between fat mass, which was estimated by bioelectric impedance analysis, and overall functional disability, and a significant negative association was shown between fat-free mass and overall functional disability in both men and women (Broadwin et al. 2001). In agreement with these previous findings, we demonstrated that AMA levels in the study participants were lower than Japanese norms and that AMA levels of the study participants were correlated with ADL score after adjusting for gender and age (i.e., lower AMA levels with lower ADL function). Although recent observation suggested that lower extremity muscle mass is a strong independent predictor of the level of functional impairment in community-dwelling older adults (Reid et al. 2008), our results may also suggest that not only leg muscle mass but also arm muscle mass is an important determinant of physical performance among functionally limited elders.

Our study results were also consistent with previous findings of higher TSF levels in the study participants than those in Japanese subjects without impairment of physical function. However, we observed that TSF levels were not correlated with ADL function after adjusting for gender and age among study participants. When analysis was conducted after adjustment for BMI, ADL score was still correlated with AMA ($r = 0.151$, $p = 0.001$), but not with TSF ($r = -0.081$, $p = 0.072$). These results indicated that TSF levels are influenced by other factors, such as nutritional status, besides only the level of physical function, at least among our participants with ADL disabilities.

40.3.7 Anthropometry of Mid-Arm and 2-Year Mortality

Among the 957 participants, 236 died during the 2-year follow-up period. Tables 40.4 and 40.5 show the univariate and multivariate Cox proportional hazards regression models to identify independent predictors of 2-year mortality. The following baseline data were used in a Cox proportional hazards model to identify independent predictors of 2-year mortality: age, gender, ADL status, comorbidity status, and levels of MAC, TSF, and AMA. The risk of a variable was expressed as a hazard ratio (HR) with a corresponding 95% confidence interval (CI). For the analysis, age was categorized into three groups: 65–74 years, 75–84 years, and 85 years or older. The ADL score (range: 0–20) and the Charlson comorbidity index score, which represents the sum of a weighted index that takes into account the number and seriousness of preexisting comorbid conditions, were categorized into three groups with approximately equal numbers of participants in each group: ADL, high function, ≥18; mild function, 12–17, and low function, ≤11; the Charlson comorbidity index score, <2, 2–3, ≥4. AMA (cm^2) was categorized into three groups by tertile: high, ≥33.4; mild, 23.5–33.3; and low, <23.5. TSF (mm) was categorized into three groups by tertile: high, ≥17; mild, 10–16; and low, <10. MAC (cm) was also categorized into three groups by tertile: high, ≥25.2; mild, 24.5–25.1; and low, <24.5 (Tables 40.4 and 40.5).

Unadjusted univariate analysis suggested that the oldest age category (≥85 years), low ADL function, ≥4 Charlson comorbidity index score, <10 mm TSF thickness, <23.5 cm^2 AMA, and <24.5 cm MAC were associated with 2-year mortality (Tables 40.4 and 40.5). A multivariate Cox proportional hazards regression model based on the all the variables used in univariate analysis showed that low TSF(<10 mm) and low AMA (<23.5 cm^2) were associated with 2-year mortality (Table 40.4). In addition, when MAC was used instead of TSF and AMA, it (mild: 24.5–25.1 cm and low: <24.5 cm) was associated with mortality (Table 40.5) with higher hazard ratio than that of TSF or AMA.

In the general population, it has been demonstrated that fat-free mass and TSF, an indicator of fat mass, have clear negative and positive relationships, respectively, with mortality (lower fat-free mass and higher TSF with higher mortality) (Zhu et al. 2003; Allison et al. 2002). Consistent with those

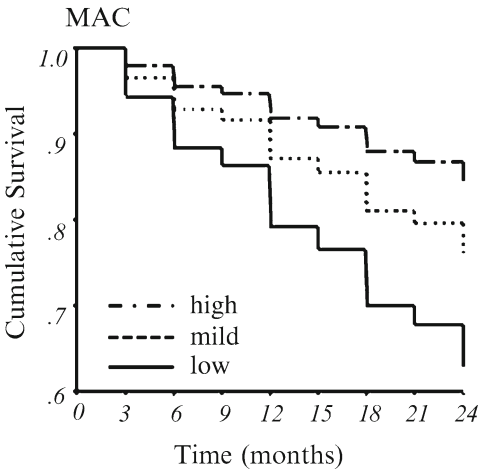

Fig. 40.1 Kaplan–Meier survival curves for elderly subjects with various levels of MAC (cm). MAC (cm) levels were classified as low (<24.5), mild (24.5–251), and high (25.2≤). Survival curves were plotted using the Kaplan–Meier method, adjusting for age, gender, ADL status, and Charlson comorbidity index

findings, a number of studies have demonstrated that AMA or AMC, another indicator of muscle mass, is a predictor of mortality in older people (Miller et al. 2002; Muhlethaler et al. 1995). As described above, controversial results have been reported in terms of the relationships between TSF and mortality in older people. Our prospective observation demonstrated that lower TSF was an independent predictor of 2-year mortality among community-dwelling dependent older people, even after adjusting for possible confounding factors. The inconsistency between our study and previous studies targeting the general population in terms of the relationship between TSF and mortality may be due to the difference in study population, that is, a healthy younger population versus frail older people with some disabilities. A higher TSF seems to reflect obesity and hyperalimentation in the general population, but in our frail elderly participants, a lower TSF seems to reflect undernutrition. However, it may be possible that cultural differences between Japan and other Western countries may affect this inconsistency. Recently, a study demonstrated that fat mass index, measured with a gold standard technique (X-ray absorptiometry) and bioelectrical impedance analysis, is a predictive marker of morbidity and mortality in hospitalized elderly patients (Bouillanne et al. 2009), suggesting that, at least among vulnerable older people, fat mass including TSF has protective role on adverse outcomes of the elderly.

We also observed that MAC was a better predictor of 2-year mortality among community dwelling dependent older people compared with AMA or TSF. This result is not surprising. Because MAC takes into account the humeral diameter as well as the skeletal muscles and fat covering the limb, therefore reflecting both TSF and AMA.

40.3.8 Kaplan–Meier Survival Curves

Figures 40.1 and 40.2 show the multivariate-adjusted Kaplan–Meier survival curves exploring the association between MAC, TSF, or AMA categories and time to death (3-month interval). The lowest category of MAC (<24.5 cm), TSF (<10 mm), and AMA (<23.5 cm^2) showed an increased risk of death during the 2-year follow-up compared with the middle and highest categories (Figs. 40.1 and 40.2a, b).

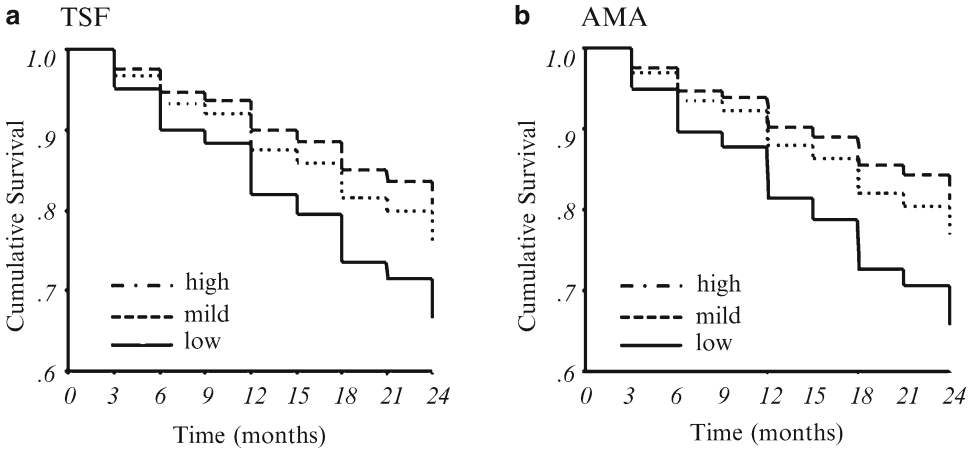

Fig. 40.2 Kaplan–Meier survival curves for elderly subjects with various levels of TSF (A) and AMA (cm^2) (**b**). (**a**) TSF (mm) levels were classified as low (<10), mild (10–16), and high (17≤). (**b**) AMA (cm^2) levels were classified as low (<23.5), mild (23.5–33.3), and high (33.4≤). Survival curves were plotted using the Kaplan–Meier method, adjusting for age, gender, ADL status, and Charlson comorbidity index (Reprinted from Enoki et al. (2007). With permission from Elsevier)

40.3.9 Combined Evaluation of AMA and TSF

We further characterized study participants using a nine-level measurement that combined AMA levels and TSF levels. Within each level of TSF, risk of mortality rose as levels of AMA decreased. Within each level of AMA, risk of mortality rose as TSF decreased. A striking increase in the risk of 2-year mortality, adjusted for age and gender, was observed in the low TSF with low AMA group (HR: 3.83, 95% CI: 1.97–7.47), versus the high TSF with high AMA (Fig. 40.3). These findings indicate that a combined evaluation of AMA and TSF strengthens the prediction of relative short-term mortality among community-dwelling dependent older people (Fig. 40.3).

40.3.10 Limitations

The current study had several limitations. NLS-FE is a large-scale observational study but does not include the complete spectrum of elderly patients in the Nagoya area, an urban area. In the analysis, baseline data of the anthropometric measurements were included, but changes in the measurements during the follow-up period were not considered. Although recent study suggested that muscle strength is more powerful predictor of mortality than muscle mass (Newman et al. 2006), data of muscle strength were not available in our study. Another limitation is that we enlisted each station to perform evaluation because of a shortage of hands and the large number of settings. This may have biased assessors' evaluations and limited the validity of the results. The results of the present study cannot transfer to the non-frail independent older population, as there should be many differences between the participants of NLS-FE and the standard non-frail older, including ADL levels and comorbidity. In addition, these findings may not be generalizable to other populations given that they may have been influenced by cultural differences, health practices, and a variety of social and economic factors.

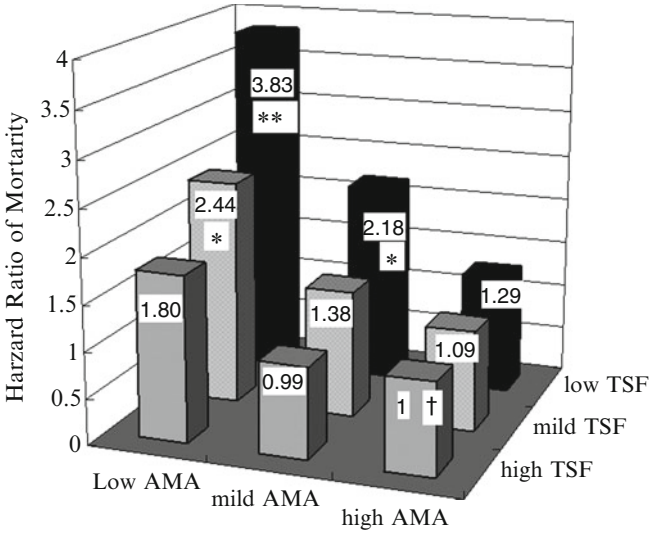

Fig. 40.3 Relative risks for all-cause mortality. Estimations were obtained from Cox regression models adjusting for age and gender. Eight independent variables, created for each level of AMA (low: <23.5 cm^2, mild: 23.5–33.3 cm^2, high: 33.4 cm^2≤) and TSF (low: <10 mm, mild 10–16 mm, high: 17 mm ≤) combined, were used as indicator variables and compared with the reference group (defined as those with high AMA and high TSF). Number on each bar indicates hazard ratio. *: $p < 0.05$, **: $p < 0.01$, †: reference group (Reprinted from Enoki et al. (2007). With permission from Elsevier)

40.4 Conclusion

Anthropometric measurements of the mid-upper arm are performed often in research, but rarely on a clinical basis, even although they are a quick, inexpensive, and non-invasive way of measuring nutritional status. In the present study, we demonstrated a striking picture of increased mortality risk associated with lower AMA levels, lower TSF, and lower MAC. Anthropometric measurements of the mid-arm may be a more practical and suitable index not only for nutritional assessment but also for capturing the vulnerable subset of older people living in the community.

40.4.1 Applications to Other Areas of Health and Disease

In the text, we focused on older people in terms of the mid-upper arm anthropometric measurements as nutritional markers and indicators of mortality risk. However, numbers of researches are using upper arm measurements as nutritional as well as growth markers for the children. The World Health Organization (WHO) introduced the Child Growth Standards, which included MAC and TSF, for assessing the growth and development of children, (WHO Multicentre Growth Reference Study Group 2006). In addition, upper arm measurements were also established as an indicator of mortality risk for children (Lapidus et al. 2009).

Summary Points

- Higher average triceps skinfold (TSF) levels were observed in community-dwelling dependent elderly, compared with age-matched (5-year intervals) individuals of the standard Japanese population.
- Lower average arm muscle area (AMA) levels were observed in community-dwelling dependent elderly, compared with age-matched (5-year intervals) individuals of the standard Japanese population.
- AMA levels of community-dwelling dependent elderly were correlated with their physical function.
- TSF levels of community-dwelling dependent elderly were not correlated with their physical function.
- Lower AMA levels of community-dwelling dependent elderly were associated with 2-year mortality.
- Lower TSF levels of community-dwelling dependent elderly were associated with 2-year mortality.
- Lower mid-arm circumference (MAC) levels of community-dwelling dependent elderly were associated with 2-year mortality.

Chapter 41
The Arm Span to Height Relationship and Its Health Implications

Maw Pin Tan and Sushil K. Bansal

Abstract The Roman architect, Vitruvius, had noted in the first century BC that the arm span closely approximated to height. This relationship has been exploited by medical science by using arm span to estimate height in situations where height measurement is not possible. This can be done by directly substituting height with arm span, a fixed ratio, or specific regression equations. It has also been noted that height decreases with increasing age due to physiological changes, degenerative changes and osteoporosis, while the arm span remains unchanged. The arm span–height difference (AHD) or arm span to height ratio (AHR) can therefore be used as a marker for age-related loss of height. Several studies have also investigated AHD as a predictor for osteoporosis-related vertebral fracture, due to the association of vertebral fractures with height loss. These studies have however yielded conflicting results, probably due to the lack of an agreed definition for vertebral fractures. A recent study demonstrated that AHR is inversely correlated with lung airflow volumes measured with spirometry, and directly correlated with severity of shortness of breath. By using AHR as a quantitative index for loss of height, the authors were able to demonstrate that loss of height is associated with breathing difficulties. The reduction in height with ageing may also result in underestimation of the severity of lung airflow problems and nutritional problems. Involving arm span measurements in the calculation of predicted lung airflow volumes and body mass index may potentially be the solution to overcoming this problem.

Abbreviations

AHD	Arm span to height difference
AHR	Arm span to height ratio
BMD	Bone mineral density
BMI	Body mass index
FEV1	Forced expiratory volume in 1 min
FVC	Forced vital capacity
NYHA	New York Heart Association

41.1 Introduction

Arm span is the closest physiological measurement to standing height. In the healthcare setting, the measurement of standing height is crucial in the estimation of nutritional status and in determining the severity of lung airflow limitations. Arm span is therefore sometimes substituted for standing height in clinical situations where the accurate measurement of standing height is not possible. In addition, the discrepancy between arm span and height measurements may also be a useful clinical marker for loss of height in relation to either physiological ageing or pathological processes. Over the past 2 decades, there has been some research activity into the validity and clinical implications of using the discrepancy between arm span and height in assessing loss of height, vertebral deformity and associated health implications.

41.2 Estimating Height with Arm Span

The relationship between arm span and height had been noticed by the Roman architect, Vitruvius, in first century BC, who stated that 'the distance from fingertip to fingertip (arm span) should be equal to the distance from head to heel (height)'. The Vitruvian theory has been most elegantly depicted by Leonardo da Vinci in his drawing of the 'Vitruvian Man'. Assessments of various other anthropometric measures, which include knee height, sitting height, and demispan indicate that arm span has the strongest correlation with standing height (Fig. 41.1). As a result, arm span is often used to estimate standing height in situations where measurements of standing height is not possible, such as in patients with difficulty standing due to neuromuscular weakness, amputees, congenital limb deformities and vertebral deformities. The methods employed for estimating height with arm span include:

1. Direct substitution of arm span for height
2. Correction with a fixed ratio and
3. Gender and ethnicity specific regression equations in increasing order of complexity and accuracy (Table 41.1).

The use of a correction factor for the estimated of height with arm span has been practiced for several decades due to reports by various studies involving predominantly Caucasian adult populations, that the mean arm span to height ratio for their population is 1.03 for men and 1.01 for women (Hepper et al. 1965). However, later studies observed progressive increases in mean arm span to height ratio with increasing age (Hepper et al. 1965; Linderholm and Lindgren 1978). The mean arm span to height ratio also appeared to differ according to ethnicity (Parker et al. 1996). This had lead to the development of specific regression equations in specific geographical areas, taking into account age, gender and ethnic differences. The accuracy of estimated height with regression equations have been consistently shown to be superior to the direct substitution of arm span for height. However, as arm span remains strongly correlated with height, the direct substitution of arm span for height may be acceptable in cultural groups for which regression equations are not available (Aggarwal et al. 1999). In the paediatric age group, there is much higher correlation between arm span and height ($r = 0.97$ for girls and $r = 0.98$ for boys), suggesting that direct substitution may actually be more applicable in children than adjustments with correction factors (Hibbert et al. 1988).

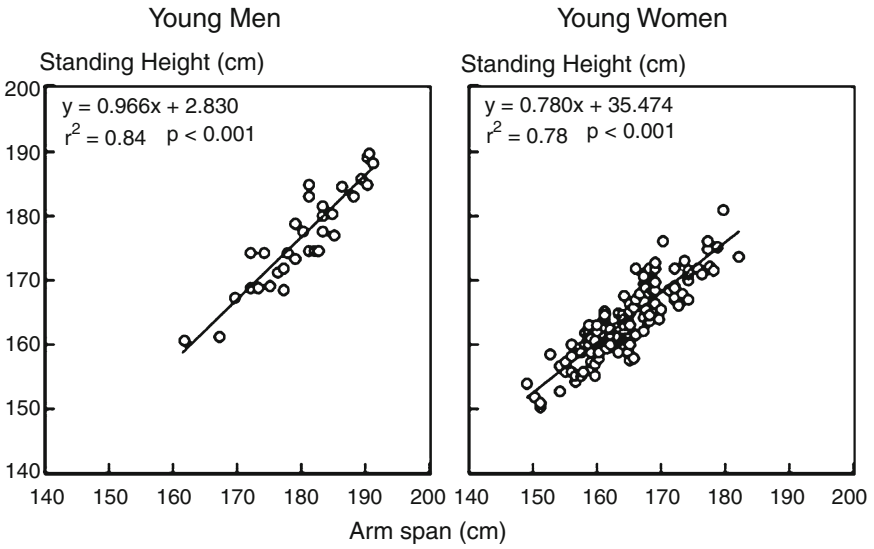

Fig. 41.1 The relationship between arm span and height. A scatterplot demonstrating the strong correlation between arm span and standing height measurements in younger men and women. (With kind permission from Springer Science + Business Media: Wang et al. (2004), Figure 2, © 2003 International Osteoporosis Foundation and the National Osteoporosis Foundation)

Table 41.1 Using arm span to estimate height

Method	Indications
1. Direct substitution of arm span for height	(a) Cultural groups for which no regression equations are available. (b) May be more applicable for children.
2. Calculation using a correction factor or fixed ratio (a) Women: Height = Arm Span/1.01 (b) Men: Height = Arm span/1.03	This method is widely used, but the correction factor has been determined in predominantly Caucasian adult populations and may not be applicable to children, the elderly as well as other ethnic groups and non-Western geographical areas.
3. Calculation using Predetermined Regression Equations (Parker et al. 1996) White males: Height (cm) = 68.7363 + 0.63008 Arm span −0.1010 Age White females: Height(cm) = 33.1453 + 0.79499 Arm span Black males: Height (cm) = 60.1273 + 0.65336 Arm span −0.08399 Black females: Height (cm) = 59.0745 + 0.61442 Arm span	Estimation of height using regression equations is dependent on the availability of gender- and ethnic group-specific regressions. Specific regression equations have not published for some ethnic and cultural groups.

Methods of estimating height with arm span. The methods currently used and available conversion equations are listed in the table above

41.3 Practical Methods and Techniques

41.3.1 Arm Span Measurements

Several methods of assessing arm span have been described. The three most commonly described methods are listed below (Fig. 41.2). The first method of measurement is the one most widely used in published studies and the method used in establishing the conversion equations described above.

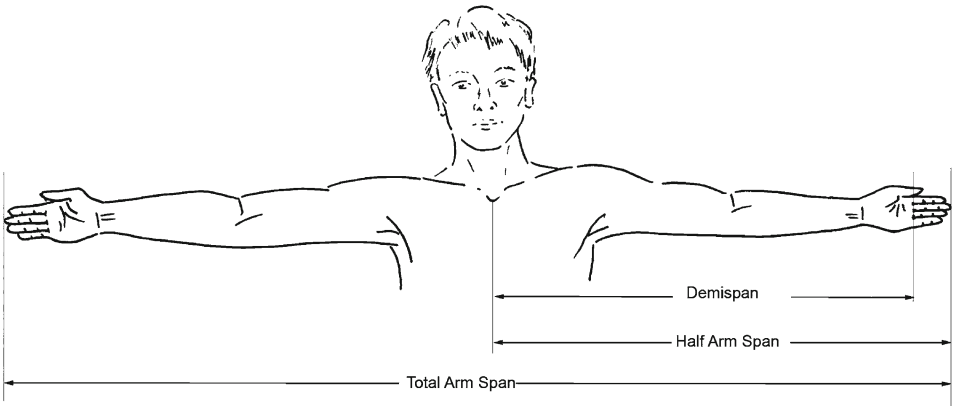

Fig. 41.2 Arm span measurements. The total arm span is considered the maximal distance between the two middle fingers. The half arm span is the maximal distance between the midpoint of the suprasternal notch to the tip of the middle finger. The demispan is the distance between the mid-suprasternal notch to the root of the middle finger

1. Total Arm Span: The maximal distance between the tips of the two middle fingers. The subject is upright with his or her back against the wall. The arms are fully abducted, with straight elbows, at 90° from the torso. Some publications have described a similar technique with the subject facing the wall. The measurement is made with a rigid extended calibrated rule, a flexible metal tape or an adapted stadiometer.
2. Half arm span: This technique is usually performed in the sitting or recumbent position. The distance between the sternal notch and the tip of the middle finger is measured with the arm outstretched at 90° to the body. The measurement is then multiplied by 2 to obtain the full arm span.
3. Demispan: This measurement is also performed usually in the sitting or lying position. It has the advantage of not being affected by subjects with finger deformities, which is particularly common in elderly subjects due to arthritic processes or contractures. It is, however, a less published method. The distance between the suprasternal notch and the root of the middle finger is measured. A height conversation equation for demispan has been devised by Bassey (Bassey 1986):

    - Females: Height (cm) = [1.35 × demispan (cm)] + 60.1
    - Males: Height (cm) = [1.40 × demispan (cm)] + 57.8

41.3.2 Measuring Loss of Height

Actual standing height could be affected by various congenital and acquired conditions, including ageing, congenital kyphoscoliosis, inflammatory arthritis, osteoarthritis and vertebral fractures due to osteoporosis. In individuals with the above conditions, while standing height is usually reduced, arm span may be unaffected. The discrepancy between arm span and height may therefore be a useful measure of the magnitude of height loss.

41.3.3 The Discrepancy Between Arm Span and Height

1. Arm span–height difference [arm span – height]: Most publications have adopted this simple way of calculating the difference between arm span and height. However, this index does not take into account differences in stature. It therefore does not account for the possibility that

taller people have proportionally longer arms and potentially larger differences between arm span and height.

2. Arm span to height ratio [arm span: height] – This index was adopted as a determinant of the discrepancy in arm span and height in a recent publication. It is a unitless measure derived by dividing the arm span in metres with height in metres. An increase in the arm span to height ratio (AHR) is observed with a reduction in height. Unlike arm span–height difference (AHD), AHR assesses the proportion of increase in arm span over height. The additional advantage of using this index is that the AHR has already been extensively studied historically, albeit only in mainly white populations. There are therefore published population norms for AHR, which could be used to determine the presence of loss of height (Hepper et al. 1965), but this practice has yet to be validated scientifically.

41.3.4 Arm Span, Height and Age

Loss of height is a feature of ageing. Data published from the Baltimore Longitudinal Study of Ageing reported a cumulative height loss of 5 cm for men and 8 cm for women, from age 30–80 years (Sorkin et al. 1999). A reduction in vertebral disc spaces, alterations in posture and increases in spinal curvature have been suggested as plausible causes for age-related height loss. The reduction in intervertebral space has been attributed to reduction in disc height as part of a degenerative process. An increase in spinal curvature is also often observed with increasing age. Possible causes of increased spinal curvature include increases in the laxity of the vertebral ligaments, degenerative arthritic processes and osteoporosis. Osteoporosis is very much an age-related condition, which is far more common in women. Vertebral wedge fractures occur in individuals with osteoporosis with little or no trauma resulting in an increase in spinal curvature, which often progresses as the individual sustains further wedge fractures, should the condition remain untreated. Osteoporosis patients may therefore experience extreme reductions in height. Whereas some patients with osteoporosis may present with severe back pain from the vertebral fractures, others with the disease may remain entirely asymptomatic. The prevalence of silent vertebral fractures has not been well established. The overall prevalence of vertebral fractures in European women has been estimated as 23.5% in women aged 65–69 years, and 34.8% in women over 75 years of age (O'Neill et al. 1996). As arm span tends to remain unchanged with age, the discrepancy between arm span and height can be considered a marker of the extent of height reduction associated with age. The relationship between height and arm span with age has been clearly demonstrated in several studies (Fig. 41.3).

41.3.5 Arm Span, Height and Vertebral Deformities

As mentioned earlier, the arm span is often used to estimate standing height in individuals with vertebral deformities. A reduction in standing height is usually observed in individuals with acquired vertebral deformities, whereas the arm span remains unchanged. It can therefore be postulated that an index of the discrepancy between arm span and current standing height could predict the presence or severity of vertebral deformities. The literature behind AHD as a predictor of vertebral deformities has been mixed (Table 41.2). Verhaar et al. (Verhaar et al. 1998) devised a prediction

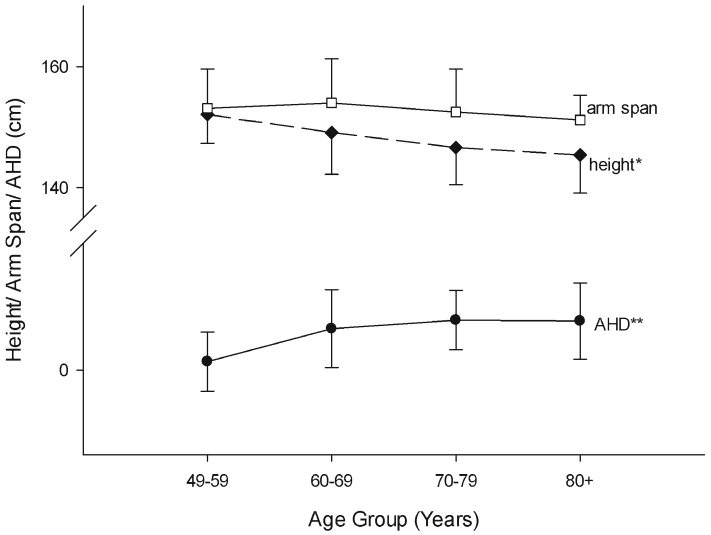

Fig. 41.3 Height, arm span and arm span to height differences according to age. Arm span is unchanged with increasing age, whereas a decline in age is observed, alongside an increase in arm span to height difference (AHD). *$p = 0.001$; **$p < 0.001$. (Figure adapted from Abe et al. (2008). Open access material

curve (Fig. 41.4) and a decision rule for the probability of having osteoporosis (Table 41.3) for which they reported a sensitivity of 81% and specificity of 64% for prediction of osteoporosis (Verhaar et al. 1998). Abe et al. (Abe et al. 2008) reported a sensitivity of 85% and specificity of 52% for the cut-off value for AHD ≥ 4 cm as a predictor of vertebral deformities (Abe et al. 2008). The remaining studies have yielded less convincing results.

The differences in outcomes of the studies may be explained by differences in case selection and the methods used to assess vertebral deformities. The validity of vertebral bone mineral density (BMD) is questionable as a marker for vertebral deformities, as vertebral BMD is no longer considered a useful test for osteoporosis in the presence of vertebral deformities. Clinical diagnoses based on history taking and physical examination have potentially high false negative rates because a large number of osteoporotic vertebral fractures escape clinical diagnosis, whereas radiographic measurements are complex and difficult to interpret. In addition, loss of height may also occur from other causes such as degenerative disc changes and other age-related processes.

Arm span–height difference therefore cannot be recommended as a marker or screening test for osteoporosis-related vertebral fractures at present. While further evaluation may be justified, this is currently limited by the lack of clear diagnostic criteria for vertebral fractures. However, arm span measurements are quick to perform, non-invasive, and cost nothing. It could therefore be a potentially useful screening test, particularly in less wealthy societies, where widespread use of DXA is not economically plausible. Future studies evaluating AHD/AHR with other clinical risk factors, such as age, sex, self-reported loss of height, family history, low body weight, and early menopause may also be justified.

41.3.6 Health Implications of Loss of Height

Congenital kyphoscoliosis is an established cause of respiratory failure due to the presence of a restrictive lung defect and increased work of breathing. The clinical suspicion that respiratory compromise from acquired vertebral deformities from osteoporosis may also occur has been

present for some time. Published studies supporting this clinical observation has been limited, but a recent metanalysis of four small case-control studies suggested that osteoporosis-related kyphosis is associated with impairment in pulmonary function (Harrison et al. 2007). The pattern of pulmonary involvement was mainly restrictive, and the level of impairment is related to the number of vertebral fractures and the clinical severity of kyphosis. This topic is particularly important as osteoporosis is becoming an increasing health problem with the ageing world population.

While the value of AHD as a marker for height loss due to vertebral fractures remains unclear, the arm span to height difference remains a useful marker of age-associated loss of height. Loss of

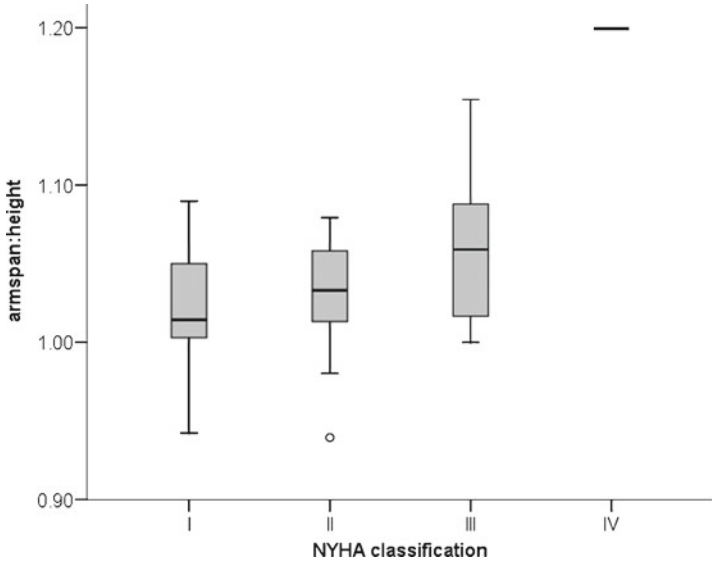

Fig. 41.5 The relationship between arm span–height ratio and the severity of breathlessness. This is a box and whiskers plot, with the thick horizontal line representing the median, the upper and lower borders of the boxes representing the interquartile range and the error bars representing the minimal and maximal values. The severity of breathlessness is measured by the New York Heart Association classification: I = no limitation, II = slight limitation, III = marked limitation, IV = breathless at rest

height, regardless of aetiology (physiological ageing, degenerative or vertebral fractures), may also have potential deleterious effects on respiratory function. A reduction in height by 10 cm is said to correspond to a 700 ml reduction in lung volume in women with osteoporosis (Leech et al. 1990). This problem may be accentuated with old age, due to loss of the elastic recoil of the lung, reduced chest wall compliance and decreased muscle strength. Older people are also more likely to suffer from other coexisting medical problems.

The arm span: height ratio (AHR) has been shown to be negatively correlated with forced expiratory volume (FEV1) and forced vital capacity (FVC) (Tan et al. 2009). FEV1 and FVC are measurements of lung airflow volumes obtained with a spirometer. These measurements are therefore also called spirometry, and are widely used in clinical practice as diagnostic and monitoring tools for obstructive airways diseases, such as asthma and chronic obstructive airways disease (COPD).There was also a significant positive correlation between AHR and the New York Heart Association (NYHA) classification for heart failure, a simple four-point scale widely used to assess the severity of shortness of breath in heart failure patients (Fig. 41.5). Class I on the NYHA classification represents no restriction of activity, whereas class IV indicates severe restriction with symptoms occurring at rest. The authors suggest that the findings of their study imply that loss of height as measured by AHR is significantly associated with reduction in airflow volumes as well as with increasing shortness of breath. Their study was performed on a highly selected population of individuals with suspected heart failure, referred for routine echocardiography by their primary care physicians. As the symptoms of heart failure, dyspnoea and ankle swelling are highly non-specific, the authors claim that the patient group represent individuals being investigated for underlying causes of shortness of breath.

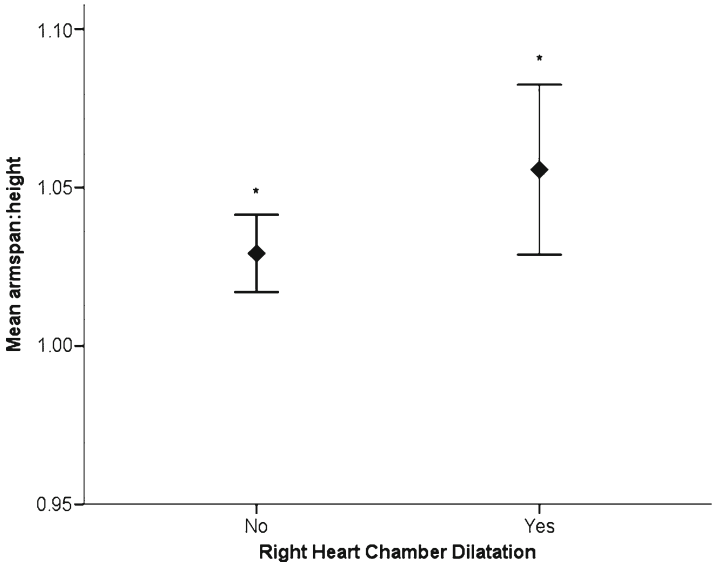

Fig. 41.6 The relationship between arm span–height ratio and right-heart chamber dilatation. The mean arm span for individuals with right-heart chamber (right atrial or right ventricular) dilatation is significantly higher than those with normal right-heart chambers. Error bars represent 95% confidence intervals. *$p<0.05$

In addition to evaluation of respiratory function, as their subjects were recruited from patients attending echocardiography, the authors were also able to determine the association between AHR with cardiac structural changes on echocardiography. The arm span: height ratio was significantly higher in individuals with right atrial and right ventricular dilatation, but not echocardiographically estimated pulmonary arterial pressure (Fig. 41.6). They suggested that this could signify the possibility of right heart failure due to chronic hypoxia as a result of the respiratory compromise associated with loss of height. The generalisability of the above study will have to be assessed in other clinical situations. Arm span: height ratio measurements in individuals with shortness of breath may be a useful indicator of the presence of loss of height, and therefore help identify potential underlying diagnoses, as many cases of shortness of breath remain unexplained at present.

41.3.7 Arm Span-Estimated Height Loss Versus Self-Reported Height Loss

Self-reported height loss is now an accepted risk factor for osteoporosis (Siminoski et al. 2006). Some suggest that the difference between self-reported maximal height and current actual height may also be a useful quantitative marker of height loss. However, this measurement relies on accurate recall of maximal height, which is a subjective process, and research evidence suggests that men tend to overestimate their height, whereas women have a tendency to underestimate their height. One study directly comparing the self-reported height loss and arm span-estimated height loss found the former to be more strongly correlated with osteoporosis risk (Twiss et al. 2002). The authors used an osteoporosis risk questionnaire rather than objective clinical markers of osteoporosis, which would have biased the results against the more objective measurement. However, as both self-

reported height loss and arm span-estimated height loss are less than perfect measurements, and both indices are extremely simple to perform, they are likely to be complementary, and therefore more effective, if used together to identify the presence of height loss.

41.4 Applications to Other Areas of Health and Disease

41.4.1 Pulmonary Function Tests

Assessment of pulmonary function using spirometric measurements requires comparison between the patients' measured airflow volumes against the predicted airflow volumes for their height and age. The current practice is to measure arm span in situations where standing height measurements are not possible as in patients with skeletal deformities, lower limb amputations or neuromuscular weakness. Some experts have suggested that arm span measurements should also be considered in older people, particularly those with osteoporosis, as the severity of airflow limitation could be underestimated, if only height measurements are used to determine predicted airflow volumes in the presence of height loss. Allen (1989) assessed the value of predicting spirometric volumes using arm span in healthy, physically active older women. He concluded that while arm span can be used to replace height, there was little difference between the two measurements suggesting that routine arm span measurement is not justified (Allen 1989). However, in older individuals who have symptoms of breathlessness, the severity of airflow limitation can be underestimated (Tan et al. 2009).

41.4.2 Nutritional Status

The estimation of nutritional status required the use of height as well as weight measurements to estimate the body mass index (BMI). However, in clinical situations where assessment of nutritional status are particularly important, such as in intensive care units and stroke units, patients are often physically obtunded or have significant disabilities such that height measurements are not possible. As a result, demispan or half arm span measurements are often used to estimate standing height. In addition, nutritional assessments are also vital in frail elderly individuals. Frail older people are most likely to experience loss of height due to osteoporosis or other age-related physical changes. Some experts are beginning to recognise that BMI estimation in this group of subjects may be liable to clinically significant overestimation of nutritional status (Hirani and Mindell 2008). The BMI is calculated with the formula: weight/(height^2). As the height measurement is squared in this index, even small reductions in height are magnified, with a small reduction in standing height resulting in a proportionally larger increase in calculated BMI. There have been a handful of studies evaluating the value of replacing standing height with arm span or demispan measurements, but further more conclusive studies are still required.

41.4.3 Limitations

While arm span measurements are highly correlated with standing height measurements, some studies have suggested large variability in arm span to height ratio between individuals, as well as large variability between arm span-estimated height and actual standing height for individuals.

The large interindividual variability of AHR and arm span-estimated height may limit the value of using arm span measurements to replace height measurements in clinical contexts, such as respiratory function tests and nutritional assessments (Hickson and Frost 2003). It is therefore important for clinicians to be aware of this potential limitation, and to exercise appropriate clinical vigilance.

The accuracy of arm span measurements may be affected by congenital and acquired musculoskeletal disorders. Older patients may have difficulty fully abducting the shoulder or fully extending the elbow due to traumatic damage or arthritis. Both inflammatory and degenerative arthritis are associated with finger deformities, which will also affect arm span measurements, but this difficulty could be avoided by measuring the demispan. Genetic disorders, such as Marfan's syndrome and Klinefelter's syndrome, are associated with unusually long arms, which will render any assessments of arm span–height difference or arm span-estimated height inapplicable.

41.5 Conclusion

Arm span measurements are often used in clinical practice to estimated height in situations where actual height measurements are not possible. A reduction in standing height occurs with increasing age, whereas arm span usually remains unchanged. An increase in the difference between arm span and height is therefore observed with ageing. The arm span–height difference can therefore be a useful marker of age-related height loss. While osteoporosis is associated with both height loss and ageing, the evidence for arm span–height difference as a predictor for osteoporosis or vertebral fractures is currently inconclusive. Increases in the arm span: height ratio, which is increased with loss of height, is associated with severity of breathlessness, reducing respiratory airflow and right-sided heart failure. The severity of impairments in lung function and nutritional status in older individuals may be underestimated, if height measurements alone are used in lung function tests and BMI calculations. The role of arm span-estimated heights in these clinical situations needs to be studied.

Summary Points

- Arm span is strongly correlated with standing height.
- Arm span measurements can be used to estimate height in clinical situations where height measurements are not possible.
- Height reduces with age, whereas arm span remains unchanged.
- The difference or ratio between arm span and height is a marker for age-related loss of height.
- The value of arm span–height difference, as a predictor for osteoporosis related vertebral fractures, remains uncertain.
- Arm span to height ratio increases with increasing severity of breathlessness.
- Arm span–height ratio is negatively correlated with lung airflow volumes measured with spirometry, suggesting that increasing height loss is associated with increasing restriction in lung function.
- Age-associated height loss may result in underestimation of the severity of lung airflow problems and nutritional problems in older people, which may be overcome by using arm span-estimated height.

Key Features of the New York Heart Association Classification

The New York Heart Association (NYHA) classification is the system most widely used to assess the severity of symptoms in patients with heart failure. It divides patients into four categories:

Class	Functional impairment
I	No symptoms and no limitation in ordinary physical activity.
II	Mild symptoms and slight limitation during ordinary activity. Comfortable at rest.
III	Marked limitation in activity due to symptoms, even during less-than-ordinary activity. Comfortable only at rest.
IV	Severe limitations. Experiences symptoms even while at rest.

Key Factors Associated with Loss of Height with Age

- Reduction in intervertebral space (reduced disc height).
- Change in posture.
- Increased spinal curvature due to:
  - Ligamentous laxity
  - Degenerative changes and
  - Osteoporosis-related vertebral crush fractures

Chapter 42
Proximal Femoral Anthropometry by Computed Tomography

Thomas F. Lang

Abstract Age-related and pediatric disorders of the hip are common and confer strong risk factors for current and future disability. Because many of these disorders are associated with variations in proximal femoral structure, the study of the anthropometry of the hip has been of considerable interest to the medical research community. Imaging has become critical to the evaluation of human proximal femoral morphology in clinical research studies and in surgical practice. Using this overall approach, a simple radiograph or a computed tomography (CT) scan may be obtained, and landmarks identified either on radiographic films or digital images. As long as the physical size of the pixels is known, the distance between landmarks may be quantified. In this chapter, we will describe the use of computed tomography (CT) images for morphological assessment of the proximal femur. CT images provide a full three-dimensional assessment of the hip bone, allowing for morphometric analysis of both external and internal structures. Because of the inherently volumetric nature of the data, the orientation of the CT image can be standardized, allowing for reproducible metrics of size and distance. The discussion of CT morphology will be focused on the use of CT to characterize response of the proximal femur to aging, on the limitations of this technique for visualizing anatomic detail, and on practical considerations for using CT in studies of cadaveric specimens and in vivo human studies.

42.1 Introduction

The femur is the largest and strongest bone in the body, and the structure of its proximal portion allows the leg to move in three dimensions relative to the torso, thus serving as a linchpin of human mobility. Moreover, age-related and pediatric disorders at this skeletal site are common, and confer strong risk factors for current and future disability. Because many of these disorders are associated with variations in proximal femoral structure, the study of the anthropometry of the hip has been of considerable interest to the medical research community. Moreover, variations in hip morphology are also of critical interest to surgical planning, where the ability to take hip morphology into account on a patient-specific basis is crucial for success in choosing designs of implants and other structures used for hip replacements and augmentations of hip stability.

Imaging has become critical to the evaluation of human proximal femoral morphology in clinical research studies and surgical practice. Using this overall approach, a simple radiograph or a computed tomography (CT) scan may be obtained, and landmarks identified either on radiographic films or digital images. As long as the physical size of the pixels is known, the distance between landmarks may be quantified. For example, studies linking variants of hip structure to relatively rare outcomes, such as osteoporotic hip fracture or osteoarthritis of the hip, often require large sample sizes, often thousands of subjects, to estimate risk factors conferred by anatomic measurements. Such measurements must be taken in vivo, with a measurement protocol that can be easily standardized between the different clinical sites at which subjects might be recruited. Similarly, planning of hip surgeries, involving the selection of prosthesis design, or the direction and size of a femoral neck pin, must take into account the specific anatomic features of the subject. The principal manner by which this information can be obtained is through medical imaging.

In this chapter, we will describe the use of computed tomography (CT) images for morphological assessment of the proximal femur. CT images provide a full three-dimensional assessment of the hip bone, allowing for morphometric analysis of both external and internal structures. Because of the inherently volumetric nature of the data, the orientation of the CT image can be standardized, allowing for reproducible metrics of size and distance. In contrast, earlier technologies, such as plain X-rays, compress the three-dimensional anatomy of the proximal femur onto an anteroposterior plane, and, thus, size and distance metrics are confounded by the variable orientation of the subject at the time of the acquisition. Further, although magnetic resonance imaging (MRI) can also provide this information, CT has the advantage that bone anatomy is clearly delineated against the surrounding soft tissue, making it easier to identify bony landmarks. The discussion of CT morphology will be focused on the use of CT to characterize response of the proximal femur to aging. As with all skeletal structures, the proximal femur responds dynamically to its mechanical environment by changing size, shape, and the distribution of bone. In the context of aging, age- and menopause-related bone loss in the presence of continued mechanical loading associated with normal physical activity increases the strain on the hip. The proximal femoral response to age-related bone loss encompasses changes in morphology that have been quantified, and related to endpoints, such as fracture, in research studies carried out in our laboratory and others.

42.2 Key Anatomic Features

The proximal femur consists of the *head*, the *neck*, the *greater and the lesser trochanters, and* several related structures (Fig. 42.1).

The head of the femur serves as the interface between the femur and the acetabulum of the pelvis, forming the *hip joint*. The femur is held in place by the ligament of the head of femur

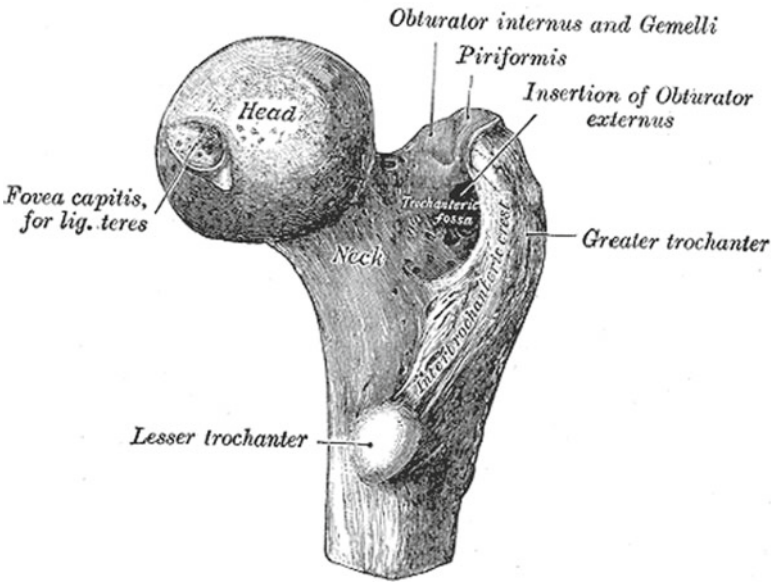

Fig. 42.1 Anatomic landmarks of proximal femur

(*ligamentum capitis femoris*), which is attached to the femur at the *fovea capitis*, a crater-like structure slightly inferior and posterior to the center of the head of the femur, and the *iliofemoral ligament*.

The femoral *neck* is a flattened pyramidal process of bone that connects the *head* to the *proximal femoral shaft*. The *greater trochanter* is a relatively large, quadrilateral projection, oriented slightly inferior and approximately 2 cm lateral to the femoral head in adults. The greater trochanter serves as the point of insertion for numerous muscles of the hip joint, including the *gluteus medius*, *gluteus minimus*, *obturator internus*, *piriformis*, gemelli, and *obturator externus*, which inserts into the *trochanteric fossa*, a deep depression on the medial aspect of the greater trochanter. The *lesser trochanter* is a conical protuberance situated distally and medially from the greater trochanter, and joined via a bony ridge referred to as the *intertrochanteric crest*. The lesser trochanter serves as the insertion of the *psoas major*, a dominant muscle in flexion of the hip.

42.2.1 Types of Bone/Arrangement of Types of Bone/Mechanical Properties

Bone is divided into two types. While bones share a basic chemical composition and contain inorganic matter giving them rigidity, each of the two bone types serve different functions (Pratt 1991). Additionally, its mechanical properties depend on the distribution of the type of bone within a given region. *Compact bone* or *cortical bone* is generally thin and is composed of a very dense arrangement of fibers that makes up the outer layer or shell of long bones. Cortical bone has quite varied mechanical properties, but is very well adapted to providing resistance to shear and compressive forces (Panjabi and White 2001). *Cancellous* or *trabecular* bone is composed of a porous inner layer consisting of

large networks of column-like structures called *trabeculae*. The trabecular bone of the proximal femur functions to uniformly distribute contact stresses at the articular surfaces, and to absorb dynamic loads (such as those in stance/gait). Cancellous bone is found in larger quantity in the proximal femur; however, its density is only about 5–50% that of cortical bone (Panjabi and White 2001).

42.2.2 Movements and Functions

The hip joint is spheroidal, and commonly referred to as a *ball and socket* joint. As such, it has the ability to produce a wide array of movements. Movements of the hip include varying degrees of flexion and extension, internal and external rotation, and abduction and adduction and combinations thereof. For example, the hip may be extended and internally rotated simultaneously when rising from a chair and turning. The primary roles of the proximal femur, in conjunction with the acetabulum of the pelvis, are to support loads related to upright stance and locomotion, and act as a lever for producing muscular force. Loads between 238% and 260% of a person's body weight must be supported at the hip during routine activities, such as walking and stair climbing (Bergmann et al. 2001); higher forces are present during activities, such as running and skiing where loads at the hip can range from 520% to 1,240% of a person's body weight (running and mogul skiing, respectively) (van den Bogert et al. 1999).

42.3 Computed Tomographic Imaging

Computed tomography (CT) is an imaging technique in which information from a set of X-ray measurements obtained at different angles through the body is reconstructed to obtain the distribution of linear X-ray attenuation coefficient in a thin cross section of tissue. Figure 42.2 depicts the geometry of a CT measurement. The patient cross section is contained within a fan of X-rays, defined between the edges of the detector array and an X-ray point source. The X-ray absorption through the patient is measured along rays defined between the individual detector elements and the X-ray source. The thickness of the cross section in which the absorption measurements are obtained can range from 0.5 to 10 mm. The fan of X-rays circumscribes a circular field of view, which is itself contained within a square image matrix, consisting of a square array of square pixel elements, or "pixels." A typical cross section is contained within an array of 512 × 512 pixels. Because the image represents a "slice of tissue," the picture elements have a thickness, and thus are volume elements, or "voxels." The dimensions of the voxels may be adjusted depending on the size of the organ being imaged. For example, in a whole body survey corresponding to a 50-cm field of view, the voxels are typically 1 mm in dimension within the image plane, and 5–10 mm in the slicing dimension. For high-detail bone images, the field of view may be as small as 10–15 cm, resulting in voxel dimensions of 0.2–0.3 mm in the reconstruction plane. The CT image is acquired when the X-ray source and detector rotate around the patient, and the absorption is continuously measured for each detector element. Through a 360-degree source–detector rotation, each voxel is intersected by several ray paths. The X-ray absorption measurements taken at the different angles are recorded in a computer and combined in a process known as back projection to calculate the linear attenuation coefficient at each voxel. In the resulting CT image, the voxel values are based on these linear attenuation coefficients. Because these coefficients depend on the effective X-ray energy (which varies between CT scanner models and different kVp settings of the same scanner),

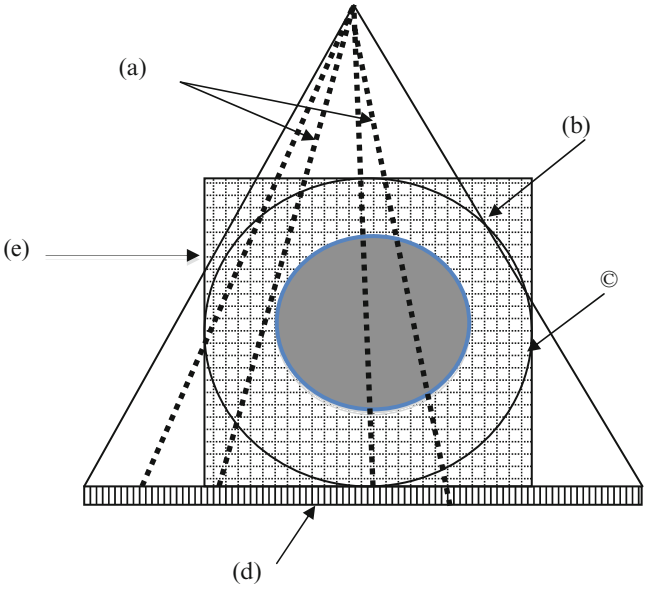

Fig. 42.2 Schematic for CT acquisition

a simple scale, known as the Hounsfield scale, is used to standardize them. The gray-scale value of each voxel is represented as a Hounsfield Unit, given by:

$$HU_T = \left(\frac{\mu_T - \mu_W}{\mu_W} \right) \times 1000$$

where HU_T is the HU of a volume element of tissue and μ_T and μ_w are the linear attenuation coefficients of the tissue and of water, respectively. The HU scale is a linear scale in which air has a value of –1,000, water 0, muscle 30, and bone typically ranging from 300 to 3,000 units.

The value of the Hounsfield unit for a given tissue type depends on several technical factors. First, if the sizes of the structures in the tissue are smaller than the dimensions of the voxel, the HU value is subject to partial volume averaging, in which the HU value is the average HU of the constituent tissues of the voxel, weighted by their volume fractions. For example, a 0.78 × 0.78 × 10 voxel of trabecular bone is a mixture of bone, collagen, and cellular and fatty marrow, and HU is the volume-weighted average of these four constituents. Beam hardening is a second source of variation in HU. Beam hardening occurs because the X-rays used to generate the image have an energy spread. The average energy of the spectrum thus changes as a function of the position within the subject because the lower-energy X-rays are preferentially absorbed. This means that for an object of uniform position, the apparent Hounsfield unit is lower toward the center of the object compared to the periphery, resulting in a cupping artifact. Although manufacturers of CT equipment have implemented beam-hardening corrections, the efficacy of these corrections varies between manufacturers and between technical settings on different machines.

Image data for multiple cross sections are acquired by moving the patient table through the CT gantry (Fig. 42.3). In older models of CT scanners, the patient table stepped in discrete increments, and a 360-degree rotation of the source/detector was performed at each position. Helical CT scanning was introduced in the early 1990s. In this scanning approach, the detector and X-ray tube rotates while the table moves continuously, resulting in acquisition of a volume of data. The X-ray spot describes a spiral trajectory, with use of interpolation to fill in data between the arms of the spiral. Introduction of this technology resulted in significant reductions in image acquisition time (Kalender and Polacin 1991;

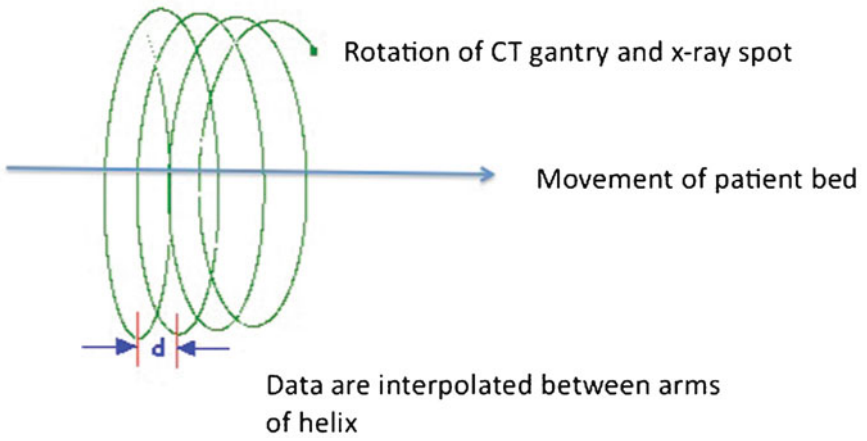

Fig. 42.3 Schematic for helical CT scanning

Kalender et al. 1990) and combined with the advent of powerful inexpensive computer workstations, has enabled the clinical development of volumetric CT analyses of the spine and hip, as will be discussed in the following sections. In the late 1990s and early 2000s, the first multidetector CT systems were introduced, and are expected to have an important impact in skeletal assessment. In multidetector systems, the single detector array is replaced by a series of detector segments, allowing for the reduction of imaging time and improved usage of radiation dose. Initial multidetector systems featured 4–16 detector rows, and the newer systems feature 128–256 rows of detector data. The newest multidetector systems allow for acquisition of CT cross sections of submillimeter thickness, resulting in the ability to acquire high-quality volumetric scans, with the resolution along the table axis comparable to the in-plane spatial resolution (Rubin 2000). As will be described later, this technology will allow for improved analyses of skeletal sites, such as the proximal femur, which must be re-sampled through oblique reformations of the scan data.

42.4 Physical Significance of CT Bone Measurements

CT images provide a three-dimensional depiction of the distribution of bone tissue at a particular skeletal site. The use of CT for quantitative assessments of morphology requires the correct assignment of voxels to bone or to other tissues. In order to standardize the identification of bone voxels based on their image intensity, quantitative CT imaging of bone is often performed with a calibration standard imaged simultaneously within the field of view of the subject (Cann, 1981; Cann and Genant 1981; Faulkner et al., 1993). Bone mineral calibration standards normally consist of a wedge of water-equivalent resin containing cylindrical or square-shaped rods of bone-equivalent materials with different concentrations of calcium hydroxyapatite. During the analysis of the CT image, regions of interest are placed in each of the calibration objects, and linear regression analysis is used to determine a relationship between the mean HU measured in each region and the known concentrations of bone-equivalent material. This calibration relationship is then used to convert the mean HU in a given bone voxel into a concentration (reported in mg/cm^3; i.e., the *mass of bone per unit tissue volume*) of bone-equivalent material within that voxel. The CT image can then be mapped from a distribution of HU onto a distribution of equivalent concentration of calcium hydroxyapatite.

There are two major sources of error that impact the ability to make morphometric measurements from CT images. The first major source of error in the CT bone measurement is the phenomenon of

partial volume averaging. Because the voxel dimensions in CT measurements (0.8–1.0 mm in the imaging plane, 3–10 mm slice thicknesses) are larger than the dimensions and spacing of trabeculae, a CT voxel includes both bone and marrow constituents. Thus, a CT measurement is the mass of bone in a volume containing bone, red marrow, and marrow fat. A single-energy CT measurement is capable of determining the mass of bone in a volume consisting of two components (e.g., bone and red marrow), but not in a three-component system. Resolving the mass fractions of bone, red marrow, and marrow fat in the CT voxel requires a dual-energy CT measurement. Because fat has a HU value of –200, compared to 30 HU for red marrow and 300–3,000 HU for bone, the presence of fat in the CT volume depresses the HU measurement. Thus, the presence of marrow fat causes single-energy CT to underestimate the mass of bone per unit tissue volume, an error which can be corrected using two acquisitions at different energies to resolve a system with more than two tissue components. The effect of marrow fat on CT measurements is larger at the spine than at the hip or peripheral skeletal sites (Gluer and Genant 1989; Goodsitt et al. 1994). Whereas the conversion from red to fatty marrow tends to complete by the mid-1920s in the hip and peripheral skeleton, the vertebrae show a gradual age-related increase in the proportion of fat in the bone marrow, which starts during youth and continues through old age (Dunnill et al. 1967) The inclusion of fatty marrow in CT assessment measurement results in accuracy errors in estimated bone content that range from 5% to 15%, depending on the age group. However, because the increase in the proportion of fat in the marrow is age related, single-energy CT data can be corrected using age-related reference databases; the residual error is not considered to be clinically relevant.

42.5 Processing of CT Data

Measurements of anthropometry from CT images require reproducible orientation of the femur in three dimensions in order to consistently quantify distances between anatomic points of interest. Such procedures can be carried out manually using commercially available 3D display software programs in which the bone can be rendered as a surface, or as a volume, which can be rotated in 3D space. Automated and semiautomated approaches, however, offer much greater reliability in that they remove or reduce the role of human interaction in these measurements.

In our laboratory, and in several others, semiautomated procedures have been developed to assess the morphology of the femoral neck, an important site for age-related hip fractures, as it is affected by aging and by changes in mechanical unloading (Bousson et al. 2006; Camp et al. 2004; Kang et al. 2003, 2004, 2005; Lang et al. 1997; Prevrhal et al. 1997). In the aging process, the femoral neck is the site of extensive age-related bone loss, with extensive resorption of trabecular bone and thinning of the femoral neck cortex (Mayhew et al. 2005; Meta et al. 2006; Riggs et al. 2004). One of the central features of skeletal tissue is its dynamic responsiveness to changes in mechanical loading (Frost 1997, 2003). This responsiveness takes the form of three-dimensional morphological changes on the surface and in the interior architecture of the hip, which can be detected with imaging. In the context of age-related bone loss, the strain experienced by skeletal tissue is increased due to loss of load-bearing skeletal mineral in the presence of continued mechanical loading. Thus, one of the features of aging in the proximal femur is a redistribution of bone from less mechanically loaded to more heavily loaded structures, to best maintain skeletal stiffness in loading conditions associated with normal function. In imaging studies, this can take the form of morphologic changes on the femoral neck, including increased periosteal volume and cross-sectional area, and regional changes in cortical thickness, as well as quantifiable changes in the 3D distribution of imaged bone.

The analytic approaches for proximal femoral morphometry developed in our laboratory (Lang et al. 1997, 2004) and subsequently by others (Camp et al. 2004; Kang et al. 2005), involve

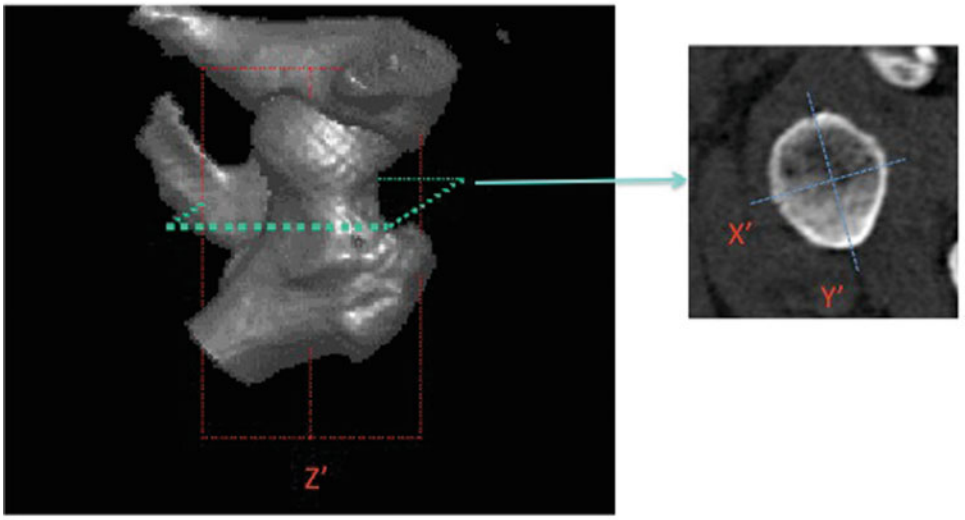

Fig. 42.4 Hip anatomic coordinate system

two primary steps. The first step involves extraction of the structure of interest, the proximal femur, from the CT scan, and the re-sampling of that structure into an anatomic coordinate system, of which the primary axes are based on natural common fixed axes of the bone (Fig. 42.4). In our case, and others, that involves marking the axis of the femoral neck on two planes, coronal and axial. This allows for full 3D specification of a new *z*-axis, permitting re-sampling of the scan along that natural *z*-axis of the bone as opposed to the axis of the scanner, which moves along the femoral shaft. Once the subvolume containing the proximal part of the femur has been rotated, so that the *z*-axis is along the axis of the femoral neck, an image segmentation program then automatically defines the periosteal surface of the bone. Figure 42.4 shows the placement of the anatomic coordinate system on a 3D rendering of a proximal femur from a CT scan.

With the proximal femoral subvolume resampled into an anatomic coordinate system aligned with the femoral neck, and the outer surface of the proximal femur mapped, it is possible to use fully automated landmark detection approaches to divide the proximal femur into anatomic subvolumes. Our approach is based on measurement of the cross-sectional area contained within the periosteal proximal femoral surface as a function of position along the femoral neck axis. In this approach, the femoral neck is bounded by two landmarks: the global minimum of this curve along the axis between the intertrochanteric plane and the lateral aspect of the femoral head, and the maximum of the curve at the plane between the greater and lesser trochanters. We have devised a scheme to subdivide the proximal femoral volume into the femoral neck and trochanteric subvolumes. This subdivision is based on use of the distance between the minimum and maximum cross-sectional area planes, as an intrinsic metric of distance matched to each sample. Thus, each location along the femoral neck axis is parameterized as a function of this intrinsic metric. The femoral neck volume is bounded medially by the cross section having minimum total area and laterally by a plane located 25% of the distance between the minimum cross-sectional area plane and the cross section along the femoral-neck axis having maximum total area. Within the region that encompasses the periosteal volume of the femoral neck, image processing procedures may be employed to isolate the cortical and trabecular compartments for morphologic assessments. These include assessments of total tissue volume, cortical tissue volume, and volume of the medullary space. Although the initial re-sampling of the femoral neck into its anatomic coordinate system involved specification of only a *z*-axis, we can define intrinsic in-plane axes by computing the

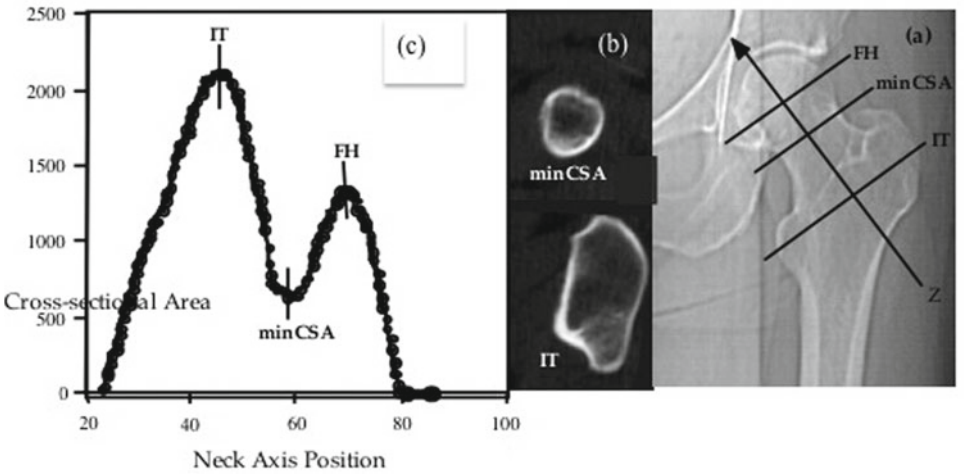

Fig. 42.5 Variation of cross-sectional area along femoral neck axis

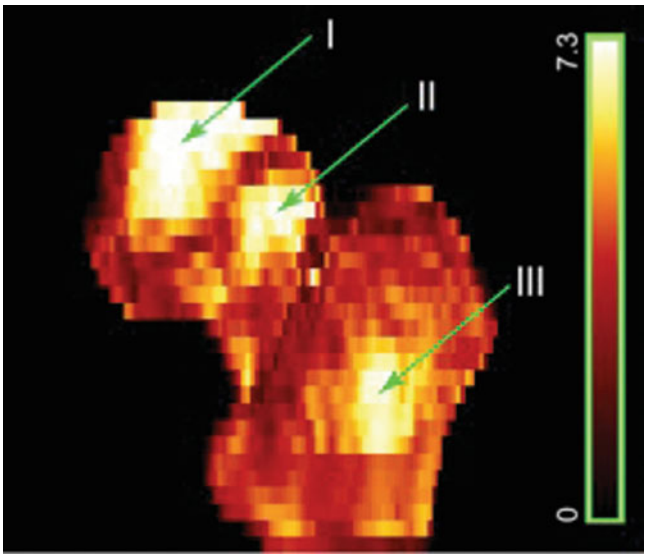

Fig. 42.6 Voxel-based morphometry

axes of inertia of the minimum cross-sectional femoral neck cross section. These axes of inertia may then be employed to define a series of rays, along which the overall bone thickness and the thickness of the cortical shell may be analyzed. Thus, the anatomic coordinate system described earlier may be used for a series of anthropometric and structural measurements that characterize the femoral neck as it changes as a function of age and disease. The method for segmenting the proximal femur into anatomic subvolumes for measurements of morphometry and density is summarized in Fig. 42.5.

In addition to anatomic coordinate system-based measurements, it is also possible to carry out measurements where the proximal femoral surface is defined using the segmentation methods described above, as well as to use three-dimensional image registration techniques in a procedure called voxel-based morphometry (Fig. 42.6) (Li et al. 2007, 2009a, b). In this approach, the surface of the proximal femur is mapped to the surface of a reference femur, or template, using a series of rotations, translations, and scaling to approximately match the two samples, followed by local deformations to achieve the

final fit. With this approach, scans from a study cohort can be warped to a single template, providing a voxel-based statistical model of the cohort. With this model, each voxel of the model contains information from all of the corresponding voxels in the scanned femorae. Thus, within each small subvolume of tissue, it is possible to carry out statistical tests showing three-dimensional morphometric differences between different subgroups of the cohort characterized by different clinical variables. This can include age, gender, fracture status, physical activity, or genotype. Moreover, a cohort may be examined longitudinally by analyzing the statistical significance of voxel values at different time points.

42.6 Applications

Studies of morphologic changes in proximal femur with age and osteoporotic fracture status: Our own group and others have utilized morphometric analysis of computed tomography scans to discern age-related changes in proximal femoral structures. One of the primary findings of this study has been the responsiveness of measures of periosteal cross-sectional area and volume to age. Meta et al. compared young and elderly women in a cross-sectional study, noting that older women had larger cross-sectional areas and periosteal volumes in the femoral neck, even after adjustment for differences in body weight and height. Despite the larger bone sizes, older women had smaller volumes of cortical bone (Meta et al. 2006). This finding agreed with another cross-sectional study of a similar design undertaken at Mayo Clinic (Riggs et al. 2004), which found that, in a thin section of the femoral neck, older men and women had larger cross-sectional areas and smaller cortical thickness measures. While these studies have involved cross-sectional studies of femoral neck morphometry parameters, our own group has utilized another clinical model of bone loss, of long-duration spaceflight, to detect longitudinal evidence for changes in periosteal area and cortical thickness measures. In a study which illustrates the role of bone morphometric measures as descriptors of skeletal adaptation to changing mechanical environment, we followed 16 crew members making long-duration flights of 4–6 months on the International Space Station (Lang et al. 2006). The goal of this study was to examine the changes in the proximal femur, which take place as a function of sustained weightlessness during the flight and re-adaptation of the proximal femur to full weight bearing on return to Earth's gravity. Long-duration spaceflight is associated with extensive bone loss, particularly in the proximal femur, where, on average 1–1.5% of bone mass is lost per month. In our study, we observed that, during the course of the flight, bone loss consisted of loss of trabecular bone and thinning of the proximal femoral cortex, without any change in the outer dimensions of the femoral neck. The loss of trabecular bone density averaged 20%, and, on average, over 10% of the cortical tissue volume was lost. Thus, when subjects were re-exposed to Earth's gravity, they underwent increased mechanical strain on the hips, associated with load bearing in the presence of skeletal atrophy. In our study, we observed increases in femoral neck cross-sectional area and cortical thickness without substantial increases in density. This was consistent with an adaptive process, where new bone formation took place in regions required for optimal load bearing, with reduced accretion of bone in areas that incur less bending load.

42.7 Practical Methods and Techniques

Procedures for carrying out CT-based morphometric measures using CT of the proximal femur vary depending on whether one is scanning a specimen or a human. For human scanning, the scans will typically take place in the clinical radiology department of a hospital. The subject

should typically be dressed in a light hospital gown, with no metal in the field of view of the CT imager. For ideal imaging of the hip, subjects should undergo a localization image, called a scoutview, to first delineate the proximal femoral anatomy, with good coverage of the proximal femur ensured by starting the scan a few centimeters above the acetabulum and ending a few centimeters inferior to the lesser trochanter. In the case of specimens, these can be imaged in a water bath to simulate overlying layers of soft tissue, or simply scanned in air in the case of a dried femoral specimen. In the case of a fresh frozen specimen, biosafety precautions need to be taken into account.

One of the major limiting considerations for analysis of proximal femoral anatomy using CT images is the spatial resolution of the image data as well as noise in the images. The limited spatial resolution affects the detail with which structures of interest can be detected and quantified, and the image noise limits the ability of segmentation programs to isolate the proximal femur for analysis. An additional factor to take into account is partial volume averaging. Partial volume-averaging errors affect measurement of structures that are small compared with the spatial resolution of the imaging device. For thin cortices, such as the superomedial aspect of the femoral neck, this results in underestimation of bone density and overestimation of volume or thickness measurements, with smaller errors for estimation of mass (Augat et al. 1998). Our hip cortical region of interest is primarily composed of the inferomedial cortex of the proximal femur, for which thickness values exceeding 3–4 mm have been reported in humans, and also includes the thin superomedial cortex (thickness 0.3 mm) (Bagi et al. 1997). In a study based on a helical CT scanner similar to our own, Prevrhal et al. reported that detection of changes in cortical thickness is possible for cortices with thicknesses of about 1.2 mm (Prevrhal et al. 1999).

Image noise is a function of the imaging technique used by the scanner and the body size of the human subject being scanned. Noise is essentially determined by the number of X-ray photons used to reconstruct an image, and is reflected in the Poisson-shaped distribution of the brightness values of the reconstructed voxels. For a fixed X-ray tube current, the smaller the voxel size, the lesser the number of photons used to determine the value of a given voxel, and the noisier the image. Thus, there is an effective trade-off between reducing the size of the voxel, which provides higher levels of detail, and the noise.

The trade-off between noise and spatial resolution impacts the techniques chosen for imaging specimens or humans for anthropometric measurements. When imaging specimens, it is important to choose the smallest possible field of view to obtain the maximum resolution possible with the imaging system. It is also important to use the maximum tube current settings to minimize image noise. Settings for human scanners are limited by the radiation dose to which one can ethically expose humans in obtaining the images. Experiments involving scanning of humans must be approved by Internal Review Boards set up for each institution, which are responsible for weighing the experimental risk to the subjects against the value of the knowledge obtained in the experiment. This limits the ability to use high X-ray doses to overcome the noise limitations associated with small pixel sizes and high magnifications. For such protocols, we have found that committees will generally approve imaging with 1-mm slice thicknesses, with 120 kVp and 150–250 mAs, resulting in an effective absorbed radiation dose of 2–4 milliSieverts (mSv) compared to a yearly background of 3.6 mSv. In these cases, we advise carrying out a whole body field of view with roughly 1-mm pixels in plane, but reconstructing the data in magnified fields of view that allow the data to be sampled at pixel sizes corresponding to half of the spatial resolution of the image. Because of the limitations of the CT scanner, it will not be possible to accurately image the superior aspect of the femoral neck, but will be possible to image characteristics, such as inferior neck thickness, total cross-sectional area, and other morphometric parameters of interest.

Summary Points

- Volumetric X-ray computed tomography scans depict the proximal femur in three dimensions, allowing its orientation to be standardized for reproducible morphometric measurements.
- CT images are expressed in units of X-ray attenuation, a measure of the density and atomic number of tissue. These images have limited spatial resolution, and objects less than 0.5–1 mm in dimension are not depicted accurately in size or density.
- CT images of the hip are often sampled into hip-centered anatomic coordinate systems, which provide a position and angular reference for area, width, and distance measures.
- Morphometric studies using CT have documented increases in overall femoral neck size (width and cross-sectional area) with age.
- Morphometric measurements of the femoral neck cortex have documented extensive variability in age-related changes in cortical thickness; sections that are load bearing in normal ambulation and physical activity tend to retain their thickness, whereas sections of the femoral neck that undergo less mechanical stress tend to show extensive thinning.
- Voxel-based morphometry has been used to quantify internal structural variations in the hip that are associated with risk of osteoporotic hip fracture.
- The technical approaches to CT imaging of the hip in living subjects must weigh the need for anatomic detail against the higher amounts of radiation required to visualize these details.

Key Points

Table 42.1 Key points

A. Volumetric Nature of CT Imaging	A1. The 3D orientation of the proximal femur can be standardized, allowing for reproducible definition and measurement of distances between landmarks
B. Volumetric CT Acquisitions	B1. Current CT systems acquire a volume of data, which can be considered as a series of transverse cross-sectional images, which are stacked up to form the CT volume.
	B2. The CT image unit is the Hounsfield unit, a measure of X-ray absorption in a volume of tissue called a voxel
C. Errors in CT	C1. CT images are affected by partial volume averaging, which occurs when the size of the voxels is larger than the structure being imaged. In this case, the Hounsfield unit in a voxel containing multiple unresolved constituents is the volume-weighted average of these constituents
	C2. CT images are sometimes affected by beam hardening, which introduces non-linearities and artifacts into the images
D. Segmentation of Image Data	D1. CT images of the hip can be segmented to remove the bone from the surrounding soft tissue
E. Anatomic Coordinate Systems	E1. To ensure that morphometry is consistently done within and between individuals, standard practice involves resampling the hip image along the axes of a hip-fixed anatomic coordinate system
F. Femoral Neck Morphometry	F1. The cross-sectional area increases with age to preserve its mechanical competence with respect to normal usage
	F2. The cortex of the femoral neck thins with age, with considerable variation depending on femoral neck location
	F3. Voxel-based morphometry can be used to determine differences in the interior architecture of the hip as a function of age, drug treatment, and fracture status
G. Practical Considerations	G1. Imaging approaches must weigh the quality of the image, which allows discernment of smaller features, against increased radiation dose to the human subject

Chapter 43
Leg Length and Anthropometric Applications: Effects on Health and Disease

Maria Inês Varela-Silva and Barry Bogin

Abstract Decomposing stature into its major components is proving to be a useful strategy to assess the antecedents of disease, morbidity and death in adulthood. Human leg length (foot + tibia + femur), sitting height (trunk length + head length) and their proportions (e.g. leg length in proportion to stature, and the sitting height ratio [sitting height/stature × 100], among others) are used as epidemiological markers of risk for overweight (fatness), coronary heart disease, diabetes and certain cancers. There is also wide support for the use of relative leg length as an indicator of the quality of the environment for growth during infancy, childhood and the juvenile years of development. Human beings follow a cephalo-caudal gradient of growth, the pattern of growth common to all mammals. A special feature of the human pattern is that between birth and puberty the legs grow relatively faster than other post-cranial body segments. For groups of children and youth, short stature due to relatively short legs (i.e. a high sitting height ratio) is generally a marker of an adverse environment. The development of human body proportions is the product of environmental x genomic interactions, although few if any specific genes are known. The short stature homeobox-containing gene (SHOX) is the first genomic region that may be relevant to human body proportions. For example, one of the SHOX related disorders is Turner syndrome. However, in most cases research has been showing that environment is a more powerful force to shape leg length and body proportions than genes.

Abbreviations

BMI	Body mass index
BP	Blood pressure
BW	Birth weight

43.1 Introduction

Leg length has been widely used in biomedical sciences as an indicator of general health, socioeconomic status and propensity for disease. For many years, it was also wrongly used as a racial marker (Bogin et al. 2001; Bogin 2008; Frisancho et al. 2001). However, the concept of 'leg length' has different meanings for different authors, and there is more than one single measurement for leg length. Table 43.1 lists a few key facts about the role of leg length in human biology and evolution.

Table 43.1 Key facts about the role of leg length in human biology and evolution

1. Human beings are distinguished from the non-human primates by several anatomical features and among these are proportions of the arms and legs relative to total body length. The living apes have arms that are longer than their legs, which reflects their adaptations for brachiation (arm swinging). Bipedal fossil hominins of the species *Ardipithecus*, *Australopithecus* and *Homo habilis*, dating from about 4.5 to 1.6 million years ago (MYA) were similar to apes in body proportions, or had long arms in proportion to their legs. Since the evolution of *Homo erectus*, about 1.8 MYA, human ancestors have had essentially modern body proportions.
2. Leg length must approximate 50% of total stature to achieve the lower limits of the biomechanical efficiency of the adult human striding bipedal gait. In modern humans, this happens at the end of the childhood life history stage, which occurs at about 7.0 years of age. By adulthood, human species-specific body proportions allow for not only the bipedal striding gait, but also for long-distance running, which may have been important for hunting and survival to our ancestors.
3. Relatively long legs in modern humans and in human ancestors allows for more efficient thermoregulation in a tropical savannah environment, which was the birthplace of humanity. Long legs allow for greater body surface area for the cooling of the body by evaporation of sweat.
4. Long legs, which allow for human bipedalism, free the hands for carrying objects and infants, for technological manipulation, for gesticulation and communication, and for the type of social–emotional contact that is one of the hallmarks of humanity.

43.2 Leg Length Defined

In principle, leg length (LL) is the length of the femur plus the tibia, and possibly the height of the foot from the tibia-talus articulation to the ground. In a living human being, these lengths are difficult to measure. Consequently, LL is often defined by easier to measure dimensions, such as iliac height (IH) and subischial leg length (SLL). It is also possible to estimate LL via the combination of thigh length (TL) and knee height (KH). Some studies employ only one of these measures as the indicator of LL.

Each of these measurements can be transformed into ratios, generally in relation to total stature (see entry on stature) and sitting height (SH), to give indications of body proportions. In this entry, we will discuss the sitting height ratio (SHR), relative subischial leg length (RSLL) and the knee height ratio (KHR).

43.3 Population Variation in Body Proportions

For many years, there has been the perception that body proportions are genetically determined, immutable and, therefore, a good indicator of 'racial' markers (Eveleth and Tanner 1976, 1990). It is true that, on an average, Native Australians and people of sub-Sahara African origin have the longest leg length in proportion to total stature, followed by people of European ancestry, and those of Asian ancestry (including Native Americans). There is, however, considerable overlap in the range of both absolute and relative leg length values between these general geographic groups (Fig. 43.1).

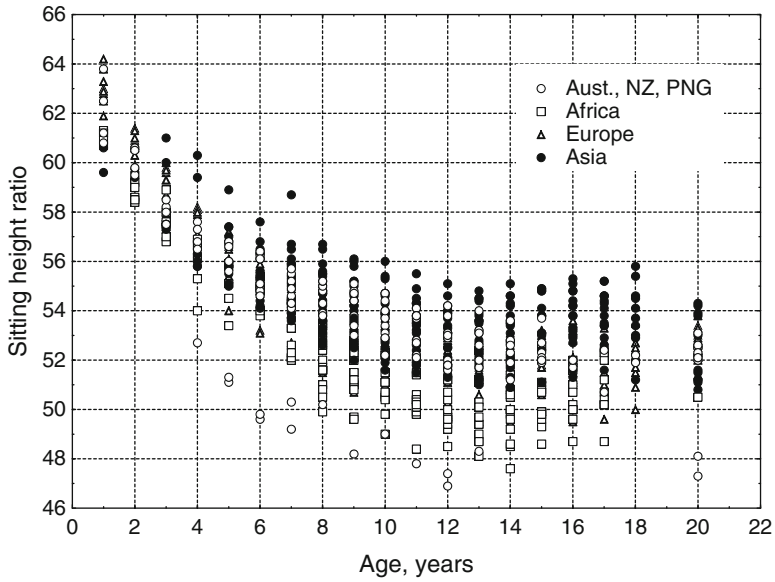

Fig. 43.1 Relative leg length as measured by the sitting height ratio by age for the four geographic groups defined by Eveleth and Tanner (1976, 1990). Age 20 years includes data for adults over the age of 18 years. (From Bogin et al. 2001)

Additionally, socioeconomic factors explain as much of the variation in leg length as does geographic origin or so-called 'race' (Bogin et al. 2001, 2002).

Moreover, leg length and body proportions are plastic, meaning that these phenotypic properties of the human body change in response to external (environmental) factors. Studies conducted in Japan (Kondo and Eto 1975; Tanner et al. 1982; Ohyama et al. 1987) show that environmental improvements in nutrition (mainly the inclusion of milk in the Japanese diet), health and general socioeconomic status are powerful modifiers of body proportions, resulting in longer legs in proportion to total stature in most cases. Between 1957 and 1977, the Japanese population showed a strong positive secular trend in height, and all the increase in height was due to the increase in leg length, with very little increase due to changes in trunk length (sitting height). Bogin et al. (2002) found even greater plasticity in the children of Maya families emigrating from Guatemala to the USA. The Maya families migrated due to precarious conditions in Guatemala, including hunger, poverty and civil war. In the new North American environment, the living conditions improved considerably in terms of basic health care and vaccination, education and availability of clean drinking water. Maya children and adults in Guatemala are typically of very short stature, with disproportionately short legs. Maya-American children experienced a 10–11 cm increase in stature over their Guatemalan living age mates across the ages from 5 to 12 years, and 70% of this increase was due to leg growth. These studies show how body proportions are sensitive to the quality of the environment.

43.4 The Usefulness of Leg Length

The biological and clinical usefulness of LL is based on the cephalo-caudal gradient in growth of all mammals, including humans. The ontogenetic development of human body shape is similar in all human populations, as shown in Fig. 43.2. During the foetal, infant and childhood stages of life, the brain grows faster than the body (Scammon and Calkins 1929). At birth, head length is approximately one-quarter of the total body length, whereas, at 25 years of age, the head is only approximately one-eighth of the total length. There are also proportional changes in the length of the limbs, which become longer relative to the total body length during the years of growth (Scammon 1930). Leitch (1951) was the first medical researcher to propose that a ratio of LL to total stature could be a good indicator of the nutritional history and general health in the early life of an individual. Leitch (p. 145) wrote, '… it would be expected on general principles that children continuously underfed would grow into underdeveloped adults…with normal or nearly normal size head, moderately retarded trunk and relatively short legs.' Leitch found that improved nutrition during infancy and childhood did result in a greater increase in LL than in total height or weight.

A general principle of growth is that those body parts growing the fastest will be most affected by a shortage of nutrients, infections, parasites, physical or emotional traumas and other adverse conditions. The legs, especially the tibia, grow faster relative to other body segments from birth to about the age of 9 years. Relatively short LL in adolescents and adults, therefore, is likely to be due to adversity during infancy and childhood. The alterations in body proportions described by Leitch, and in the studies of Japanese and Maya, are likely due to competition between body segments, such as trunk versus limbs, and between organs and limbs, for the limited nutrients available during growth (Bogin et al. 2001, 2002).

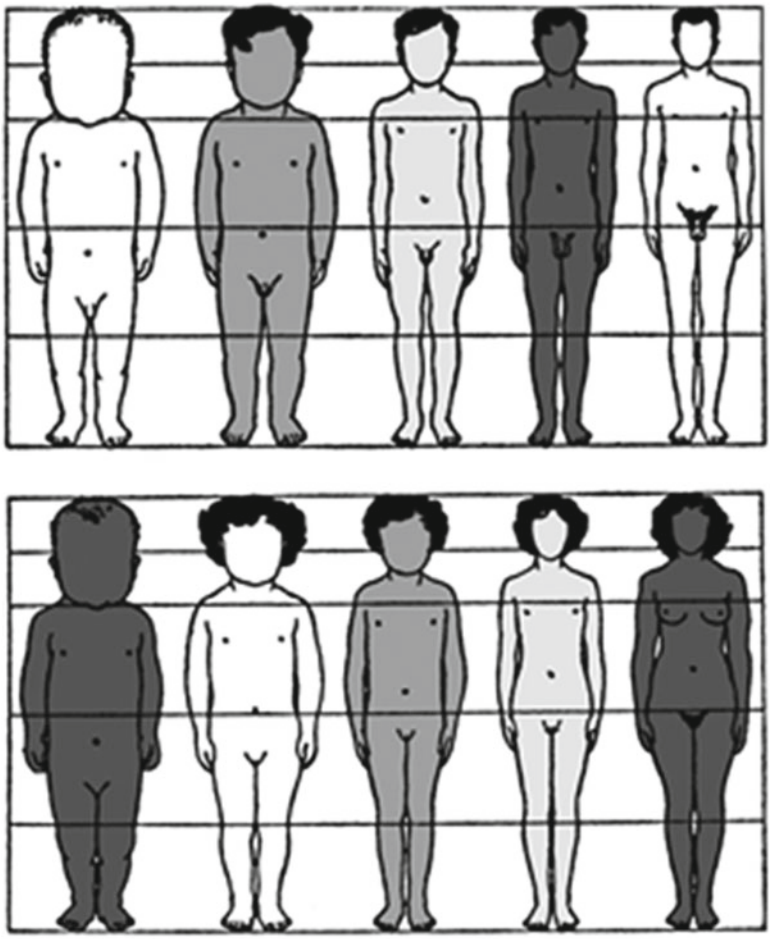

Fig. 43.2 Changes in body proportion during human growth after birth. Ages for each profile are, from left to right, newborn, 2 years, 6 years, 12 years, 25 years. The hair style and shading of the cartoon silhouettes are for artistic purposes and is not meant to imply any ethnic, eco-geographical, or "racial" phenotypic characteristics of the human species [provided courtesy of Dr. J. V. Basmajian]

43.5 Leg Length and Human Health

Table 43.2 summarises several studies that show how leg length and body proportion ratios are powerful indicators of the quality of the environment, and of the plasticity of the human body. The table refers to only a few studies. The table is not a systematic review, and is meant to provide examples of the range of studies available. What is important to note is that regardless of the specific leg measure taken (e.g. IH, SLL, TL and KH), or ratio calculated (SHR, RSLL and KHR), the longer LL is associated with better environments, better nutrition, higher SES and better general physical and psychological health, overall.

Lawlor et al. (2003) present the hypothesis that maternal leg length is associated with birthweight and later health of her infants, meaning that the shorter the maternal leg length, the lower the birthweight of the infant. In turn, low birthweight individuals have increased risk of cardiovascular diseases, among others, as adults. Li et al. (2007) found that taller childhood stature better predicts longer adult leg length than trunk length. Moreover, socioeconomic adversity in childhood

Table 43.2 Summary of studies employing measures of leg length in relation to early life living conditions and health

Measure of leg length	Sample sizes	Sample	Results	Source
IH	Total: 2,209 M: 1,062 F: 1,147	2–14 years Extracted from The Boyd Orr Survey. Children from 1,343 working class families in England and Scotland, measured between 1937 and 1939	M and F: Positive association with length of breastfeeding, decreasing numbers of children in the household and increasing household income. Overall, the individual components of stature mostly associated with childhood environment was leg length (measured as IH) and foot length (not in the scope of this entry).	Whitley et al. (2008)
	Total: 916 M: 376 F: 540	65+ years' inhabitants of Kwangju, South Korea, assessed in 2003.	Shorter limb length is associated with markers of lower early life socioeconomic status and is associated with dementia later in life, especially in women.	Kim et al. (2008)
SLL	Total: 2,338 M: 1,040 F: 1,298	30–59 years (United Kingdom)	M and F: Inverse association with systolic BP, diastolic BP, total cholesterol and fibrinogen. Direct association with FEV, FVC, BW and BMI.	Gunnell et al. (2003)
	Total: 10,308 M: 6,895 F: 3,413	35–55 years (London)	M and F: Strong inverse association with pulse pressure and systolic BP. Strong positive association with lower total/HDL cholesterol ratio, triglycerides and 2-hr glucose M: Strong inverse association with total cholesterol. F: Strong inverse association with diastolic BP.	Ferrie et al. (2006)
	Total: 3,262	Longitudinal study, births from 3–9 March 1946. Twenty-one assessment occasions between birth and 53 years. MRC National Survey of Health & Development (United Kingdom)	M and F: Positive association with mother's and father's height, BW. SLL greater among individuals from the non-manual social class and among individuals who were breastfed.	Wadsworth et al. (2002)
	Total: 5,900	The 1958 British Birth Cohort. Participants assessed at birth and at ages 7, 11, 16, 23, 32, 42 and 45 years.	Adult SLL is associated with parental height and birth weight. Taller prepubertal stature is associated with higher SLL. Maternal smoking during pregnancy resulted in lower adult SLL. Overall, adult SLL is related to a greater extent than trunk length to early life factors and prepubertal height.	Li et al. (2007)
KH	Total: 50 M: 27 F: 23	Infants grouped by gestation time at birth: <28 weeks, 28–31 weeks, 32–36 weeks, >36 weeks. Births occurred in 2004–2005, in the neonatal intensive care, Christchurch, New Zealand.	Changes in KH (using a kneemometer) correlate very well with changes in weight. If gain in weight is achieved, normal linear growth may be assumed. Because of this, kneemometry is not a useful addition to routine measurements of growth in the neonatal unit.	Dixon et al. (2008)

SHR	Total: 2,985 M: 1,465 F: 1,520	2–17 years Mexican Americans (NHANES III, USA)	M and F: Individuals with relatively shorter legs in proportion to total stature are poorer than longer legged individuals (poverty assessed by Poverty Income Ratio)	Frisancho et al. (2001)
	Total: 1,472 M: 747 F: 707	6–13 years, Oaxaca, Southern Mexico Urban settings in 1972: Total:409, M:218, F:173 Rural settings in 1978: Total:363, M:179, F:184 Urban settings in 2000: Total:339, M:173, F:166 Rural settings in 2000: Total:361, M:177, F:184	Positive time trend in leg length from 1972 to 2000 both in rural and urban settings	Malina et al. (2008)
	Total: 2003 M: 2003 F: 0	7–16 years. Two cross-sectional surveys among school aged boys from Kolkata, India. 1982–1983 (n = 816) 1999–2002 (n = 1187)	Positive time trend in relative leg length. Boys measured in 1999–2002 had relatively longer legs in proportion to total stature than their counterparts in 1983–1983.	Dasgupta et al. (2008)
	Total: 1995 M:977 F: 1018	5–12 years. Maya migrants to the USA in 1992 (n = 211), Maya migrants to the USA in 2000 (n = 431) and Maya in Guatemala in 1998 (n = 1353)	Leg length is a sensitive indicator of the quality of the environment. Maya children in the USA show relatively longer legs in proportion to stature than their counterparts in Guatemala. By 2000, Maya migrants to the USA were 11.54 cm taller and 6.83 cm longer-legged than Maya children in Guatemala.	Bogin et al. (2002)
RSLL	Total: 273	Intergenerational sample Parents' generation: Total:165, M:80, F:85 Offspring generation: Total:108, M:49, F:59 From Auckland and Taipei	Is an effective marker of intergenerational changes	Floyd (2008)
KHR	Total: 273	Intergenerational sample Parents' generation: Total:165, M:80, F:85 Offspring generation: Total:108, M:49, F:59 From Auckland and Taipei	Is an effective marker of intergenerational changes. Lower leg growth, as represented by KHR is similar to changes in overall leg length as regards sensitivity to environmental change.	Floyd (2008)

is associated with shorter adult leg length and stature. These two studies are examples of how early life environments, in combination with an intergenerational component, mainly through matrilineal lines, shape body size and proportion.

There are complications in the relationship between LL, health, SES and better environments for growth. One such complication is noted by Schooling et al. (2008a, b), in an analysis of a cross-sectional sample of 9,998 Chinese people aged at least 50 years, and measured in 2005–2006. Sitting height and height were measured and leg length estimated as height-sitting height (SLL). The growth environment for the 50+ year-old adults was estimated via a questionnaire asking about own education, father's occupation, parental literacy and parental possessions. The authors find that leg length and height, but not sitting height, vary with some childhood conditions. Participants with two literate parents, who owned more possessions, have longer legs. The participants' level of education and their father's occupation have no effect on height or leg length, but higher scores for these variables do associate with an earlier age at menarche. The authors explain that earlier menarche for girls, and earlier puberty for boys, will terminate growth at an earlier age. This may explain why higher SES, as measured by education and father's occupation, did not associate with longer LL.

Another complication is noted by Padez et al. (2009), who analyzed the growth status of Mozambique adolescents. The sample comprised 690 boys and 727 girls, aged between 9 and 17 years, from the capital city of Maputo. The sample is divided between those living in the centre of Maputo (higher SES) and those living in the slums on the periphery of the city. Height, weight and sitting height were measured, and the sitting height ratio was calculated. The hypothesis that relative leg length is more sensitive than total stature as an indicator of environmental quality is not uniformly confirmed. Overall, mean stature is greater for the centre group than for the slum group, but relative leg length as measured by the sitting height ratio does not differ. Compared with African-American references (NHANES II), all the girls from the centre group, 9–14-year-old slum girls, all slum boys and the oldest centre boys show relatively shorter legs. These findings show that, within the Mozambique sample, relative leg length is not sensitive enough to distinguish the quality of the living environment between the centre of Maputo (regular housing and higher SES) and the slums in the periphery. A reason for this is that Mozambique was a colony of Portugal until 1975. Civil unrest and warfare characterised the late Colonial period and the post-independence period, until a peace settlement was concluded in 1992. It is possible that all socio-economic status groups within the country, exposed to the war, suffered sufficiently to reduce relative leg length, especially when compared with the better-off African-American reference sample.

43.6 Applications to Other Areas of Health and Disease

The development of human body proportions has a likely genomic basis, although few, if any specific genes are known. *Hox* and homeobox genes are known to regulate the growth of body segments (Mark et al. 1997), and these genes are shared across all taxa. The short stature homeobox-containing gene (SHOX) is the first genomic region that may be relevant to human body proportions. 'SHOX, located on the distal ends of the X and Y chromosomes, encodes a homeodomain transcription factor responsible for a significant proportion of long-bone growth' (Blum et al. 2007, p. 219). One SHOX-related disorder is Turner syndrome (45, XO karyotype), which results in approximately 20 cm deficit in expected stature. Some studies find that legs are disproportionately affected (Neufeld et al. 1978; Ogata et al. 2002), but other studies find no disproportion

(Hughes et al. 1986). Specific candidate genes for body shape are known from some non-human mammals, especially livestock in which body proportions have considerable economic value (Quignon et al. 2009).

Leg length discrepancy (LLD), one leg shorter than the other, poses biomechanical impediments, may predispose people to a variety of musculoskeletal and psychological disorders and may require surgical correction (Gurney 2002). There are several causes for LLD, including *coxa vara*, dislocation of the hip, hemiatrophy or hemihyperatrophy as well as deformities due to rickets or other metabolic diseases. Early and accurate measurement may detect such discrepancy and allow treatment before the period of growth has been completed, when it is easier to correct.

Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency is associated with alterations in body size, composition and proportion. CAH impairs limb growth, especially of the leg, hand and foot. Medical intervention can improve leg growth, especially if the intervention occurs before puberty.

43.7 Practical Methods and Techniques

We define several measurements and ratios of leg length, their anthropometric applications and their biocultural associations with health and disease. We present a brief description of the anthropometric methods required to obtain these measures of leg length. More details of the methods may be found in Lohman et al. (1988) and the NHANES anthropometric manual (http://www.cdc.gov/nchs/data/nhanes/nhanes3/cdrom/NCHS/MANUALS/ANTHRO.PDF).

Table 43.3 shows the usefulness of leg length measurements and ratios in terms of ease of accurate collection, comparison to reference data, as an indicator of body proportions, as an indicator of nutritional status and ease of accurate calculation or interpretation. From all the ratios presented, only the SHR has population-based- and statistically valid reference values (Frisancho 2008).

43.7.1 Iliac height

This is the distance between the summit of the iliac crest and the floor (see Fig. 43.3). The iliac crest is sometimes difficult to find, especially in overweight people. It also may cause ethical concerns as it requires extensive palpation at the hip level to find the landmark required to perform the measurement accurately. There are no reference data available. IH does not easily provide a good indication of body proportions because, by itself, it does not standardise against height or sitting height. This means that comparisons between individuals do not take into account their total stature. Also, as an indicator of nutritional status, it does not provide ready and easy interpretation.

43.7.2 Subischial Leg Length (SLL)

SLL is the distance from the inferior border of the ischium to the floor when the participant is in the standing position. In practice, the border of the ischium is very difficult to locate, and poses serious

Table 43.3 Usefulness of leg length measurements and ratios in terms of ease of assessment, comparison with reference data, as an indicator of body proportions, as an indicator of nutritional status and ease of calculation of the ratio and/or interpretation of the value

	Ease of accurate collection	Comparison with reference data	As an indicator of body proportions	As an indicator of nutritional status	Ease of accurate calculation and/or interpretation
Iliac height	4	4	3	3	4
Subischial leg length	1	4	3	3	3
Thigh length	3	1	3	3	4
Knee height	1	1	2	3	2
Sitting height ratio	1	1	2	1	3
Relative subischial leg length	1	4	2	2	3
Knee height ratio	1	4	2	2	3

1 excellent; *2* good; *3* difficult; *4* very difficult

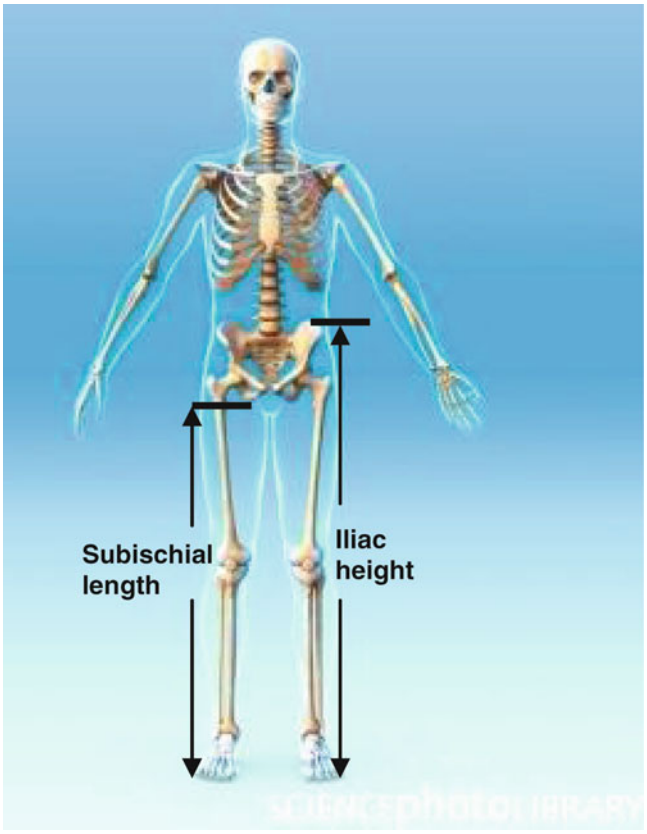

Fig. 43.3 Landmarks for the measurement of iliac height (IH) and subischial leg length (SLL). (Credit: ROGER HARRIS/SCIENCE PHOTO LIBRARY)

ethical concerns (see Fig. 43.3). Therefore, it is a common practice to estimate SLL as the difference between stature and sitting height (see Fig. 43.6). There are no reference data available. It is not a good indicator of body proportions because SLL is dependent on sitting height and it may underestimate leg length values, especially if the participants have high levels of gluteo-femoral subcutaneous fat

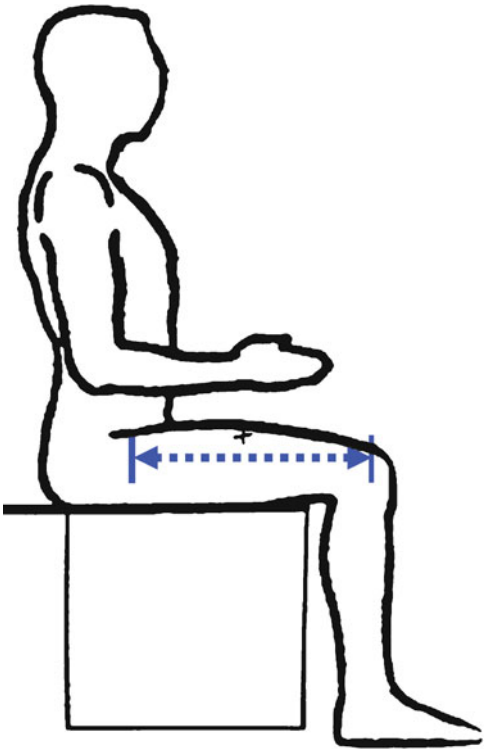

Fig. 43.4 Landmarks and correct body position for the assessment of thigh length

(Bogin and Varela-Silva 2008). Also, it does not take into account the total stature of the individual. As an indicator of nutritional status, it does not provide ready and easy interpretation.

43.7.3 Thigh length (TL)

This is the distance between the hip and the knee. Because in living humans, it is difficult to locate these joints, TL is measured from the midpoint of the inguinal ligament to the proximal edge of the patella (see Fig. 43.4). In overweight or obese people with excessive abdominal subcutaneous fat, it may be difficult to find the inguinal ligament. Also, palpation around the inguinal ligaments may cause ethical concerns. Reference data proposed by Frisancho (2008) are available. TL does not easily provide a good indication of body proportions because, by itself, it does not standardise against height, sitting height or knee height. As an indicator of nutritional status, it does not provide ready and easy interpretation.

43.7.4 Knee Height (KH)

Knee height is the distance between the anterior surface of the thigh (above the condyles of the femur and about 4 cm above the patella) and the floor (see Fig. 43.5). Knee height is regularly used in paediatric assessments, and correlates well with weight during the first month of postnatal life (Dixon et al. 2008). It is relatively easy to collect and does not pose as many ethical concerns as the

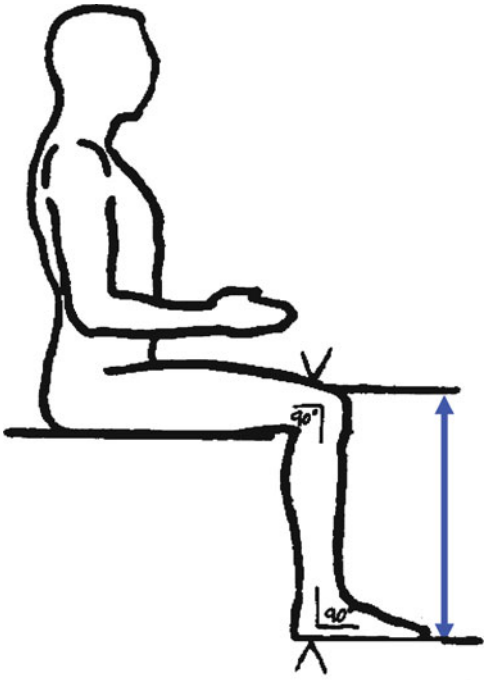

Fig. 43.5 Landmarks and correct body position for the assessment of knee height

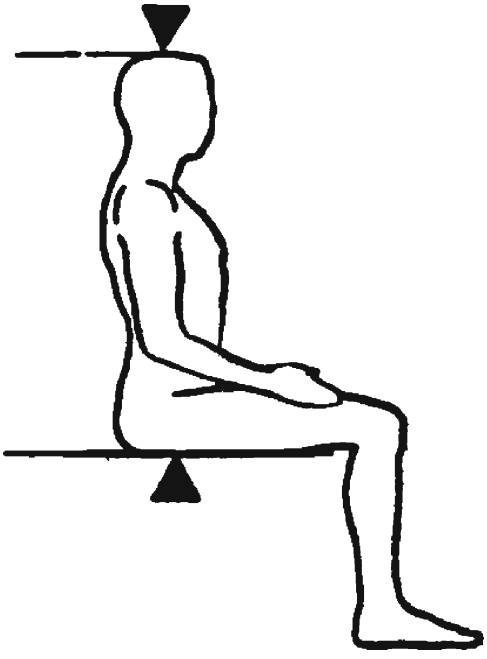

Fig. 43.6 Landmarks and correct body position for the assessment of sitting height

measurements mentioned above. There are reference data proposed by Frisancho (2008). It is a relatively good indicator of body proportions because the tibia grows at the fastest rate and for the longest amount of time relative to the femur and skeleton of the trunk. As an indicator of nutritional status, it does not provide ready and easy interpretation.

43.7.5 Sitting Height Ratio (SHR)

SHR is calculated as SH/H × 100. It defines the percentage of total stature that is comprised by head and trunk (see Fig. 43.6 for details on sitting height measurements). The remaining portion of the body will be the length of the legs. The lower the SHR, the relatively longer the legs are. The ease of accurate collection is high and there are international references (Frisancho 2008) that allow the comparison of any values and the conversion of SHR raw data into percentiles and *z*-scores. SHR is a good indicator of body proportions because it allows individuals with different heights to be compared in terms of the percentage of the body that is composed by the relative length of legs. However, because it is sitting height dependent, this measure can be overestimated in individuals with high levels of gluteo-femoral fat, therefore underestimating the relative contribution of the lower limb to total stature (Bogin and Varela-Silva 2008). It is a good indicator of nutritional status because it allows the classification of the individuals into different degrees of leg stunting, based on the *z*-scores calculated from the references.

43.7.6 Relative Subischial Leg Length (RSLL)

RSLL is calculated as H-SH/H × 100. It defines the percentage of total stature that is comprised by the legs. The lower the RSLL, the shorter are the legs. The ease of accurate collection is high. There are no international reference values. Similar to SHR, RSLL is a good indicator of body proportions because it allows individuals with different heights to be compared in terms of the percentage of the body that is composed by the relative length of legs. However, because it is sitting height dependent, this measure can be overestimated in individuals with high levels of gluteo-femoral fat, therefore underestimating the relative contribution of the lower limb to total stature (Bogin and Varela-Silva 2008). RSLL requires a more difficult computation of values of stature and sitting height than does the SHR.

43.7.7 Knee Height Ratio (KHR)

KHR is calculated as KH/H × 100. It defines the percentage of total stature that is comprised by the lower segment of the leg (tibia + foot height). The higher the KHR, the longer is the leg segment. The ease of accurate collection is high but there are no international reference values. KHR is a relatively good indicator of body proportions because it allows individuals with different heights to be compared in terms of the percentage of the body that is composed by the relative length of legs.

Summary Points

For groups of people:

- Leg length is generally associated with the quality of the environment for human growth and development.
- Longer legs, especially long legs relative to total stature, indicate better quality environments.
- Leg length and body proportions do vary between the major geographic regions of the world, but are not ‘racial’ markers.

- Leg length and body proportions may be useful in the diagnosis of genetic, endocrine and metabolic disorders.
- Different ways of measuring leg length (e.g. IH, SLL, TL and KH) make comparison among studies difficult – if one wishes to compare raw data. However, regardless of what measurement is taken, the overall results are similar, in a sense that longer legs generally show better health status overall and better early life environments.

Chapter 44
Measures and Application of Lower Leg Length: Fracture Risk Assessment

Jian Sheng Chen

Abstract The standardized measurement of lower leg length (knee height) is easy to perform with a high degree of precision. Lower leg length (LLL) is a reliable index of stature in older people because it is virtually unaffected by aged-related high loss. Height has been identified as a risk factor for fracture in middle-aged men and women. In frail older people, vertebral deformities and muscular contraction are common; and these conditions contribute to height loss and lead to increase risk of fracture. The relationship between height and risk of fracture in older people is therefore confounded, and was investigated using LLL rather than using directly measured height. In a prospective cohort of 2,005 institutionalized older men and women, LLL as a risk factor for fracture was examined in different ways in number of studies. The results showed that LLL was a significant risk factor for hip fracture and any fractures after adjusting for the influences of other risk factors. For residents with LLL ≥ 50.5 cm compared to residents with LLL < 50.5 cm, the adjusted relative risk (RR) was 1.45 (95% confidence interval: 1.07–1.99; $P = 0.02$) for hip fracture and 1.27 (95% confidence interval: 1.00–1.60, $P = 0.05$) for any fractures. The results also demonstrated that LLL affected the risk of fracture through one or two fracture pathways, namely bone fragility and/or the force of the impact of falling. It is most likely that both the mechanical impact of a fall and the correlation between LLL and hip axis length contribute to the fracture effect of LLL. In conclusion, LLL should be considered as a component for inclusion in future fracture risk assessment tools, especially those tools that to be used among frail older people.

44.1 Introduction

Since the end of the nineteenth century, the anthropometric technique has been used by anthropologists to estimate body size. Medical scientists adopted this technique and attempted to regress on height from LLL (knee height) in the last few decades (Chumlea et al. 1985). The height of certain individuals or groups, such as elderly, mobility impaired or diseased people may be difficult or impossible to measure directly. Because of postural problems, vertebral deformities, or confinement to a wheelchair or bed, measuring height with accuracy in many frail, older people poses a great challenge. Height is a component of several nutritional and health indicators, such as body mass index, body surface area, total body water, energy expenditure, and creatinine clearance. An accurate estimation of height is of special importance for specialists in nutritional medicine, geriatrics and pediatric orthopedics, etc. Chumlea et al. (1985) and others have recommended the estimation of height from LLL in older people.

Height has been reported to predict the risk of fracture in middle-aged men and women (Meyer et al. 1993; Hemenway et al. 1995), and the recalled height at the age of 25 has also been reported to predict such risk in older people (Cummings et al. 1995; Gunnes et al. 1996). Age-related height loss may explain this pattern. Height loss is common in older people, mainly due to vertebral deformities; and this loss has been shown to associate strongly with low vertebral and femoral bone mineral density (Bunout et al. 2007). Therefore, the relationship between mature skeletal height and risk of fracture in older people may be confounded. LLL, which is virtually unaffected by the aging process and not subject to recall bias, may be a good surrogate for assessing this relationship in older people. This chapter reviews the application of LLL to health and disease, and specifically addresses its relationship with risk of fracture in older people living in old-age care facilities.

44.2 Measuring Lower Leg Length

Chumlea et al. (1985) and others reported that the estimated height from LLL corresponded well with mature skeletal height in older people, and recommended its use. Key reasons for the recommendation are listed in Table 44.1.

Several stature estimation equations from LLL have been published (Chumlea et al. 1985, 1998; Knous and Arisawa 2002). However, the diversity of these equations has drawn attention to the variation in anthropometric standards among different races. Specific stature estimation equations have been developed by Chumlea et al. (1998) for non-Hispanic white, non-Hispanic black, and Mexican-American ethnic groups (Table 44.2). Accordingly, it is probably appropriate to measure a representative sample of young and older health subjects to obtain a regression equation that can be applied with greater accuracy in very frail, older subjects in the same community.

Table 44.1 Key features of lower leg length (LLL)

1. LLL is highly correlated with mature skeletal stature (Chumlea et al. 1985).
2. Aging process does not affect LLL as it does vertebral height (Mitchell and Lipschitz 1982).
3. Fatness does not bias LLL as it does sitting height (Bogin and Varela-Silva 2008).
4. The standardized measurement of LLL is easy to perform with a high degree of precision and can be applied to almost any persons, including elderly, mobility impaired or diseased people.
5. The estimated height from LLL corresponds well with the measured height in healthy persons (Chumlea et al. 1985) and is a valid surrogate of height in the construction of nutritional and health indicators (Ritz 2004).

This table lists the key reasons for the estimation of height from LLL in frail older people

Table 44.2 Stature estimation equations from lower leg length (LLL) for specific ethnic groups

Targeted population	Estimation equation (Chumlea et al. 1998)
Non-Hispanic white men	Height (cm) = 78.31 + (1.94 × LLL in cm) – (0.14 × Age in year)
Non-Hispanic black men	Height (cm) = 79.69 + (1.85 × LLL in cm) – (0.14 × Age in year)
Mexican-American men	Height (cm) = 82.77 + (1.83 × LLL in cm) – (0.16 × Age in year)
Non-Hispanic white women	Height (cm) = 82.21 + (1.85 × LLL in cm) – (0.21 × Age in year)
Non-Hispanic black women	Height (cm) = 89.58 + (1.61 × LLL in cm) – (0.17 × Age in year)
Mexican-American women	Height (cm) = 84.25 + (1.82 × LLL in cm) – (0.26 × Age in year)

This table lists formulas for calculating height using LLL for specific ethnic groups from Chumlea et al. (1998)

Fig. 44.1 Lying position of lower leg length measurement. Lower leg length (*LLL*) is the distance between the sole of the foot and the apex of the knee with each joint flexed at a 90° angle

44.2.1 Practical Methods and Techniques

LLL is the distance between the sole of the foot and the apex of the knee, with each joint flexed at a 90° angle (Chumlea et al. 1985). It is measured using a sliding caliper. A device designed for this purpose is commercially available. While lying face up with the knee and the ankle at a 90° angle (Fig. 44.1), the flexed blade of the caliper is placed under the heel of the foot, and the mobile blade placed on the anterior surface of the thigh. The shaft of the caliper is held parallel to the long axis of the lower leg, and slight pressure is applied to compress the soft tissue. The measurement can be taken to the nearest 0.1 cm on some calipers. The estimated height (cm) is then calculated from an

Fig. 44.2 Sitting position of lower leg length measurement. *LLL* is measured from floor to knee (bent at 90°)

estimation equation that best fits the subject. LLL can also be measured from a sitting position (Fig. 44.2). In this case, it is measured from floor to knee (bent at 90°). If there are difficulties in using calipers, the measurement can be taken using flexible tape, which also provides a reliable reading. Repeat measurements may be considered to reduce intra-observer variability, if high accuracy is required.

44.3 Application to Fracture Risk Assessment

44.3.1 Magnitude of Osteoporotic Fractures

Osteoporotic fractures resulting from low trauma events are very common, affecting up to one-half of women and one-third of men after the age of 50 years. Fractures can cause long-standing pain, functional impairment, disability, and death, especially in frail, older people. A rise in crude and sex- and age-adjusted fracture rates over the past century has been observed. For example, in Finnish people, aged 50 years or more, the age-adjusted incidence of hip fractures (per 100,000 people) showed a steady increase from 1970 to 1997: in women, from 292 to 467, and in men, from 112 to 233 (Kannus et al. 1999). The rise has been attributed to the aging of the population and an increased risk of falls-related injuries, which is affected by social and lifestyle changes. However, a secular increase in height, especially leg length (Tanner et al. 1982), in the past century may also contribute to the phenomenon. Table 44.3 presents the key facts of osteoporotic fractures.

Table 44.3 Key facts of osteoporotic fractures

1.	Osteoporosis related fractures are very common, affecting up to one-half of women and one-third of men after the age of 50 years.
2.	Although osteoporosis is a disease affecting the whole skeleton, and any bone may fracture, hip fractures are the most important economically and clinically, being associated with the greatest costs relating to treatment and significant morbidity and mortality.
3.	The lifetime risk of hip fracture at the age of 50 years is about one in six in women and one in 16 in men, and the risk increases exponentially beyond the age of 60 years (Cumming et al. 1997).
4.	In institutionalized older people, hip fracture incidence rate per annum can be as high as 6.2% for females and 4.9% for males (Kannus et al. 1996).
5.	About one in five hip fracture patients will die in the first year and most of the survivors will not fully recover. According to the Royal Australasian College of Physicians' estimation, one in two hip fracture patients will require long-term nursing care.
6.	A rise in the fracture incidence over the past century has been observed (Kannus et al. 1999). This could be attributed to population aging, social and lifestyle changes, and a secular increase in height.
7.	As population ages, it is projected that the worldwide annual number of hip fractures will rise to 6.26 million by the year 2050 from an estimated 1.66 million hip fractures in 1990 (Cooper et al. 1992).

This table lists the key facts of osteoporotic fractures with respect to risk, trend, and consequences

44.3.2 Is height a risk factor for fracture in older people?

Several studies have reported a positive relationship between height and risk of hip fracture in women (Meyer et al. 1993; Hemenway et al. 1995; Cummings et al. 1995; Gunnes et al. 1996). The increasing risk of hip fracture in middle-aged women, who were taller, was reported by Meyer et al. (1993) and Hemenway et al. (1995). However, studies of older women have generally found no relationship of current standing height with risk of hip fracture (Cummings et al. 1995), or a reduced effect of current standing height on risk of hip fracture (Gunnes et al. 1996). On the other hand, recalled height at the age of 25 years or lower extremity length (difference between standing and sitting heights) has been shown to predict the risk in women in all ages (Cummings et al. 1995; Gunnes et al. 1996; Opotowsky et al. 2003). Details of these studies are presented in Table 44.4. The relationship between height and risk of other fractures is less clear as there were few studies available for the evaluation. Gunnes et al. (1996) reported that recalled height at the age of 25 years was a consistent risk factor for all fracture types in a retrospective study of 29,802 post-menopausal women aged 50–80 years. The relationships of current standing height, recalled height at the age of 25 years and lower extremity length with risk of fracture (hip or other fractures) in males appeared to be the same as the relationships observed in females (Meyer et al. 1993; Hemenway et al. 1994).

The apparent discrepancy between older- and middle-aged subjects in the outcomes of fracture risk for current standing height may be due to aged-related height loss. Height loss is common in older people, and the magnitude of the loss is largely dependent on the severity of vertebral deformities and muscular contraction. Chen et al. (2009a) examined risk profiles of osteoporosis for 37,957 patients in primary care settings in Australia, and found that 43.4% of the patients had a self-reported height loss, with the estimated mean loss of 3.9 cm, and 31.8% had a change in spinal posture recorded as "round back" or kyphosis. In many cases, vertebral deformities can be attributed to osteoporotic vertebral fracture, which is a strong indicator of future fracture risk. Also, muscular atrophy can increase response time to a sudden event, resulting in high risk of falls, and reduce the flexibility to protect the body from the impact of the fall, therefore increasing the risk of fracture. Hence, the relationship between height and risk of fracture in older people is confounded; and the chance of finding a positive relationship is therefore reduced or even reversed. In a study of 1,427 white female nursing home residents, with a median age of 86 years, Girman et al. (2002) reported

Table 44.4 Studies of the relationship between height and hip fracture risk

Studies	
Meyer et al. (1993) – a prospective cohort	
Population:	23,270 women and 23,665 men aged 35–49 years
Type of height:	Height measured at baseline
Adjusted effect size:	HR = 3.6 (95% CI: 1.46–8.97; ≥1.7 m vs. <1.55 m) for women HR = 2.96 (95% CI: 0.94–9.05; ≥1.85 m vs. <1.70 m) for men
Adjusted for:	Age
Hemenway et al. (1994) – a prospective cohort	
Population:	49,895 male health professionals aged 40–75 years
Type of height:	Height reported by participants at baseline
Adjusted effect size:	HR = 2.24 (95% CI: 1.14–4.41; ≥1.83 m vs. <1.75 m)
Adjusted for:	Age, BMI, cigarette smoking status and alcohol consumption
Hemenway et al. (1995) – a prospective cohort	
Population:	Over 92,000 female nurses aged 35–59 years
Type of height:	Height reported by participants at baseline
Adjusted effect size:	HR = 2.40 (95% CI: 1.43–4.02; ≥1.73 m vs. <1.57 m)
Adjusted for:	Age, BMI, cigarette smoking status and alcohol consumption
Cummings et al. (1995) – a prospective cohort	
Population:	9,516 white women aged ≥ 65 years with no history of hip fracture
Type of height:	Height measured at baseline and recalled height at the age of 25 years
Adjusted effect size:	HR (adjusted for age only) = 1.0 per 6.0 cm or 1 SD (95% CI: 0.8–1.1) for height measured at baseline HR (adjusted for all risk factors listed below) = 1.3 per 6.0 cm or 1 SD (95% CI: 1.1–1.5) for recalled height at the age of 25 years
Adjusted for:	Age, maternal hip fracture, weight increase since the age of 25 years, self-rated health, previous hyperthyroidism, long-acting benzodiazepine use, anticonvulsant drug use, caffeine intake, exercise, standing time per day, ability to rise from chair, distant depth perception, contrast sensitivity, resting pulse rate, any fracture since 50 years of age and bone mineral density
Gunnes et al. (1996) – a retrospective cohort	
Population:	29,802 post-menopausal women aged 50–80 year (mean 68.3 years)
Type of height:	Height reported by participants at examination and recalled height at the age of 25 years
Adjusted effect size:	OR = 1.22 per 5.6 cm or 1 SD (95% CI: 1.13–1.31) for height reported at examination HR = 1.35 per 5.4 cm or 1 SD (95% CI: 1.24–1.47) for recalled height at the age of 25 years
Adjusted for:	Age
Opotowsky et al. (2003) a prospective cohort	
Population:	4,264 women aged 40–75 years
Type of height:	Height and lower extremity length (difference between standing height and sitting height) measured at baseline
Adjusted effect size:	HR per 6.34 cm or 1 SD for standing height: 1.81 (95% CI: 1.25–2.67) for age 40–59 years, 1.29 (95% CI: 1.05–1.60) for age 60–69 years and 1.10 (95% CI: 0.84–1.44) for age 70–74 years HR per 4.16 cm or 1 SD for lower extremity length: 1.43 (95% CI: 1.05–1.93) for age 40–59 years, 1.30 (95% CI: 1.07–1.58) for age 60–69 years and 1.33 (95% CI: 1.04–1.69) for age 70–74 years
Adjusted for:	age, weight, age at menopause, history of hormone replacement, history of chronic disease, alcohol use, physical activity and history of fracture

This table presents some of the studies that examined whether height is a risk factor for hip fracture and depicts the study population, index of height, and effect size. Abbreviation – *BMI* body mass index, *CI* confidence interval, *HR* hazard ratio, *OR* odd ratio, *SD* standard deviation

that current height from nursing care charts was negatively associated with risk of any fractures. Residents who were taller than 1.60 m had a fracture rate of 11.2% over 18 months, compared to a rate of 15.9% among residents, who were less than or equal to 1.47 m in height.

44.3.3 Lower Leg Length and Risk of Fracture

LLL appears to be a good measure for accessing relationship between height and risk of fracture in frail, older people. LLL is a valid index of mature skeletal stature and can be measured easily with a high degree of precision in almost any frail, older subject. It does not have issues that other measures, such as current standing height, lower extremity length, and recalled height, may have in measuring frail older subjects. Measuring standing height with accuracy in very frail, older people can be difficult or impossible, and in many older people, it is not representative of peak skeleton stature. Self-report of height is inaccurate, and often overestimates the true loss (Arnett et al. 1988), and is not possible for those with dementia. LLL also has advantages over current standing height in older people in expression of body composition by measures, such as body mass index (BMI) (Roubenoff and Wilson 1993), an important risk factor for fracture. LLL should therefore be chosen over other measures as an index of mature skeletal stature in any study of frail, older people. However, this has been uncommon in fracture risk epidemiology studies.

Due to limited data available in the literature, the evaluation of the relationship between LLL and risk of fracture is based largely on a prospective cohort study called the Fracture Risk Epidemiology in the frail Elderly (FREE) study (Sambrook et al. 2007). The FREE study is a study designed to evaluate falls and fracture risk in institutionalized older people in Northern Sydney, Australia. Participants were 2,005 residents (76% female) aged 65–104 years (mean 85.6 years), living in 82 aged care facilities (30 intermediate care nursing care facilities and 52 nursing homes) and were randomly selected from all registered facilities in the region. Individuals, who were bedbound, bilateral amputees, or non-English speaking, were excluded. The participation rate of eligible residents was 54.5% (self-consent, 77.3%; proxy consent, 32.7%). The non-participants were similar in age and gender to the participants, but had higher care needs, and hence a greater likelihood of living in a nursing home. LLL was measured once at baseline from floor to knee (bent at 90°) using a sliding caliper. With slight pressure applied to the blade, the measurement was recorded to the nearest 0.5 cm. Table 44.5 shows the baseline characteristics of the FREE participants. LLL, as a risk factor for fracture, was examined in different ways in number of studies using the FREE study cohort (Sambrook et al. 2007; Chen et al. 2008a, b, 2009b). Table 44.6 presents the key findings of these studies.

44.3.3.1 Any Fractures

In a study aiming to develop and evaluate a simple fracture risk index for use in frail, older people (Chen et al. 2008a), all 2,005 participants were examined. The outcome was 401 fractures, which occurred in 338 participants in two years from baseline. Cox regression modeling was used to identify risk factors for fracture. LLL was a significant and independent risk factor for any fractures after adjusting for institution type, balance, history of fracture since the age of 50 years, cognitive function, number of medications, and weight. Residents with LLL ≥ 50.5 cm were 1.27 (95% CI: 1.00–1.60, $P = 0.05$) times as likely to sustain a fracture consistently over the study period as residents with LLL < 50.5 cm. The effect of LLL on risk of any fractures was not modified by gender. The fracture risk index derived from the independent risk factors, including LLL, was capable of

Table 44.5 Baseline characteristics of the residents from the Fracture Risk Epidemiology in the frail Elderly (FREE) study

Variables	No.	Mean (standard deviation) or %
Demographics		
Age (years)	2,005	85.7 (7.07)
Gender (male: female)	2,005	24: 76
Institution type (intermediate-care facility: nursing home)	2,005	55: 45
Physical measures		
Lower leg length (cm)	1,953	50.6 (2.98)
Walking aids (walks unaided: uses a stick: uses frame: wheelchair)	1,990	30: 22: 32: 16
Balance (good: fair: fair/poor: poor: not capable)	1,993	29: 22: 18: 11: 20
Weight (kg)	1,876	60.1 (14.2)
Broadband ultrasound attenuation (dB/MHz)	1,975	51.6 (22.2)
Medical condition

Fall in the previous 12 months (yes: no)	1,946	53: 47
Fracture since age 50 years (yes: no)	1,982	45: 55

This table presents baseline information regarding demographics, physical measures and medical conditions collected on the 2005 participants in a cohort study, designed to evaluate falls and fracture risk in institutionalized older people in Northern Sydney, Australia

Table 44.6 Key findings of lower leg length (LLL) as a fracture risk factor

1. LLL was an independent and significant risk factor for any fractures and hip fracture in very frail older people.
2. Compared to residents with LLL < 50.5 cm, residents with LLL ≥ 50.5 cm had a 27% (95% CI: 0–60%) increase in risk for any fractures and a 45% (95% CI: 7–99%) increase in risk for hip fracture after controlling for the influences of other risk factors.
3. LLL was also a significant risk factor for fracture following a fall, indicating a higher fracture risk per fall for residents with longer LLL. For each standard deviation or 2.98 centimeters increase in LLL, the risk of fracture following a fall was increased by 19% (95% CI: 2–39%) for any fractures or by 48% (95% CI: 19–85%) for hip fracture.
4. The effect size of LLL on risk of any fractures increased after adjusting for the falls risk (the falls' incidence rate during the follow-up).
5. The fracture effects of LLL were not dependent on gender or institution type.
6. LLL affected the risk of fracture through one or two fracture pathways, namely bone fragility and/or the force of the impact of falling.

This table lists the key findings of LLL as a fracture risk factor, examined in different ways in a number of studies (Sambrook et al. 2007; Chen et al. 2008a, b, 2009b) using the FREE study cohort
Abbreviation – *CI* confidence interval

identifying higher risk individuals for any fractures in these very frail, older people from both intermediate care nursing care facilities and nursing homes. The fracture risk index had a slightly better fracture discriminating ability among institutionalized older people than the algorithm developed by Girman et al. (2002) (i.e., the area under the receiver operating characteristic curve = 0.69 ± 0.018 and 0.68 ± 0.015 for identifying someone who would have a fracture in 1 and 2 years, respectively, in the FREE study vs 0.63 ± 0.043 for identifying someone who would have a fracture in 1.5 years

in the Girman study). The better discriminating ability of the fracture index from the FREE study might be a result of the inclusion of LLL in the index. However, this cannot be determined, as neither of the two studies measured the same risk factors.

44.3.3.2 Hip Fracture

For hip fracture analysis, 111 residents were excluded [bilateral total hip replacements at baseline ($N = 44$), answering "yes" to the question of total hip replacement but not recording whether it was one or both legs ($N = 50$), or not answering the question of total hip replacement ($N = 17$)], and 1,894 residents (1,433 females, 461 males; mean age 86 years, SD 7.1 years) were then studied (Chen et al. 2009b). Survival analysis with age as a time-dependent covariate was used to analyze the data. Follow-up time was limited to 4 years to maintain the validity of the proportional hazards assumption. During a mean follow-up period of 2.65 years (SD 1.38), 201 hip fractures in 191 residents were recorded, giving an overall hip fracture incidence rate of 4.0% per person year (males 3.6% and females 4.1%). Even in this very high risk population, and after controlling for age, cognitive function, history of fracture since age 50 years, balance, institution type, and total hip replacement, residents with LLL ≥ 50.5 cm were still significantly more likely to sustain a hip fracture compared to residents with LLL < 50.5 cm (i.e., HR 1.45, 95% CI: 1.07–1.99; $P = 0.02$). The effect of LLL on hip fracture appeared to be larger than the effect on any fractures reported above. Also, in this study, broadband ultrasound attenuation (BUA, an indicator of bone fragility) was not a significant risk factor for hip fracture. The result might indicate that, in this very frail older people, the risk for falls played a dominant role in determining the incidence of hip fracture. In a study of the impact of a fall and the breaking point of the proximal part of the femur, Lotz and Hayes (1990) concluded that energy absorbed during falling and impact, rather than bone fragility, may be the dominant risk factors for hip fracture.

44.3.3.3 Influence of Falls

Sambrook et al. (2007) investigated the influence of falls on risk of fracture in the FREE cohort. Negative binomial regression modeling was used to assess the association of LLL with any fractures while adjusting for falls' incidence rate. During a median follow-up period of 1.93 years, 6,646 falls and 375 fractures were recorded, giving a falls' incidence rate of 214 per 100 person years, and a fracture rate of 12.1 per 100 person years. The majority of these fractures (82%) could be attributed to falls. The incidence rate ratio was 1.41 (95% CI: 1.11–1.80, $P = 0.006$) in residents with LLL ≥ 50.5 cm compared to residents with LLL < 50.5 cm in a multivariate model that included risk factors, such as falls' incidence rate, history of fracture since age 50 years, BUA, weight, balance, cognitive function, and institution type. Compared to the effect of $RR = 1.27$ reported above (Chen et al. 2008b), the effect of LLL on risk of any fractures was increased in this study by taking the influence of the falls' risk into consideration.

44.3.3.4 Fracture Pathways

To explore LLL's fracture pathways, the risk of falling was taken out of the fracture risk analysis in a study of risk factors for fracture following a fall (Chen et al. 2008b). This was done by studying only the 1,342 participants (1,035 women and 307 men), who experienced a fall in the follow-up period.

A fall, the mechanical impact of the fall on the skeleton, and the degree of bone fragility usually determine the process leading to peripheral osteoporotic fractures. Risk factors identified in this study are therefore only associated with bone fragility and/or the force of the impact, and not associated with falling. Logistic regression analysis was used to calculate the odds ratio (OR) for fracture for LLL. Each fall was treated as an observation, and lack of independence between falls for the same person (clustering) was taken into account using generalized estimating equations. The analysis was performed separately for any fractures and hip fracture. All 6,646 falls recorded in the FREE study were used. These 6,646 falls resulted in 308 fractures, giving a fracture rate per 100 falls of 4.6. LLL was identified as an independent risk factor for any fractures as well as for hip fracture. For each standard deviation (SD) or 2.98 centimeters increase in LLL, the odds ratio was 1.19 (95% CI: 1.02–1.39, $P = 0.02$) for any fractures and 1.48 (95% CI: 1.19–1.85, $P = 0.001$) for hip fracture after adjusting for other risk factors.

These four studies demonstrate that LLL is an important risk factor for fracture in this very frail older population with high risk of fracture. It has advantages over current standing height as an index of mature skeletal stature in the assessment of fracture risk in frail older people.

44.3.4 Why Is Lower Leg Length a Fracture Risk Factor?

Figure 44.3 presents fracture pathways for some known risk factors, including body height. Two possible fracture pathways of LLL as mature skeletal stature are in its associations with the impact of falling and bone fragility, as demonstrated in the FREE cohort by Chen et al. (2008b).

The effect of height on risk of fracture may be explained by the mechanical impact of a fall. Meyer et al. (1993) suggested that taller people could hit the ground with greater force as they fell from a greater vertical distance and, therefore, had higher risk of fracture. However, a long LLL in frail, older people is not necessary to produce the higher impact from a fall on the upper part of the body. An older person with long LLL, who also has a vertebral deformity due to osteoporosis, may have a similar standing height as that of a healthy older person with short LLL. This could partly explain why the effect size of LLL on hip fracture is larger than on any fractures in the FREE study cohort. Nevertheless, the risk of fracture from an impact with similar force is still higher in a person with osteoporosis than in a healthy person. Also, there are no particular reasons to believe that a tall person is more likely to have height loss due to osteoporosis compared to a short person. As a result, aged-related height loss due to osteoporosis does not obscure the relationship between LLL and risk of fracture in frail, older people. So, the relationship between LLL and risk of any fractures is likely to be a result of the high impact from a high-position fall. The stronger association of LLL with risk of hip fracture, than with risk of any fractures, may be explained by a possible positive correlation between LLL and hip axis length. Faulkner et al. (1993) reported that height was positively correlated with hip axis length, and hip axis length was an independent and significant risk factor for hip fracture. It is quite possible that LLL is also strongly correlated with this femoral geometry. The correlation of hip axis length with LLL is probably higher than that with height. A third explanation is that of genetic differences, with body height as a surrogate for unknown risk factors for fracture propensity, suggested by Gunnes et al. (1996). However, there is no good evidence to support this hypothesis. It is most likely that both the mechanical impact of a fall and the correlation between LLL and hip axis length contribute to the effect of LLL on risk of fracture. Further studies are needed to find out which one is relatively more important in determining a hip fracture when falling.

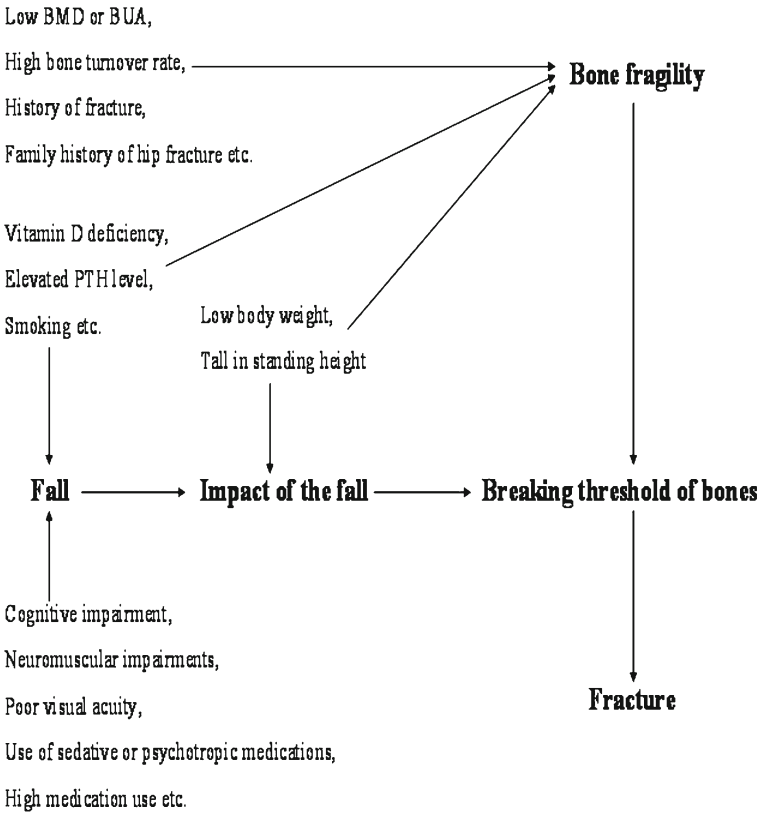

Fig. 44.3 Fracture model showing risk factor pathways. This figure shows fracture pathways for some known risk factors. The occurrence of an osteoporotic fracture usually depends upon first, a fall, second, the nature and impact of the fall, and third, the degree of skeletal fragility. Abbreviations – *BMD* bone mineral density, *BUA* broadband ultrasound attenuation, *PTH* parathyroid hormone

44.3.5 Lower Leg Length as a Parameter in Fracture Risk Index

Many fracture risk factors, such as age, gender, bone mineral density, fracture after 50 years of age, family history of hip fracture, glucocorticoid use, weight or body mass index, current smoking, and alcohol consumption, have been used to construct a fracture risk index. Fracture risk assessment tools, including FRAX (developed by the World Health Organization), are useful in identifying a group of people who are at high risk of fracture. However, the accuracy of these tools in identifying fracture risk at personal level is generally poor. Black et al. (2001) developed a fracture risk index from a large prospective cohort of 7,782 women aged 65 years or older, including parameters, such as age, fracture after 50 years of age, history of maternal hip fracture, weight, current smoking, and use of arms for standing up. They reported a sensitivity of 66.0%, specificity of 66.3%, and positive predictive value of 5.6% for the index at a cut-point of four. To improve fracture discriminating ability, these risk assessment tools may need to include more independent risk factors. Additionally, a useful risk assessment tool should include only risk factors that can be easily assessed and accurately measured in a primary care setting.

Unlike standing height or recalled height, LLL can be measured easily with a high degree of precision in almost any older subject in any setting. More importantly, LLL is an independent and significant risk factor for fracture in very frail, older people. LLL should therefore be considered as a component for inclusion in future fracture risk assessment tools, especially those tools that to be used among frail older people.

44.4 Application to Other Area of Health and Disease

LLL is first considered for older people, who are non-ambulatory or with vertebral deformities, as an estimated height to be included in nutritional status indicators (Chumlea et al. 1985). Its application has been extended to be used as a marker of early life environment, in children with cerebral palsy, and in calculation of height loss, etc. For example, Huang et al. (2008) studied 2,798 men and women for an average of 5.4 years, and found that shorter LLL was associated with higher risk of dementia and Alzheimer's disease in women but not in men. LLL could be considered as a marker of early life environment because most growth before puberty is due to increases in leg length. The authors therefore suggested that LLL might reflect nutritional or other deficits during early development, which could play a role in the determination of future dementia risk. Table 44.7 lists the main medical applications of LLL other than fracture risk assessment.

Summary Points

- LLL can be easily measured with accuracy even in older persons with postural problems, vertebral deformities, or confinement to a wheelchair or bed.
- The estimated height from LLL has advantages over current standing height, lower extremity length or recalled height at the age of 25 years, as an index of mature skeletal stature in older people as it is almost unaffected by aged-related high loss or recall bias.

Table 44.7 Other medical applications of lower leg length (LLL)

LLL as	Area of application
Index of mature skeletal stature	Body mass index (BMI) (Roubenoff and Wilson 1993)
	Body surface area (Ritz 2004)
	Energy expenditure (Cheng et al. 2002)
	Total body water (Ritz 2004)
	Ideal weight (by the Lorentz formula) in the Geriatric Nutritional Risk Index (Bouillanne et al. 2005)
	Creatinine clearance (Schut et al. 2009)
	Height loss (Bunout et al. 2007)
Marker of early life environment	Risk assessment for dementia or Alzheimer's disease in women (Huang et al. 2008)
	Risk assessment for mortality from sex hormone dependent cancers (Gunnell et al. 1998)
	Risk assessment for insulin resistance and coronary heart disease (Smith et al. 2001)

This table lists some applications of LLL as an index of mature skeletal stature or a marker of early life environment in medical fields other than fracture risk assessment

- Institutionalized older people with longer LLL have increasing risk of fracture, and LLL appears to affect risk of hip fracture more than risk of other fractures.
- The effect of LLL on risk of fracture may be explained by the high impact from a high-position fall, and its positive association with hip axis length, which is an independent risk factor for hip fracture.
- LLL should be considered for inclusion in future fracture risk assessment tools to improve the fracture discriminating ability of the tools, especially those tools targeting frail older people.

Chapter 45
Anthropometry and the Knee Joint

A.J. Teichtahl, A.E. Wluka, Y. Wang, and M. Flavia Cicuttini

Abstract Assessing how human anthropometry (i.e. measures of the size and proportions of the body) influences the knee has provided important information about risk factors for common arthropathies, such as osteoarthritis (OA). Nevertheless, until recently, there has been a paucity of data identifying associations between anthropometric measures and structural aberrations in the knee. This is likely to have resulted from difficulties in assessing knee structures. Previous studies have been largely reliant upon joint radiography to image the knee. Radiographs are limited and provide a two-dimensional assessment of a three-dimensional structure, without the ability to examine the non-radiographically opaque intra and extra-articular structures. New imaging modalities, such as magnetic resonance imaging (MRI), have enabled novel and sensitive opportunities to measure knee structures *in vivo*. MRI has helped to confirm OA to affect the whole joint, enabling a detailed examination of the relationship between human anthropometry and the knee. This chapter seeks to discuss how different dimensions of assessment of knee structure can be related to human anthropometry, and improve our understanding of factors affecting the risk and progression of knee OA. This may facilitate novel preventive strategies for the disease.

45.1 Introduction

Assessing how human anthropometry (i.e., measures of the size and proportions of the body) influences the articular knee joint has provided important information about risk factors for common arthropathies, such as osteoarthritis (OA). The most pertinent example of this is the unequivocal link between an increased body mass index (BMI) and the risk for the onset and progression of knee OA (Felson et al. 1997; Gelber et al. 1999; Schouten et al. 1992).

Nevertheless, until recently, there has been a paucity of data identifying associations between other anthropometric measures and structural aberrations in the knee joint. This is unlikely to be a result of the way in which anthropometric measures (e.g., height, weight or body composition) have been collected, as these have proven to be consistently valid, reliable, sensitive and robust. Rather, the lack of association between knee joint structures and anthropometric measures may be attributable to the difficulties in assessing the knee joint.

In both the clinical and research settings, joint imaging provides a non-invasive means of measuring knee joint structures, and therefore assessing the presence and extent of an arthropathy. The most common arthropathy is OA, and radiographic knee OA is estimated to be prevalent in 30% of people aged over 65 years (Felson et al. 1987). Radiographic OA is characterised by joint space narrowing (JSN), osteophytes, subchondral cysts and subchondral sclerosis. While previous radiological measurements have largely been dependent on the joint radiograph, they provide only a two-dimensional assessment of three-dimensional structures, and cannot identify changes occurring in all intra- and extra-articular structures. Some of the limitations associated with joint radiography may have influenced the lack of association between human anthropometry and the knee joint.

The advent of new imaging modalities, such as magnetic resonance imaging (MRI), has, for the first time, enabled the measurement of all knee structures sensitively and non-invasively, in vivo. In particular, MRI enables direct visualisation of joint structures in three dimensions. This has offered a more sensitive quantitative and qualitative alternative to radiographs for examining knee joint arthropathies. Such advances have helped to characterise disease processes, such as OA, as a whole organ phenomenon, and have enabled a more detailed investigation of the relationship between human anthropometry and the knee joint in both health and disease.

This chapter seeks to explore the associations between human anthropometry and the knee joint using OA as a disease paradigm. However, to enable a discussion of how anthropometry is related to the knee joint, an appreciation of how the knee joint can be measured must first be understood.

45.2 Radiological Assessment of the Human Knee Joint

45.2.1 The Joint Radiograph

The World Health Organisation (WHO), in 1961 adopted the Kellgren and Lawrence (K-L) system for grading radiographic OA (see Table 45.1). Although the radiographic features of OA are recognised as osteophytes, JSN, subchondral sclerosis, and cysts, the presence of osteophytes and joint space narrowing have predominantly been used to identify the presence and examine the progression of disease respectively (Fig. 45.1).

Osteophytes are fibrocartilaginous-capped bony outgrowths that can be detected on the joint radiograph. Although the presence of osteophytes is crucial to radiographic grading systems examining the presence and severity of disease, the relevance of osteophytes in the pathogenesis of OA remains unclear.

Table 45.1 Kellgren & Lawrence grading system of knee osteoarthritis

Grade	Classification	Criteria
0	Normal	No features of OA
1	Doubtful	Minute osteophyte, doubtful narrowing of joint space
2	Minimal	Definite osteophyte, absent or questionable narrowing of joint space
3	Moderate	Moderate osteophyte, definite narrowing of joint space, some sclerosis, possible deformity
4	Severe	Large osteophyte, marked narrowing of joint space, severe sclerosis, definite deformity

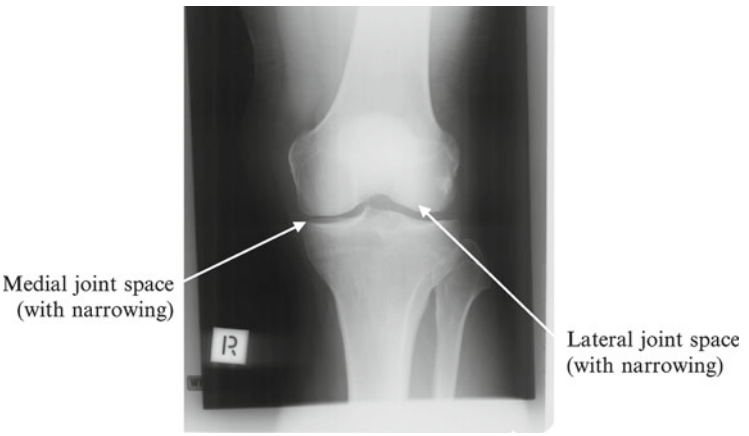

Fig. 45.1 Anterior–posterior knee X-ray

Studies examining individual radiographic features of OA have predominantly reported results related to osteophytes, as their measurement tends to yield better reproducibility than measurements of JSN (Spector et al. 1996). Nonetheless, it has recently been shown that plain radiography may not be the most sensitive means of determining the presence of osteophytes, in particular, central osteophytes. Of 44 asymptomatic volunteer subjects, 25% had osteophytes detected by MRI, of whom three-quarters had no evidence of osteophytes on radiography (Beattie et al. 2005).

According to the K-L grading system, radiographic studies may have therefore under-classified the prevalence of disease by failing to recognise the presence of osteophytes. In contrast, without recognising that other structural changes may not occur in parallel with osteophytes, there has been the potential to underemphasise findings related to other individual radiographic features, such as JSN.

JSN is a continuous radiographic measure used to assess the potential space between opposing bony surfaces (see Fig. 45.1). It has been employed as one of the major outcome variables in studies of disease progression in knee OA (Reginster et al. 2001).

Underlying the measurement of JSN is the assumption that a longitudinal diminution in this potential space is a valid measure of a reduction in articular cartilage volume. This is not necessarily true, as the radiographic joint space is comprised of structures other than articular cartilage (Bruyere et al. 2007; Adams et al. 1999). For instance, mensical extrusion has been shown to account for much early joint space loss at the tibiofemoral joint (Fife et al. 1991). Reliability issues related to JSN are also problematic, primarily because of measurement error related to positioning of the knee. For example, the conventional anterior–posterior knee radiograph is highly observer dependent when determining JSN at the tibiofemoral joint (Gunther and Sun 1999), and measurement error may relate to both the positioning of the knee, and its alignment with respect to the radiograph and source

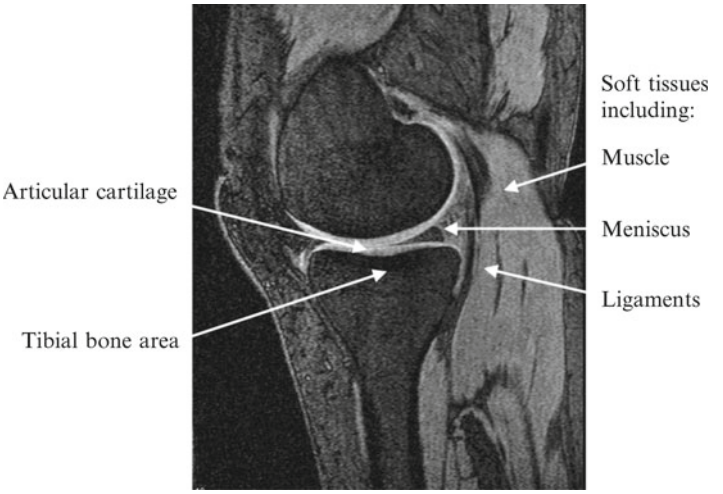

Fig. 45.2 T1 weighted sagittal MRI

of radiation (Altman et al. 1996; Ravaud et al. 1996; Buckland-Wright et al. 1995). Finally, JSN is relatively insensitive to change, and few studies have demonstrated significant change over short-term periods (Raynauld et al. 2004; Vignon et al. 2003).

45.2.2 Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a non-invasive and non-ionising modality, enabling the three-dimensional imaging of all joint structures simultaneously. Thus, MRI enables valid, reliable, and direct measurement of cartilage and bone, as well as other intra- and extra-articular structures (see Fig. 45.2). Since the advent of MRI, OA is more widely appreciated to involve the whole organ, with abnormalities identified in multiple joint structures.

45.2.2.1 Quantitative Measurements of Cartilage

MRI studies examining knee OA initially focussed on the assessment of articular cartilage as the main outcome measure as an extension of the previous radiographic work examining JSN. MRI has been seen as a potentially major advance because it enables the direct assessment of cartilage, rather than the indirect approach allowed by the use of radiography. Epidemiological studies have tended to use cartilage thickness and volume as the main quantitative outcome measures in both cross-sectional and longitudinal studies of subjects with and without established knee OA.

Several limitations have been identified when adopting cartilage thickness as a means for assessing knee OA. In particular, diurnal variability in articular cartilage thickness, but not volume, has been demonstrated (Waterton et al. 2000). Additionally, longitudinal studies examining change in cartilage thickness may be limited by the difficulty in reselecting identical section locations at follow-up assessment (Pilch et al. 1994). Rather than measuring cartilage thickness at a particular geographical location, it is also possible to quantify the entire cartilage plate by measuring cartilage volume.

MRI assessment of knee cartilage volume has been demonstrated to be a valid (Peterfy et al. 1994b; Cicuttini et al. 1999; Burgkart et al. 2001; Graichen et al. 2004) (Cicuttini et al. 2004; Hunter et al. 2003;

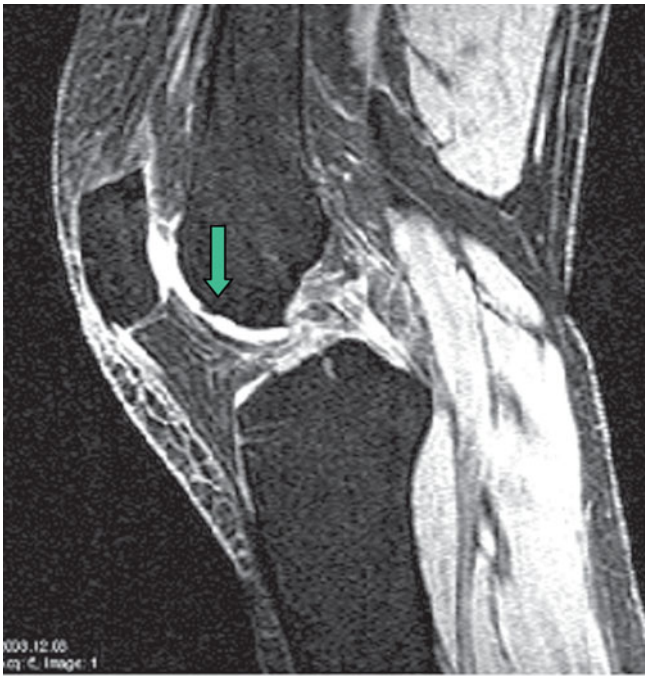

Fig. 45.3 Cartilage defects. *Arrow* demonstrates a tibial cartilage defect

Wluka et al. 2004; Peterfy et al. 1994a; Wluka et al. 2002) and reliable (Marshall et al. 1995; Cicuttini et al. 2000) assessment of the entire geographical cartilage plate. The technique also provides a far more sensitive measure of change in cartilage volume than the joint radiograph, with 11–13% of cartilage volume being lost before the first changes of radiographic JSN can be detected (Jones et al. 2004). Similarly, MRI has demonstrated that, over consecutive 6-month intervals for a period of 2 years, cartilage volume loss occurs, despite no diminution in the radiographic joint space in people with established knee OA (Raynauld et al. 2004).

45.2.2.2 Qualitative Measurements of Cartilage

Although early MRI studies focussed on quantitative measures of cartilage (i.e., thickness and volume), more recent studies have also assessed the quality of cartilage.

Cartilage defects are irregularities on the surface of the usually smooth articular cartilage that can be detected and assessed via MRI (see Fig. 45.3), using a technique developed from arthroscopy (Ding et al. 2006). Histologically, these are highly correlated with the Mankin scale for grading cartilage (McGibbon and Trahan 2003). These lesions are thought to represent early aberrations in the cartilage plate that may be apparent prior to radiographic change (Ding et al. 2005d) and may herald a reduction in cartilage volume, and thus represent a very early form of OA (Ding et al. 2005a, b, c, Cicuttini et al. 2005a).

45.2.2.3 Quantitative and Qualitative Measurements of Subchondral Bone

Once considered primarily a degenerative process of articular cartilage, studies that have employed MRI have enabled greater appreciation that the pathogenesis of OA also involves changes at the articular bone surface.

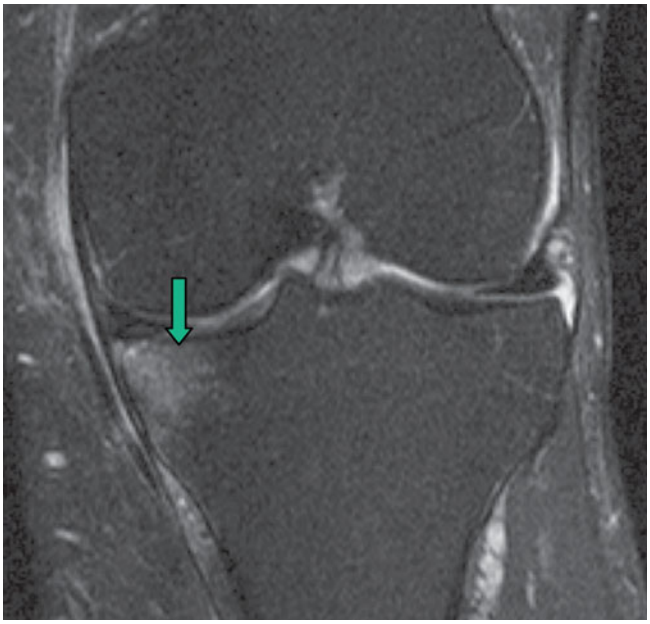

Fig. 45.4 Bone marrow lesions. Large bone marrow lesion identified at medial tibia

Persons with knee OA have been shown to have a larger bone surface area at the tibial plateau than healthy controls, and it has also been demonstrated that the rate of bone expansion is greater in persons with OA than in healthy subjects (Wang et al. 2006, 2005). Radiographically, for each increase in grade of JSN in a compartment, tibial plateau bone area was also shown to be increased (Wluka et al. 2005). In terms of directly assessing cartilage aberrations, it has also been shown that a larger bone area at baseline was predictive of an increase in the severity of knee cartilage defects over 2 years (Ding et al. 2005d). Moreover, increased tibial plateau surface area was a major determinant in mediating reduced knee cartilage volume among people without clinical knee OA (Ding et al. 2007).

Bone marrow lesions (BMLs) are measured via MRI, and are represented by high-signal-intensity areas on fat-suppressed T2-weighted images (see Fig. 45.4). BMLs are correlated with increased bony uptake on bone scintigraphy (Boegard et al. 1999; McAlindon et al. 1991) and, in OA studies, demonstrate histological features consistent with ongoing bone trauma, including marrow necrosis, abnormal bone formation with excessive fibrosis and extensive bony remodelling with reversal lines and areas of osteonecrosis (Zanetti et al. 2000).

BMLs have been shown to be prevalent in approximately 13% of healthy middle-aged subjects with no clinical knee OA (Baranyay et al. 2007). In these healthy subjects, BMLs were positively associated with tibial bone area, and were associated with an increased risk for the presence of cartilage defects (Guymer et al., Baranyay et al. 2007). In subjects with knee OA, BMLs are associated with the radiographic progression of compartment-specific JSN, although some of this progression may have been attenuated by frontal plane knee alignment (Felson et al. 2003). Similarly, knee compartments with a higher baseline BML score also had greater cartilage loss at follow-up, although adjusting for knee alignment attenuated this relationship (Hunter et al. 2006).

Subchondral bone attrition is defined as a flattening or depression of the osseous articular surface. The causes of attrition are unknown, although it is speculated that chronic overload and subsequent remodelling processes may be an important contributor. For instance, bone attrition was associated with knee alignment in a compartment-specific manner, suggesting the importance of biomechanical factors

that increase compartment loads (Neogi et al. 2009). Moreover, in a study of 1,025 knees with or deemed to be at high risk of knee OA, subchondral bone attrition and BMLs were found to coexist, whereby there was an increased risk of bone attrition in areas of prevalent BMLs (Roemer et al. 2009).

45.3 The Relationship Between Human Anthropometry and the Knee Joint

As radiographic OA (assessed by plain radiography) and articular cartilage and bone morphology (assessed by MRI) are the most commonly employed outcome variables in studies examining the articular knee joint, it is important to appreciate how these measures are related to the size and proportions of the human body (see Table 45.2).

45.3.1 Developmental and Gender Differences in the Knee Joint

During development, cartilage accrual is greater in the lateral, rather than the medial knee compartment (Jones et al. 2003). Moreover, paediatric data demonstrates that cartilage volume at the knee peaks during Tanner stage two of development (Jones et al. 2003). Overweight children have lower cartilage volume at all knee sites than their non-overweight counterparts (Jones et al. 2003). Boys have greater increases in cartilage volume than girls, and tibial cartilage volume accrual correlates significantly with height change (Jones et al. 2000). Similarly, adiposity and sedentary lifestyles were related to less bone accrual in children (Wosje et al. 2009). Bone area is also smaller in overweight and obese boys and girls, relative to their body weight (Goulding et al. 2000).

The paediatric trends in cartilage and bone development are also reflected in later life, whereby lateral knee cartilage volume is significantly greater than medial cartilage volume in adults, despite the medial tibial plateau bone area being larger than the lateral plateau bone area (Cicuttini et al. 2002). Adult males have been shown to have greater tibial cortical area and thickness than females (Nieves et al. 2005), as well as greater cartilage thickness and volume at all sites within the knee joint (Cicuttini et al. 1999, 2002). However, although gender has been estimated to account for 33–44% of the variation in adult knee cartilage volume, this estimate is reduced to 8–18% after adjustment for height, weight and bone size (Ding et al. 2003). This suggests that independent of gender, other measures of body size and proportions are key determinants of articular knee joint morphology.

45.3.2 Height and Weight

As the body mass index (BMI) accounts for both height and weight in a single measure, the predominance of studies have tended not to examine height or weight separately. Of the small number of studies examining weight and height separately, weight, including a past history of heavy weight, has been documented as a risk factor for the presence of radiographic knee OA (Abbate et al. 2006; Yoshimura et al. 2004). It has also been demonstrated that increased knee height was associated with an increasing prevalence of radiographic OA, especially among women (Hunter et al. 2005), and is a risk factor for knee joint replacement (Liu et al. 2007). The rationale for knee and body height being an important determinant of knee OA is based on the theory that greater limb length would contribute to larger moments around the knee, producing more torque and subsequent joint load.

Table 45.2 Key features of the anthropometric determinants of joint structure

	ROA	Cartilage volume	Cartilage defects	Metaphyseal bone expansion	Bone marrow lesions
↑ Height	↑ (Hunter et al. 2005)	↑ (Nishimura et al. 2005)	N/A	N/A	↑ (Guymer et al. 2007)

Arrows indicate direction of association (↔ represents equivocal relationship)
N/A data not yet examined, *ROA* radiographic osteoarthritis

Only a small number of MRI studies have examined height and weight separately. Nevertheless, significant correlations have been documented between the tibia and femoral cartilage thickness, and body weight ($R = 0.64$; $P < 0.05$) and height ($R = 0.60$; $P < 0.05$) (Connolly et al. 2008). Likewise, knee cartilage volume is positively correlated with body weight and height (Nishimura et al. 2005). The association between bone and height or weight has not been well examined, but there is some evidence that these anthropometric measures are associated with the presence of BMLs (Guymer et al. 2007).

45.3.3 Body Mass Index and Body Composition

BMI, which is defined by weight (kg)/height (m^2), is an unequivocal risk factor for severe radiographic knee OA and knee replacement (Wendelboe et al. 2003, Liu et al. 2007).

Despite BMI being associated with JSN on radiographs, it has not been consistently demonstrated as a significant determinant of cartilage volume when assessed by MRI (Ding et al. 2005c). Nevertheless, among the small number of studies that have examined the association between BMI and knee cartilage defects, there is a consistent positive association between BMI and the presence of severity of knee cartilage defects (Ding et al. 2005c, 2006). BMI is also positively associated with tibial bone area (Ding et al. 2005c).

However, BMI is only a surrogate measure of obesity, and it cannot discriminate between adipose and non-adipose mass. In a study of 779 females, it was demonstrated that fat mass, percentage fat mass, and waist circumference were associated with the risk of radiographic knee OA, whereas lean mass percentage was associated with lower odds for radiographic knee OA (Abbate et al. 2006). Likewise, in a recent MRI study, it was demonstrated that fat-free mass was associated with an increase in tibial cartilage volume, whereas fat-mass was associated with a reduction in tibial cartilage volume, and weakly associated with an increase in the prevalence of knee cartilage defects (Wang et al. 2007). Indeed, muscle mass has also been demonstrated to reduce the rate of knee cartilage loss (Cicuttini et al. 2005b). No study has examined the associations between body composition measures and bone morphology.

45.3.4 Knee Alignment

In persons with knee OA, radiographic studies have demonstrated that knee alignment is associated with the compartment pattern and severity of disease (Khan et al. 2008). That is, varus alignment is a determinant of medial knee disease, whereas valgus alignment is a determinant of lateral knee disease. Indeed, much of the effect of BMI on the severity of radiographic medial knee OA was explained by varus malalignment (Sharma et al. 2000).

In MRI studies, knee alignment has consistently been associated with compartmental cartilage defects (Issa et al. 2007), both in the presence and absence of established clinical disease (Janakiramanan et al. 2008). Although the association between alignment and cartilage volume is less clear cross-sectionally, change towards genu valgum was shown to reduce the annual rate of medial knee cartilage loss in people with established disease (Teichtahl et al. 2009). Few studies have, however, examined the association between knee alignment and bone size, although the knee adductor moment, a dynamic measure of knee joint loading, is associated with medial tibial plateau bone area (Jackson et al. 2004). In OA, enlarging or new BMLs do, however, occur mostly in malaligned knees, in a compartment-specific manner (Hunter et al. 2006).

45.3.5 The Relationships Between Knee Structures

Within MRI studies, multiple relationships between articular structures have been elucidated. The following examples are non-exhaustive, and provide only an overview of significant findings that indicate that there is a potential continuum of disease in knee OA, whereby the origins of disease may begin in the asymptomatic knee joint devoid of radiographic OA. For instance, prevalent knee cartilage defects are predictive of compartment-specific cartilage loss (Ding et al. 2005a). A larger bone area at baseline was predictive of an increase in the severity of knee cartilage defects over 2 years (Ding et al. 2005d, 2006; Davies-Tuck et al.).Moreover, increased tibial bone area predicts compartmental cartilage volume loss over 2 years (Ding et al. 2007, 2008). BMLs were positively associated with tibial bone area and were also associated with an increased risk for the presence and progression of cartilage defects, as well as cartilage loss in people with and without established knee OA (Guymer et al.; Baranyay et al. 2007, Wluka et al. 2009).

In studies that have combined both radiographic and MRI data, it has been shown that tibial plateau area increased with each increase in grade of osteophyte and joint space narrowing (Wluka et al. 2005). In a separate study, osteophytes were associated with the severity and prevalence of knee cartilage defects and, once again, tibial bone area. The severity of knee cartilage defects was also associated with increased grade of JSN (Ding et al. 2005d).

45.4 Applications to Other Areas of Health and Disease

The acknowledgement of knee OA as a whole-organ disease can predominantly be attributed to advances in imaging, such as MRI. Such progressions have furthered our understanding of how anthropometrical measurements may be related to the knee joint. However, while knee OA has been exemplified in this chapter as the disease paradigm, the principles discussed here are not limited to OA alone. For instance, other arthropathies, including inflammatory processes, such as rheumatoid arthritis and gout, can also be investigated in the context of these anthropometrical measures. Moreover, the application of such principles need not necessarily be limited to the knee joint, and could be examined at other anatomical sites (e.g., hip, carpometacarpal) where different risk factors may be apparent, even for the same disease (e.g., OA). Such investigations will allow a greater understanding of how human anthropometry is related to articular structures in both health and disease.

45.5 Conclusion

Joint radiographs have provided the ability to study important relationships between knee joint structures and measures of size and proportions of the human body. However, newer imaging modalities, such as MRI, have provided a more comprehensive and sensitive means for assessing knee joint morphology. MRI has enabled a more complete appreciation that OA is a disease of the whole joint. Using the sensitive tools facilitated by MRI, the examination of knee structural changes can be made on a continuum, from the normal through to the diseased knee joint. MRI has extended our ability, for the first time, to directly examine all intra- and extra-articular structures non-invasively and three-dimensionally, prior to the development of established radiographic disease. Novel findings include

identification of the potential role of height (total body and knee height) and knee alignment as affecting factors for knee structure, as well as further clarification of developmental and gender differences in the knee joint structure. The importance of body composition (e.g., fat mass), as opposed to obesity per se (as measured by the BMI) in the pathogenesis of knee OA is also becoming increasingly clear. Likewise, the importance of interactions between knee structures (e.g., bone marrow lesions, cartilage defects, metaphyseal bone expansion and cartilage defects) and the continuum from the healthy knee joint to end-stage knee OA are all contributing to our understanding of the pathogenesis of disease. Together, these new findings may lead to improvements in preventive strategies for diseases, such as OA.

Summary Points

- Assessing how human anthropometry (i.e., measures of the size and proportions of the body) influences the knee has provided important information about risk factors for common arthropathies, such as osteoarthritis (OA).
- Until recently, outcome measures at the knee have relied upon the radiograph of the joint to explore the relationships with human anthropometry. However, the joint radiograph provides limited outcome measures in knee OA, and other more valid, reliable and sensitive imaging modalities are now available.
- MRI has provided the opportunity to directly examine intra- and extra-articular structures three-dimensionally prior to the development of clinical disease.
- MRI studies have therefore enabled the associations between anthropometric variables and articular structures to be characterised and help better understand the pathogenesis of knee OA.
- Novel findings include:
    - Height (total body and knee height) and knee alignment being identified as risk factors for radiographic knee OA;
    - Developmental and gender differences in the knee joint structure;
    - The importance of body composition (e.g., fat mass), as opposed to obesity (as measured by the body mass index) in the pathogenesis of knee OA; and
    - Interaction between knee structures (e.g., bone marrow lesions, cartilage defects, metaphyseal bone expansion and cartilage defects) and the potential for a continuum to exist between the healthy knee joint and end-stage knee OA.

Chapter 46
Knee Anthropometry and Total Knee Arthroplasty: Relationship Between Anthropometry, Surgical Difficulty, and Outcomes

Luis Ma. Lozano, Montserrat Núñez, Ester Nuñez, Josep Ma. Segur, and Francisco Maculé

Abstract The Body Mass Index is usually used to identify patients who may present difficulties during surgery and poor outcomes. In severe and morbidly obese patients some anthropometric parameters may be useful in predicting surgical difficulty and outcomes after total knee arthroplasty surgery. We carried out two prospective studies with an initial hypothesis that the Body Mass Index is not associated with surgical difficulty in obese patients and that knee anthropometry influences outcomes after total knee arthroplasty.

In both studies, consecutive patients diagnosed with knee osteoarthritis with a Body Mass Index equal or more than 35 kg/m^2 scheduled for total knee arthroplasty were prospectively studied. The suprapatellar, infrapatellar and supra/infrapatellar anthropometric indexes were calculated before surgery. The tourniquet time was determined as a measure of surgical difficulty. The health-related quality of life, measured by the disease-specific Western Ontario and McMaster Universities Osteoarthritis Index questionnaire of each patient, was determined before and after surgery.

There was no association between the Body Mass Index and tourniquet time/surgical difficulty. The suprapatellar index was negatively associated with tourniquet time/surgical difficulty ($p = 0.038$). The infrapatellar index percentile < 75 was associated with higher Western Ontario and McMaster Universities Osteoarthritis Index questionnaire pain and function dimension scores after total knee arthroplasty.

The Body Mass Index is not the only parameter that should be considered in order to identify severe and morbidly obese patients who may have more surgical difficulties during total knee arthroplasty. Preoperative determination of the suprapatellar index helped us to classify these patients according to the morphology of the knee and predicted a longer tourniquet time and, therefore, greater surgical difficulty, in patients with a suprapatellar ratio below 1.6 in this study.

Outcomes after total knee arthroplasty surgery are influenced not only by the Body Mass Index but also by the anthropometric characteristics of the knee. An infrapatellar index less than 1.75 predicts worse outcomes after total knee arthroplasty surgery.

46.1 Introduction

Total knee arthroplasty (TKA) in patients with severe and morbid obesity is one of the current challenges in prosthetic knee surgery (Stickles et al. 2001; Bourne et al. 2007; Guss and Timothy 2006; Naik 2006; Gilliespie and Proteus 2007) In our hospital, 15% of patients undergoing primary TKA have a body mass index (BMI) >35 kg/m^2. Various studies have reported greater technical difficulties in operating on these patients (Winarsky et al. 1998; Booth 2002; Rottman et al. 2005; Krushell and Fingeroth 2007) The BMI (Stickles et al. 2001; Miric et al. 2002; Namba et al. 2005; Foran et al. 2004a, b; Amin et al. 2006; Bourne et al. 2007; Patel et al. 2007) is used to identify patients, who may present difficulties during surgery, and may have postoperative complications. However, other reports have not found these differences in TKA outcomes with respect to the BMI (Spicer et al. 2001; Deshmukh et al. 2002). Many patients with a high BMI do not have greater surgical difficulties than the rest of the population (Núñez et al. 2007). The problem is more often focused on the anthropometric profile presented by the obese patient with respect to the distribution of body fat: in some patients, this accumulates in the trunk, whereas in others, it is distributed uniformly, affecting the lower limbs (Booth 2002). Just as the waist-to-hip ratio has been used to predict cardiovascular risk in obese patients in preference to the BMI (Chen et al. 2007), determination of a new anthropometric index in the limb in patients undergoing TKA might help to identify patients, who may present greater surgical difficulties (prolonged tourniquet time (ischemia time)) and worse outcomes, in addition to the BMI.

Reports show a link between knee OA and obesity (Mason 2008), which is reflected by the increased number of TKA in obese individuals (Fehring et al. 2007). TKA can improve the health status of patients with knee OA, reducing pain and increasing functional capacity, when conservative treatment fails. Reports show that the most significant changes in pain and function occur 3–6 months after surgery.

However, reviews have reported that patient characteristics are important determinants of outcomes in TKA. Most studies on TKA outcomes in patients with severe and morbid obesity have concentrated on aspects, such as surgical complications and mechanical failure (Fehring et al. 2007; Gilliespie and Proteus 2007). Few short- or long-term studies have focused on health outcomes or health-related quality of life (HRQL) in these patients and the few that do are heterogenous methodologically.

Measures of the health status or HRQL are useful in evaluating TKA outcomes from the patient's perspective. Disease-specific instruments focus on issues related to a particular health condition, and can be used in therapeutic management. In knee OA, the disease-specific Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC LK 3.0) questionnaire is valid for assessing functional outcomes in TKA.

We present two prospective studies on whether anthropometry affects surgical difficulty and on outcomes after TKA surgery.

46.2 Relationship Between Knee Anthropometry and Surgical Difficulty

We carried out a prospective study with an initial hypothesis that the BMI is not associated with tourniquet time in obese patients undergoing TKA, and that some anthropometric parameters may be useful in predicting tourniquet time in severely (Class II) and morbidly (Class III) obese patients (Nuñez et al. 2007). A total of 100 consecutive patients diagnosed with knee osteoarthritis with BMI ≥35 kg/m^2 (Miric et al. 2002; Namba et al. 2005), undergoing TKA between November 2005 and November 2006 in the Knee Unit of the Hospital Clinic of Barcelona (Spain), were prospectively studied. Exclusion criteria were joint instabilities or angular deformities of the knee to be operated that required constrained prosthetic models. Radiographic measurement of the limb axis was carried out in the anteroposterior telemetric projection in a standing position by goniometry. Using the data collected during the pre-anesthesia visit carried out 2 weeks before the operation, which determined the weight and the size of the patient, BMI levels were obtained using the formula: BMI = weight (kilograms)/height^2 (meters) (Stickles et al. 2001; Bourne et al. 2007). The tourniquet time, measured from the inflation of the pneumatic cuff, just before the beginning of the operation to its liberation, once the components were cemented to carry out hemostasis, was determined.

The operation was carried out by a specialist surgeon from the knee unit using the same surgical technique and the same prosthetic model in all cases, with cemented implants (Profix; Smith & Nephew Inc., Memphis, TN, USA).

46.2.1 Determination of Knee Anthropometric Parameters

Before the operation, the suprapatellar circumference (measured at 4 cm proximal to the superior pole of the patella), the infrapatellar circumference (measured at the anterior tibial tuberosity (ATT)), and the length of the limb to be operated (measured from the anterior superior iliac crest to the center of the anterior face of the ankle joint) (Fig. 46.1) were determined. The same flexible, inelastic tape measure, calibrated in centimeters, was used for all measurements. The anthropometric indexes calculated were the length of the limb/suprapatellar circumference ratio (suprapatellar index), length of the limb/infrapatellar circumference ratio (infrapatellar index), and the suprapatellar circumference/infrapatellar circumference ratio (supra-/infrapatellar index).

46.2.2 Relationship Between BMI and Knee Anthropometry

Of the 100 patients, 87 were female and 13 male. The mean age was 70.43 years (SD ± 7.73); the mean BMI was 39.81 kg/m^2 (SD ± 3.75). The main sociodemographic and clinical patient variables are shown in Table 46.1. A total of 58% of patients were classified as having Class III obesity (BMI

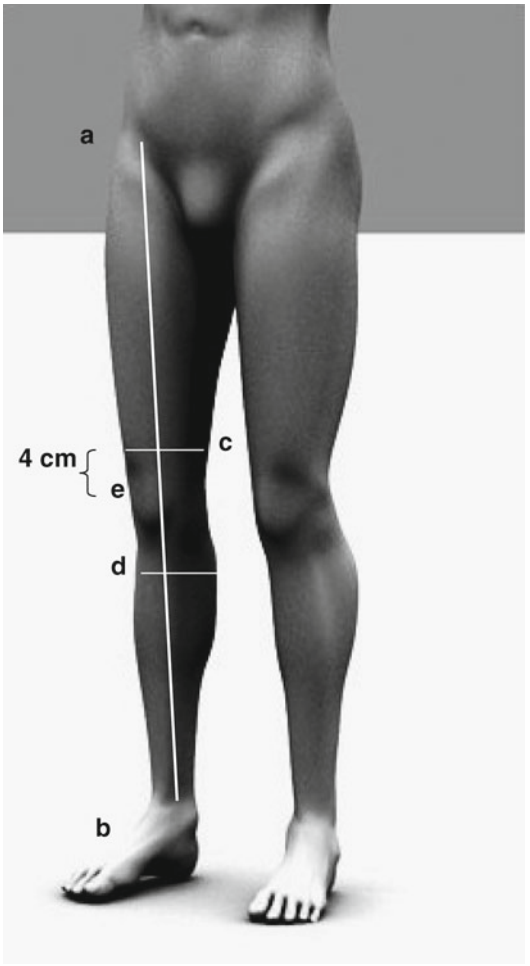

Fig. 46.1 Determination of knee anthropometry. (**a**) anterior superior iliac spine; (**b**) center of the ankle; (**c**) measurement point of the suprapatellar circumference; (**d**) anterior tibial tuberosity; (**e**) superior pole of the patella. This figure shows how the anthropometric parameters of the knee were calculated. The anterior superior iliac spine of the patient and the center of the ankle are palpated, calculating the distance between the two points: this provides the length of the limb. Four centimeters above the superior pole of the knee, the circumference of the knee is measured at the suprapatellar level with a metric tape measure, and the same procedure is carried out at the anterior tuberosity of the tibia to provide the infrapatellar circumference

35–39.99) and 42% as Class IV (BMI ≥40). The mean tourniquet time was 41.67 min (SD± 9.26). The mean values of the anthropometric indexes in the operated knee were:

Suprapatellar index 1.63 (SD ± 0.17)
Infrapatellar index 1.99 (SD ± 0.21)
Supra-/infrapatellar index 1.22 (SD ± 0.08)

There was no association between the BMI and tourniquet time.

When patients were grouped according to a BMI above or below 40 kg/m^2, and above or below 45, non-significant differences, which were not associated with tourniquet time, were found:

BMI < 39.99 kg/m^2:Tourniquet time 40.34 min (SD ± 8.77)
BMI > 40.00 kg/m^2:Tourniquet time 43.27 min (SD ± 9.78).
BMI < 44.99 kg/m^2:Tourniquet time 41.08 min (SD ± 9.04)
BMI > 45 kg/m^2: Tourniquet time 45.70 min (SD ± 10.68)

There was no statistically significant association between tourniquet time and the infrapatellar and supra-/infrapatellar indexes.

The suprapatellar index was negatively associated with tourniquet time ($p = 0.038$). As the suprapatellar index decreased, the tourniquet time increased.

Table 46.1 Sociodemographic and clinical characteristics in the surgical difficulty study

Gender	
Male (*n*)	13
Female (*n*)	87
Age mean (SD)	70.43 (7.73)
BMI mean (SD)	39.81 (3.75)
Class III (IMC 35–39.99)	58
Class IV (IMC ≥ 40)	42
Anthropometric indexes mean (SD)	
Suprapatellar index	1.63 (0.17)
Infrapatellar index	1.99 (0.21)
Supra-/infrapatellar index	1.22 (0.08)
Tourniquet time mean (SD)	41.67 (9.26)

This table shows the demographic characteristics of patients undergoing total knee arthroplasty. The majority were women and the mean BMI was near to the level of morbid obesity. The anthropometric values (indicated by the mean of the indexes calculated) and the ischemia time (tourniquet time) provide an idea of the difficulty of the surgical intervention

n number, *SD* standard deviation

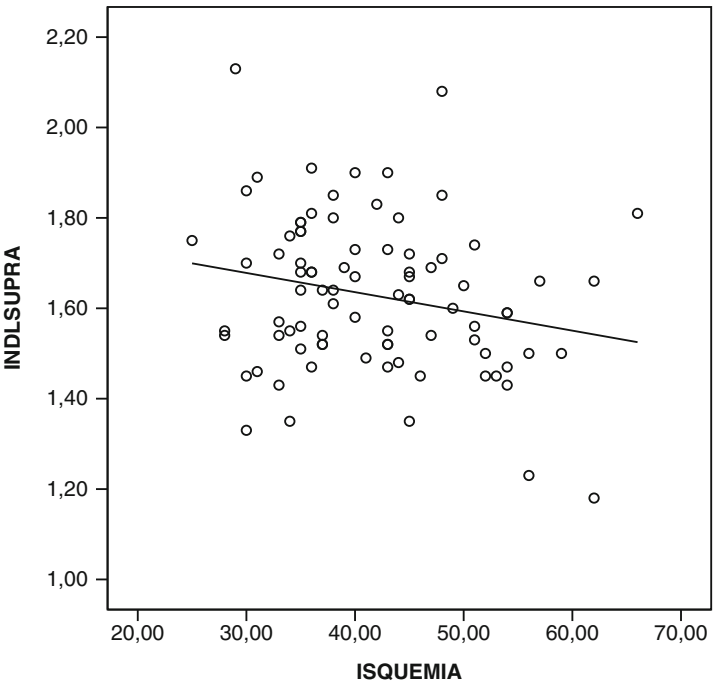

Fig. 46.2 Correlation between tourniquet time and the suprapatellar index. This figure shows the correlation between the ischemia time (variable of surgical difficulty) and the suprapatellar index. The correlation shows that the lower the suprapatellar index, the greater the ischemia time and, therefore, the greater the surgical difficulty. The cut-off value is 1.63. Below this value, the surgery can be forecast to involve greater difficulty

In patients with a suprapatellar index <1.6, the tourniquet time increased significantly (Fig. 46.2).

When the anthropometric indexes were compared according to BMI (<40 kg/m^2 vs. >40 kg/m^2), there were statistically significant differences in the suprapatellar and infrapatellar indexes between the two groups (Table 46.2). In patients with a BMI ≥40 kg/m^2 (Class III obesity) the suprapatellar ($p = 0.001$) and infrapatellar ($p = 0.004$) indexes were significantly lower than in patients with Class II obesity.

Table 46.2 Anthropometric indexes according to BMI in patients undergoing TKA

	BMI < 40 mean (SD)	BMI ≥ 40 mean (SD)	*P*
Suprapatellar index	1.68 (0.15)	1.56 (0.17)	0.001
Infrapatellar index	2.05 (0.18)	1.92 (0.22)	0.004
Supra-/infrapatellar index	1.22 (0.08)	1.23 (0.10)	0.715

This table shows the variations in anthropometric indexes according to the BMI. Both the suprapatellar and infrapatellar indexes vary according to the BMI. The higher the BMI, the lower the anthropometric indexes, suggesting that the limbs to operate are shorter and wider, in accordance with a pattern of uniform obesity. As expected, the supra-/infrapatellar index does not vary, as this index does not take the length of the limb into account
SD standard deviation

46.2.3 Application of Knee Anthropometry in TKA Surgery as a Predictor of Surgical Difficulty

The relationship between obesity and deterioration of the knee joint has been widely reported by many large studies (Nevitt 2002; Focht et al. 2005; Messier et al. 2005; Powell et al. 2005). Obesity is directly related to knee osteoarthritis, and the probability of an obese patient requiring knee replacement increases with the degree of obesity measured according to the BMI (Bourne et al. 2007; Liu et al. 2007). The anthropometric parameters of obese patients that might correlate with deterioration of the knee observed in radiographies have also been studied (Liu et al. 2007).

These studies show that the weight and the BMI are the factors most closely correlated with joint deterioration, and that other anthropometric parameters, such as the waist diameter or the waist-to-hip ratio, are not necessary to predict joint deterioration in obese patients.

The complexity of the obese patient with knee osteoarthritis has also been reported in various studies (Deshmukh et al. 2002; Miric et al. 2002; Foran et al. 2004a, b; Namba et al. 2005; Amin et al. 2006; Fehring et al. 2007; Gilliespie and Proteus 2007; Krushell and Fingeroth 2007; Patel et al. 2007). However, possible surgical difficulties due to the anthropometric type of the knee have not been sufficiently studied.

We often see patients with obesity Class II and III who, in theory, should present more operational difficulties, but whose morphologic characteristics do not differ from those of patients with less (Class I) or no (Class 0) obesity. An explanation could be the various types of distribution of fat in obese patients (Booth 2002). When the fat concentration is predominantly in the thorax and abdomen, following a truncal pattern, the knee to operate (which has suffered osteoarthritic degeneration due to mechanical overload in most cases) (Nevitt 2002; Powell 2005), does not usually present increased subcutaneous fat that would make the operation more difficult.

The opposite situation occurs in patients, whose fat distribution is uniform in the trunk and limbs, following a generalized pattern. In this situation, the knee circumference is increased by the accumulation of subcutaneous fat (Ding et al. 2005). We considered that preoperative identification of these two types of patients could be useful in planning the surgical requirements and the use of resources. The waist-to-hip ratio may be useful in predicting cardiovascular risk in obese patients (Chen 2007), and we hypothesized that a similar type of anthropometric index in the limb might also be useful in predicting surgical difficulties. Thus, in patients with Class II or III obesity, we determined anthropometric parameters at the knee. We hypothesized that determining only the knee circumference at the suprapatellar and infrapatellar levels, without relating them to the length of the limb, would not provide evidence of the anthropometric type, as a high circumference measurement may be accompanied by a long limb in which the fat is not accumulated in the subcutaneous region, creating operating difficulties. Tourniquet time was selected as the objective criterion of operating difficulty, as all operations were carried out by surgeons specializing in knee prostheses, using the same protocol and the same type of prosthesis.

However, in patients with Class II and III obesity, when we studied the anthropometric type of the knee according to the aforementioned indexes, there was a negatively significant association between the suprapatellar index and the tourniquet time, with a lower suprapatellar index being associated with longer tourniquet time. A suprapatellar index <1.6 was significantly associated with longer tourniquet time ($p < 0.038$).

Morphologically, a suprapatellar index <1.6 indicates patients with shorter, wider limbs with greater thickness of subcutaneous tissue in the suprapatellar region and consequent difficulties in various steps of the TKA (in the access route, patellar eversion, positioning of separators, orientation of the cutting guides and positioning of the implants, as well as more complex wound closing) (Winarsky et al. 1998; Booth 2002; Rottman et al. 2005; Krushell and Fingeroth 2007), resulting in a longer tourniquet time. A suprapatellar index > 1.6 indicates patients with longer limbs and smaller suprapatellar perimeters with less operating difficulties.

Although the study had some limitations, including the fact that anthropometric characteristics vary between populations, we believe that the results are valid for our patients. Determination of preoperative BMI, together with evaluation of the knee morphology and determination of the suprapatellar index, identifies patients belonging to a subgroup of obese patients who may present greater operating difficulties. The specific value of 1.6, which determined greater difficulty in our patients, would have to be calculated for each population group with different anthropometric characteristics, but we believe that the manner of determining it may be reproducible in other populations.

46.3 Knee Anthropometry Influencing Health Outcomes in Severe and Morbidly Obese Patients with Knee Osteoarthritis Undergoing Total Knee Replacement

We carried out another study to evaluate general health in severe and morbidly obese patients undergoing TKA and determine whether patient characteristics influenced postoperative WOMAC dimension scores.

46.3.1 Study Design and Setting

A prospective 12-month study was carried out in the Rheumatology Service and Knee Unit of the Hospital Clínic, Barcelona (Spain).

Inclusion criteria. Consecutive patients with knee OA and severe or morbid obesity (Class II BMI ≥ 35 kg/m^2 and Class III BMI ≥ 40 kg/m^2), respectively, according to the World Health Organization [WHO] classification admitted to our hospital for TKA. Patients with functional illiteracy or psychopathology severe enough to prevent complete participation in study procedures were excluded. All patients received a standard (non-constrained) prosthesis.

46.3.2 Study Variables

We determined the following variables:

1. Self-reported general health measured by the WOMAC questionnaire validated for the Spanish population (Escobar et al. 2002). This questionnaire contains three dimensions (pain, stiffness, and

Table 46.3 Baseline patient characteristics of patients undergoing TKA in the outcomes study

Age mean (SD)	70.2 (6.7)
Gender n (%)	
Male	7 (11.7)
Female	53 (88.3)
N of preexisting comorbidities mean (SD)	2.5 (1.5)
Type of preexisting comorbidities n (%)	
Hypertension	42 (70)
Diabetes	14 (23.3)
Respiratory disease	12 (20)
Digestive disease	11 (18.3)
Psychiatric disease/depression	9 (15)
Heart disease	7 (11.7)
BMI mean (SD)	39.9 (3.8)
Class II: 35–39.9 kg/ m^2 *n* (%)	33 (55)
Class III: ≥ 40 kg/ m^2 *n* (%)	27 (45)

This table shows that the patients were mainly women (88%) and that the majority, in addition to presenting knee osteoarthritis, suffered hypertension and that almost half were morbidly obese
SD standard deviation, *N* number, *BMI* Body Mass Index (kg/m^2)

function). WOMAC dimension scores are normalized to a 0 (best)–100 (worst) scale (Escobar et al. 2002).

2. Sociodemographic (age and sex) and clinical (number and type of preexisting comorbidities and BMI) data were recorded.
3. Lower limb anthropometry was measured using the suprapatellar, infrapatellar, and supra-/infrapatellar indexes (Fig. 46.1), which was carried out by an independent researcher.

46.3.3 Anthropometry and Outcomes After TKA

Sixty patients were included in the analyses. Table 46.3 shows baseline patient characteristics. The mean anthropometric index scores were: suprapatellar 1.6 (SD 0.2), infrapatellar 2 (SD 0.2), and supra-/infrapatellar 1.2 (SD 0.1).

The results of the multiple regression models are shown in Table 46.4. An infrapatellar index percentile <75 was associated with worse scores in the WOMAC pain and function dimensions ($p = 0.007$ and 0.025, respectively).

46.3.4 Anthropometry and TKA Outcomes

The health status of our patients improved after TKA. WOMAC dimension scores were negatively influenced by comorbidities and lower limb morphology (infrapatellar index), which were independently associated with worse WOMAC scores at 12 months. Comorbidities were associated with worse functional dimension scores, and the infrapatellar index was associated with worse functional and pain dimension scores. Previous studies have also suggested that comorbidities have an independent negative effect on function (Krushell and Fingeroth 2007) and suggested that therapy and

Table 46.4 Variables independently associated with the WOMAC pain and stiffness and function dimensions at 12 months in the multiple linear regression models in the outcomes study

	Dependent variables								
	WOMAC scores at 12 months								
	Pain			Stiffness			Function		
	R^2 adjusted 0.148						R^2 adjusted 0.232		
	Coefficients	95% CI	*P-value*	Coefficients	95% CI	*P-value*	Coefficients	95% CI	*P-value*
Independent variable									
N comorbidities	–	–	–	–	–	–	6.8	3.5–10.2	<0.001
Infrapatellar index percentile <75	16.2	4.6 – 27.7	0.007	–	–	–	11.5	1.5–21.5	0.025

The coefficients of regression models indicate whether an increase in the independent variables is related with an increase or worse (positive coefficient) or decrease or better (negative coefficient) WOMAC dimensions score. R^2 adjusted is the proportion of variance in the dependent variable explained by the relevant independent variables shown. The three WOMAC scales were normalized to a 0–100 scale for each separate WOMAC dimension, where 0 represents the best health status and 100 the worse health status

This table shows that there is an association between WOMAC scores and the infrapatellar index. This suggests that patients with a lower infrapatellar index have higher WOMAC pain and function dimension scores (worse health status). Likewise, patients with a higher number of comorbidities had higher WOMAC function dimension scores (worse health status)

SD Standard deviation; *CI* confidence interval; *N* number; *WOMAC* Western Ontario and McMaster Universities Osteoarthritis Index

active control may be required. Studies have shown that severe and morbidly obese patients have more associated comorbidities, and longitudinal studies demonstrate evidence of the relationship between comorbidity and functional limitations. Lower limb anthropometry (infrapatellar index percentile <75) was significantly associated with worse pain and function, and indicated a knee with more difficulties in prosthesis implantation, regardless of the BMI. However, patients with a BMI ≥35 kg/m^2 had greater surgical difficulties, including more subcutaneous fat, and difficulties in patellar eversion, exposing the surgical field and prosthesis orientation.

In conclusion, lower limb morphology influenced WOMAC dimension scores in patients undergoing total knee arthroplasty, and health improved 12 months after TKA surgery.

46.4 Applications to Other Areas of Health and Disease

Our studies show that the morphology of the limb affects the results of surgery and surgical difficulties. This could be applicable to other orthopedic techniques in addition to TKA. Anthropometry can identify groups of patients that need more resources, and its application in improving outcomes may be useful in total hip arthroplasty, arthroscopy surgery, and in trauma surgery of the lower limbs and pelvis.

46.5 Practical Methods and Techniques

46.5.1 Determination of Knee Anthropometry

As shown in Fig. 46.1, the anthropometry of the lower limb takes into account the length of the leg and the circumferences of the knee. The length is determined by two easy-to-locate points: the anterior–superior iliac spine and the center of the ankle. The circumferences are determined at two points: the anterior tibial tuberosity and a point located 4 cm above the superior pole of the patella. The indexes are then calculated using the formulas:

Suprapatellar index: length of leg/suprapatellar circumference
Infrapatellar index: length of leg/infrapatellar circumference
Supra-/infrapatellar index: suprapatellar circumference/infrapatellar circumference.

Low suprapatellar or infrapatellar indexes indicate a short leg with a wide knee and more difficulties. These values are related to the BMI as shown in Table 46.2, although, in itself, the BMI is not a predictor of outcomes and difficulty in orthopedic surgery, as shown by the results of the first study.

Summary Points

- The body mass index is a measurement of body anthropometry, and is calculated as the relationship between weight and height.
- The body mass index classifies patients in four categories. Class II (BMI 35–40 kg/m^2) and III (BMI > 40 kg/m^2) indicate a greater risk of complications and possibly worse outcomes after total knee arthroplasty surgery.

- The distribution of body fat in obese individuals may be truncal or uniform, and the body mass index is not the only parameter that should be taken into account when predicting worse outcomes after total knee arthroplasty surgery.
- The morphology of the knee is important in total knee arthroplasty surgery, and determination of its anthropometry can help to detect patients, who may require more resources.
- When the fat concentration is predominantly in the thorax and abdomen, following a truncal pattern, the knee to operate does not usually present increased subcutaneous fat that would make the operation more difficult.
- In patients whose fat distribution is uniform in the trunk and limbs, following a generalized pattern, the knee circumference is increased by the accumulation of subcutaneous fat.
- The anthropometry of the knee is calculated as the relationship between the length of the leg and various circumferences of the knee, and determines two main indexes: the suprapatellar index and the infrapatellar index.
- A suprapatellar index less than 1.6 predicts more difficult surgery, and an infrapatellar index less than 1.75 predicts worse outcomes in total knee arthroplasty surgery.
- These indexes, together with the body mass index, help to more accurately detect patients at risk of more complications and poorer outcomes after surgery and the possible need for more resources.
- Determination of knee anthropometry before total knee arthroplasty surgery can improve results and patient satisfaction.

Key Features of the Suprapatellar Index

- The suprapatellar index is calculated by measuring the circumference of the knee at a point located 4 cm proximal of the superior pole of the patella with a metric tape measure.
- This value is divided by the length of the limb (obtained by the distance between the anterior superior iliac spine and the center of the ankle) is divided by the suprapatelar circumference to calculate the suprapatelar index.
- The suprapatellar index varies according to the BMI of the patient.
- The suprapatellar index classifies the knee to be operated, as liable to encounter greater or lesser difficulty.
- The lower the suprapatellar index, the greater the expected surgical difficulty.
- In our Western Mediterranean population, a value below 1.6 in the suprapatellar index forecasts greater surgical difficulty (longer surgical time) and the need for greater technological resources in the operating room.

Key Features of the Infrapatellar Index

- The infrapatellar index is calculated by measuring the circumference of the knee at the level of the anterior tibial tuberosity.
- The value of the length of the limb is divided by the infrapatellar circumference.
- The infrapatellar index varies acording to the BMI of the patient.
- Knees with an infrapatellar index less than 1.75 have worse functional results after total knee arthroplasty, as measured by the Western and McMaster Universities quality of life assessment scale.
- Patients with an infrapatellar index below 1.75 should be advised that the results expected after total knee replacement are worse than those expected in the general population.

Chapter 47
Standardization of Sizes of Knee–Ankle–Foot Orthoses (KAFO) Through Anthropometry

L. Narendra Nath

Abstract Lower limb orthoses enable the locomotor disabled, who have flail or weak lower limbs, to ambulate. The medical causes for these disabilities are many out of which poliomyelitis, cerebral palsy, traumatic paraplegia are common. Though, poliomyelitis is almost eradicated in underdeveloped countries, it still remains a challenge to provide orthosis to the large number of people already affected by polio in childhood. It is also to be noted that such orthosis will need replacement once in 2 years on an average. Hence, there is a huge demand for orthoses year after year. One way to address this problem is to standardize the sizes of orthosis and manufacture cost effective and durable light weight calipers. In order to standardize the sizes of orthosis, there was a need to collect anthropometric data of polio affected lower limbs in different geographical areas and their analysis to arrive at standard sizes for polio affected lower limbs. Towards this, an anthropometric device (AD) was designed and developed to collect anthropometric data of feet and knees of the patients suffering from poliomyelitis. A modular concept in Knee–Ankle–Foot Orthosis (KAFO) was developed making use of this anthropometric data. The modules of this orthosis were essentially foot plate and knee piece in standardized sizes and lateral uprights of universal size which could be cut to the required sizes depending on the length of the lower limb. The anthropometric data led to the development of seven sizes for foot plates and six sizes for knee pieces which could cater to the needs of almost all the patients. These modules of the orthosis were produced by plastic injection moulding and compression moulding processes using glass fibre reinforced polypropylene. These components could be assembled into an orthosis in less than 2 h time whereas a thermoformed KAFO used to take 6–8 h for fabrication. Also, the need to make plaster of Paris replica of polio affected limbs, as in the case of thermoformed KAFO, was done away with saving both, time and cost. The results of field trail of these standardized KAFO were encouraging and it vindicated the concept of standardization of sizes.

47.1 Introduction

Mobility and communication are absolute requirements for the survival and welfare of every human being today. Most of the people with locomotor disability are not only deprived of these absolute requirements but also of their dignity because of their disability. In most cases, lack of mobility also makes them suffer from low self-esteem.

It is estimated that t-here are approximately 50 million locomotor-disabled people in the world. The medical causes for these disabilities are many. However, a significant number of them can be helped with their ambulation by providing them with a suitable orthosis. Most of the orthoses available currently are tailor-made, and it is a time-consuming process to make these orthosis for each and every needy person. It is also to be noted that fitment of the orthosis is not a one-time affair, as it has to be replaced at periodic intervals and maintained for effective usage. Hence, there is a huge and repeated demand for these orthoses. This mammoth task can be addressed by the standardization of orthoses, so that they can be provided off the shelf to the locomotor disabled at a low cost, with good quality and durability.

Poliomyelitis is one of the major causes of locomotor disability among the existing locomotor-disabled population in the world. In recent years, effective immunization programs have almost eradicated poliomyelitis. Still, there are millions of people who were victims of this infection in their childhood. Apart from poliomyelitis, people affected by cerebral palsy and paraplegia also form a sizable population of the locomotor disabled. Different kinds of orthoses are needed by these people. Many of them can be helped with the fitment of knee–ankle–foot orthoses (KAFO). Fitment of such a huge number of orthoses is possible only if their production is made easy by standardizing the sizes and also by simplifying the assembly technique. This task of standardizing is more challenging in case of polio-affected individuals, as the development of muscles, bones and joints is significantly affected by the severity of initial infection, and because of which the measurements of girth of limbs at various levels and their length vary grossly from individual to individual. To standardize the sizes for a lower limb orthosis in such individuals, an anthropometric survey of individuals affected by poliomyelitis in different geographical areas was needed. An analysis of these data was needed before standardizing the sizes.

Anthropometry is a branch of science, which has played a major role in understanding the region-wise behavior, functions, lifestyle, etc., of human beings (Churchill and McConville 1976). Anthropometric surveys for weight, strength, etc. are quite common. Generation of data on elderly persons and disabled, for the development of consumer products and devices (Chung and Weimar 1989); calculation of bone mass in the human body (Davis et al. 1999); cross-cultural investigation of the role of foot size in physical attractiveness (Fessler et al. 2005); garment design; calculation of human body surface area (Jianfeng and Hihara 2004), etc., have been reported.

The data generated through anthropometry form the basis for various studies, and benefit the society at large. The design specifications of the workplace have been drawn in the past for employees, based on the anthropometric data obtained regarding their physical ability and limitations (Boussena and Davies 1987). Similarly, the assessment of human obesity through the measurement of body composition has also been carried out (Mahoney et al. 1979). The role of anthropometry in rehabilitation research is quite large. The methods of dynamic anthropometry have been used in

ergonomics, and with suitable modifications, these methods have been used in rehabilitation. The measurements of movement of head, hand, foot, arm, and leg have formed the basis for the assessment of the efficiency of the rehabilitated part of body (Nowak 2003).

Anthropometry provides data on desired points in free space with their interrelation. An anthropometric device (AD) is an instrument, which generates data with respect to a fixed frame of reference of lower limbs of the locomotor disabled. These data could be processed to define various locations of the lower limb in terms of physical measurements. Further, these data could be useful in designing a KAFO in a modular form. In this study, the modular concept of KAFO was developed with standardization of the sizes of its modules. The standardized modules were foot plate, knee piece, and, later, uprights. The knee pieces and foot piece were joined together by universal size lateral uprights to form a KAFO. This standardization and modular concept enabled mass production of orthoses, which are cost-effective and easy of fit. The standardized KAFOs were fitted to sizable polio population to obtain their feedback. Later, the production of standardized KAFOs helped in the fitment of a huge number of individuals in need.

47.2 An Overview of the Locomotor Disabled

Reported disability prevalence rates from around the world vary dramatically, for example, from under 1% in Bangladesh (Bangladesh Bureau of Statistics 1987) and (Kenya Central Bureau of Statistics 1996) to 20% in New Zealand (Statistics New Zealand 1998). This variation is caused by several factors: differing definitions of disability, different methodologies of data collection, and variation in the quality of study design. Therefore, listing disability prevalence rates that are understandable and internationally comparable is a difficult task. This situation is made more complex as there is no comprehensive definition of disability, and the nature and severity of disabilities vary greatly. How the degree of disability is assessed also varies grossly, depending on the purpose for which it is done. The prevalence of disability in some selected countries is tabulated in Table 47.1.

Table 47.1 Prevalence of disability in selected countries

Censuses			Surveys		
Country	Year	Percent of population with a disability	Country	Year	Percent of population with a disability
United States	2000	19.4	New Zealand	1996	20.0
Canada	2001	18.5	Australia	2000	20.0
Brazil	2000	14.5	Uruguay	1992	16.0
United Kingdom	1991	12.2	Spain	1986	15.0
Poland	1988	10.0	Austria	1986	14.4
Ethiopia	1984	3.8	Zambia	2006	13.1
Uganda	2001	3.5	Sweden	1988	12.1
Mali	1987	2.7	Ecuador	2005	12.1
Mexico	2000	2.3	Netherlands	1986	11.6
Botswana	1991	2.2	Nicaragua	2003	10.3
Chile	1992	2.2	Germany	1992	8.4
India	2001	2.1	China	1987	5.0

India has a sizable number of locomotor-disabled population. Poliomyelitis, injury other than burns, arthritis, and cerebral palsy are the main causes of locomotor disability in the country. It has been reported that people in the states of south, east, and central India are highly prone to incidence of various causes of disabilities. Overall, poliomyelitis (32%), injury other than burns (28%), other illness (12%), medical/surgical interventions (3%), burns (2%), arthritis (2%), and cerebral palsy (2%) are the major causes of locomotor disability among the working age disabled population (Patel 2009). As on date, approximately seven million poliomyelitis patients and three million amputees form a significant majority of the locomotor disabled in India.

47.3 Anthropometric Measurement

The anthropometric data have proved to be valuable in the field of medical sciences, ergonomics, apparel design, accessories design, automotives, and so on. The anthropometric surveys on range of motion have led to the rehabilitation of people with disabilities (Nowak 1996). There are many techniques for measuring the dimensions of the human body, ranging from usage of a measuring tape or scale, to a coordinate measuring machine (CMM), laser scanning technology, and magnetic resonance imaging (MRI) (Brown et al. 1995; Nishimura et al. 2005), depending upon the need and application. The measurement of external dimensions of the lower limb does not require tight tolerances. The important requirement is that the measurement should be systematic and could be correlated with other measured locations of the limb. Hence, an AD was designed and developed to measure the affected lower limb in a systematic and scientific way. The basic design principle of the AD was to provide data regarding the lower limb in well-defined coordinate system with a fixed frame of reference, so that the positions and locations of various parts of the limb can be correlated. Also, it was so designed that the data obtained from an AD would be useful inputs to design and develop orthoses in standard sizes. Apart from this, ease of portability and maintenance were desired design features of AD.

The materials for the manufacture of AD were chosen on the basis of their functional aspects, processability, durability, and cost, so that lightweight, portable, and cost-effective ADs could be manufactured. All the operations of ADs were mechanical in nature, and the AD provided data for the knee in terms of the cylindrical coordinate system (x, r, θ), and for the foot in terms of the Cartesian coordinate system (x, y, z) including equinus on the foot in degrees (θ) (Dwivedi et al. 2009). The major parts of the AD are listed in Table 47.2 and shown in Fig. 47.1.

The semi-cylindrical canopy assembly was made by fixing it on sliding sockets. The canopy, with the help of sliding probes, could define a point on the knee in terms of the cylindrical coordinate system. However, two side plates were mounted on sliding sockets and placed on the two parallel rails for generating a coordinate, in the Cartesian coordinate system, on any point on the foot. The side plates generated data on the medial and lateral sides of the foot. There was a back plate, which had a tilting mechanism with a protector fitted on its base. This plate was not allowed to slide but tilt. This plate enabled the measurement of degree of equinus of the foot. The pin probe could measure the location and depth of the medial arch.

Apart from the above advantages, the AD had some design limitations. These are mentioned below:

- Limbs having significant contractures were difficult to place in the AD.
- Feet having severe varus or valgus deformity were difficult to measure.

Table 47.2 Major parts of AD

S. No.	Components	Material	Dimension (mm)	No.
1	Base plate	E-glass reinforced polyester composites	1,000 × 275 × 18	1
2	Cylindrical canopy	Poly-methyl-metha-acrylate	Diameter: 200 Width: 80 Thickness: 5	1
3	Side plate	-do-	320 × 60 × 10	2
4	Back plate	-do-	-do-	1
5	Pin probe	Brass	Length: 150	5
6	Sliding rail	Mild steel	Length: 800	2
7	Sliding socket	-do-	Length: 50	4

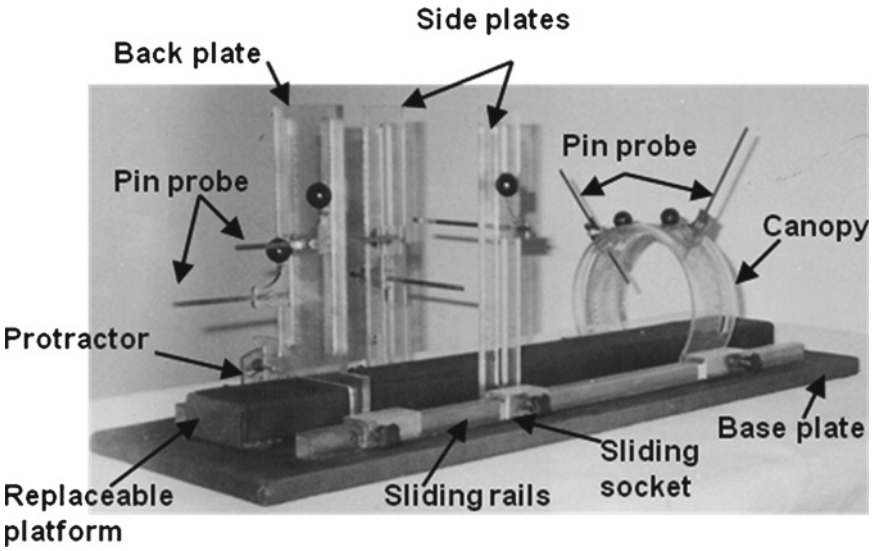

Fig. 47.1 Anthropometric device. (Reproduced from Dwivedi et al.2009)

- No movement of limb was permitted once it was placed and strapped in the AD.
- It was not possible to collect data for the thigh, as there were no well-defined points, such as bony prominences, present.

47.4 Modules of KAFO

The shape of all three KAFO modules originated from the topographical appearance of the knee and foot. Hence, a structure resembling a thin shell over the limb was conceived for the orthosis. The design of the orthosis was not only aimed at its performance but also at minimizing the cost and weight, ease of wearing, air circulation, ability to conceal it in the garment, and esthetic looks. The three modules, that is, foot plate, knee piece, and the lateral uprights, were designed on the basis of pressure-sensitive- and load-bearing parts of the lower limb of the locomotor disabled. Accordingly, enough allowances

were provided in the design of the orthoses. For all the standardized parameters, tolerance values were decided so that, at the time of fitment of an orthosis to a patient, modification and fine-tuning by thermoforming is possible for proper fitment.

47.5 Practical Methods and Techniques

47.5.1 Generation of Anthropometric Data

In order to collect data, the lower limb of a patient was placed on the AD in such a way that the sole of the foot touched the back plate. Then, the limb was tied with two Velcro straps, which were attached to the base plate, as shown in Fig. 47.2. This allowed no relative motion of the lower limb with respect to the AD.

The relevant points of foot and knee were identified. These are tabulated in Table 47.3. These relevant points were mostly the bony prominences.

The side plates and canopy were brought to the desired location on the limb and a pin probe was slid to touch the particular location. The data collection of knee and foot is shown in Figs. 47.3 and 47.4.

The tilt angle on the back plate provided the value of the θ–ordinate for equinus. The length of limb below knee was derived from the difference of the x-ordinate values of the epicondyles and heel. This enabled us to take all the coordinates of relevant points on the lower limb with respect to the fixed frame of reference. The anthropometric data for approximately 1,600 patients, of various age groups ranging from 3 to 60 years at different geographical locations in India, were generated in order to have a broad range of sample size. Accurate sampling is critical to the creation of a database. Sampling involves the process of selecting a group of individuals thought to be representative

of an entire population (Churchill et al. 1988). During the collection of data, it was observed that the data collection for the patella was also critical, as it had to be accommodated in the knee piece without any pressure. Hence, the location of the top of the patella, with reference to epicondyles, was extrapolated in the direction of the *x*-axis. In the cases of poliomyelitis, it was observed that the size and location of the patella was not consistent with respect to epicondyles. Similarly, in the

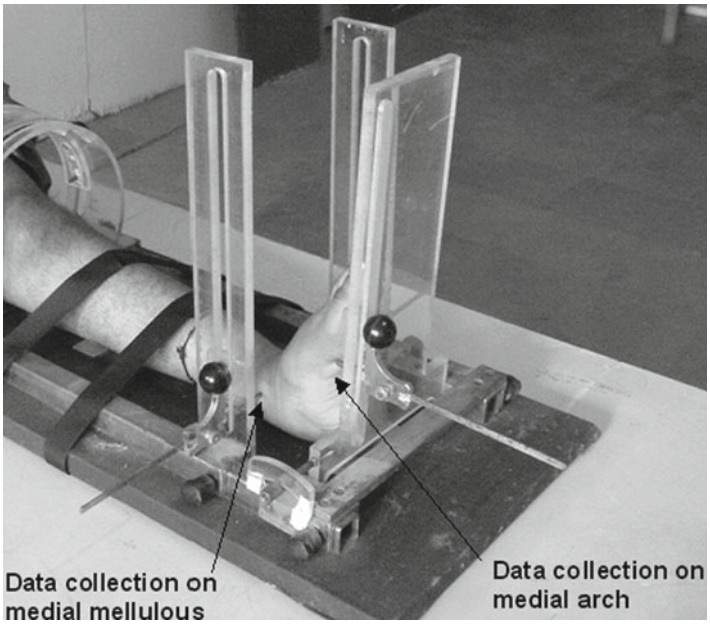

Fig. 47.4 Data collection on foot in an anthropometric device. (Reproduced from Dwivedi et al. 2009)

measurements of the foot, the variation in metatarsal width for the same foot span was observed. Also, variation in malleolus width, and offset between medial malleolus and lateral malleolus for the same heel width was observed. The analysis of these variations of parameters in the foot and the knee led to the finalization and implementation of tolerances in some of the parameters (refer to Tables 47.4 and Tables 47.5).

Two locations, namely navicular bone and head of fibula on the foot and knee, respectively, were pressure sensitive; hence, enough clearance in the orthosis was given at these locations, so that the orthosis did not hurt the users during walking. A point on the medial side was needed to arrive at the below-knee width; hence, any point on the medial side in the same plane as the head of the fibula was taken to arrive at below-knee width. Invariably, it was observed that below-knee width was much lesser than the epicondyle width in the cases of poliomyelitis; hence, this parameter was essential and measured. The knee pieces were designed for left and right sides in order to accommodate the medial epicondyle. These sides were mirror images of each other, whereas, in the foot plate, no side was assigned because the footprint for both the sides matched closely.

47.5.2 Standardization Methodology

Standardization is a method to define any product or system in terms of finite relevant parameters. In the case of locomotor disability, the big challenge is the diversity of the affected population. Disability may be caused by a variety of conditions. The quality of fitment of the KAFO mainly depends upon the fitting of the foot and the knee in the orthosis, and the alignment of orthotic knee joints, if any.

Table 47.4 Knee piece – standard sizes and their standardized parameters

	Standardized parameters				
Size no.	Width EC (mm)	Width BK (mm)	Height TP-ECL (mm)	Distance BP-TT (mm)	Height TP-TT (mm)

The generation of specific computer programs for anthropometric surveys, and their analysis to achieve desired results have been reported (Nowak 1992). For this study, a computer program using C language was developed for computing the parameters, as tabulated in Table 47.3, using the coordinates measured from the AD. Appropriate calibration and correction factors relevant to the AD were also incorporated. The parameters so computed were invariant to the foot or knee regarding translation and rotation of the limb on the AD. All the parameters were grouped and categorized. The analysis of these parameters resulted in three modules, namely foot plate, knee piece, and pair of lateral uprights. These modules along with the KAFOs assembled from them are shown in Fig. 47.5.

The foot plate was standardized in seven sizes and the knee piece was standardized in six sizes with left and right sides (Dwivedi et al. 2009). The standard sizes for the knee piece and the foot plate along with their standardized parameters are tabulated in Tables 47.5 and 47.6, respectively. The lateral upright was made in one universal size as per the longest possible length measured in the anthropometric survey.

The three standardized modules for all sizes were mass produced using the materials and technologies mentioned in Table 47.7. The modules of KAFO were assembled by thermoplastic hot-air welding using polypropylene homopolymer filler wire.

47.6 Fitment and Field Trail of Standard Modular KAFO

The modules were assembled into KAFO and fitted to patients after checking the size of the limb of the locomotor disabled. Metallic knee joints and thigh bands were provided where thigh muscles were frail. The total time taken was approximately 1 h for fabrication and fitment of orthosis. It was desirable to wear a pair of shoes with a KAFO, and the locomotor disabled could wear the shoes of their choice, which appealed to them esthetically. They were advised not to wear shoes with high heels.

The medial arch was absent in the majority of polio cases, and wherever it was present, a medial arch carved out of polyethylene vinyl acetate (EVA) microcellular rubber was adhesively bonded on the

Fig. 47.6 (**a**) Locomotor disabled without orthosis; and (**b**) Walking with KAFO. (Reproduced from Dwivedi et al. 2009)

foot plate at the desired location. Feedback was obtained from a group of captive locomotor disabled persons fitted with standardized modular KAFO, all over the country. The life of a KAFO was predicted to be more than 2 years on the basis of fatigue life of the glass-reinforced polypropylene used for its manufacture. So far, more than 26,000 such orthoses have been fitted all over India. In most of the cases, the KAFO lasted approximately two and half years. The first sign of failure was observed on the foot plate either at the metatarsal or the ankle region. A few failures were reported due to accidents.

A systematic feedback was obtained in a proforma, which had two parts. The first part covered personal details, medical history, muscle chart, previous orthosis used (if any) and tabular periodic feedback along with the comments of the orthotist. The second part consisted of a tabular periodic feedback proforma shown in Table 47.7. This proforma also covered the information on walking terrain (flat/uneven/muddy/marshy) and reaction on walking on staircase, ramp, and wet surfaces.

Two sample cases, suffering from poliomyelitis and fitted with standardized KAFOs, are shown in Fig. 47.6. These patients are satisfied with the standardized KAFO and have started leading a near-normal life. The efficacy of the standardized KAFO is evident by the patients changed postures of walking, as shown in Fig. 47.6b).

The feedback obtained on the standardized KAFO was satisfactory and it indeed helped many in improving their socioeconomic status. Due to the affordable price, light weight, lesser fitment time, durability, and esthetic look, it was accepted and used by the locomotor disabled. It was reported in feedback that many children joined school and adults were able to perform better at the workplace due to the enhanced mobility after the fitment of the standardized modular KAFO. This orthosis has certainly shown a way to tackle the challenge of mass fitment of orthoses in the shortest possible time.

47.7 Application in Other Areas of Health and Disease

The concept of anthropometry, using simple probes and an easy-to-understand mechanism, has shown that ADs could be designed and developed for the collection of data from any part of the body with good accuracy. With some design modifications in the AD, accurate data on the spine could be generated for making suitable splints. This concept of the AD will enable the medical fraternity to map any part of the body, for its topography, in three dimensions. The standardization concept generated for KAFOs may have future applications in solving problems concerning lower limb fractures, walking aids for paraplegics and old aged persons, etc. It helps in designing footwear for diabetics and leprosy patients. The data can also be generated for standardization of sizes for lower limb prosthesis. Similarly, braces and splints for the hand can be fabricated or standardized for orthotic and prosthetic applications.

47.8 Conclusion

Anthropometry is the basis for standardization of clothing, consumer goods, public utilities, transportation, and so on (Tikuisis et al. 2001). Anthropometric data obtained through the AD was utilized in standardization of sizes of KAFO modules. The KAFOs so designed were fitted to thousands of patients with a satisfactory outcome.

The evolution of seven standard sizes in the foot and six standard sizes in the knee has accelerated the pace of the fitment of orthosis to the locomotor disabled. This endeavor has brought many locomotor-disabled persons into the mainstream of life.

Summary Points

The outcome of anthropometry and size standardization is summarized below:

- Anthropometric measurements, with respect to a fixed frame of reference, have provided data of not only the particular location but also their interrelation with other locations.
- The design of the AD is made versatile with an ease of operation so that it could be used to collect anthropometric data of the upper limbs too. If the diameter of the canopy is increased and its platform is extended, then it can provide anthropometric data for the entire human body.
- For the first time, a modular concept was developed in lower limb orthosis through an anthropometric analysis. Also, standardization of sizes of KAFO was made possible through anthropometric data.
- The standardization of KAFO has decreased the fabrication and fitment time from 8 h to less than 2 h. Also, the additional cost and time to make a PoP replica has been eliminated, as the modules of standardized KAFO were made available off the shelf.

- The standardized KAFO is a well-engineered product. It is durable, light in weight, and cost-effective. The life of standardized KAFO is above 2 years.
- The response of the patients using standardized KAFO is quite encouraging.

Acknowledgments The author wishes to thank Mr. Mayank Dwivedi and Mr. K.D. Shetty for their cooperation and support throughout this work. He thanks Dr. A. Sivathanu Pillai, Dr. D. Prasada Rao, Dr.V.B.N. Prasad Rao, Mr. S.S. Chandran, and Mr. G.V. Rao for their invaluable suggestions in completing this work.

Chapter 48
Sex Differences and Age Changes in Digit Ratios: Implications for the Use of Digit Ratios in Medicine and Biology

John T. Manning

Abstract The term digit ratio is often taken to mean the ratio of the lengths of the second and fourth digits (2D:4D). This ratio has been reported to show sex differences such that on average males have longer fourth digits relative to their second digit than do females. The sex difference in 2D:4D appears in the foetus as early as the ninth week, it is found in infants, children and adults, and the 2D:4D of infants is strongly correlated with their 2D:4D when they become adults. The sex difference results from a different male and female growth trajectory of 4D relative to 2D. It has been suggested that the sex dependent growth trajectory of 4D relative to 2D is the consequence of the effects of prenatal testosterone (PT) relative to prenatal estrogen (PE) on finger growth, such that high PT and low PE may result in low values of 2D:4D. Excluding the thumb, the fingers show six ratios and a number of these show sex differences. However, only 2D:4D, 2D:3D and 3D:4D show both sex differences and are relatively stable with growth in children. Therefore, 2D:4D, 2D:3D and 3D:4D are the most likely digit ratios to reflect levels of prenatal sex steroids. Diseases that show a sex difference in their expression may be influenced by PT and PE. Most work has concentrated on 2D:4D and its links to developmental disorders (e.g. autism, Asperger's syndrome and ADHD), cardio-vascular disorders (e.g. MI), cardiovascular efficiency (e.g. running speed), and cancers (e.g. breast and cervical cancer). Further work is necessary to quantify the strength of such links in order to establish whether 2D:4D may be of predictive value for these diseases. In addition other links with such diseases as prostate cancer are likely to be investigated.

48.1 Introduction

It has been known for more than 100 years that the relative lengths of the second and fourth digits show a sex difference such that men tend to have longer fourth digits relative to their second digits than do women (Baker 1888). This dimorphism may be seen clearly in some 'extreme' male and female hands. In the male hand, the tip of the fourth or ring finger extends beyond the tip of the second or index finger, whereas in the female hand, the tip of the second finger extends beyond that of the fourth finger. The sex difference may be measured by comparing the distal extents of the second and fourth finger to each other, or by a comparison to the distal extent of the third or middle finger (e.g. Manning 2002; Peters et al. 2002). An alternative method of comparison is to calculate the ratio of the length of the second and fourth digits (2D:4D).

The sex difference in 2D:4D is of small to medium effect size (Cohen's *d*, 0.20–0.50; Manning 2002). However, of late, attention has been directed towards this sexual dimorphism because it has been suggested that it may reflect sex differences in the levels of prenatal testosterone (PT) and prenatal estrogen (PE). That is, high PT and low PE are suggested to be causally related to low values of 2D:4D, and low PT and high PE to be causally related to high values of 2D:4D (Manning et al. 1998; see Table 48.1 for key features of testosterone of PT and adult testosterone). If this proves to be the case, 2D:4D could be a useful biomarker for a number of diseases, such as breast and cervical cancer and myocardial infarction, with an aetiology associated with in utero sex steroid levels (Manning 2002). In support of this suggestion, lower 2D:4D in males compared to females has been described in the 2D:4D of foetuses (Malas et al. 2006), in children (Manning et al. 1998, 2004) and in adults across ethnicities and countries (Manning et al. 2007). In addition, longitudinal studies have shown 2D:4D in infants and children to be strongly related to subsequent 2D:4D after development across puberty and into early adulthood (McIntyre et al. 2005; Trivers et al. 2006).

Of course, there are other finger ratios to consider. Excluding the first digit or thumb (which lacks clearly defined basal creases), there are in total six digit ratios (2D:4D; 2D:3D; 2D:5D; 3D:4D; 3D:5D and 4D:5D). Adult sex differences have been described in a number of these ratios (McFadden and Shubel 2002). However, we do not know whether they show sexual dimorphism in the foetus, or whether they are relatively stable with growth.

Here, I consider sex differences and age changes in digit ratios. In particular, I concentrate on the implications of my findings with regard to the use of digit ratios as biomarkers for diseases that have their origins in utero.

Table 48.1 Key features of testosterone

Key features of testosterone
Testosterone is a steroid hormone, which is synthesised from cholesterol.
It is produced by the testes, the ovaries and the adrenal glands.
In the foetus, testosterone production peaks at 8–12 weeks.
At 8–12 weeks, testosterone levels are higher (3–4×) in males compared to females.
Prenatal testosterone (PT) is thought to have gender-identity effects on the brain.
PT also controls the formation of the genitalia (penis and scrotum) and prostate gland.
The second developmental peak of testosterone is at puberty.
Adult males produce substantially more testosterone (40–60×) than females.

Sites of synthesis and aspects of testosterone produced prenatally (PT) and by the adult

48.2 The Measurement of Digit Ratios and Its Relationship to Sex Differences

I am concerned here with the measurement of digit lengths and their use in the calculation of digit ratios. Digit length may be measured from soft-tissue markers, such as the ventral crease proximal to the palm and the tip of the finger (Manning et al. 1998), or from X-rays of the bones of the finger (McIntyre et al. 2005). With regard to the former method, finger length may be measured directly from the fingers, or indirectly from 2D representations of the finger in photocopies, scans or photographs of the hands. The measurement of digit ratios requires that very small differences between fingers be accurately captured. Widespread inaccuracy in the measurement of finger differences may lead to high frequencies of null findings and failure to replicate studies. In regard to this, there is concern that two-dimensional images of fingers are not sufficiently accurate representations of three-dimensional fingers. Manning et al. (2005), reporting on data from a UK population, have shown that the direct method yields higher mean values of 2D:4D than does the indirect method. This finding has been replicated in populations in the UK (Burriss et al. 2007; Caswell and Manning 2009), Germany (Fink et al. 2006) and the USA (Allaway et al. 2009). However, one 'group' has reported a number of non-replications of these findings in Austrian samples (e.g. Voracek and Dressler 2006). The implications of this discrepancy with regard to the accuracy of 2D:4D are not yet clear, and is likely to be a focus of further study. One particular point of concern that is relevant to this chapter is the finding that the distortional effect of indirect measurement is greater for males than for females. Thus, indirect measurement of finger length may increase the sexual dimorphism of 2D:4D (Manning et al. 2005). At present, we should accept 2D:4D data from indirect measurements of fingers, but avoid mixing such data with 2D:4D from direct finger measurement. However, we need to bear in mind that distortions in data from indirect measurements may be complex and not readily adjusted by simple arithmetical means. Whether similar distortional effects are seen in indirect methods with regard to ratios other than 2D:4D is not yet known. This question will have to be carefully addressed by a number of 'groups' before we get an accurate picture. For the time being, digit ratios from indirect finger measurements should not be mixed with digit ratios from direct measurements.

48.3 Sex Differences in 2D:4D

There have been many studies that have reported significant sex differences in 2D:4D, such that males tend to have lower 2D:4D than females (for reviews see: Manning 2002; Peters et al. 2002). The sexual dimorphism is widespread, and although there are marked ethnic differences in 2D:4D, the sex difference is seen across the macro-ethnic groups of Caucasians, Blacks and East Asians, and across countries with similar ethnicities (Manning et al. 2007).

It has been suggested that lower 2D:4D in males compared to females originates at the end of the first trimester (Manning et al. 1998). The development of fingers and the urinogenital system is under the control of two groups of *Homeobox* genes (*Hoxa* and *Hoxd*). Interaction between hormonal products of the urinogenital system (including PT and PE) and *Hox* genes may then result in patterns of finger growth that correlate with concentrations of PT and PE (Manning et al. 1998). Studies of foetuses have confirmed that 2D:4D is sexually dimorphic, such that males have lower 2D:4D than females (Malas et al. 2006). Therefore, very early growth of 2D relative to 4D does show sex differences at a time when sexual dimorphism of absolute finger length is not strong.

In order to consider sex-dependent patterns of 2D relative to 4D length, I considered sex differences in a sample of adult Caucasian males and females from Hertfordshire. There were 748 participants (344 males) in the sample recruited from a large number of geographically widespread sites. Therefore, for ease of measurement, finger length was measured indirectly from photocopies of the ventral surface of the hands. Repeatabilities for 2D:4D were high, with intraclass correlations for right 2D:4D of $r_1 = 0.96$, $p = 0.0001$, and for left 2D:4D of $r_1 = 0.941$, $p = 0.0001$. As expected, there were sex differences in mean 2D:4D, such that males had lower mean 2D:4D compared to females in both hands (right hand 2D:4D, males 0.949 ± 0.036SD, females 0.961 ± 0.036, $t = 4.7$, $p = 0.0001$: left hand 2D:4D, males 0.939 ± 0.031SD, females, 0.952 ± 0.031SD, $t = 5.48$, $p = 0.0001$). With regard to the relationship of 2D regressed on 4D, there was evidence of sex differences in both the slope and the *Y*-intercept, and these were significant for left 2D:4D and close to significance for right 2D:4D. Thus, for the left hand, the equation for the line of 2D regressed on 4D was $y = 0.74x + 16.069$ for males, and $y = 0.823x + 9.556$ for females (females vs. males: slope −6.513 ± 3.23SE, $t = 2.02$, $p = 0.04$; *Y*-intercept 0.08 ± 0.042, $t = 1.99$, $p = 0.047$: Fig. 48.2). Because males had a higher *Y*-intercept and lower slope than females, the regression lines crossed with the intersection at 4D = 16.069 – 9.556/0.823 – 0.74 = 78.47 mm. For the right hand, the equation for the regression line was $y = 0.722x + 18.239$ for males and $y = 0.805x + 11.492$ for females (females vs. males: slope −6.748 ± 3.501SE, $t = 1.93$, $p = 0.054$; *Y*-intercept 0.08 ± 0.045SE, $t = 1.842$, $p = 0.07$). The intersection of male and female regression lines occurred at 4D = 81.29 mm.

If we know the regression line of 2D on 4D, we can calculate the average 2D:4D for each value of 4D. Figure 48.3 shows this for the left hand. Note that 2D:4D reduced with an increase in 4D; this is because 2D tended to be shorter than expected when 4D was long. The differences in slope and *Y*-intercept of males and females resulted in higher 2D:4D for males compared to females, when 4D was shorter than the 4D point of intersection (4D = 78.47 mm), and in lower 2D:4D for males compared to females when 4D was higher than the point of intersection. Overall, males had longer 4D than females. That is, on either side of the intersection point, there were 350 females and 108 males with 4D < 78.47 mm, and 236 males and 54 females with 4D > 78.47 mm. Therefore, males tended to have lower 2D:4D than females because growth patterns of 2D relative to 4D resulted in sex differences in the slope and *Y*-intercept of 2D on 4D. There was no evidence in this sample for the suggestion that males and females share a common regression line of 2D on 4D, as suggested by Kratochvil and Flegr (2009) (Fig. 48.1).

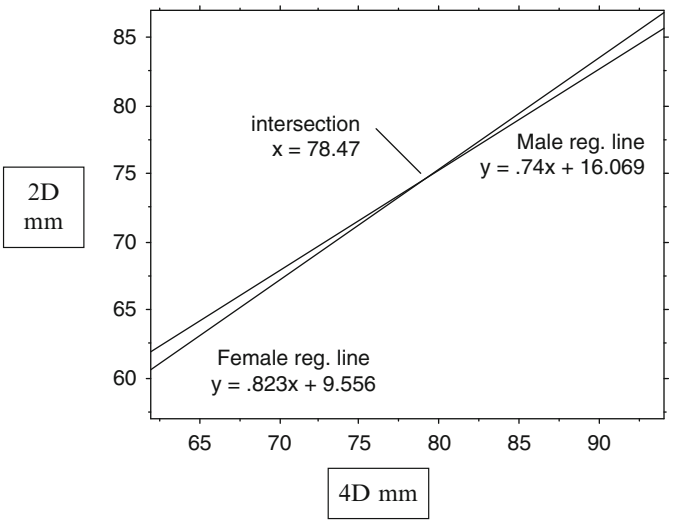

Fig. 48.1 Regression lines of left 2D on left 4D for males and females. The sample consisted of males ($n = 344$) and females ($n = 404$). Males had a significantly lower slope and a significantly higher *Y*-intercept than females. This meant the regression lines intersected (in this case at 4D = 78.47 mm)

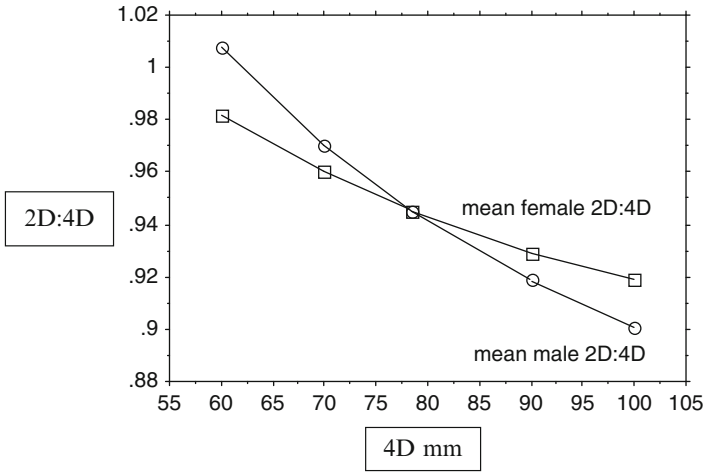

Fig. 48.2 The relationship between 4D length and mean 2D:4D. The sample consisted of 344 males and 404 females. Note that 2D:4D showed no sex difference at the value of 4D where male and female regression lines for 2D on 4D intersect (in this case at 78.47 mm). Below this value of 4D, females had lower 2D:4D than males. Above this value, they had higher 2D:4D than males and the sex difference in 2D:4D increased in size with increasing 4D

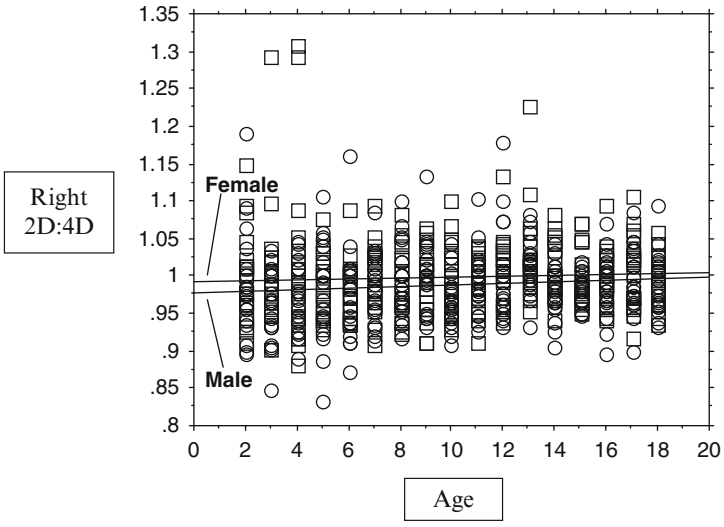

Fig. 48.3 The relationship between right 2D:4D and age (2–18 years). The sample was 340 males and 340 females. Note, there was a significant tendency for 2D:4D to be higher in females compared to males and 2D:4D tended to rise with age, but this tendency was non-significant. Thus, mean 2D:4D from 2 to 18 years showed sex differences but no age differences

48.4 Prenatal Sex Steroids and 2D:4D

Prenatal sex steroids, particularly prenatal testosterone (PT) and prenatal estrogen (PE), are thought to have important organising effects on foetal body systems. The evidence that 2D:4D is a negative proxy for levels of PT, and a positive proxy for PE, derives from studies of direct manipulation of sex steroids in animal foetuses and correlational studies in humans. Here, for brevity, I consider only the more important aspects of this evidence.

Manipulation experiments have been performed in birds and rats. In the former, increases in testosterone in the eggs of pheasants resulted in a significant increase in toe 2D:3D ratio and a non-significant increase in 2D:4D (Romano et al. 2005). With regard to PE, there was significant reduction in 2D:4D and 2D:3D when oestrogen was added to pheasant eggs (Saino et al. 2007).

In rats, exogenous testosterone applied to foetuses increased the length of forelimb 4D, but did not affect 2D. Thus, forelimb 2D:4D was reduced by PT (Talarovicova et al. 2009). In addition, it is known that foetal testosterone is reduced by alcohol, and rat foetuses exposed to alcohol showed a significant reduction in forelimb 2D:4D (McMechan et al. 2004).

A large number of studies of a correlational nature have suggested a link between 2D:4D and prenatal sex steroids. Perhaps most persuasive in this regard are the reports that 2D:4D is linked with congenital adrenal hyperplasia (CAH). Children with CAH have enlarged adrenals and produce high levels of prenatal androgens. In three studies, 2D:4D was reported to be lower in children with CAH than in healthy controls (Okten et al. 2002; Brown et al. 2002; Ciumas et al. 2009).

48.5 Sex Differences and Age Changes in Digit Ratios

In addition to 2D:4D, there are five other digit ratios (I have excluded the thumb because soft-tissue markers for measurement are not easily discerned in 1D). These are: 2D:3D, 2D:5D, 3D:4D, 3D:5D and 4D:5D. Adult sex differences have been noted in some of these ratios (McFadden et al. 2002).

Here, I consider all six ratios for evidence of sex differences and stability with growth. My sample was 680 Caucasian participants (340 males) from the northwest area of England (see Manning et al. 1998 for a description of the sample). The age range was 2–18 years, with 40 participants (20 males) per year group. Finger lengths (2D, 3D, 4D and 5D) were measured directly on the fingers using vernier callipers measuring to 0.1 mm. The influence of sex and age was tested (2 × 17 ANOVA) on all 12 finger ratios (six right hand and six left hand ratios). The results are shown in Table 48.1, and the mean ratios by sex and age are shown in Tables 48.2 and 48.3. If ratios are to be useful as prenatal indicators of sex steroids, they should ideally show significant sex differences but non-significant age changes. I found three ratios that fulfilled or nearly fulfilled these criteria (2D:4D right, sex $p = 0.0008$, age $p = 0.10$; 2D:3D right, sex $p = 0.03$, age $p = 0.06$; 3D:4D right, sex $p = 0.053$, age $p = 0.23$: see Table 48.2 for mean ratios). Note that these ratios are not

Table 48.2 The influence of sex and age on 12 finger ratios

	Sex		Age		Interaction	
Ratio	*F*	*p*	*F*	*p*	*F*	*p*
2D:4D right	11.35	0.0008	1.49	0.10	0.70	0.81
2D:4D left	14.80	0.0001	2.68	0.0004	0.79	0.69
2D:3D right	4.75	0.03	1.60	0.06	0.60	0.89
2D:3D left	15.26	0.0001	6.94	0.0001	3.39	0.0001
2D:5D right	20.96	0.0001	2.82	0.0002	1.27	0.21
2D:5D left	16.86	0.0001	4.15	0.0001	0.98	0.48
3D:4D right	3.76	0.053	1.24	0.23	0.33	0.99
3D:4D left	0.20	0.65	4.59	0.0001	3.25	0.0001
3D:5D right	12.12	0.0005	4.70	0.0001	1.10	0.35
3D:5D left	3.15	0.08	7.95	0.0001	1.04	0.41
4D:5D right	5.11	0.02	3.80	0.0001	1.40	0.14
4D:5D left	2.12	0.15	4.49	0.0001	0.86	0.62

The ratios comprised six from the right hand and six from the left-hand ratios in a sample of 680 Caucasian participants (340 males) aged from 2 to 18 years

Mean digit ratios (±SE) by sex and age across 17-year groups (2–18 years) for right and left digit ratios 2D:4D, 2D:3D and 3D:4D

independent of each other, so that they share at least part of the variance for the influence of sex and age. On this point, the interdependence may also arise because fingers sit next to each other and share developmental trajectories. For example, 2D:4D and 3D:5D do not share fingers, but, in these data, they are positively correlated (right hand, 2D:4D and 3D:5D $r = 0.14$, $p = 0.0002$: left hand, 2D:4D and 3D:5D $r = 0.08$, $p = 0.04$). Considering ratios other than 2D:4D, 2D:3D and 3D:4D, many showed significant age effects, suggesting that they were unlikely to be reliable proxies for prenatal sex steroid levels (for mean ratios see Table 48.4). It is appropriate to point out at this stage that these data are cross-sectional and not longitudinal. It is of course preferable to consider change in ratios in the latter type of data rather than in the former. McIntyre et al. (2005) did

Mean digit ratios (±SE) by sex and age across 17-year groups (2–18 years) for right and left digit ratios 2D:5D, 3D:5D and 4D:5D

this with serial radiographs of the left hand from infancy to age 17 years in the Fels data set. They found that digit ratio sex differences in infancy were maintained through to post puberty despite a tendency for ratios to increase. In partial replication of my findings, this effect was best developed in 2D:4D and 3D:4D. Finally, it should be noted that sexual dimorphism of children's 2D:4D and other ratios is found when sexual dimorphism of finger length is absent. Thus, there is little evidence in childhood ratios for the suggestion by Kratochvil and Flegr (2009) that sexual dimorphism in 2D:4D is determined by sex differences in finger length (Fig. 48.4).

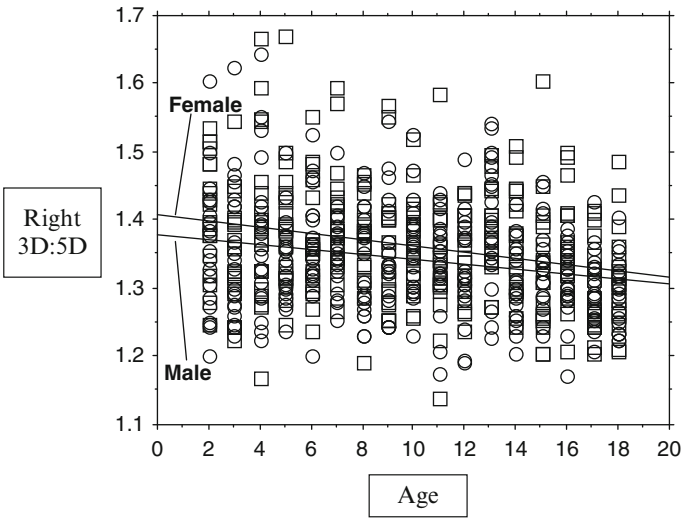

Fig. 48.4 The relationship between right 3D:5D and age (2–18 years). The sample was 340 males and 340 females. Note, there were significant sex differences such that females had higher 3D:5D than males and there was also a significant tendency for 3D:5D ratios to reduce with age. Thus, mean 3D:5D from 2 to 18 years shows both sex differences and age differences

48.6 Applications to Areas of Health and Disease

PT and PE may have important influences on the aetiology of many sex-dependent diseases. Therefore, 2D:4D, 2D:3D and 3D:4D may be useful biomarkers of such diseases (see Huo, Chap. 49). Most work thus far has been conducted with 2D:4D. In particular, the strong links between 2D:4D and sport suggest that 2D:4D may be a proxy for cardiovascular function, musculoskeletal fitness, health and disease (for a detailed consideration of 2D:4D and physical fitness see Honekopp, Chap. 113). I briefly consider here three areas of health: developmental disorders, cardiovascular disease and cancers, in which digit ratios could prove useful as biomarkers for disease.

A number of studies have shown links between low 2D:4D and childhood psychopathologies, such as social difficulties, hyperactivity and poor social cognition (e.g. Williams et al. 2003). In addition, developmental disorders presenting at an early age have also been reported to be associated with low 2D:4D. They include autism and Asperger's syndrome (e.g. Manning et al. 2001; de Bruin et al. 2006) and ADHD (e.g. de Bruin et al. 2006, Martel 2008).

With regard to cardiovascular disease, there is a strong negative association between 2D:4D and running speed over middle- and long-distance races. This suggests that cardiovascular function may be linked with 2D:4D, such that vascular disease is associated with high 2D:4D. Thus, Manning and Bundred (2001) have reported that age at first myocardial infarction (MI) in men is negatively related to 2D:4D. That is, among men, who present with MI, those with low 2D:4D tend to have their MI later in life than those with high 2D:4D. There is some evidence that neck circumference independent of BMI may correlate positively with 2D:4D (Fink et al. 2006). Neck circumference is linked with the metabolic syndrome (a breakdown of normal physiology that includes hypertension and insulin resistance; for further details see Fink, Chap. 36).

With regard to cancers, high 2D:4D in women may be a biomarker for some cancers of the reproductive system. These include cancer of the breast and the cervix. Manning and Leinster (2001) have reported that women with high 2D:4D tended to be younger at presentation of breast cancer than women with low 2D:4D. With regard to cervical cancer, infection with human papillomavirus (HPV)

is a risk factor here, but not all women with this cancer have HPV. Brabin et al. (2008) reported that women with cervical cancer, but without HPV, had significantly higher 2D:4D than controls. Patients with cervical cancer and HPV also tended to have higher 2D:4D than controls, but this was not significant.

It is likely that the potential of digit ratios as biomarkers for disease will be investigated further. Links between 2D:4D and eating disorders, depression, schizophrenia, bipolar disorder, rheumatoid arthritis and cancers (such as prostate cancer) may be strong enough to yield insights into their aetiology. Whether these links will be sufficiently strong enough for 2D:4D to be predictive for these diseases will have to wait on the accumulation of more data.

Summary Points

- 2D:4D (digit ratio) is the ratio of the lengths of the second and fourth digits.
- 2D:4D has been reported to show sex differences such that, on average, males have longer fourth digits relative to their second digit than do females (i.e. they have lower values of 2D:4D than do females).
- The sex difference in 2D:4D appears in the foetus as early as the ninth week, is found in infants, children and adults and the 2D:4D of infants is strongly correlated with their 2D:4D when they become adults. The sex difference results from a different growth trajectory of 4D relative to 2D.
- 2D:4D may be sexually dimorphic as a consequence of the effects of PT relative to PE on finger growth, such that high PT and low PE may result in low values of 2D:4D.
- Excluding the thumb, the fingers show six ratios and a number of these show sex differences. However, only 2D:4D, 2D:3D and 3D:4D show both sex differences and are relatively stable with growth in children.
- Many sex-dependent diseases may be influenced by PT and PE. Therefore, 2D:4D, 2D:3D and 3D:4D could be useful biomarkers for susceptibility to such diseases. Most work has concentrated on 2D:4D. Links have been shown to developmental disorders (e.g. autism, Asperger's syndrome and ADHD), cardiovascular disorders (e.g. MI), cardiovascular efficiency (e.g. running speed) and cancers (e.g. breast and cervical cancer).

Chapter 49
Correlations Between Digit Ratio and Foetal Origins of Adult Diseases in a Chinese Population: A Focus on Coronary Heart Disease and Breast Cancer

Huo Zhenghao, Lu Hong, Dang Jie, and Francis L. Martin

Abstract Epidemiological studies suggest that impaired foetal growth can promote an adaptive adjustment of metabolism and the morphological development of foetal organs. This may be a significant aetiological factor in adult diseases including coronary heart disease (CHD) or breast cancer; consequently, these modulating factors are defined as foetal origins of adult diseases (FOAD). Digit ratio is determined during foetal life and may be a marker reflecting the development of foetal growth. In order to investigate the relationship between the digit ratio and CHD or breast cancer, we used anthropometric methods to measure the digit length of both hands for every study participant. Digit ratios were scored and compared between right and left hands, for CHD patients (n = 152 cases), breast cancer patients (n = 128 cases) and controls (CHD control, n = 152 cases; breast cancer control, n = 128 cases) respectively; all participants were residents of Yinchuan, Ningxia, China. We observed the following trend 2D:3D < 2D:4D < 3D:4D < 2D:5D < 4D:D < 3D:5D in both the control and the two patient cohorts. However, the digit ratio scores for both CHD and breast cancer groups exhibited higher mean values compared to the control cohort; this was especially the case for 2D:4D. Both CHD and breast cancer cohorts exhibited higher proportions of 2D>4D. These findings suggest that digit ratio, especially 2D:4D, has the potential to be an important and early diagnostic marker for future risk of developing CHD or breast cancer.

49.1 Introduction: Digit Ratio and Foetal Origins of Adult Diseases (FOAD)

Generally, many chronic adult diseases, such as CHD, diabetes or hypertension, are associated with environmental factors, such as poor lifestyle or specific exposures modulated by polygenic inheritance susceptibility. In the 1990s, Prof. Barker proposed the notion of "foetal origins of adult diseases (FOAD)," which suggests that factors governing fertilisation, embryonic and foetal development, and post-parturition nutritional (over- or undernutrition) status may play a pivotal role in the aetiology of different diseases occurring later in adulthood, or may even influence long-term lifestyle. Included within the FOAD hypothesis is the notion that intra-uterine adverse mechanisms can promote an adaptive adjustment of metabolism and structural development of foetal organs. If undernutrition is not promptly corrected, such adaptive adjustments will induce permanent changes in the metabolic integrity of specific organs, including the vasculature, liver and lung, etc., and the organism; the consequences of these alterations will be borne out in adulthood (Barker 1990; Barker and Osmond 1986). There is increasing epidemiological evidence that impaired foetal growth has long-term effects on the body's morphological development and physiological functions, which in turn are associated with adverse health consequences in adult life. These studies have relied on showing correlations between crude indices of foetal growth, such as overall weight or length at birth and adult health outcomes. There is a need to develop improved morphological markers of impaired foetal growth and, in particular, to identify markers which persist into adult life.

An individual's fingers and toes begin to develop in the 6th week of pregnancy. Digital ratios are determined while the embryo forms, and will then remain the same during individual development. The foetus grows quickly from the 9th week of pregnancy, and this is the sensitive period for foetal development. The major feature of the foetal period is cell differentiation, which is sensitive to external environmental changes. So, during this period, if the foetus encounters changes in the intra-uterine environment, such as intra-uterine undernutrition or hormone level changes, not only will the foetal structures of the organs and organism be modified, but the development of foetal fingers and toes will also be affected. Therefore, studies on digit ratios can reflect development during the foetal period, and indirectly reflect the interference of intra-uterine environment changes. Thus, digit ratio is an important index for studies into morphological development and physiological abnormalities during the foetal period (Manning et al. 2004).

Human fingers are numbered consecutively from one (thumb) to five (little finger). Because thumb length is difficult to measure, digit ratios generally just include the six ratios of digit lengths, 2D:3D, 2D:4D, 2D:5D, 3D:4D, 3D:5D and 4D:5D (Manning 2002). A number of studies have shown that finger and toe development and differentiation of the genitourinary system (including gonads) are related to *HOX* genes (*HOX* A–*HOX* D). Gonads and their foetal products, such as androgens, may influence the morphological development of fingers (and toes) (Manning et al. 2003a).

Among all the digit ratios, the ratio between the length of the second and fourth digits (2D:4D ratio) may be the most important marker during the foetal period. It has been shown in recent studies that human digit ratios (especially 2D:4D) differ between the genders. Generally, the male ring finger is longer than the index finger (4D>2D), and the female index finger is equal in length to or slightly longer than the ring finger (2D≥4D). Thus, the mean female 2D:4D of 1.00 is generally higher than that the male 2D:4D mean of 0.96; as a result, males are designated as having low digit ratios, whilst females have high digit ratios. This gender difference, where females have obviously higher 2D:4D than males, is more pronounced in certain ethnic groups (McIntyre et al. 2006). A large number of studies have indicated such ethnic differences in 2D:4D (Manning et al. 2003b). It has been reported that British, Spanish and Polish populations exhibit higher digit ratios, whereas South African (i.e. Zulu), Chinese (Lu et al. 2008), Finnish and Jamaican population have lower digit ratios; populations in other countries exhibit medial digit ratios (Manning 2002).

Other studies have suggested that 2D:4D is related to individual characteristics such as aggressive behaviour, confidence and competitiveness, and it has been found that 2D:4D also significantly correlates with some abnormal developmental diseases or abnormalities, such as breast cancer, reduced sperm count, and autism (Manning and Bundred 2000; Manning et al. 2003a, b). Ronalds and co-workers studied the correlation between digit ratios and myocardial infarction, HIV susceptibility, foetal dysplasia, leukaemia and tumours, etc., in different ethnic groups in Poland, Spain, Germany and Britain; similar conclusions were obtained (Ronalds et al. 2002). As 2D:4D is related to various gender-dependent diseases, such as CHD (Fink et al. 2006) and breast cancer (Manning and Leinster 2001), we surveyed the digit ratios of a normal control cohort (males and females) and two patient cohorts (CHD and breast cancer) among the Han people in Ningxia, China. We set out to study the 2D:4D correlations of controls compared to patients, to age of onset of the two diseases in order to investigate the relationship of digit ratios and FOAD.

Studies into correlations between digit ratios and abnormalities of different individual characteristics, including morphological development and physiological functions, have drawn much attention from many scholars, and have become extensively debated issues in the fields of developmental biology, anthropology and behavioural science. In 2000, a related paper published in *Nature* introduced studies into digit ratios, and pointed out that "finger length ratio may reveal some surprising information of development" (Williams et al. 2000).

49.2 A Chinese Cohort Sampling: Guidelines

We studied the digit ratios (2D:3D; 2D:4D; 2D:5D; 3D:4D; 3D:5D; and 4D:5D) of the left and right hands from 560 individuals of Han nationality in Ningxia, China, including patient and normal control cohorts. The patient cohorts included CHD cases (n = 152) between the ages of 30–73 years (y) (mean = 47.5 years, standard deviation [s.d.] = 6.7); all CHD patients were male. We selected 152 healthy males as controls with a mean age ± s.d. of 55.9 y ± 7.7. In the breast cancer cohort, there were 128 cases aged between 30 and 73 y (mean = 55.0 years, s.d = 8.2); all the breast cancer patients were female. As such, we selected 128 healthy females as normal controls with a mean age ± s.d. of 54.6 y ± 8.2. Normal control subjects were resident natives of Ningxia, China, and all exhibited healthy physical and mental states. Subjects of the patient group were diagnosed cases in the hospital affiliated to Ningxia Medical University; the parents of all cases were from the same Han ethnic group, and disease had arisen in the absence of either inherited mutations or congenital defects.

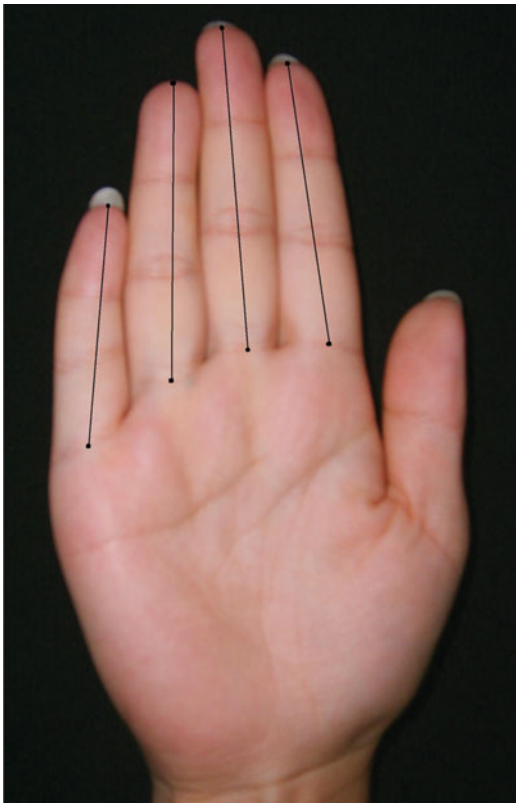

Fig. 49.1 Schematic diagram of digit length measurement. A right hand from a Chinese female; the picture was taken as part of the study

We adopted a photocopy measurement methodology in our study. By using this method, the hand images were captured by using a digital camera and then the images were input into a computer (Fig. 49.1). We then marked all sign spots by ACD image analysis software and measured them by using electronic Vernier callipers; samples with finger injuries were excluded. Samples stored in the computer were either required to have distinctive flexure creases, or repeat imaging was required. All the digits (2D:3D, 2D:4D, 2D:5D, 3D:4D, 3D:5D and 4D:5D) were measured from the basal crease proximal to the palm to the tip of the finger using electronic Vernier callipers capable of measuring to a spatial resolution of 0.01 mm. Repeat measurements were acquired for each finger. We used repeat measures ANOVA to calculate the ratio (F) between measurement error (the differences between successive measures of 2D:4D) and between-participant differences. The t-test and correlation analysis were applied to analyse the results.

49.3 Digit Ratio and Coronary Heart Disease (CHD)

Repeat measures ANOVA was performed on the results of digit ratios of left and right hands in normal control and CHD cohorts of the Han people in Ningxia, China, and the results showed that:

Control cohort: 2D:3D (F = 0.31, P = 0.58); 2D:4D (F = 0.002, P = 0.964); 2D:5D (F = 0.16, P = 0.91); 3D:4D (F = 2.19, P = O.13); 3D:5D (F = 1.08, P = 0.30); 4D:5D (F = 1.49, P = 0.19);
Patient cohort: 2D:3D (F = 0.27, P = 0.62); 2D:4D (F = 0.001, P = 0.973); 2D:5D (F = 1.10, P = 0.37); 3D:4D (F = 145, P = 0.23); 3D:5D (F = 1.07, P = 0.31); 4D:5D (F = 0.27, P = 0.604).

Table 49.2 Percentage distributions of 2D:4D patterns of left (L) and right (R) hands between control group and CHD patient group

		2D:4D					
		L			R		
Sample	number	2D < 4D (%)	2D = 4D (%)	2D >4D (%)	2D < 4D (%)	2D = 4D (%)	2D >4D (%)
Controls	152	85.52	1.32	13.16	86.84	0.66	12.50
CHD	152	84.87	0.66	14.47	85.52	0.66	13.82

The comparison of 2D:4D values for both hands (left, L; right, R) between the healthy control and coronary heart disease (CHD) cohorts of Han people in Ningxia, China

P values showed no significant differences ($P > 0.05$) in the digit ratios of both hands of control and CHD subjects between two measurements, indicating that differences of digit ratios of both hands were not induced by measurement errors in the control and CHD cohorts. The mean values of digit ratio and paired *t*-test results of both hands of control and patient cohorts are listed in Tables 49.1.

The results showed that: (1) the mean digit ratios of samples were similar in both hands, and a consistent trend was observed, that is, 2D:3D < 2D:4D < 3D:4D < 2D:5D < 4D:5D < 3D:5D; the mean digit ratios of both hands were higher in the CHD cohort compared to the control cohort; and (2) there were significant differences in 2D:3D (left hand) and particularly 2D:4D (left hand, $P < 0.01$; right, $P < 0.05$) between these two groups. These were the only significant differences between the observed digit ratios.

Relevant studies from other countries have shown that 2D:4D might be correlated with gender-related diseases, such as CHD, breast cancer, etc.; thus, this could potentially be used as a surrogate biomarker as an important early predictor of susceptibility to various gender-related diseases emerging as a consequence of influencing factors occurring during the foetal period. Therefore, we examined further the comparison of 2D:4D values for both hands between the healthy control and CHD cohorts of the Han people in Ningxia, China; the results are shown in Table 49.2.

The results indicated that, in the healthy control cohort and CHD patient cohort, 2D:4D displayed three patterns: 2D > 4D, 2D = 4D and 2D < 4D, with 2D < 4D as the dominant characteristic observation.

Table 49.3 Results of correlation and regression analysis on digit ratios of left (L) and right (R) hands of Han people between control subjects and CHD patients in Ningxia, China

				Statistical results	
Hands	Subjects	Number	Age (years)	*r* value	*P* value
L	Control subjects	152	55.87 ± 7.65	0.043	0.601
	CHD patients	152	47.48 ± 6.70	0.636	0.000
R	Control subjects	152	55.87 ± 7.65	0.055	2.585
	CHD patients	152	47.48 ± 6.70	0.561	0.000

	CHD patients	152	47.48 ± 6.70	0.561	0.000

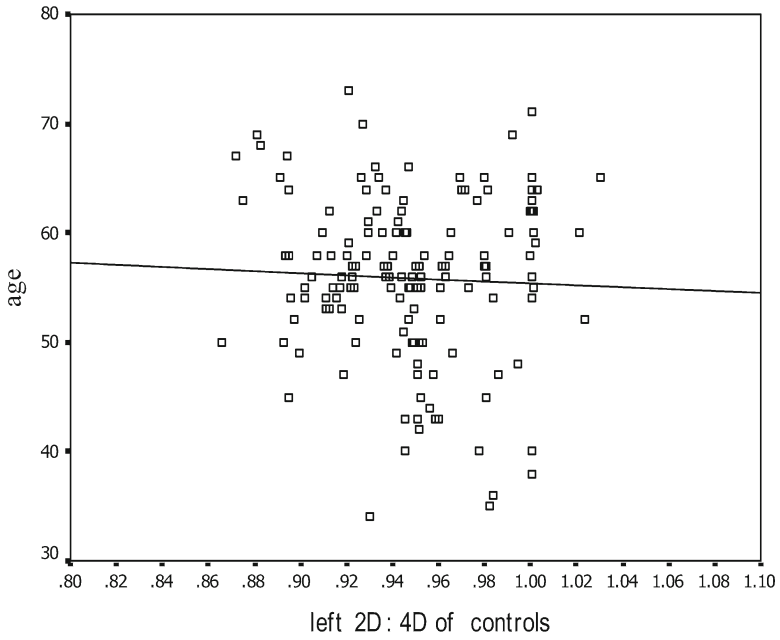

Fig. 49.2 Correlation analysis between 2D:4D of left hands and age in coronary heart disease (CHD) control cohort

There was a higher percentage of 2D > 4D in the CHD group compared to the control group, but without any apparent significant differences ($x^2 = 0.1105$, $P > 0.05$).

In order to investigate whether there were correlations between 2D:4D of both hands and age in normal control and CHD cohorts in the Han people (Ningxia, China), SPSS (version 11.5) was adopted for correlation analysis in our study and the results are shown in Table 49.3, Figs. 49.2 and 49.3.

The results of correlation analysis showed that: (1) there were no significant correlations between 2D:4D or mean 2D:4D of both hands *versus* age in the control cohort; (2) however, the CHD cohort exhibited a negative correlation between 2D:4D or mean 2D:4D of both hands versus age of onset of the diagnosed pathology. However, little is known regarding the reason why the correlation is more significant in 2D:4D and mean 2D:4D of the left hand compared to the right hand.

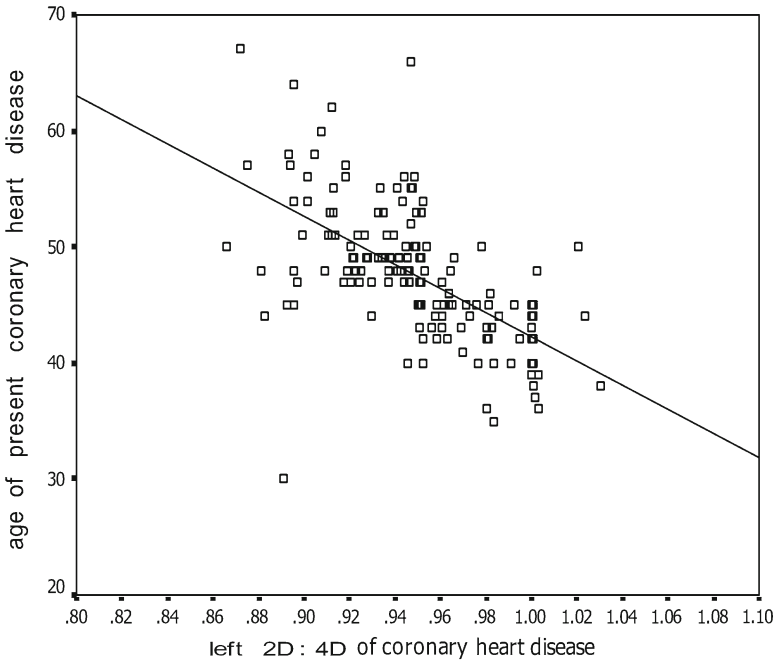

Fig. 49.3 Correlation analysis between 2D:4D of left hand and age of coronary heart disease (CHD) patient cohort

49.4 Digit Ratio and Breast Cancer

Repeated measures ANOVA was conducted on the results of the digit ratios of left and right hands in the normal control compared to the breast cancer cohort of the Han people in Ningxia, China; the results showed that:

Control group: 2D:3D ($F = 0.28$, $P = 0.61$); 2D:4D ($F = 0.005$, $P = 0.943$); 2D:5D ($F = 0.15$, $P = 0.91$); 3D:4D ($F = 2.18$, $P = 0.12$); 3D:5D ($F = 1.09$, $P = 0.29$); 4D:5D ($F = 1.48$, $P = 0.20$);
Patient group: 2D:3D ($F = 0.32$, $P = 0.57$); 2D:4D ($F = 0.001$, $P = 0.975$); 2D:5D ($F = 0.20$, $P = 0.93$); 3D:4D ($F = 0.26$, $P = 0.603$); 3D:5D ($F = 1.07$, $P = 0.31$); 4D:5D ($F = 1.46$, $P = 0.22$).

P values showed no significant differences in digit ratios of both hands of control subjects and breast cancer patients between two measurements ($P > 0.05$), indicating that measured differences in digit ratios of both hands were not a consequence of measurement errors in acquiring the data from the control and patient cohorts. The mean values of digit ratio and paired *t*-test results of both hands of the control group and patient groups are listed in Table 49.4.

The results showed that: (1) the mean digit ratios of samples were similar in both hands, and a similar trend of 2D:3D < 2D:4D < 3D:4D < 2D:5D < 4D:5D < 3D:5D, as previously observed, was noted, and the mean digit ratios of both hands were higher in the breast cancer cohort compared to the control cohort; (2) there were significant differences in 2D:3D (both hands, $P<0.05$), 2D:4D (both hands, $P < 0.01$) and 2D:5D (left hand, $P < 0.05$) in the breast cancer cohort compared to the control cohort, and no significant differences were observed for the remaining digit ratios. We particularly analysed the comparison of 2D:4D values for both hands between the normal control and the breast cancer cohorts of the Han people; the results are shown in Table 49.5.

				Statistical results	
Hands	Subjects	Number	Age (years)	*r* value	*P* value
L	Control subjects	128	54.57 ± 8.21	0.084	0.171
	Breast cancer	128	47.06 ± 6.35	0.616	0.000
R	Control subjects	128	54.57 ± 8.21	0.062	0.263
	Breast cancer	128	47.06 ± 6.35	0.598	0.000
Mean	Control subjects	128	54.57 ± 8.21	0.065	0.254
	Breast cancer	128	47.06 ± 6.35	0.600	0.000

There was also a higher percentage of 2D > 4D in the breast cancer group compared to the control group, but without significant differences ($x^2 = 0.2427$, $P > 0.05$). The correlation between 2D:4D of both hands and age in the normal control and breast cancer cohorts are shown in Table 49.6, Figs. 49.4 and 49.5.

The results of correlation analysis showed that: (1) there were no significant correlations between 2D:4D and mean 2D:4D of both hands and age in the control group; (2) the CHD group showed a negative correlation between 2D:4D and mean 2D:4D of both hands and onset ages.

49.5 Applications to Other Areas of Health and Disease

We have used this approach to study CHD and breast cancer in the context of FOAD. These studies also had a control arm consisting of ethnic Han Chinese residents in Ningxia. We intend to advance our studies in order to investigate possible relationships between azoospermia, diabetes and

schizophrenia, amongst other diseases, and digit ratio. Our study's immediate value is that it is an easy-to-obtain potential biomarker of health status that is non-invasive. Such a characteristic allows one to derive data from large cohorts that might then be associated with the presence or absence of particular diseases. This approach can also then be used to compare differences in disease susceptibility between different ethnic groups in greater detail.

49.6 Discussion

CHD is an age-related degenerative disease associated with a variety of genetic influences, environmental factors and poor lifestyle (e.g. smoking and excessive alcohol consumption, etc.), but the underlying aetiological factors remain unknown. Previous studies indicate that the genesis and development of CHD are correlated with age, and that the disease can be accelerated and aggravated by smoking, hypercholesteraemia, hypertension, diabetes, obesity, psychological factors, etc. However, several studies suggest that only 50% of CHD patients can be associated with these classical risk factors. Proposed the hypothesis of the foetal origin of CHD, in which they proposed that if the foetus suffers from undernutrition, it will adapt to the environmental change by physiological and metabolic adaptive responses. These responses persist after birth and will programme susceptibility to a diverse range of diseases. Environmental factors after birth also play very important roles in the development of CHD. Therefore, if a foetus suffers from undernutrition and, then, at a later stage, experience compensatory growth that accelerates the increase in body weight, the risk of developing CHD will increase in adulthood. Epidemiological studies support this hypothesis. Barker conducted an epidemiological survey in England and Wales, and found that populations with low birth weight and low infant body weight exhibited a high mortality induced by CHD in adulthood (Barker and Osmond 1986).

Another study has also indicated that, taking into account aetiological risk factors, intra-uterine sex hormone levels during early pregnancy are closely related with adult diseases, such as myocardial infarction and breast cancer (Manning 2002). Some of these studies strongly suggest that if the foetus is exposed in utero during the first trimester to excess oestrogens, progesterone will induce cardiovascular abnormalities including ventricular septal defects, atrial septal defects and patent ductus arteriosus (Manning and Bundred 2000). Thus, the foetal intra-uterine environment may be a predictor of whether the foetus post parturition will be at a higher risk of developing CHD. As peripheral blood cannot be drawn from a foetus in utero, and is rarely drawn from infants for research purposes, the study of effects of perinatal testosterone in humans had to rely on other methods. One method which has come into focus is the use of digit ratios, especially the second to fourth fingers (2D:4D).

Human digit ratios differ between the sexes, and these are related in the first instance with the effects of perinatal hormones. Perinatal hormone levels, of which the androgen level has the most important effects, affect the development of fingers and toes. The strongest evidence for direct effects of perinatal androgens comes from the study on patients with congenital adrenal cortical hyperplasia (CAH). This disease is initially induced by excess androgens secreted by the perinatal adrenal gland, and a study of digit ratios of these patients has indicated that the 2D:4D of the right hand in female patients is significantly lower than that in control females, whereas 2D:4D of the left hand of the male patient group is obviously lower than that of the non-patient male group (Brown et al. 2002).

In studies on male patients with myocardial infarction and aged-matched healthy control males, it was found that myocardial infarct patients have higher 2D:4D, lower androgen levels and higher oestrogen levels (Phillips et al. 1994; Manning and Bundred. 2000). It has been suggested that high

testosterone concentrations may be a protective factor for males, which can reduce the risk of heart diseases and postpone the age of onset of myocardial infarction (Fink et al. 2006). Some evidence has also suggested that male CHD patients have lower androgen levels, with higher digit ratios and lower androgen levels; this may become an important index to predict male myocardial infarct.

With regard to the relationship between digit ratio and cancer, the relationship between digit ratio and breast cancer has been studied most frequently. Trichopoulos has proposed that higher oestrogen levels in utero during the foetal period are a risk factor for breast cancer after birth (Trichopoulos 1990). Manning and Leinsfer have demonstrated in their study that 2D:4D is positively related with the onset of breast cancer, that is, females with a higher 2D:4D have a higher incidence of breast cancer compared to their aged-matched counterparts with a lower 2D:4D (Manning and Leinster 2001). Therefore, some investigators have proposed that digit ratio could be adopted as a judgement index of susceptibility, diagnosis and therapeutic effects for tumours. They presume that disordered gene regulation induces tumours of the genital system, kidney, intestines, etc., which will be represented morphologically by changes in 2D:4D. Therefore, 2D:4D may be correlated with endometrial cancer, ovarian cancer, and primary renal carcinoma and colon carcinoma, though these correlations need to be confirmed.

Our study revealed that the digit ratios of the patient cohort were higher than those of controls, with significant differences observed in 2D:4D of the left hand between the control and patient groups. However, the underlying reasons for this remain to be further investigated. These results suggest that patients may have lower androgen levels and higher oestrogen levels during their foetal periods compared to healthy controls. In adults, 2D:4D is directly correlated with oestrogen levels. If the foetus is exposed to higher oestrogen levels, the risk of developing CHD and breast cancer will be increased. Higher digit ratios and lower androgen levels (or higher oestrogen levels) may be important indices for screening CHD and breast cancer. The 2D:4D ratios, especially 2D:4D of the left hand, may provide more information for early diagnosis of CHD or breast cancer.

Compared to controls, the two patient cohorts had higher percentages of 2D>4D, which might be a reason for higher mean 2D:4D in the patients. The results suggest that these patients may have had lower androgen levels and higher oestrogen levels during their foetal period. The higher 2D > 4D percentages in the patients suggests that intra-uterine oestrogen levels during the foetal period may have certain stimulating effects on growth of the index finger, whereas androgen levels have certain stimulating effects on growth of the ring finger. So, we can presume that the intra-uterine hormone environment during early pregnancy may be a factor to determine whether there will be a higher risk of developing CHD and breast cancer in adulthood. Compared to reports in the European population, 2D > 4D percentages in CHD or breast cancer patients of the Han people in Ningxia are significantly lower, indicating why the lower digit ratio may be one reason for lower incidences of CHD and breast cancer the Chinese than in the European population.

Correlation analysis indicates that for patients with higher 2D:4D (lower androgen levels or higher oestrogen levels), CHD or breast cancer may arise earlier compared to their aged-matched counterparts with lower 2D:4D (higher androgen levels or lower oestrogen levels). On the other hand, it is also demonstrated that lower androgen levels in the foetus and the corresponding intra-uterine environment may be a risk factor for CHD or breast cancer; the 2D:4D of the left hand provides more effective information for early onset risks of developing CHD or breast cancer.

The hypothesis of the foetal origins of adult diseases provides a new avenue for understanding cardiovascular diseases and metabolic diseases, such as coronary disease and diabetes, and it provides evidence for prevention against these common diseases in the embryonic period and during pregnancy. It also helps to achieve breakthroughs in studies on mechanisms of diseases with unknown aetiological factors. Because the digit ratio can indirectly reflect the interferences of the intrauterine environment on the foetal period, it becomes an effective marker to presume whether individuals

have encountered intra-uterine environmental changes during the foetal period. A large number of studies have confirmed that digit ratios are related to human behaviours, such as aggressive behaviour, cooperation, left handedness, etc., and human diseases, such as autism, dyslogia, infertility, myocardial infarct, breast cancer, etc. So, digit ratios may lend valuable support to early diagnosis and prognosis of many adult diseases. Simultaneously, with the implementation of further studies on 2D:4D, more effective information will be available to postpone the onset of diseases including myocardial infarction by modifying lifestyle, and determine the onset of risk factors for diseases, such as breast cancer.

Summary Points

- Foetal origins of adult diseases (FOAD) are associated with factors governing fertilization, embryonic and foetal development and post-parturition nutritional (over- or undernutrition) status. Such modulating factors may play a pivotal role in the aetiology of different diseases occurring later in adulthood or may even influence long-term lifestyle.
- Digit ratio is an important index for studies into morphological development and physiological abnormalities that may emerge during the foetal period.
- The ratio between the length of the second and fourth digits (2D:4D ratio) may be a good marker of normal development during the foetal period. Previous studies have shown that human digit ratios (especially 2D:4D) differ between genders and different ethnic groups.
- It has also been shown that 2D:4D is related to such characteristics as aggressive behaviour, confidence and competitiveness. Additionally, 2D:4D appears to correlate significantly with some abnormal developmental diseases or abnormalities, including breast cancer, reduced sperm count and autism.
- Our studies revealed that the digit ratios of patient groups are higher than those of control groups. It is suggested that these patients may have had lower androgen levels and higher oestrogen levels during their foetal period.
- Our observations suggest that the intra-uterine hormone environment at early pregnancy may be a factor determining subsequent risk of coronary heart disease (CHD) or breast cancer in adulthood.

Key Features

Table 49.7 Key features of foetal origins of adult diseases (FOAD) and disease susceptibility

Feature number	Foetal origins of adult diseases (FOAD)
1.	Epidemiological studies suggest that impaired foetal growth can promote an adaptive adjustment of metabolism and the morphological development of foetal organs.
2.	It has a potential to be a significant aetiological factor in adult diseases.
3.	Digit ratio is determined during foetal life and may reflect development.
4.	Digit ratio scores for CHD and breast cancer patients are higher compared to those for healthy controls.
5.	2D:4D appears to be the most important digit ratio.
6.	Digit ratio, especially 2D:4D, is potentially an early marker for future risk.

This table lists the key facts associating FOAD and future risk of adult disease

Part VIII
Regions and Anatomical Areas of the Body: Abdominal and Trunk Regions

Chapter 50
Anthropometry of Abdominal Subcutaneous and Visceral Adipose Tissue with Computed Tomography

Amir Abbas Mahabadi, Pál Maurovich-Horvat, and Udo Hoffmann

Abstract Obesity is a major health care problem with further increasing prevalence in the industrialized world. Multiple studies have outlined the exceptional role of subcutaneous abdominal adipose tissue (SAT) and more importantly visceral abdominal adipose tissue (VAT). VAT is the largest visceral adipose tissue of the human body and drains directly into portal circulation. Both VAT and SAT are strongly associated with other cardiovascular and metabolic risk factors such as hypertension, dyslipidemia, diabetes and the metabolic syndrome. The prevalence of cardiovascular disease is increased with excessive VAT and SAT amount. Moreover, both fat tissues are correlated with systemic markers of inflammation, as they secrete pro- and anti-inflammatory mediators and hormone like peptides. CT imaging of the abdomen is considered the gold standard for VAT and SAT quantification. Three- and two-dimensional measures have been established. Three-dimensional fat volume is more accurate, however, it is relatively time consuming and requires full abdominal CT-imaging. Despite the VAT and SAT volume, the fat area at the level of the umbiculus is most commonly used in the literature. Normative values for different VAT and SAT measures have been established in the literature. However it has to be acknowledged that abdominal adipose tissue distribution differs by age, gender, and ethnicity.

50.1 Introduction

Obesity is one of the most prevalent cardiovascular risk factors in the industrialized world, promoted by the modern lifestyle with a lack of physical activity and a high-caloric diet. In accord with increasing incidence of obesity, obesity-related disorders such as diabetes, dyslipidemia, and hypertension are of increasing prevalence, leading to an increased risk of cardiovascular diseases. While adipose tissue has simply been considered an energy storing compartment in the past, over the last two decades, it has gained more and more interest, and is now regarded as a complex organ, contributing to energy management of the body, and interacting with systemic and local inflammation. However, there is growing evidence that not only overall adiposity (as assessed by body mass index), but also visceral adiposity is strongly associated with metabolic syndrome, cardiovascular risk factors and present cardiovascular disease, whereas other fat compartments (e.g., hip fat) are of less importance, or may even be protective. Visceral adipose tissue differs from subcutaneous fat in cell size, fatty acid composition, protein content, fatty acid metabolism, enzyme expression, and glucose utilization. Visceral adipose tissue of the abdomen (VAT) is the largest visceral fat depot of the body, and consists of fat deposits in the retroperitoneal, omental and mesenteric spaces. Besides its size, VAT gains specific interest due to its location, directly draining into the portal circulation. In this chapter, we will overview the clinical implications of VAT and subcutaneous abdominal fat (SAT), association with other fat tissues of the body, and changes during growth and lifestyle modifications. Moreover, we will discuss the frequently used measures of pericardial fat, and provide normative values for different measures in different patient populations.

50.2 Practical Methods and Techniques: Planimetric and Volumetric Quantification Techniques of Subcutaneous and Visceral Abdominal Adipose Tissue Compartments

It was previously demonstrated that, for a given BMI or total amount of body fat, the subgroup of patients with excessive intra-abdominal adipose tissue depot is at substantially higher risk of developing insulin resistance and metabolic syndrome (Despres 2006). Other studies demonstrated that the waist circumference correlates with measures of risk, for coronary heart disease, such as hypertension or blood lipid levels (Ledoux et al. 1997; Seidell et al. 1992). Thus, not surprisingly, there has been a great interest during the past decade to develop quantification methods that allow for precise and reproducible assessment of abdominal adipose tissue compartments. Both magnetic resonance imaging (MRI) and computed tomography (CT) allow for three-dimensional, volumetric data collection. Computed tomography is a widely available technique and has several advantages over MRI in adipose tissue quantification. The superior accuracy of CT over MRI for adipose tissue assessment can be attributed thus: (1) in CT images, absolute Hounsfield-unit (HU) values of pixels correspond directly to tissue property, whereas, in MRI, there is no direct association between tissue property and pixel value; (2) MRI-based signal intensities may be inhomogeneous, in particular at a larger field of view (FoV); and (3) CT has better spatial resolution than MRI ($0.4 \times 0.4 \times 04$ mm^3 vs. $1.5 \times 1.5 \times 15$ mm^3 isotropic resolution, respectively). In addition, the feasibility of MRI is limited due to the long acquisition time and high expenses. However, it is important to note that CT utilizes ionizing radiation for image acquisition.

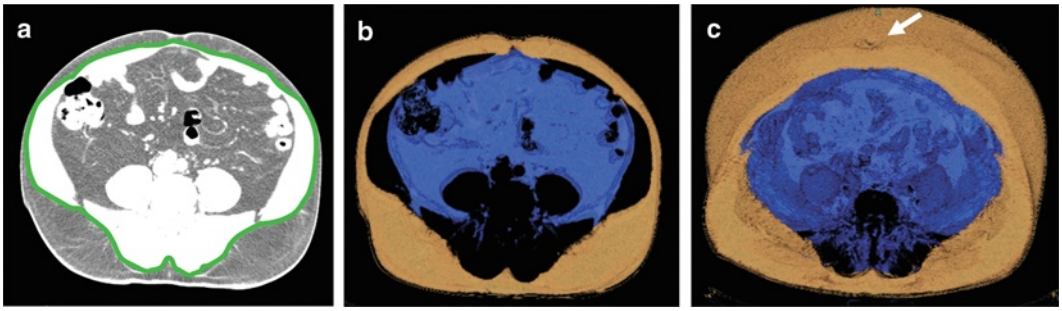

Fig. 50.1 VAT and SAT quantification using CT. *For the black and white image*: Single cross-sectional CT scan at the umbilical level (*panels A and B*) and a 12.5-cm wide volumetric data set (*panel C*). The inner border of subcutaneous abdominal adipose tissue (*SAT*) is traced automatically (*black*). The SAT (*light gray*) area is calculated by subtracting the visceral abdominal adipose tissue (VAT) (*dark gray*) area from the total cross-sectional fat area or total abdominal fat volume. The *arrow* points to the umbilicus in the three-dimensional data set. *SAT* subcutaneous adipose tissue, *VAT* visceral adipose tissue. *For the color image*: Single cross-sectional CT scan at the umbilical level (*panels A and B*) and a 12.5-cm wide volumetric data set (*panel C*). The inner border of subcutaneous abdominal adipose tissue (*SAT*) is traced automatically (*green line*). The SAT (*orange color*) area/volume is calculated by subtracting the visceral abdominal adipose tissue (*VAT*) (*blue color*) area/volume from the total cross-sectional fat area or total abdominal fat volume. The arrow points to the umbilicus in the three-dimensional data set. *SAT* subcutaneous adipose tissue, *VAT* visceral adipose tissue

As the CT attenuation value (Hounsfield unit) of each voxel corresponds directly to the tissue property, a predefined HU range is used for identifying the fat-containing voxels in the CT image. Voxels containing fatty tissue have negative CT attenuation, with values ranging between −100 and −50 HU (Barnes 1992). Several threshold-level settings have been used in the literature for adipose tissue quantification, with an upper attenuation limit of −50 to −30 HU, and a lower attenuation limit of −195 to −150 HU (Maurovich-Horvat et al. 2007; Rossner et al. 1990; Yoshizumi et al. 1999; Table 50.1).

50.2.1 Planimetric or Two-Dimensional Adipose Tissue Quantification

Controversy exists regarding the level of abdominal adipose tissue area measurements. The most commonly used anatomical landmarks for image acquisition are the umbilicus and the level of L4/5, which were highly correlated with the total visceral fat volume (Sjostrom et al. 1986; Yoshizumi et al. 1999; Araki et al. 2010; Chung et al. 2008; Hayashi et al. 2008). Measurement of SAT and VAT area at other anatomical landmarks have been described as well (Hyun et al. 2008; Mundi et al. 2010). Notably, in the Framingham Heart Study cohort, the SAT and VAT area measured at L3/4 provided the best proxy of SAT and VAT burden for both sexes and at different ages (Irlbeck et al. 2010).

The pixels containing fatty tissue are identified in the cross-sectional scan by using predefined HU settings, and the total fat area is calculated by counting the number of pixels. The abdominal muscular wall taken as the inner border of SAT is traced manually or automatically. The SAT area is calculated by subtracting the VAT area from the total cross-sectional fat area (Yoshizumi et al. 1999) (Fig. 50.1, panels A and B).

Table 50.1 Key facts of visceral abdominal adipose tissue subcutaneous abdominal fat

Key facts of visceral abdominal adipose tissue (VAT) and subcutaneous abdominal fat (SAT)
– VAT is the largest visceral adipose tissue compartment of the human body.
– VAT has stronger association with cardiovascular and metabolic risk factor than SAT.
– VAT is associated with increased prevalence of cardiovascular events.
– VAT secretes several adipokines, modulating energy balance, utilization, and metabolism, and also local and systemic inflammation.
– CT is the gold standard for VAT and SAT quantification, with both area and volume measures being established in the literature.

This table summarizes key facts about visceral abdominal adipose tissue (*VAT*) and subcutaneous abdominal fat (*SAT*) and their implication for healthcare-related issues

50.2.2 Volumetric or Three-Dimensional Adipose Tissue Quantification

The inhomogeneous distribution of VAT and SAT throughout the axial length of the abdomen may introduce great variation between the planimetric measurements performed at different anatomical levels. This variation may result in significantly different adipose tissue distribution estimates (Maurovich-Horvat et al. 2007). During volumetric adipose tissue assessment, the SAT and VAT quantities are measured across the total imaging volume (Fig. 50.1, panel C). Using image display settings similar to the previously described planimetric measurements, an automatic or semiautomatic segmentation technique can be performed. The volumetric quantification technique has reproducibility similar to the single cross-section-based planimetric method (Maurovich-Horvat et al. 2007). However, it is important to note that this more robust quantification method comes with an expense of higher radiation dose (2.7 vs. 0.5 mSv).

50.3 Normative Values for Male and Female

As indicated earlier (chapter Measurement Techniques of SAT and VAT), there exist different measurement techniques for the assessment of VAT and SAT mass. Computed tomography is the most commonly used imaging tool for abdominal fat quantification. Three-dimensional volume assessment of VAT and SAT is considered the gold standard. However, it is relatively time consuming, and requires full abdominal CT imaging. Two-dimensional measures may not be accurate (see above). As not a single standard measure for VAT and SAT quantification is established, different normative values have to be acknowledged. Framingham investigators have established normative values for both three-dimensional VAT and SAT volume, as well as fat compartment areas, at multiple specific anatomical landmarks in unselected general population (Table 50.2) (Fox et al. 2007; Irlbeck et al. 2010). When comparing different anatomical landmarks with the fat volume, investigators found close correlation for all investigated landmarks ($r \geq 0.87$, $p < 0.001$), with best performance at the level of L3/4 ($r = 0.96$ for SAT volume in women, 0.99 for VAT volume in women and both fat compartments in men, $p < 0.001$ for all). In contrast, the absolute values for axial fat area differed by more than twofold, depending on location (Irlbeck et al. 2010). These results indicate that axial area measures satisfactorily represent VAT and SAT volume; however, a consistent location for the axial fat measure should be assured.

It has to be acknowledged that normative values, established by investigation of the Framingham cohort, are predominantly based on Caucasian Americans. Therefore, generalization to other ethnic groups may be uncertain. When investigating middle-aged African-American, Hispanic, and white American men and women, Carroll et al. found that African-American men and women had significantly

Table 50.2 Normative values for three-dimensional VAT and SAT volume as well as axial VAT and SAT area at different anatomical landmarks demonstrated as means ± standard deviation, as defined in the unselected general population of the Framingham Heart Study (modified from Fox et al. 2007; Irlbeck et al. 2010)

	Men		Women	
	VAT	SAT	VAT	SAT
Volume (cm^3)	2,159 ± 967	2,603 ± 187	1,306 ± 807	3,071 ± 1,444
L 1/2 (cm^2)	234 ± 99	172 ± 88	104 ± 72	170 ± 86
L 2/3 (cm^2)	208 ± 101	168 ± 79	104 ± 77	192 ± 107
L 3/4 (cm^2)	198 ± 94	215 ± 93	115 ± 81	235 ± 119
Umbilicus (cm^2)	181 ± 78	229 ± 105	118 ± 78	258 ± 137
L 4/5 (cm^2)	158 ± 72	240 ± 115	122 ± 73	297 ± 126
Iliac crest (cm^2)	156 ± 71	241 ± 109	119 ± 69	307 ± 132
L 5/S 1 (cm^2)	108 ± 44	207 ± 110	100 ± 56	320 ± 135

Men tend to have more VAT, whereas women have more SAT. The largest areas of VAT are present at upper parts of the abdomen, whereas the SAT area is higher at lower anatomical landmarks
VAT visceral adipose tissue, *SAT* subcutaneous adipose tissue

Table 50.3 VAT and SAT volume and area in selected studies of different ethnic groups and collectives

Collective	Gender	Measurement site	VAT	SAT	Reference
Non-diabetic Caucasians	Women	L2–L5	40 cm^2	169 cm^2	Mundi et al. (2010)
	Men	L2–L5	74 cm^2	133 cm^2

	Men	Volume	96 cm^3	612 cm^3	

VAT visceral adipose tissue, *SAT* subcutaneous adipose tissue
A selected list of publications demonstrating that normal values of VAT and SAT are dependent on age, gender, ethnicity, and measurement technique

less VAT compared to white and Hispanics. In contrast, the amount of SAT was higher in African Americans, and whites had the least total abdominal fat volume (Carroll et al. 2008). Table 50.3 summarizes selected findings of different studies on VAT and SAT in different ethnic groups and collectives.

Moreover, there is a significant gender difference in the amount and distribution of abdominal fat. Men have a significantly larger VAT volume, whereas women tend to have slightly more SAT, especially at lower abdominal regions (L4/5 and below) (Maurovich-Horvat et al. 2007; Fox et al. 2007; Irlbeck et al. 2010).

50.4 Applications to Other Areas of Health and Disease: Association with Metabolic Risk Factors and Cardiovascular Disease

The association of VAT and SAT with cardiovascular risk factors has been investigated in multiple studies. Framingham investigators described that both VAT and SAT were significantly associated with hypertension, dyslipidemia, impaired fasting glucose, and the metabolic syndrome; however,

Table 50.4 Multivariable-adjusted regression for SAT and VAT with metabolic risk factors in the Framingham Heart Study (modified from Fox et al. 2007)

VAT visceral abdominal adipose tissue, *SAT* subcutaneous abdominal adipose tissue, *SBP* systolic blood pressure, *TG* triglycerides, *HDL* high-density lipoproteins, *HTN* hypertension, *IFG* impaired fasting glucose, *MetS* metabolic syndrome

Both VAT and SAT are significantly associated with cardiovascular and metabolic risk factors in women and men. However, associations are stronger for VAT when compared to SAT

when comparing VAT and SAT, the visceral fat volume had significantly stronger association compared to subcutaneous fat (Table 50.4) (Fox et al. 2007). Potential explanations for the specific metabolic risk factors are listed as follows:

- VAT and hypertension: It is estimated that about 70% of cases of hypertension could be attributed to obesity. Besides the liver, adipose tissue is an additional source of angiotensinogen. Therefore, an increased amount of VAT leads to increased levels of angiotensin I and, consecutively, angiotensinogen II. Interestingly, adipocytes themselves express angiotensinogen II receptors, which can hamper the differentiation of preadipocytes to adipocytes. This leads to formation of large dysfunctional adipocytes, which secrete increased amounts of angiotensinogen. Additionally, leptin, which is produced and secreted by adipose tissue, activates the sympathetic nervous system through a melanin-dependent pathway within the hypothalamus (Tallam et al. 2005).
- VAT and dyslipidemia: Due to its location, surrounding the vasculature that drains into the portal vein, VAT can influence hepatic metabolism. It has been suggested that an increased amount of VAT leads to increased delivery of free fatty acids to the liver. This may contribute to the synthesis of triglyceride-enriched very low density lipoproteins (VLDL) and consecutively small, dense, low-density lipoproteins (LDL), one of the key features of visceral adiposity-related risk (Lamarche et al. 1998). Moreover, in viscerally obese individuals, high-density lipoproteins (HDL) levels are decreased, and HDL particles are smaller and denser, resulting in a reduced efficiency in quenching reactive oxygen species (Navab et al. 2005).
- VAT and impaired fasting glucose and diabetes: There is substantial evidence that VAT, and not SAT, is predictive of insulin resistance. For instance, when matching individuals for SAT, the amount of VAT is markedly differentiated by levels of insulin resistance and glucose tolerance, whereas after matching for VAT, the amount of SAT is not of additional value (Ross et al. 2002). It is proposed that the link between VAT and disordered glucose metabolism is a mixture of increased free fatty acid exposure to the liver, the endocrine activity of the visceral adipose tissue itself, and the fact that excessive visceral adiposity is a marker of the relative inability of the subcutaneous fat to store the increased energy surplus.

Consecutively, increased amounts of VAT are associated with presence of cardiovascular disease. It has been acknowledged that VAT is associated with presence of plaque in vascular territories in the whole body, indicating a systemic proatherogenetic effect of VAT (Table 50.5) (Mahabadi et al. 2009).

Table 50.5 Multivariable adjusted associations of VAT with presence of overall cardiovascular disease, coronary heart disease, myocardial infarction, and stroke in the Framingham Heart Study. Multivariable adjustment included age, gender, body mass index, and waist circumference (modified from Mahabadi et al. 2009)

	Odds ratio (95% Confidence Interval)	*p*-Value
Cardiovascular disease	1.46 (1.11–1.92)	0.007
Coronary heart disease	1.36 (1.02–1.82)	0.04
Myocardial infarction	1.38 (0.91–2.08)	0.13
Stroke	1.83 (1.01–3.30)	0.046

Visceral abdominal adipose tissue is significantly associated with the presence of cardiovascular disease and both coronary heart disease and stroke, even after adjustment for general measures of obesity. This suggests a systemic influence of VAT on development of cardiovascular disease

50.5 Diet, Exercise, and Obesity Surgery-Induced Changes of VAT and Total Fat

Because of its implications for cardiovascular disease risk, reduction of visceral adipose tissue is of specific interest. Fortunately, the amount of VAT decreases to a greater degree than total fat mass during negative energy balance. Multiple studies have investigated whether low-calorie diet alone, physical activity alone, or combination of both is most beneficial. However, results from the different studies are conflicting. A meta-analysis of 37 studies on VAT reduction by weight-loss interventions including caloric restriction, endurance exercise, resistance exercise, and bariatric surgery found that changes in VAT are primarily determined by the overall fat mass changes as well as the initial VAT to total fat mass ratio. Interestingly, results were not significantly different for men and women (Hallgreen and Hall 2008).

When investigating factors leading to visceral and subcutaneous adiposity primarily, researchers from the Fels Longitudinal Study found that rapid infant weight gain, male gender, maternal age, and low physical activity were associated with presence of visceral adiposity at a mean age of 47 years. Absolute birth weight as well as maternal weight are associated with later increased amounts of SAT, however, not with VAT (Demerath et al. 2009).

50.5.1 Associations Between Abdominal Adipose Tissue Compartments and Other Adipose Tissue Depots of the Body

Both VAT and SAT are associated to general measures of obesity, such as BMI and waist circumference (Table 50.6). However, in humans, the development of obesity not only leads to an increase in adipose tissue depots in classical locations, such as in the subcutaneous and visceral adipose tissue compartments, but also around specific organs, such as the heart (pericardial), blood vessels (perivascular), and the kidney (renal), or internal organs, such as skeletal muscle (intramuscular) and liver (intrahepatic), which have all been described as locations for ectopic fat storage (Speliotes et al. 2008; Thalmann and Meier 2007). The excessive regional adipose tissue deposits may alter organ function by means of mechanical compression or through secreted cytokines and chemokines (Thalmann and Meier 2007). Visceral adipose tissue assessment requires tomographic imaging

Table 50.6 Association of VAT and SAT with BMI, waist circumference, and waist/hip ratio (modified from Snell Bergeon et al. 2004)

	VAT	SAT
BMI	0.70*	0.88*
Waist circumference	0.78*	0.83*
Waist/hip ratio	0.57*	0.46*
SAT	0.65*	–

Both VAT and SAT are closely associated with general measures of overall and abdominal obesity
VAT visceral adipose tissue, *SAT* subcutaneous adipose tissue, *BMI* body mass index
*$p < 0.001$

techniques, which are expensive and time consuming. By using an "easier to access" adipose tissue depot, such as the pericardial fat compartment, as proxy for visceral adipose tissue quantification, a refined clinical cardiometabolic risk assessment might be feasible.

50.5.1.1 Intrathoracic Adipose Tissue, Pericardial Adipose Tissue, and VAT

Intrathoracic adipose tissue is defined as any adipose tissue located within the thorax from the diaphragm, to the level of the right pulmonary artery; the pericardial adipose tissue compartment is located within the pericardial sac (Rosito et al. 2008). It is about one-tenth of the size of the VAT compartment; however, due to its proximity to the coronary arteries, it might have a significant role in the development of coronary artery disease (Mahabadi et al. 2009). Both intrathoracic and pericardial fat volumes were closely correlated with VAT in women (r = 0.76 and 0.62, respectively) and men (r=0.76 and 0.63, respectively) in the Framingham Heart Study (Rosito et al. 2008). Another study, utilizing ultrasound for pericardial fat assessment, and CT for VAT quantification, showed a similarly good correlation between VAT and pericardial fat compartments (Iacobellis et al. 2003). Thus, pericardial fat may be an overall marker of VAT accumulation. Pericardial fat can be quantified with echocardiography, or during chest CT, without incurring excess abdominal radiation. Pericardial fat may yield additional information on metabolic risk, which may be particularly useful when abdominal imaging with VAT quantification is not feasible (Rosito et al. 2008).

50.5.1.2 Intramuscular and Intrahepatic Adipose Tissue and VAT

Similar to VAT, insulin resistance correlates tightly with the intramuscular and intrahepatic lipid content, which can be quantified non-invasively using computed tomography (Speliotes et al. 2008). With increased lipid content, decreased CT attenuation values are measured in muscle or liver cross-sectional images. This is because CT attenuation values for skeletal muscle, or for the liver, are positive, whereas attenuation values for adipose tissue are negative. Further research is warranted to determine the association between the intramuscular and the intrahepatic adipose tissue and VAT.

50.6 Endocrine Activity of Adipose Tissue

Since the discovery of the first adipokine, leptin, in 1994, the understanding of adipose tissues has changed from a simple energy-storing compartment to a complex organ, contributing to energy management of the body, and interacting with systemic and local inflammation. During the last few years, an increasing number of adipokines, such as adiponectin and resistin, have been discovered. Moreover, associations of adipose tissues with pro- and anti-inflammatory cytokines and chemokines, including tumor necrosis factor alpha, different interleukins, monocyte chemotactic protein 1, and others, were established in the literature. This field of research is of constant novel discoveries; however, certain mechanisms have been established and will be discussed as follows:

- *Leptin*: Leptin is a 16 kDa peptide that is predominantly secreted by white adipose tissue. The levels of circulating leptin are directly proportional to the total amount of fat in the body. Moreover, leptin levels are positively correlated with levels of insulin, and negatively correlated with glucocorticoid concentration. By stimulating receptors in the cortex, the hippocampus, and, most importantly, the hypothalamus, leptin plays a key role in regulating energy intake and energy expenditure, including appetite and metabolism. However, it also has been described to regulate pancreatic islet cells, growth hormone levels, immunology homeostasis, osteogenesis, gastrointestinal function, and puberty. Congenital leptin deficiency is a rare but severe cause of early onset obesity, hypogonadism, hyperinsulinemia, hyperphagia, and impaired T-cell mediated immunity, which can be treated with recombinant leptin. In contrast to patients with congenital leptin deficiency, chronically obese patients have enduringly increased levels of leptin, leading to resistance due to leptin receptor signaling defects, downstream blockade in neuronal circuits, and defects in leptin transport across the blood–brain barrier. As a vicious circle, this leads to a lack in the feeling of satiety after eating.
- *Adiponectin*: Adiponectin is a 30 kDa protein that accounts for 0.01% of human plasma protein. It is exclusively secreted by the adipose tissue into the bloodstream, but also locally affects surrounding tissue as well as blood vessels. In contrast to most other adipokines, plasma levels of adiponectin decreases with increasing fat volume. Accordingly, adiponectin is also negatively correlated with VAT and SAT volumes. It is suggested to have an anti-thrombotic effect by acting as an endogenous anti-thrombotic factor; additionally, an anti-inflammatory effect by inhibition of macrophage activation and foam cell accumulation has been described. Moreover, adiponectin has been reported to act as a stabilizer of the inhibitor of nuclear factor kappa B. On a cellular level, adiponectin induces endothelial intercellular adhesion molecule 1 (ICAM-1) and vascular cell-adhesion molecule 1 (VCAM-1) expression and augments endothelial nitrous oxide production. Moreover, hypoadiponektinemia is correlated with increased atherosclerosis-related compounds, such as adipocyte fatty-acid-binding protein (A-FABP), lipoclin-2, and other markers of oxidative stress. Cardiovascular disease, such as stroke and coronary heart disease, and also non-alcoholic fatty liver disease and insulin resistance, are associated with decreased levels of adiponectin, with data suggesting a predictive value of plasma adiponectin levels for cardiovascular disease.
- *Resistin*: Resistin is a 12 kDa protein that is predominantly produced by mononuclear cells, and also by a number of other tissues, including white adipose tissue. Accordingly, it is positively correlated with VAT and SAT volume. Resistin stimulates inflammatory cytokines, such as interleukin 1, 6, and 12 as well as tumor necrosis factor alpha through a nuclear-factor-kappa-B-dependent pathway. Additionally, it reduces the production of intercellular adhesion molecule 1 (ICAM-1), vascular cell-adhesion molecule 1 (VCAM-1), and CC chemokine ligand 2 (CCL-2) in the endothelial cell. In mice, a diabetologic role of resistin has been described; however, whether these results can be assigned to human diabetes remains controversial.

- Further, hormone-like proteins, such as apelin, visfatin, hepcidine, omentin, vaspin, adipsin, and angiopoietin, have suggested association to visceral and subcutaneous adipose tissue. However, more research is needed to define established mechanisms and pathways.
- *Chemokines and cytokines*: Adipocytes secrete numerous pro-inflammatory (interleukin 1, 6, and 8, tumor necrosis factor alpha, and others) as well as anti-inflammatory (including interleukin 4 and 10 and transforming growth factor beta) cytokines and chemokines. Therefore, together with the adipokines, they can influence local and systemic inflammation.

As indicated above, there is a direct relationship between obesity and inflammation. Due to its size, it being the largest visceral adipose tissue of the body and due to its location, thereby draining directly into portal circulation, VAT plays a key role in this association. Accordingly, the amount of VAT was found to be associated with systemic inflammatory markers, including C-reactive protein (CRP), monocyte chemoattractant protein (MCP), intracellular adhesion molecule (ICAM)-1, and plasminogen activator inhibitor type 1 (PAI-1) antigen, with associations to all but CRP reaching statistical significance, even after adjusting for global adiposity (Sam et al. 2009). However, in the same study, SAT was not found to be related to any systemic inflammatory markers after adjustment for body mass index. As inflammation is a key player in the development of atherosclerotic plaque, this may, in addition to the association of obesity with other cardiovascular risk factors, such as hypertension, diabetes, and dyslipidemia, as demonstrated above, explain the association of obesity and of visceral obesity, in particular, with cardiovascular disease.

Summary Points

- Visceral and subcutaneous adipose tissue of the abdomen differ with respect to cell size, fatty acid composition, protein content, fatty acid metabolism, enzyme expression, and glucose utilization. These differences lead to diverse implications on the metabolic and cardiovascular status.
- Both VAT and SAT are significantly associated with cardiovascular risk factors, such as hypertension, dyslipidemia, impaired fasting glucose, and the metabolic syndrome; however, when comparing VAT and SAT, the visceral fat volume has significantly stronger association compared to subcutaneous fat.
- Increased amounts of VAT are associated with presence of cardiovascular disease. It has been acknowledged that VAT is associated with presence of plaque in vascular territories in whole body, indicating a systemic proatherogenetic effect (of VAT).
- For VAT and SAT quantification using CT, the abdominal muscular wall is manually or automatically traced on axial images. Fat areas and volumes are calculated by summation of pixels, attributable to fat (upper attenuation limit of −50 to −30 HU and lower attenuation limit of −195 to −150 HU).
- Three-dimensional volume assessment of VAT and SAT is considered the gold standard. However, it is relatively time consuming and requires full abdominal CT imaging. Despite the VAT and SAT volume, the fat area at the level of the umbilicus is most commonly used in the literature.
- There is significant gender and ethnicity difference in abdominal fat distribution. Men have more VAT; women have slightly more SAT, especially at lower abdominal regions (L4/5 and below). African Americans have less VAT but more SAT than whites and Hispanics, whereas whites have the least total abdominal fat volume.
- Rapid infant weight gain, male gender, maternal age, and low physical activity are predictors of adult visceral adiposity. Absolute birth weight and maternal weight are associated with later increased amounts of SAT, however, not with VAT.

- Overall fat mass changes as well as the initial VAT to total fat mass ratio are primarily determinants of VAT reduction during weight-loss interventions in both men and women.
- VAT and SAT are correlated with general adiposity measures, such as BMI and waist circumference, and also with other ectopic fat storage, including pericardial, intrathoracic, intramuscular, and hepatic fat.
- Adipose tissue secretes several hormone-like peptides (adipokines), such as leptin, adiponectin, resistin, and others. These modulate not only energy balance, utilization, and metabolism, but also local and systemic inflammation. In addition, adipocytes themselves secrete multiple pro- and anti-inflammatory cytokines and chemokines.
- As inflammation is a key player in the development of atherosclerotic plaque, the relation of obesity with local and systemic inflammation may, in addition to the association of obesity with other cardiovascular risk factors, explain the association of obesity and of visceral obesity, in particular, with cardiovascular disease.

Chapter 51
Measures of Waist Circumference

Paul B. Higgins and Anthony G. Comuzzie

Abstract Waist circumference measurement is recommended in the clinical assessment of obesity and is a useful marker of total and abdominal body fat in genetic and epidemiologic research. Waist circumference measurement is non-invasive and is easily accomplished by trained observers in clinical and research settings. Consensus on the most appropriate measurement location has yet to be reached and several different sites and measurement protocols have been proposed. The importance of developing a systematic approach for identifying and marking the measurement site, positioning the tape, and recording the measurement cannot be understated. In this chapter, we present a description of the measurement of waist circumference. We include information on tape measures, measurement sites, and measurement guidelines. We present a detailed outline that will help clinicians and researchers to efficiently and reliably obtain accurate measurements of waist circumference.

Abbreviations

WAIST Waist circumference

51.1 Introduction

Waist circumference (WAIST) is a measure of abdominal girth. WAIST reflects both total body and central adiposity, predicts intra-abdominal adipose tissue mass better than the body mass index, and is associated with cardiometabolic disease risk (Klein et al. 2007). WAIST measurement is recommended in the clinical assessment of obesity and related metabolic disorders, and has proven to be a highly informative marker of adiposity in genetic and epidemiologic research.

WAIST measurement is non-invasive and is easily accomplished by trained observers in clinical and research settings. Self-measurement of WAIST is not recommended (Bigaard et al. 2005). Observers can routinely take measurements using an accurately calibrated and non-stretch tape measure. Patients must expose their midriff so that measurements can be made on the skin.

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_51,

The measuring tape is positioned parallel to the floor and perpendicular to the long axis of the body. Unfortunately, the medical and research communities have not yet reached consensus on the most appropriate measurement location. Several different sites and measurement protocols have been used to determine WAIST. Important anatomical landmarks used in the location of measurement site include the iliac crest and the lower costal margin. Consolidation of WAIST measurement guidelines into a universally accepted methodology would have many advantages; however, further research will be required before consensus is reached (Misra et al. 2005).

In this chapter, we describe the measurement of WAIST from a practical standpoint, by evaluating and synthesizing information from professional consensus statements, original research reports, and online resources. We include information on tape measures, measurement sites, and measurement guidelines. Our objective was to create a detailed guideline that will enable clinicians and researchers to efficiently and reliably obtain accurate measurements of WAIST.

51.2 Measuring Tapes

Body measuring tapes are made of plastic or steel. These tapes have been used to measure head, leg, arm, and WAIST and have a long history of use in anthropometry. An appropriate body measuring tape must be non-stretch, accurately calibrated, durable, portable, and ergonomic. Tapes made from flexible material are often required to take accurate measurements. It is also important that the tape maintains its dimensions through repeated use; this should be evaluated at predetermined intervals. Furthermore, the width of the tape is also an important consideration, given that it must be of sufficient size so that the calibration marks are clearly visible when the tape is placed, with appropriate tension, around the abdominal site. Tape tension indicators and fixed tension tapes have been developed, and should help to minimize observer error.

Steel tapes, such as the Lufkin W606PM, are stretch resistant, and should retain accuracy indefinitely. As steel tapes do not easily adjust to irregular surfaces, plastic fiber tape measures may be more appropriate for use in obese individuals, and are widely available. The Gulick II plus (Fig. 51.1) measuring tape was developed specifically to ascertain body circumferences, and features an indicator device containing a steel spring that purportedly enables the observer to apply a consistent tension during each measurement. Each indicator is calibrated to clearly indicate when 4 oz (100 g) of tension is applied. Similarly, the Figure Finder Tape Measure (Fig. 51.2) also enables a consistent 100 g of tension to be applied during the measurement. The Seca 201 (Fig. 51.3) was also developed specifically for body circumference measurements. The zero end of the tape can be positioned into a slot in the casing, enabling the observer to free one hand during tape placement. This feature also eliminates the need to have the subject hold the casing at any point during the measurement procedure. The tape is then allowed to retract around the abdomen and presumably exert an appropriate tension that is consistent across consecutive measurements. Devices that enable observers to apply a constant tension during measurement are not typically found in measuring tapes and, if accurate, should improve measurement accuracy and precision. Manufacturer details are presented in Table 51.1.

Unfortunately, objective evaluations of the accuracy, precision, and durability of these tapes are unavailable. The details presented above are meant to expose the reader to some of the options available. We encourage observers to test several tapes to determine the one most appropriate for their needs, "*The carpenter who uses a tool is a better judge of its efficiency than the smith who forges it*" (Pearson 1900).

51.3 Measurement Sites

Multiple measurement sites have been proposed. The most commonly used sites are the:

1. Narrowest waist
2. Midpoint between the lower costal region (lowest rib) and the upper border of the iliac crest
3. Upper border of the iliac crest (suprailiac crest)
4. Lower costal margin (lowest rib); and
5. Umbilicus

Sites 1, 2, and 3 have been recommended by Anthropometric Standardization Consensus Group (Lohman et al. 1988), the World Health Organization (www.who.int/chp/steps), and the United States National Institutes of Health (NIH 1998; www.nhlbi.nih.gov/guidelines/obesity), respectively. Studies linking WAIST to disease and disease risk have typically used sites 1, 2, and 4. Reproducibility is generally reported to be high at all of these sites (Wang et al. 2003; Mason and Katzmarzyk 2009). Studies have demonstrated, however, that WAIST can differ significantly depending on measurement site (Wang et al. 2003; Mason and Katzmarzyk 2009), and universal agreement has not been reached regarding the most appropriate site (Tables 51.2 and 51.3). Recently, consensus on the use of the site just above the upper border of the iliac crest has been reached by a number of professional societies in the USA (Klein et al. 2007). The bony landmarks used in the identification of these sites are illustrated in Fig. 51.4.

51.3.1 Narrowest Waist

This measurement must be taken at the narrowest region between the lowest rib and the iliac crest (Fig. 51.5). Although reported to be easy to identify in the majority of subjects (Wang et al. 2003), a single narrowest waist may be difficult to determine in individuals with abdominal obesity. Furthermore, as no anatomical landmarks are used to identify this site, WAIST measures taken at this location may be prone to greater inter- and intra-observer errors than at other sites. Multiple measurements of abdominal circumference may be required to determine this location. These concerns notwithstanding, reproducibility has been reported to be high at the narrowest waist site (Wang et al. 2003; Mason and Katzmarzyk 2009).

51.3.2 Midpoint Between Iliac Crest and Lowest Rib

To accurately identify this site, the lowermost costal region and the upper border of the iliac crest must be located (see later for details on identifying these landmarks). The distance between the two landmarks is measured, and a third horizontal line is drawn at the midpoint where the measurement is taken. Identification of this site is time-consuming, but its use is recommended by the World Health Organization. The location of this site is shown in Fig. 51.6.

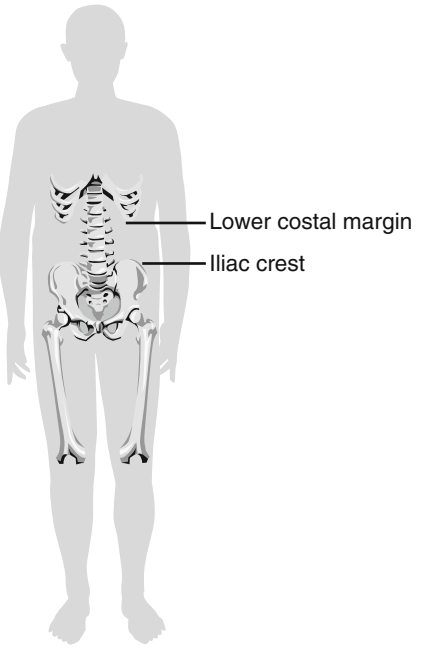

Fig. 51.4 Bony landmarks used to identify waist circumference (WAIST) measurement sites. The lower costal margin, also known as the lowest rib, is located by palpating the anterior region of the right lateral costal margin. The iliac crest is identified by palpating the right hip region to locate the ileum

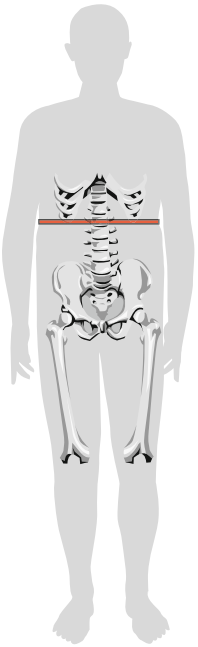

Fig. 51.5 Measuring tape positioned at the narrowest waist location. Measurements at this location are taken on the right side of the body at the narrowest identifiable region between the lowest rib and the iliac crest

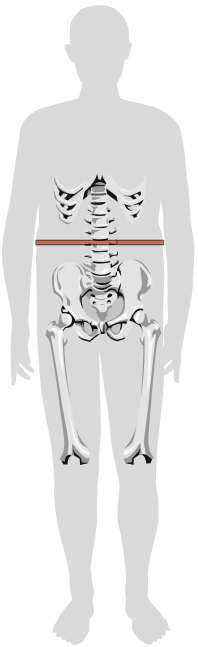

Fig. 51.6 Measuring tape positioned at midpoint between the iliac crest and the lowest rib. Measurements at this location are taken on the right side of the body halfway between the lowest rib (lower costal region) and the uppermost border of the right ileum

51.3.3 Upper Border of the Iliac Crest

This site is readily identified by palpating the right hip bone to locate the ileum. The measurement is taken immediately superior to the uppermost border of the right ileum (Fig. 51.7). Abrupt abdominal curvature often occurs at this location and, consequently, problems with positioning the measuring tape have been reported (Wang et al. 2003). Nevertheless, WAIST measurements taken at this site are

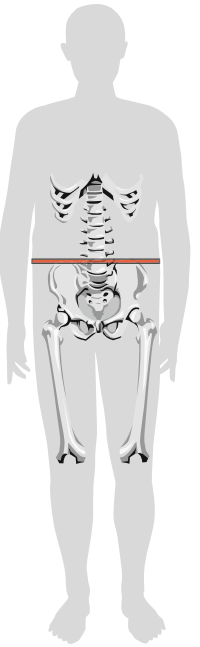

Fig. 51.7 Measuring tape positioned at the upper border of the iliac crest site, Measurements at the upper border of the iliac crest are taken immediately above the uppermost border of the right ileum

reproducible and are strongly related to intra-abdominal adipose tissue and total body adiposity (Wang et al. 2003). This site was used in the National Health and Nutrition Examination Survey (NHANES III), and is recommended by the National Institutes of Health and several other professional medical societies in the United States (Klein et al. 2007).

51.3.4 Lowest Rib

This site is relatively easy to identify and can be located by palpating the anterior region of the right lateral costal margin (Fig. 51.8). If difficulty in locating the lowest rib is encountered, request the subject to inhale deeply, and then palpitate to locate the lowest rib as the subject exhales (www.phenxtoolkit.org). The measurement should be taken immediately beneath the lowest rib (inferior margin of lowest rib). This use of this site is not typically advanced and is likely to correspond to the narrowest waist site in many subjects (Wang et al. 2003).

51.3.5 Umbilicus

Measurement of WAIST at the umbilicus is common, likely due, in part, to the ease at which this site can be identified. Reports also indicate that this site is associated with cardiometabolic morbidity and mortality (Ross et al. 2008). Measurement at this site has not been recommended by any national or international bodies, but is likely to coincide with measurements taken at the upper border of the iliac crest in most subjects.

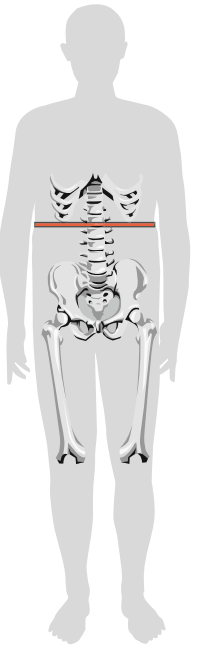

Fig. 51.8 Measuring tape positioned at the lower costal margin. Measurements at this location are taken on the right side of the body immediately below the lowest rib

51.4 Measurement Guidelines

The procedural guidelines detailed here have been adapted from guidelines proposed by the United States National Institutes of Health (National Institutes of Health 1998; www.nhlbi.nih.gov/guidelines/obesity), the Canadian Guidelines for Body Classification in Adults (Douketis et al. 2005), and the World Health Organization (www.who.int/chp/steps; WHO 2000). Furthermore, information from these guidelines has been augmented with details from a recent research report and several online resources (Agarwal et al. 2009; www.phenxtooliit.org; www.cardiometabolic-risk.org; www.hc-sc.gc.ca; and www.cdc.gov/nchs/about/major/nhanes).

51.4.1 Subject Preparation

Measurements should be taken on fasted subjects (Agarwal et al. 2009), preferably after an overnight fast. The observer should fully explain the procedure and request that the subject remove shoes and upper body clothing. Ideally, the subject would wear a hospital gown and minimal underwear during the procedure. All clothing must be removed from the abdominal area.

51.4.2 Subject Posture

WAIST is typically measured in the standing position, barefoot, either with feet touching or separated by shoulder width (25–30 cm). One established protocol recommends that measurements be taken with heels, occiput, and buttocks in contact with a wall (Lohman et al. 1988). Ultimately, feet should be

placed in a position that enables the subject to remain comfortable while standing, with eyes looking straight ahead for the duration of the procedure. The arms can hang freely at the sides or should be crossed over the chest, while the tape is being positioned and the measurement is being taken.

51.4.3 Marking the Measurement Site

The measurement must be made on the skin. A horizontal line of sufficient length should be drawn at the designated measurement site on the right side of the body to intersect the vertical midaxillary line. The midaxillary line runs parallel to the long axis of the body, from the axilla to the hip region. A second line should be drawn at the corresponding site on the left side of the body. If the midpoint of the lower costal region and the upper border of the iliac crest is used, the observer must draw three lines. Observers must ensure that lines are parallel to the floor. A short vertical line should then be drawn at the midaxillary line to intersect the horizontal line at the identified measurement site on the right side. The measuring tape is read on the right side at the intersection of these lines. A cosmetic pencil or washable marker can be used for drawing the lines.

51.4.4 Performing the Measurement

The tape casing should be held in the right hand. Using the left hand, and with the help of the subject, the zero end of the tape should be extended around the thighs and raised to the abdominal level. The zero end is then placed in the right hand so that both ends of the tape are held in the right hand. The left hand is then free to adjust the tape around the abdomen. After the tape is correctly positioned, the left hand can take control of the zero end. The zero end should be placed below the casing end, and aligned with the gradations on the casing end of the tape. Thus, the upper border of the zero end and the lower border of the casing end are juxtaposed at the horizontal line denoting the measurement site. The zero end of the tape is vertically aligned with the marking corresponding to the midaxillary line. Before the measurement is taken, a final check is made to ensure that the tape is appropriately positioned along the right and left markings, and is aligned parallel to the floor. The measurement is taken to the nearest millimeter at the midaxillary line; gradations are read at the lower border of the casing end of the tape.

The tape must be fitted tightly against the skin, but not so tight that the skin and underlying tissue are depressed. These concerns are eliminated by using a tension indicator and fixed tension tapes. Accurate tape placement is better achieved when measurements are taken in front of a wall mirror or when a second observer is present to ensure the tape is correctly positioned on the left side of the abdomen.

51.4.5 Recording the Measurement

The measurement must be taken at eye level to avoid parallax error.

If time permits, two measurements should be taken and averaged. If these differ by more than 0.5 centimeters, a third measurement should be taken. Established protocols offer equivocal guidelines on the respiratory phase at which the measurement should be taken. Given that respiratory phase may influence the measurement (Agarwal et al. 2009), measurements should be taken at a defined

point in the respiratory cycle. The World Health Organization recommends that measurements be recorded at the end of a normal expiration (www.who.int/chp/steps). In general, the subject must be instructed to relax and breathe at tidal volume (Agarwal et al. 2009).

51.5 Conclusions

In the absence of a consensus approach to measurement at this time, we recommend that each clinic or laboratory select an approach proposed by a major professional body. Observers should practice before taking measurements, and determine potential difficulties and obstacles. In particular, it is important to develop a systematic approach to identifying and marking the measurement site, positioning the tape, and recording the measurement.

Summary Points

- WAIST measurements are readily accomplished in clinical and research settings.
- Measurements are taken on the skin using a non-stretch retractable measuring tape; tapes with tension indicators may improve accuracy and precision.
- Subjects should be fasted, barefoot, and in a standing posture with eyes directed straight ahead.
- Universal agreement on the most appropriate measurement site is lacking.
- Commonly used sites include the midpoint between the upper border of the iliac crest and the lower costal margin, just above the upper border of the iliac crest, and the narrowest waist.
- Measurement sites must be clearly marked on the right and left sides of the abdomen and measurements are taken on the right side of the abdomen.
- Two measurements are taken and recorded, if they differ by more than 0.5 cm, a third measurement is made.

Chapter 52
Trunk:Periphery Fat Ratio

Rachel Novotny

Abstract Overweight and obesity are major health concerns of our time. Body fat has been found to be more predictive of health and disease than overall body mass, central or upper body fat has been more predictive than total body fat, and the distribution of body fat has been found to be more predictive than central or upper body fat. The trunk periphery fat ratio (TPFR) is a measure of the distribution of body fat throughout the body. TPFR is acquired with measures of fat of the body trunk and of the body periphery. TPFR may be measured by subcutaneous skinfold thickness obtained with calipers or by regions of interest from dual energy x-ray absorptiometry (DXA) scans of the whole body. TPFR has been found to vary by sex, ethnicity and rate of maturation where males, Asians, and earlier maturing children have higher TPFR than girls, Whites, African Americans and later maturing children. Birth weight and skeletal breadths (bi-iliac breadth in particular) have been shown to predict TPFR. Earlier versus later maturing boys and girls were also found to have higher TPFR. TPFR may have predictive value for understanding individual and population risk for disease throughout the life span. TPFR variability by sex, ethnicity, birth weight, bi-iliac breadth and maturation rate suggests a possible hormonal or genetic component to the trait. Further research to quantify these risks and protections at different life stages will be valuable to provide targets for research and clinical treatment.

52.1 Introduction

Overweight and obesity are major health concerns of our time, important in the onset of the major chronic diseases. They are often defined using the body mass index (BMI: weight (kg)/height (m^2), Flegal et al. 2009), a measure that reflects lean tissue, in addition to fat tissue. Body fat has been found to be more important than overall body mass, in relation to health; central or upper body fat has been found to be more predictive than body mass, and the distribution of body fat has been found to be more predictive than central or upper body fat (Flegal et al. 2009). Body fat distribution is more relevant to risk for chronic disease, independently of BMI or overall obesity (Calle and Kaaks 2004). BMI is known to be a less valid indicator in older adults, who experience a shift of body fat from the peripheral to the central regions of the body, and in women, who carry more total body fat in peripheral regions than do men. These facts may explain some of the inconsistencies in epidemiologic findings that relate BMI to chronic diseases.

Several measures of central adiposity have been used: especially, waist circumference, computed tomography and magnetic resonance imaging of the central portion of the body, and skinfold thickness of the subscapular, abdominal, and suprailiac fatfolds (Table 52.1). For example, in a study of 421 adult multiethnic women in Hawaii, higher subscapular skinfold thickness was associated with higher diastolic blood pressure (Novotny et al. 1998). These techniques are used to measure central adiposity, which provides important additional information as regards BMI, about risk for health and disease.

Measures of fat distribution are "android" or "gynoid" measurements where, in the former, fat is located around the abdomen, and, in the latter, it is located around the hips. This was first described by Vague (1956, Table 52.2). Vague measured two sets of skinfolds: the nape (of the neck: subscapular) to sacrum ratio, and the brachio (upper arm: triceps) to femoral (thigh) ratio. Together, these gave an index of "masculine" differentiation. Vague noted that the android pattern was associated with increased incidence of premature atherosclerosis, diabetes, gout, and uric calculous disease, whereas gynoid obesity was associated with problems of body mechanics only. More recently, DXA software has defined android and gynoid body regions, of interest (Novotny et al. 2007). Waist (circumference) to height ratio better identified cardiovascular risk than did age-specific BMI percentiles in several

Table 52.1 Techniques to measure central adiposity

Technique

Computerized tomography
Magnetic resonance imaging

These techniques are used to measure central adiposity, which provides important additional information, about risk for health and disease, as regards body mass index (BMI)

Table 52.2 Techniques to measure of body fat distribution

Measure	Source
Android fat mass/gynoid fat mass	Vague (1956)
DXA: android fat mass/gynoid fat mass	Novotny et al. (2007)
Waist circumference/hip circumference	Lin WY et al. (2002) and Hseih et al. (2003)
Waist circumference/height	Flegal et al. (2009)
Trunk fat mass/peripheral fat mass fat	Novotny et al. (2006), He et al. (2004), Rolland-Cachera et al. (1990), and Frisancho and Flegel (1982)

Measurement of fat distribution and proportion throughout the body provides more information about risk for health and disease than central adiposity measurement alone

populations, including Asians (Lin et al. 2002; Hsieh et al. 2003), and among youth (Kahn et al. 2005). High trunk to extremity fat ratio among youth may increase risk of centralized obesity in adulthood (Rolland-Cachera et al. 1990), serving as an early risk factor that is amenable to modification. Measures of fat distribution and proportion throughout the body provide more information about risk for health and disease than central adiposity measurement alone.

52.2 Practical Methods and Techniques: The Trunk:Peripheral Fat Ratio

A trunk:peripheral fat ratio (TPFR) is acquired with measures of body fat of the trunk and of the body periphery utilizing skinfold thicknesses measured with calipers (subscapular, iliac and/or abdominal for the trunk; and arm, thigh, and/or calf for the periphery), or with output that describes regions of interest from dual energy X-ray absorptiometry (DXA). With either skinfold-thickness measurement or DXA, appropriate calibration, quality control, and standardization of measurements and measurers should be confirmed.

The TPFR is derived from trunk and peripheral (arms plus legs) regions of the DXA output (Fig. 52.1). To calculate the TPFR, DXA measures of body fat from arm and leg regions are first summed from the standard output to estimate peripheral fat. The TPFR is calculated by dividing the DXA trunk regional fat (g) by the peripheral regional fat (g). Thus, TPFR estimates the relative placement of fat in the central portion of the body as compared to the peripheral portion (the limbs). TPFR serves as a tool to examine distribution of body fat throughout the body.

A slightly different formula was used by He et al. (2004), where the pelvic fat mass (i.e., the triangle on the figure) was included in the periphery portion of the ratio. Mueller and Reid (1979) have shown high covariance between the subscapular and the suprailiac skinfolds, and between the triceps and the medial calf skinfolds, suggesting that one of the pair of these measures can be used to estimate trunk and periphery, respectively. Interestingly, they also found that trunk to extremity and upper to lower body fat patterning were essentially the same.

52.3 Population Variability in TPFR

TPFR has been found to vary with sex, ethnicity, and rate of maturation, where males, Asians, and earlier maturing children have higher TPFR than girls, Whites, African-Americans and later maturing children (Tables 52.3 and 52.4). Fat distribution in boys becomes androidal in their late puberty (He et al. 2004). Although increasing evidence points to differences in body fat distribution among ethnic groups (e.g., higher central obesity among Latinos and lower among African Americans, compared to Whites; Wu et al. 2007), evidence is limited for Asian Americans in general (whose obesity-related disease risk appears higher than other ethnic groups), and for Pacific Islanders, whose overall rates of obesity are among the world's highest.

In the Female Adolescent Maturation (FAM) Study, conducted among Asian and White adolescent girls identified through Kaiser Permanente on Oahu in Hawaii, Asians were observed to have smaller total DXA fat mass and anthropometric values compared to Whites or Asian/White mixed girls, but Asians had larger values for the TPFR than both Whites and Asian/White mixed girls (Novotny et al. 2006, Table 52.3). Body fat and weight of the 9–14-year-old FAM girls ($n = 323$) were studied in relation to age, ethnicity, and physical activity. Mean age, calcium intake, weight, and iliac skinfold thickness were 11.5 ± 1.4 years, 736.5 ± 370.7 mg/day, 44.6 ± 13.0 kg, and 12.4 ± 6.1 mm, respectively

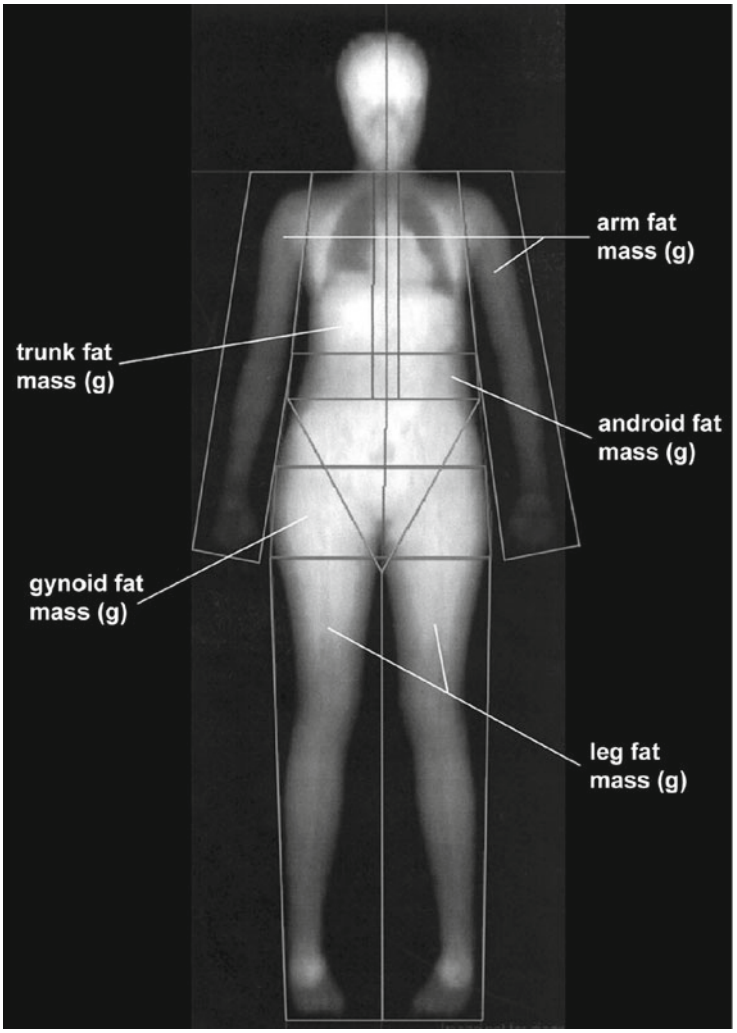

Fig. 52.1 Trunk:periphery fat ratio (TPFR) is derived from trunk (which includes the pentagon-shaped region that includes the upper trunk, android region, and the pelvic triangle) and peripheral (*arm plus leg*) regions of interest, as derived from dual energy X-ray absorptiometry (DXA) by GE Lunar Prodigy. To calculate TPFR, DXA measures of body fat from arm and leg regions are first summed to estimate peripheral fat. Trunk:peripheral fat ratioTPFR is calculated by dividing the DXA trunk regional fat (g) by the peripheral regional fat (g). Thus, TPFR estimates the relative placement of fat in the central portion of the body as compared to the peripheral portion (*the limbs*). TPFR serves as a tool to examine distribution of body fat throughout the body

(Novotny et al. 2004). Multiple regression with age, ethnicity, height, Tanner breast stage, physical activity, energy, soda, and calcium intake explained 17% of the variation in iliac skinfold thickness. Calcium intake, age, and physical activity were significantly negatively associated with iliac skinfold thickness, whereas height, Tanner breast stage, and Pacific-Islander ethnicity were significantly positively associated ($p < 0.0001$, $R(2) = 0.165$). Substituting total calcium with dairy and non-dairy calcium in separate models accounted for 16% and 15% of the variance, respectively ($p < 0.0001$, both models); 1 mg of total and dairy calcium was significantly associated with 0.0025 mm ($p = 0.01$) and 0.0026 mm ($p = 0.02$) lower iliac skinfold thickness. Thus, one additional milk serving was associated with 0.78 mm lower iliac skinfold thickness. The interaction of Asian ethnicity and dairy intake was significant ($p = 0.027$). Non-dairy calcium was not associated with weight or iliac skinfold thickness. Soda intake was significantly positively associated with weight in both models ($p = 0.01$, both models). Thus, decreasing soda and increasing dairy consumption among Asians may help maintain lower central body fat and lower weight during adolescence. Asian ethnicity was an important predictor of TPFR in the FAM study (Novotny et al. 2006). Interestingly, bi-iliac breadth (but not bi-acromial breadth or height) was significantly positively associated, and birth weight was negatively associated, with TPFR.

Table 52.3 Studies examining population differences in Trunk to Periphery Fat Ratio (TPFR)

Author, year	Population	Outcome	Exposures	TPFR
Novotny et al. (2006)	323, 9–14-year-old Asian, White, and mixed Asian/White girls	DXA: Trunk to arm plus leg fat	Ethnicity (Covariates: birth weight and bi-iliac breadth)	Asian = 1, White = 0.84, Asian/White mixed = 0.98
He et al. (2004)	920, 5–18-year-old Asian, African-American, and White children	DXA: Trunk plus pelvic to arm plus leg fat	Sex, ethnicity, and Tanner stage of puberty	Late puberty: African-American boys = 0.48 African-American girls = 0.46 Asian boys = 0.63 Asian girls = 0.52 White boys = 0.49 White girls = 0.46
Rolland-Cachera et al. (1990)	168, 1 month to 21 year old French children	Skinfold: Trunk to extremity ratio in adulthood	Sex	Boys = 1, Girls = 0.76
Frisancho, Flegel (1982) (derived from)	5,012, 1–17 year old White US children	Skinfold: Subscapular to triceps ratio	Early vs. Late maturing (Tanner stage)	Early > late maturing at age 15–16.9; Early boys = 1.0, Late boys = 0.85; Early girls = 0.69, Late girls = 0.50

TPFR has been found to be higher among males, Asians, and earlier maturing children than among girls, Whites, African Americans, and later maturing children

French girls had trunk to periphery fat skinfold ratios similar to White girls in Hawaii (0.76 and 0.84, respectively, Rolland-Cachera et al. 1990), whereas trunk to periphery fat ratio for both French boys and Asian girls in Hawaii had a value of 1. In the French study, early life TPFR was correlated with adult TPFR for girls, but not for boys. In the White children studied by Frisancho and Flegal (1982), early maturers had higher TPFR, with subscapular to triceps ratio (from age 9 years for boys and from age 3 years for girls), than did late maturers, and boys' values were higher than those of girls.

Using a ratio of a skinfold to the total body skinfolds among White children from Michigan, Hattori et al. (1987) showed that obese girls carry more body fat in the trunk, especially the upper trunk, than non-obese girls; though girls generally deposited more fat in the periphery than did boys, who tended to deposit it in the trunk. There were no ethnic differences in waist, hip circumferences, waist-to-hip ratio and subcutaneous fat distribution. Shorter stature in Asian ethnicity compared to White ethnicity was due to shorter legs ($p < 0.001$), as trunk length was not associated with Asian ethnicity ($p = 0.77$).

In a study of Asian, White, and African–American adolescents, Asians had lower gynoid fat than Whites and African Americans (He et al. 2004), among both boys and girls – especially among girls, using either skinfold and DXA measurements.

In a study in the UK, women who were born with lower birth weight were found to have a proportionately lower DXA lean-to-fat mass ratio than women born at a higher birth weight (Skidmore et al. 2009); higher birth weight was associated with a healthier body composition in adulthood. However, they were not able to control for gestational age; shorter length of gestation could explain the finding.

52.4 The Importance of TPFR

The association of larger bi-iliac breadth with higher TPFR in adolescent girls may mark early maturation, which results in broader pelvis at an earlier age, and a skeleton with relatively shorter legs and longer trunk, yielding more physical space for body fat to be placed in the trunkal versus the peripheral region of the body. Thus, early growth pattern is likely important to later distribution of body fat. The fact that central body fat becomes evident during adolescence, as seen with early versus late maturers (Frisancho and Flegal 1982), could indicate that there is mediation of these characteristics by steroid hormones. Environmental influences of late adolescence may bring about expression of genetic factors.

Fat cells in the abdominal region have been thought to be more sensitive to nutritional and/or hormonal factors than fat cells in other regions (Ktotkiewski et al. 1975). In the presence of sex steroid hormones, a gynoid distribution of body fat exists in females. With a decrease in sex steroid hormones, as occurs with aging, there is a tendency to increase central obesity (Garaulet et al. 2004), as is seen in post-menopausal women. Further, women given exogenous androgens or suffering from virilizing tumors or disorders, such as congenital adrenal hyperplasia, develop a more central adipose tissue distribution. This suggests that circulating testosterone favors an increase in trunk adipose tissue (Rosenbaum and Leibel 1997). TPFR was found to be higher in women with higher free testosterone and polycystic ovary disease, controlling for BMI. In the study by Hattori et al. (1987), increased body fat led to a more central or androidal fat patterning. Thus, the higher TPFR seen in Asian girls, as compared to Whites, suggests that Asian girls may have a higher ratio of testosterone-to-estrogen than of White girls of the same stage of pubertal development.

52.5 Applications to Other Areas of Health and Disease

The TPFR is used here to understand obesity and risk for chronic disease. TPFR variability by sex, ethnicity, birth weight, bi-iliac breadth, and maturation rate suggests a possible hormonal or genetic component to the trait. Risk ratios relating TPFR to disease risk may be helpful to clarify prevention and treatment priorities. As DXA is routinely conducted for osteoporosis screening, examination of DXA scans for TPFR may provide information about risk for chronic diseases, such as cardiovascular disease and Type 2 diabetes.

Summary Points

- TPFR measures body fat distribution in a ratio of trunkal body fat to peripheral body fat.
- TPFR may be measured by subcutaneous skinfold thickness obtained with calipers or by regions of interest from dual energy X-ray absorptiometry (DXA) scans of the whole body.
- TPFR is better than central obesity, which is better than BMI, in predicting risk for chronic disease.
- TPFR variability by sex, ethnicity, birth weight, bi-iliac breadth, and maturation rate suggests a possible hormonal or genetic component to the trait.
- TPFR may have predictive value for understanding individual and population risk for disease throughout the life span.
- Further research to quantify these risks and protections at different life stages will be valuable to provide targets for research and clinical treatment.

Key Features

Table 52.4 Key population differences in trunk periphery fat ratio (TPFR)

Greater in males than females
Highest among Asian ethnic groups
Higher among those with lower birth weight
Higher among those with greater bi-iliac breadth
Higher among those who mature earlier vs later
TPFR variability by sex, ethnicity, birth weight, bi-iliac breadth, and maturation rate suggests a possible hormonal or genetic component to the trait

Chapter 53
Anthropometry of Normal Human Auricle

Ruma Purkait

Abstract The auricle is a defining feature of the face. Its shape, size and position on the face play a key role in facial harmony. Correction of any auricular deformity or facial rejuvenation procedure involves surgical intervention for which a plastic surgeon will require normative data for auricular dimensions. The data is generated by taking various anthropometric measurements and certain visual observations of a normal auricle. For example, to understand the shape and size of a normal adult Indian auricle, six linear dimensions covering various anatomical parts of the auricle are measured. Observations on its anatomy including shape, preauricular area, form of helical fold, lobular shape, size and type of attachment to the cheek are also noted. To explore variation in dimensions of ear structure in an adult population, males ranging in age from 18 to 70 years have been included.

Generally, all auricular features increase in size steadily with age. The lobule contributes the maximum to the overall elongation of the auricle. Its dimensions are dependent on its shape and attachment to the cheek. The lobular and auricular indices decrease with increasing age indicating more elongation than widening of the structures. The data on the auricle is not only useful to physicians as a guideline while performing surgery, but data on ear protrusion above the skull is useful to industries designing hearing aid instruments for the ear. The information that the lobule undergoes rapid elongation after 60 years of age can help law enforcement agencies to update their data on the external ear while using it as a biometric tool.

53.1 Introduction

The auricle plays an important role in the clinical diagnosis of congenital anomalies and syndromes. For a physician a deformation in auricular shape and size or its spatial dislocation on the face can mean a possible anomaly. Patients of Trisomy 13 and 18 syndromes, for example, are reported to have low-set and deformed auricles, while Down's syndrome patients have smaller auricles than healthy person (Vogel and Motulsky 1982). Several studies have reported the relation of the auricle with various syndromes and anomalies (Farkas and Lindsay 1973; Farkas 1978a, b; Della et al. 2001; Beahm and Walton 2002; Chou et al. 2002; Mowlavi et al. 2004).

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_53,

Auricular appearance and symmetry contributes enormously to facial aesthetics. Any auricular defect such as disproportionate size, abnormal elongation of auricular lobe or a missing part can be corrected by surgery. Cosmetic surgery and facial rejuvenation have become quite popular, not only in the west but in other parts of the world as well. For rectifying such abnormalities a plastic surgeon would require information about normal auricular dimensions, its bilateral position on the face as well as general conformation. Such data are collected through studies applying anthropometrical techniques and making certain visual observations of the auricle. So far such studies have been conducted in different parts of the world.

53.2 Short Overview of Available Studies

53.2.1 Simple Anthropometry

The morphology of the external ear has been studied in complete detail in different populations across the world. Schwalbe (1897) was one of the first to invent a method to measure the external ear. He was also the first to attract scientific attention to racial peculiarities in the structure of the ear. He measured ear length and width in cadavers and concluded that auricular expansion occurred after the age of 50 and continued until the age of 70–80 years. Quelprud (1935), adopting the cross-section method, worked along similar lines on subjects ranging from 16–50 years of age, and reported changes in auricular width with age. He also provided a graph on the elongation of the earlobe which helps in judgeing its incremental growth.

Among 1,000 German subjects aged between 1 and 89, Pellnitz (1958) investigated sexual variation in total and cartilaginous ear length. He classified them by sex into various age groups at 10-year intervals. His study was one of the few that demonstrated a significant difference between the rate of expansion of the cartilaginous part and earlobe. A similar study was carried out by Hajnis (1969) on 626 adult Czech subjects aged between 18 and 80. He measured auricular length and width and noticed an increment in both with increasing age. Sexual variation was also obvious in both ear dimensions.

In a study on 100 American adults and 50 children, Rubin et al. (1962) measured ear height, width, scaphoconchal angle, distance of mastoid to helix edge, conchal depth and lobular height. They found that after age 60, the overall ear increased in size and width. They concluded that growth is present in the cartilage as well as in the lobule. A linear regression analysis of auricular length with age was performed by Heathcote (1995), among 206 subjects aged between 30 and 93. His results showed an annual increase of approximately 0.22 mm in auricle length within the studied age interval. Asai et al. (1996) also performed a similar study on 400 Japanese subjects aged between 21 and 94. He reported an annual increase of 0.13 mm in ear length. In another study on 996 males and 992 females, Ito and Imada (2001) compared ear length and width among various age groups using multiple comparison tests. Their results implied a steady increase in auricle length up to the latter half of the 70s in males, while the increment was significant in females even after this age. They explained that auricular expansion could be due to the reduced flexibility of the cartilage.

Brucker et al. (2003) concluded from their study on the ear lobule of Americans that it is the only ear structure that changes significantly with age but does not vary sexually, though ear height was larger in males. They concluded that lengthening of ear lobule with age is due to effect of weight of ear ring as well as the ageing process. This observation was supported by Azaria et al. (2003) in a study on Jews aged between 20 and 80 years. Sexual dimorphism was observed, with a significantly longer ear lobule in males than in females.

An anthropometric study on the adult Turkish external ear was carried out by Bozkir et al. (2006). Their study sample included 341 young adults between 18 and 25. They measured seven ear dimensions viz. ear height, ear width, lobular height and lobular width, distances from tragus to anti helix and to helix and ear projection at tragal level using electronic digital calipers. Sexual dimorphism was observed in ear height and width.

53.2.2 Auricular Growth Study

An anthropometric growth study on normal German children of both sexes (596 boys and 675 girls) aged between 3 and 18 years was carried out by Pelz and Stein (1995). They measured ear length and concluded that the ear grows very slowly from 4th to 18th year of age in both sexes. They described a new anthropometric index the "auriculocephalic index" which according to them is independent of sex and age and helps in syndrome delineation.

One of the most comprehensive growth studies till date has been conducted by Farkas (1978b) among normal and anomalous ears of 1197 North American Caucasian males and females between 6 and 19 years of age. Various measurements, viz. ear length, ear width, length of ear attachment, ear inclination, and ear protrusion, were taken on the left ear. Farkas found that ears grow much slower in width than in length and ear length attained maturation at approximately 15 years in males and at 13 years in females, while ear width developed completely in females at approximately 10 years of age and at 13 years in males.

A similar growth study of the auricle of normal Turkish children (1552) from birth to 18 years was conducted by Kalcioglu et al. (2003). Six ear measurements were taken on the right ear. The frequency of prominent ear deformity and degree of attachment of lobule were computed which provided cut-off points, in years, of development for various ear dimensions among both sexes. The study revealed important implications for the adequate timing of surgical treatment of auricular deformities.

53.2.3 Studies Adopting Indirect Method of Measurement

Apart from directly measuring the auricle, few a studies have adopted various indirect methods. Ferrario et al. (1999) used an electromagnetic digitizer for measuring ear length. They found a significant difference in auricle length between the sexes in their study on 310 Italian subjects classified by sex into three age groups. Their result showed a significant increase in auricle length between each age group.

In a recent study by Meijerman et al. (2006), auricular length, width and earlobe length were measured indirectly on images of both ears of 919 male and 434 female Dutch subjects aged between 18 and 90 years. Helix width was also measured at two positions: the intersection of a line perpendicular to the centre of base and the most posterior point of helix. All these dimensions were found to exhibit sexual dimorphism. They were smaller in females. Age and stature showed a positive correlation with auricle size.

Apart from the above mentioned cross-sectional studies, few longitudinal (follow-up) studies were also conducted in Europe. Sussanne (1977) observed an increment in the auricular length by 4.86 mm over a period of 22 years among 44 male Belgian subjects (average age 32 years at the beginning). Gualdi-Russo (1998) carried out a follow-up study with a gap of 10 years in Italy among 104 males and 58 females. He classified his subjects into four cohorts viz. 31–40 years, 41–50 years, 51–60 years and above 60 years (age at second measurement) and found a significant increase in ear length while ear width remained more or less stable.

Though various populations across the world have been covered in the above surveys, studies from countries inhabited by diverse ethnic groups like India are still scarce. Lakshminarayana et al. (1991) examined ear length and position for syndromology among 850 south Indian children from birth to 11 years of age. They observed that 2% of normal children and 3% children suffering from Down's syndrome had low set ears. In 2007 Purkait and Singh performed a detailed study on the auricle of normal males from central India.

This section will focus on defining and analyzing the anthropometric dimensions of different parts of auricle. The data used for discussion is derived from the above mentioned study conducted on 415 normal males by Purkait and Singh in 2007.

53.3 Methodological Description

Anatomical features of the external ear are shown in Fig. 53.1 (Table 53.1).

A total of nine anthropometric measurements were taken directly on the auricle. The methodology of taking measurements (Table 53.2) and instrument used (Fig. 53.2) are prescribed. The measurements shown in Figs. 53.3–53.5. are as follows:

1. *Length of Auricle* (1–2): It is the straight distance between superaurale (highest point on auricle) and subaurale (deepest point on the free margin of ear lobule) (Fig. 53.3).
2. *Width of Auricle* (3–4): It is the straight distance between preaurale (most anterior point of ear located just in front of the helix attachment to head) and postaurale (most posterior point on the free margin of ear).

Fig. 53.1 Anatomy of auricle. Various anatomical features of auricle are depicted in the figure

Table 53.1 Key features of human auricle

1. *Auricle* or the external ear, generally ovoid in form is present on the lateral aspect of face. It possesses a cartilaginous framework which gives it its characteristic shape.
2. The outer rim of auricle is *helix* which surrounds a curved prominence, the *antihelix*.
3. A deep capacious cavity located approximately in the centre is the *Concha*. It leads to auditory meatus on its medial aspect.
4. In front of the concha, projecting backward over the meatus, is a small pointed eminence, the *tragus*. Opposite the tragus, separated from it by the *intertragic notch*, is a small tubercle, the *antitragus*.
5. At its inferior aspect is the lobule, the only part of ear that does not contain cartilage. Instead, it is a wedge of adipose tissue (fat) covered by skin. It is the part of ear that is most prone to elongation.

In histology, *adipose tissue* or *fat* is loose connective tissue composed of adipocytes. Its main role is to store energy in the form of fat, although it also cushions and thermal insulation the body. The table lists a short description of anatomical features of auricle

Table 53.2 Guidelines for taking standard measurements on auricle

1. Subject should sit upright with his head in Frankfurt horizontal plane i.e. orbitale and tragion to be in the same plane. Orbitale is the lowest point on the lower margin of orbit and tragion is the point on upper margin of tragus where tangents drawn to anterior and superior margins of the cartilage cut each other.
2. Landmarks on auricle and face to be identified once the head is in Frankfurt horizontal plane.
3. Location of landmark to be marked with skin marking pencil.
4. Standard anthropometric instrument with optimal precision to be used for taking measurements.

The table lists the standard method of taking measurement

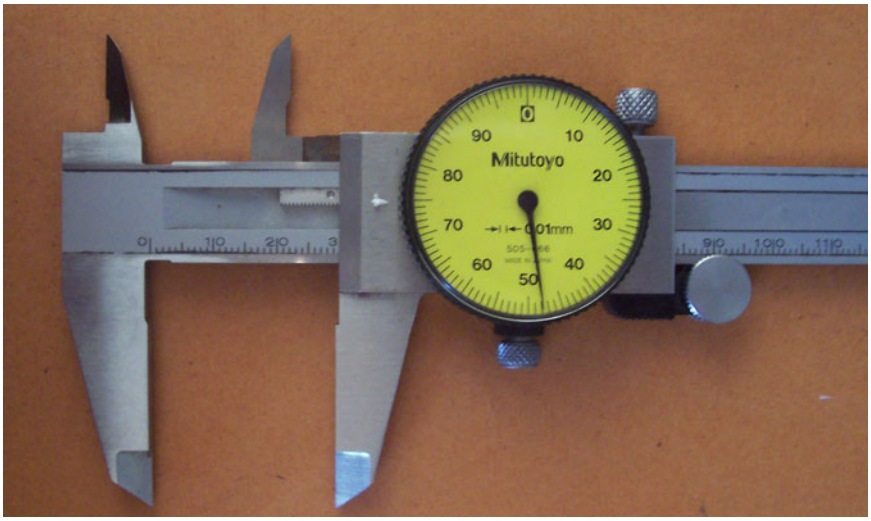

Fig. 53.2 Dial calliper. Calliper used to take linear measurements with an accuracy of 0.01 mm

3. *Lobular length* (6–2): It is the distance between incisura intertragica inferior (deepest point of incisura intertragica) and subaurale.
4. *Lobular width* (9–10): It is the distance between lobule anterior and lobule posterior.

Attachment of ear to cheek is demarcated by drawing a line joining the tip and base of ear attachment. Lobule anterior is the point on this line at midpoint level of lobular length. Lobule

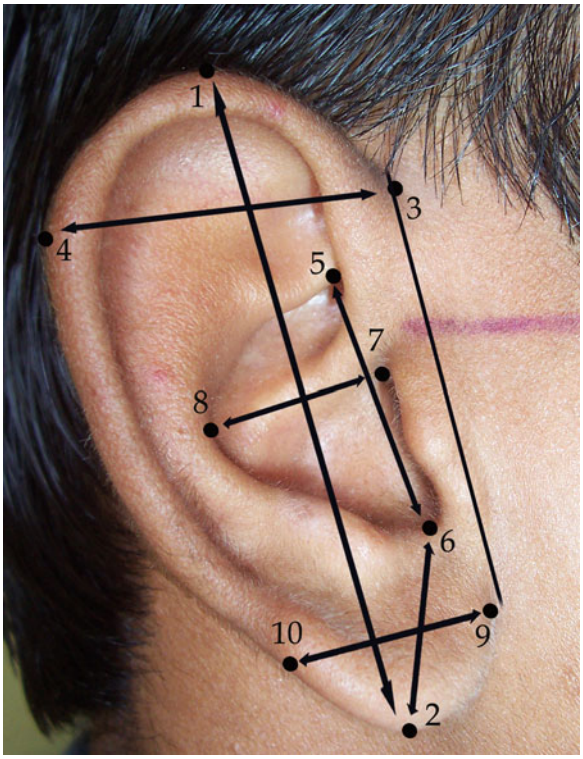

Fig. 53.3 Anatomical landmarks of auricle. (*1*) superaurale, (*2*) subaurale, (*3*) preaurale, (*4*) postaurale, (*5*) concha superior (*6*) incisura intertragica inferior, (*7*) incisura anterior auris posterior, (*8*) strongest anthelical curvature, (*9*) lobule anterior, (*10*) lobule posterior

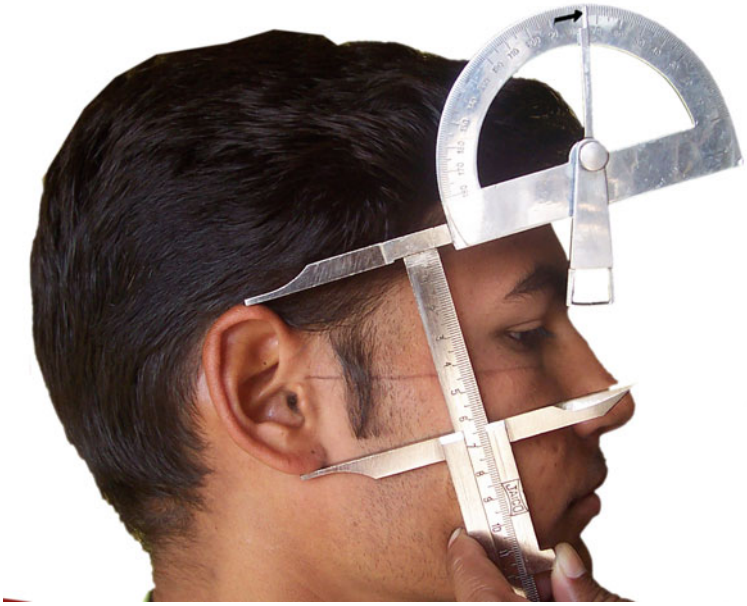

Fig. 53.4 Measuring ear inclination angle. The angle is measured with a goniometer fitted on a sliding calliper. The arrow shows the reading on the goniometer, which is 14°

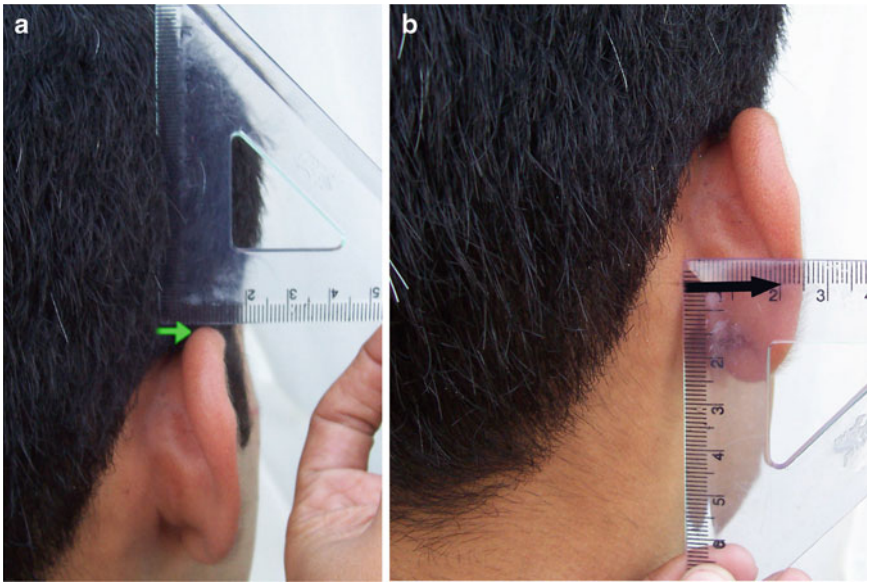

Fig. 53.5 Measuring ear protrusion. Protrusion at (**a**) superaurale and (**b**) tragal levels measured with a geometrical set square. The *arrows* show the protrusion of ear from mastoid bone

posterior is the most posterior point on margin of lobule at same level. Due care to be taken to keep limbs of calliper parallel to the medial longitudinal axis of auricle.

5. *Conchal Length* (5–6): It is the straight distance between concha superior (cross-over of lower edge of anterior end of Crus antihelicis inferius and posterior border of crus helicus) and incisura intertragica inferior.
6. *Conchal width* (7–8): It is the distance of strongest antihelical curvature and incisura anterior auris posterior (most posterior point on the edge of incisura anterior auris).
7. *Auricular inclination angle*: It is the inclination of medial longitudinal axis (line joining superaurale and subaurale) of ear from vertical plane of head and face.

   The perpendicular dropped from vertex to Frankfurt horizontal plane is considered as the vertical plane. The angle is read on the protractor of a goniometer fixed on the immovable limb of a sliding calliper (Fig. 53.4).
8. *Protrusion at superaurale level*
9. *Protrusion at tragal level*

The heights of auricular protrusion are measured with a geometrical set square with its base touching the mastoid area. The vertical limb of the set square thus measures the perpendicular distance between the posterior helical border at superaurale/tragal level and the mastoid area (Fig. 53.5a, b).

Width and length of auricle, concha and lobule can be incorporated into their respective indices to assess their proportion in various age groups.

$$\text{Auricular Index} = \text{width of auricle} \times 100/\text{length of auricle}$$
$$\text{Lobular Index} = \text{lobular width} \times 100/\text{lobular length}$$
$$\text{Conchal Index} = \text{conchal width} \times 100/\text{conchal length}$$

53.4 Analysis of Auricular Morphology

The ear is an important component of the facial complex, and it gives a subtle impression of its bearer's age and sex. Its size, shape and spatial location on the face are not only important from an aesthetic point of view but any abnormality is an indication of possible anomaly in the subject. Knowledge of the normal dimensions of the ear is useful as a guideline for the plastic surgeon while rectifying possible defects. The dimensions would vary in different ethnic groups, which necessitates that the surgeon base his observations on data specific to that ethnic group.

The auricular size continues to increase even during adulthood (Heathcote 1995). This increase is due to reduced resilience and elasticity of skin (Pasquali-Ronchetti et al. 1997), diminutive tensile strength of the connective tissue and gravitational pull (Ito and Imada 2001). The representative data reiterates this observation in almost all linear measurements (Table 53.3). The auricular index, in general, exhibits a decrease down the age groups, indicating faster increase in length than in width with ageing (Table 53.4).

All linear measurements show 6–11% increase in size from youngest to oldest age group, while lobular length registers a 23% increase. Bilateral asymmetry is apparent in all age groups for all measurements but other than auricular length and width and conchal length: none of these reached statistically significant levels. Auricular inclination angle, protrusion at super aurale and tragal levels do not show any definite trend across the age groups. The auricular protrusion increases inferiorly.

Auricular and conchal indices exhibit minor variation compared to lobular index across the age groups. Auricular and lobular indices show a general decreasing trend with advancing age.

Table 53.3 Auricular dimensions in five age groups

	Age groups									
	18–30 years ($N = 121$)		30–40 years ($N = 82$)		40–50 years ($N = 68$)		50–60 years ($N = 74$)		60–70 years ($N = 70$)

According to Farkas and Lindsay (1973) and Farkas (1978a), the auricular length and width can be useful in diagnosing syndromes suffering from microtia or disproportionately wide or narrow ears as in craniofacial syndromes. Wide ears are observed in Apert and Crouzon syndromes and narrow ears in cleft lip and palate patients.

53.5 A Note on the Ear Lobule

The ear lobule continues to elongate with age (Table 53.3). The maximum progression of growth was found to be after 60 years of age. The lobular index (Table 53.4) also supported the above observation, exhibiting a decreasing trend with advancing age. This decrease is much more than what is observed in the auricular index, which supports the observation of Brucker et al. (2003) that the lobule is the only ear structure that changed significantly with age.

Brucker et al. (2003) reported a decrease in lobular width with age in their mixed (89 females and 34 males) American data, but when males were only considered, the measurement failed to show any statistical difference across age groups. It is observed that the dimensions of the lobule are dependent on its shape and attachment to cheek. Hence, one should exercise caution while interpreting the result. Among Indians, in the 50–60 years age group, the length remained almost unchanged compared to the earlier group (40–50 years) though the width increased (Table 53.3). When further investigated, it was found that the group contained unusually large proportion (47%) of attached and bow shaped lobules (Fig. 53.6). This explained the shortness of the length and increased width. Farkas (1978b) also found attached earlobes to be hypoplastic in his North American Caucasian data. Great intra and inter-group variation in the shape and attachment of the lobule may also account for the discrepancy exhibited by the lobular index as is reflected in the 50–60 years age group (Table 53.4). Twenty-eight percent of the lobules in the data were either slightly free at the lower end or adherent to the cheek (Fig. 53.7, Table 53.5). It is an already established fact that free earlobes elongate more than its attached counterpart (Azaria et al. 2003). Hence during rectification of earlobe ptosis, an attempt is made to make it adherent to the cheek to stall its further elongation.

Fig. 53.6 Shape of lobule. *Short* and *bow* shaped lobule

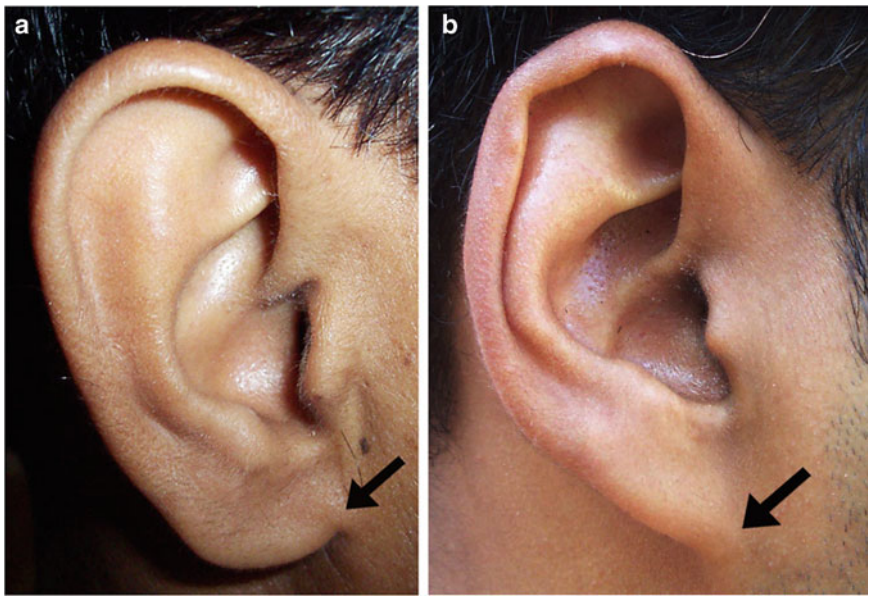

Fig. 53.7 Adherence of lobule. Ear lobule attachment to cheek (**a**) Slightly free and (**b**) completely attached

Table 53.5 Description of auricular features

Features	Classification	Sub classification	Frequency (%) Right	left
Shape of auricle	Normal	Oval	57.3	57.3
		Round	6.5	6.5
		Rectangular	5.4	5.6
		Triangular	30.8	30.6
	Abnormal		–	–
Preauricular region	Clear skin		100	99.6
	Presence of appendages	skin appendage	–	0.4
		Pits	–	–
		Fistula	–	–
Helix	Normally rolled		88.3	88.3
	Wide but not covering the scapha		–	–
	Wide, thin and collapsed above scapha		–	–
	Flat and unfolded		11.4	11.4
	Wide with a concave marginal impression on the junction of middle and upper segment		0.3	0.3
Lobule size	Normal	Large	14.6	14.6
		Proportionate	50.8	46.5
		Small	28.6	31.2
	Hypoplastic		6.0	7.7
Lobule shape	Tongue		41.7	42.6
	Bow		26.3	25.4
	Round		7.8	7.8
	Angular		19.9	19.9
	Pointed		4.3	4.3
Lobular attachment to Cheek	Free	Bilateral	65.5	
		Unilateral	3.8	
	Partially free	Bilateral	12.7	
		Unilateral	1.2	
	Attached	Bilateral	15.9	
		Unilateral	1.9	

The oval is the most common shape of an auricle, followed by the triangular. Normally rolled helices accounted for most of the helix forms. The preauricular area is generally clean. Most lobules are bilaterally free, of proportionate size, generally tongue-shaped among free- and bow shaped among attached lobules. Hypoplasia of the ear lobes is also registered

53.6 Comparative Study

On comparing with data of other populations (Table 53.6), one would find a significant variation in auricular size. Indian auricular length is shorter than any ethnic group depicted in the table. The auricular length of Indian elders (50–70 years) is comparable to young Turkish (18–25 years) (Bozkir et al. 2006) and Italian (Gualdi-Russo 1998; Ferrario et al. 1999) ears. Interestingly, the ear width is similar to Turkish males of same age group (Bozkir et al. 2006).

Among Indians, the lobular length is comparable with Jewish data in the younger age group (Azaria et al. 2003), but in older age groups there is great disparity as unlike Indians elongation continues at a greater pace among Jews. As such it seems that the lobular length is smallest among Indians, though its width is comparable with that of the Americans (Brucker et al. 2003) and Turkish (Bozkir et al. 2006) males. This is further supported by data on auricular features which classified 7.7% right and 6% left lobules as hypoplastic and 31.2% right and 28.6% left lobules as small (Fig. 53.6, Table 53.5).

Table 53.6 Comparison of male auricular dimensions in various ethnic groups

Comparative auricular data in few populations

53.7 Possible Applications of Auricular Data

Exceptionally large auricular inclination is an indication of possible anomaly. Among cleft lip and cleft palate anomaly patients, for example, the ears are set with greater inclination of the longitudinal axis (Farkas 1978b). So it may help for a clinician to be acquainted with the normal range of auricular inclination, which usually falls within a range of 9–29°.

Knowledge of protrusion of the auricle has a two-fold advantage. The first is a possible indication of the presence of a prominent ear when the superaurale distance from the scalp is greater than 20 mm (Kalcioglu et al. 2003). Its incidence is quite common in the general population, ranging from 5.5–38.7% (Preuss and Eriksson 2000). Measuring auricular protrusion also finds its use in designing hearing aid instruments. The aid may be fitted behind the ear or surgically anchored to the mastoid bone. In the bone-anchored hearing aid, a small abutment is exposed outside the skin for transmitting sound vibrations to the bone. Whatever the form of aid instrument, knowledge of the ear projection from the skull, both in the superior and inferior aspect, are essential for designing the instrument; it is also crucial for surgeons planning surgery. The dimensions of the concha can also be helpful in designing a hearing aid instrument which can fit into it.

From the above description on the external ear, one can deduce that the lobule contributes the greatest to the overall increase in ear length. Among Indians, changes in the ear form were found to continue throughout the lifespan but the maximum elongation of the lobule was after the age of 60. This inference is of great use in the field of Ear Biometrics. Ear Biometrics is a machine-based vision system in which databases of ear images are stored. During authentication, the ear image of an individual taken is automatically compared with the ear image already stored in the machine. Since constancy over time is one of the essential requirements of biometrics (Jain et al. 2000), if the ear undergoes rapid change in its form, there are chances of rejection of an authentic person at the time of verification. In other words, the False Rejection rate will be too high with increasing age. Hence it is emphasised that the ear can be used as a biometric tool with a ceiling of 60 years of age. Thus, for using the external ear as a biometric tool, either the law enforcement agencies should limit their database to 60 years or update their data from time to time.

It is essential to remember the statement of Rubin et al. (1962), that there is no ear which can be designated as standard. Even in the same ethnic group, great diversity exists in the shape and size of the external ear (Farkas et al. 1992). Grouping such diverse ears together into various age groups in a cross-sectional study gives us only a crude estimate of their average dimensions. Hence, it is necessary to reiterate to the readers that it may not be the best method for studying changes in ear dimensions with progression of age.

Summary Points

- Though various parts of auricle do exhibit changes with progression of age, the elongation of lobule contributes maximum to the overall increase of auricular length. The progression of growth of lobule was found to be at greatest speed after 60 years of age.
- When compared to other populations, the lobular length of male is found to be smallest among Indians. The observed shortness of the lobule seems to be a characteristic feature of the population of this part of India as 39% left and 35% right lobules are categorized as exceptionally short in length.
- Data on external ear are useful to physicians to detect anomalies in patients while data on ear protrusion above the skull can be used by industries for designing hearing aid instrument for the ear.

Knowledge of the rapid elongation of the lobule after age 60 can help law enforcement agencies to update their data on external ear while using it as a biometric tool.

- Besides providing standards, an objective approach is required to diagnose syndromes or any anomaly by actually measuring features, rather than relying on an impression of physical features. Sometimes, in a routine visual examination, a physician may miss minor defects of the auricle, which will be visible in a metrical analysis.

Chapter 54
Anthropometric Analysis of the Nose

Abdullah Etöz and İlker Ercan

Abstract Anthropometric evaluation begins with the identification of specific locations, called landmark points, defined in terms of visible or palpable features on the subject. Data from facial landmarks have traditionally been obtained by the direct measurement technique using standard instruments such as callipers, measuring tapes, compasses, protractors and angle finders. However, this requires physical contact by the examiner, which could lead to errors during measurement as many areas on the face are very sensitive to touch. The latest reports on craniofacial anthropometry, therefore, include laser scanning and photogrammetric techniques.

The nose is a person's most defining feature as it is at the centre of the face. The shape of the nose is a signature indicating ethnicity, race, age and sex. Anthropometric methods and surgical practice have now merged to treat congenital or post-traumatic facial disfigurements in various racial or ethnic groups successfully. Nasoplasty surgeons require access to facial data based on accurate anthropometric measurements to perform optimum correction. The photogrammetric anthropometric method will be summarized in this chapter. Anthropometry is said to be the most suitable nasal evaluation method to demonstrate the sharp nasal profile contours and eliminate differences between direct and indirect nasal measurements.

NHP	Natural head position

54.1 Introduction

Anthropometric analysis aims to provide the most reliable comparison of body forms by using specific landmarks determined in respect of anatomical prominences. It is now easier to discuss the differences between ethnic and racial groups, and to compare individual variations in both sexes thanks to previous anthropometric studies. Farkas has provided a great body of work in craniofacial

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_54,

anthropometry and established a database of anthropometric norms by measuring and comparing more than 100 dimensions (linear, angular and surface contours) (DeCarlo 1998).

Anthropometric methods and surgical practice have now merged to treat congenital or post-traumatic facial disfigurements in various racial or ethnic groups successfully (Farkas 2005). The nose is a person's most defining feature as it is in the center of the face. The shape of the nose is a signature indicating ethnicity, race, age and sex (Ofodile and Bokhari 1995; Milgrim 1996; Mishima 2002; Ochi and Ohashi 2002; Romo and Abraham 2003; Ferrario 1997; Bozkir 2004; Leong and White 2004; Uzun 2006). Nasoplasty surgeons require access to facial data based on accurate anthropometric measurements to perform optimum correction.

There are several anthropometric studies on nasal anatomy and various methods have been used. We decided to review a landmark-based geometric morphometric technique which can be easily used when analyzing the nasal shape in any condition.

On the other hand, a clinically successful outcome in nasoplasty requires thorough and accurate preoperative planning together with awareness of morphological differences. Anthropometric analysis of the nose is a way for us to provide data which should contribute to satisfactory cosmetic nasal surgery results.

54.2 Anthropometric Measurements

Anthropometric analysis of nasal anatomy is based on the comparison of measurements which are obtained separately from the anterior, lateral and inferior aspects. These measurements can be performed by direct or indirect methods. Direct methods are time-consuming and have several other disadvantages such as difficulty of patient adaptation (especially in children and infants), problems concerning repeatability of measurements and archiving of data. Indirect measurement methods including photogrammetry, cephalometry, stereophotography, laser scanning, and computerized tomography have therefore become increasingly more popular in recent years. The most frequent methods used clinically are photogrammetry and cephalometry. Photogrammetry is a fast and inexpensive method with superior patient compliance. The most important disadvantage of two-dimensional photogrammetry is its inability to assess facial depth. Three-dimensional photogrammetry appears to be a more appropriate technique in this respect.

The following issues are crucial in anthropometric analysis of the nose:

1. Standardization of the method
2. Landmark identification

54.2.1 Standardization of the Method

Details of standardization of the methods used in anthropometric analysis have previously been defined by several investigators and are beyond the scope of this review. It is important to note that a standard head position is essential for any facial measurement. The natural head position (NHP) is the most appropriate since it is the most reproducible and provides a natural face orientation for any clinical planning.

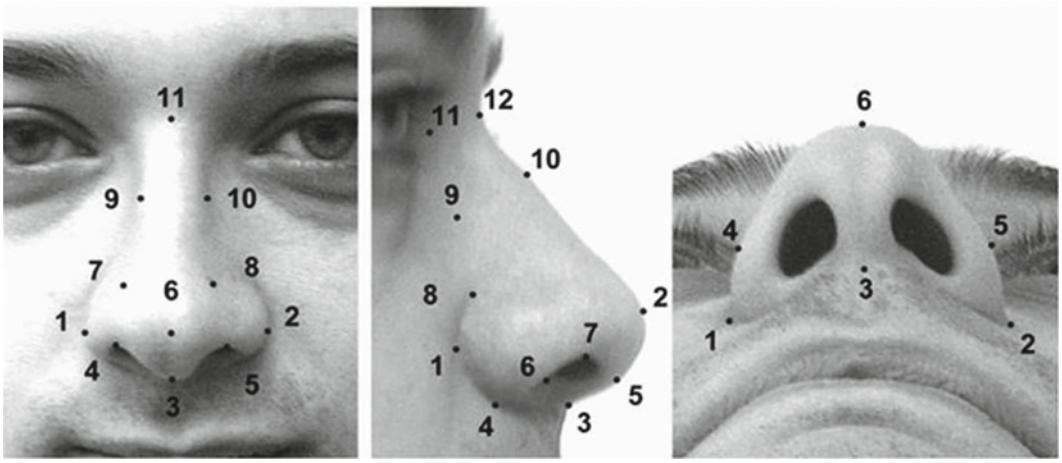

Fig. 54.1 Anthropometric (anterior 1–6, 9–11; lateral 2–4 and 12; inferior 1–3, 6) and constructed (anterior 7, 8; lateral 1, 5–11; inferior 4, 5) landmarks that were used in the anthropometric analysis of the nose (Ercan et al. 2007)

54.2.2 Landmark Identification

The accurate identification and reliability of the landmarks are the most important indicators of the accuracy of anthropometric measurements. One way to increase accuracy is to mark the landmarks before measuring. Many soft tissue landmarks reflect the underlying bony structure. The bony points must be palpated with a finger to find the soft tissue equivalent. While some soft tissue points can be marked with a dermographic pen, other tissue landmarks such as endocanthion, exocanthion, cheilion, and crista philtre can be clearly identified without palpation. Meticulous identification of soft tissue landmarks and marking of the landmarks determined by inspection and palpation before the acquisition of photographs will certainly improve the reliability of measurements in photogrammetry. Nasal landmarks are presented in Fig. 54.1 and Tables 54.1–54.6.

54.2.3 Landmark Reliability

It is important to understand the various sources of error that can affect anthropometric measurements during location of landmarks. Lack of precision results in variability among repeated measurements of the same specimen and has two components:

- Observer error in locating landmarks
- Instrument error in identifying landmark coordinates (Lele and Richtsmeier 1991; Lele 1993)

It is crucial to analyze the reliability of the landmarks. The optimal standard to achieve reliability is that all landmarks should be marked by the same investigator on all subjects. Instrumental errors should be avoided by using standardized digital photographic imaging obtained from anterior, lateral and inferior aspects using a constantly stable digital camera (Hwang and Kang 2003; Uzun 2006).

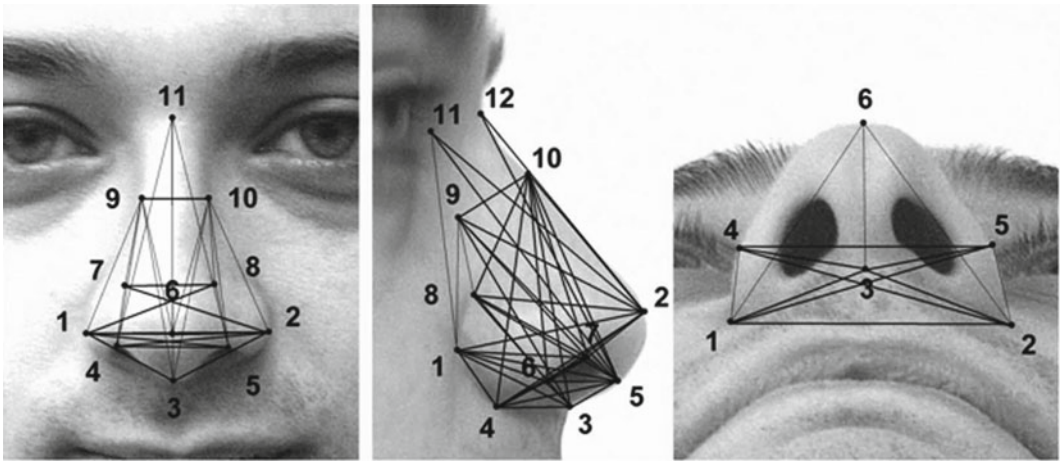

Fig. 54.2 The inter-landmark distances, viewed from anterior, lateral and inferior aspects. These distances can be measured by computer scales in photogrammetric software and the results should be proportionate to each other. For example, the thin lines in this figure indicate the inter-landmark distances that were found to be greater in females while the bold lines indicate those found to be greater in males (Ercan et al. 2007)

54.2.4 Collection of Two-Dimensional Craniofacial Landmarks of the Nose

The data collection procedure should take place in two separate steps, and followed by off-line calculations. Digital photographic images of each subject should first be taken by the same investigator using a digital camera with at least 2.0 mega pixel capacity. The second stage is marking the examined landmarks on these digital images. The anthropometric landmarks are defined in Fig. 54.1. The landmarks shown in the figure have also been accepted in previous anthropometric studies. Some "constructed" landmarks are also used for enrichment of nasal anthropometric analysis. These landmarks are determined by constructing a line tangent to another landmark or a bony edge. The descriptions of the examined landmarks are presented in Table 54.1 and shown in Fig. 54.1.

In the general use of photogrammetry, the common landmarks were selected as follows: Eleven landmarks (five anthropometric and two constructed) in the anterior aspect, twelve landmarks (four anthropometric and eight constructed) in the lateral aspect and six landmarks (four anthropometric and two constructed) in the inferior aspect of nose were defined for each subject. The landmarks were marked on the digital photographs using TPSDIG 2.04 software. This software was developed by F. James Rohlf and is one of the most frequently used software both for marking the landmarks (however, it is recommended to take photos after marking the landmarks on the person) and for determining the inter-landmark distances in pixels (Fig. 54.2). A ruler is used during photography for measurement of the distances between the landmarks on the digital images, and later the unit distance (1 cm) is calibrated with its equivalent in pixels in order to obtain measurement values separately.

This technique has proven to be reliable in studies on facial landmarks by Nechala (1999) and Ferrario (2003) that compared photogrammetry with direct measurements, and showed that sharp facial profile contours could eliminate the differences between the direct and indirect measurements of the nose. The strengths and limitations of photogrammetry must be appreciated but it is ideally suited to the evaluation of proportions, as the magnification factor is eliminated (Weigberg 2005).

Statistical studies of anatomical shape variations in the population are important in understanding the anatomical effects of diseases or biological processes. Several procedures for obtaining shape

information from landmark data have been proposed. The Euclidean Distance Matrix Analysis (EDMA) is used to calculate all possible linear distances between landmarks by creating matrices for each subject (Theodore and Richtsmeier 1998).

Ethnic influences can result in differences in the appearance of the nose, as follows: Caucasian, leptorrhine; African American, platyrrhine; Hispanic, paraleptorrhine; and Asian, subplatyrrine. For example, three types of African American noses are described: African, Afro-Caucasian, and Afro-Indian (Ofodile and Bokhari 1995). There are also variations of nasal shape related to sex in both ethnic groups. Nose shape gives information about race, ethnicity, age and sex. The size, shape, and proportions of the nose provide a personal characteristic vision. Moreover, it is an important key for a natural and aesthetically pleasing human face (Aung 2000). Accordingly, concern about the nasal shape has recently increased with many wanting to undergo nasoplasty. Any surgeon who performs nasal surgery must be keenly aware of the morphological differences in nasal anatomy. The psychological aspects, differences in skin conditions and anthropometric measurements must be taken into consideration when planning nasal surgery.

There are many methods for the anatomic evaluation of the nose and the variations in different racial and ethnic groups. However, there is an easy and reliable method to analyze nose shape: Photogrammetric nasal analysis. This method is believed to be a better way to examine nasal differences than conventional methods.

54.3 Applications to Other Areas of Health and Disease

Anthropometric methods and surgical practice have now merged to treat congenital or post-traumatic facial disfigurements in various racial or ethnic groups successfully. Nasal surgery requires access to facial data based on accurate anthropometric measurements to perform optimum correction for any condition. Cosmetic nasal surgery for men, although not technically different from such surgery for women, requires awareness of additional considerations because of different expectations. Anthropometric analysis is a step in clarifying these important points and a baseline for planning the corrective surgery.

54.4 Practical Guidelines

- The subjects were recruited from a population with no noticeable nasal or facial disfigurement and no history of previous nasal or facial surgery.
- Demographic data obtained included age, place of birth, and parental heritage.
- The subjects were rested for 10 min before the photography.
- A constant, stable three-leg camera holder was used and all subjects were positioned at the same distance from the camera.
- All the data was obtained from standardized digital photographic images taken from the anterior, lateral and inferior aspects using a 5.1-megapixel digital camera.
- Anthropometric landmarks were defined according to a previous report of Farkas et al.
- We used some ‘‘constructed’’ landmarks (the definition of the landmark is determined by constructing a line to another landmark or bony edge) to enhance shape analysis.
- The landmarks were marked on the digital photographs by the same investigator using TPSDIG 2.04 software.

Summary Points

- Statistical studies of anatomical shape variations in the population are important for understanding the anatomical effects of diseases or biological processes.
- Anthropometric analysis of facial asymmetry is based on the comparison of homolog measurements that are obtained separately from the anterior, lateral and inferior aspects.
- The standardization of the method and accurate identification of landmarks to be used in the measurements in nasal anthropometric analysis are important.
- Various anthropometric measurements have previously been used but photogrammetry is a modern and feasible method for nasal analyses.
- Anthropometric analysis is a step in clarifying these important points and provides a baseline for enhancing the corrective surgery plans.

Key Points

Photogrammetry is an easy and effective method for anthropometric analysis of the nose.

Chapter 55
Three-Dimensional Computerized Anthropometry of the Nose

Chiarella Sforza, Riccardo Rosati, Marcio De Menezes, Claudia Dolci, and Virgilio F. Ferrario

Abstract The quantitative assessment of the dimensions of facial soft-tissue structures, their relative proportions, and reciprocal spatial positions is an essential component of the clinical analysis of patients seeking maxillo-facial treatments. In particular, nasal morphology and dimensions play a key role in facial harmony, and modifications of nasal characteristics are among those most asked by patients worldwide. Currently, cosmetic rhinoplasty is the fourth most common surgical procedure in the USA. For a quantitative description of human noses, various methods have been used, both in two (photographs) and three dimensions (direct facial anthropometry, measurements on stone casts, and indirect anthropometry on digital reproductions). Additionally, intrauterine assessments for the prenatal diagnosis of chromosomal alterations and cleft lip are being made by ultrasonography.

In healthy persons, data were reported for nasal linear measurements, angles, external area and volume, nostril dimensions, angles, and symmetry. In both sexes, the fastest child and adolescent growth was found for vertical distances, which doubled their values from birth to young adulthood. Male values were always larger than female values. A large increment was also observed for the antero-posterior distances, with limited sexual dimorphism. The largest sexual dimorphism (males larger than females), and the smallest age-related increments, were found for nasal horizontal measurements. Normal growth and development of the nose did not stop in early adulthood. The cartilaginous tissues of the face continue to grow during maturity and old age, giving older people longer and larger noses. The largest ethnic variations in the nose were found in the descriptors of nasal shape, that is, the angles. During growth, nasal volume progressively increased from childhood to young adulthood, but its modifications continued even after the attainment of skeletal maturity. At 3–4 years of age, nasal volume was approximately 36% (boys) and 42% (girls) of the mean value attained in young adulthood. In old adults, nasal volume was 120% (men) and 118% (women) of the mean value of the 18–30 age group. Nasal size and shape in the different ages and ethnic groups may be usefully employed for clinical assessments, surgical interventions, and forensic reconstructions.

55.1 Introduction

The quantitative assessment of the dimensions of facial soft-tissue structures (eyes, nose, mouth and lips, chin, and ears), their relative proportions, and reciprocal spatial positions is an essential component of the clinical analysis of patients seeking maxillo-facial treatments (Yamada et al. 1999; White et al. 2004; Maal et al. 2008; Troncoso et al. 2008). Three-dimensional (3D) quantitative information on the skeleton and soft tissues of the craniofacial complex can be obtained with computed tomography or magnetic resonance (Maal et al. 2008). Unfortunately, both methods have several shortcomings that limit their widespread use in clinics and research: computed tomography uses ionizing radiations, and it cannot be used in healthy, non-patient subjects. Additionally, its use in patients should be limited, and repeated, longitudinal evaluations cannot be proposed even when there are facial alterations and deformities. Magnetic resonance is too time- and money-consuming. Therefore, simpler and less problematic methods, classic direct anthropometry and digital anthropometry, have been proposed and applied (Sforza et al. 2004; Heidari et al. 2009).

Currently, classic direct anthropometry is being coupled and even replaced with various 3D image analyzers (laser scanners, 3D range-cameras, optoelectronic instruments, stereophotogrammetry, and Moiré topography), and contact instruments (electromagnetic and electromechanical digitizers, ultrasound probes), that allow a fast and not invasive assessment of soft-tissue craniofacial morphology (Ferrario et al. 1997, 2003, 2007; Yamada et al. 1999; Aung et al. 2000; Mori et al. 2005; Honrado et al. 2006; Ghoddousi et al. 2007; Schwenzer-Zimmerer et al. 2008a, b; Ozsoy et al. 2009; Plooij et al. 2009). Three-dimensional digitizers provide the x, y, z coordinates of facial surfaces or of landmarks; Euclidean geometrical calculations can then be used to obtain 3D linear distances, angles, surface areas as well as volumes of selected facial structures (Ferrario et al. 1997, 2003).

Nasal morphology and dimensions play a key role in facial harmony, and modifications of nasal characteristics are among those most asked by patients worldwide. Rhinoplasty can improve nasal appearance and proportion, enhancing facial harmony (Troncoso et al. 2008; Heidari et al. 2009). Currently, cosmetic rhinoplasty is the fourth most common surgical procedure in the USA. In 2008, over 152,000 operations were performed, with an increase of 0.4% on 2007 data (http://www.consultingroom.com/, accessed on July, 12th 2009).

Normal, reference data for nasal morphology are therefore necessary, together with detailed information about the age-related charges in nasal dimensions and proportions, to plan a proper treatment for the surgical correction of nose dysmorphologies, traumatic disfigurements, or aesthetic imbalances.

55.2 Assessment of Nasal Morphology

In healthy persons, data were reported for nasal linear measurements, angles, external area and volume (Spalding and Vig 1990; Farkas et al. 1994; Ferrario et al. 1997, 2007; Yamada et al. 1999; Aung et al. 2000; Zankl et al. 2002; Porter and Olson 2003; Sforza et al. 2004; Troncoso et al. 2008; Heidari et al. 2009),

Table 55.1 Nasal landmarks

Landmark	Definition
Midline landmarks:	
Nasion (n)	Innermost point between the forehead and nose
Pronasale (prn)	Most protruded point of the apex nasal
Columella (c′)	Midpoint between the columella crests, level with the top of the corresponding nostril
Subnasale (sn)	Midpoint at the union of the lower border of the nasal septum and the upper lip
Labiale superius (ls)	Midpoint of the upper vermilion line
Paired landmarks (right and left sides noted $_r$ and $_l$):	
Alare (al)	Most lateral point on each alar contour
Nasal alar crest (ac)	Most lateral point in the curved base of each alar
Inferior terminal of the nostril (itn)	Inferior point of the nostril axis
Superior terminal of the nostril (stn)	Superior point of the nostril axis

The table lists and defines the most used soft-tissue nasal landmarks

nostril dimensions, angles, and symmetry (Spalding and Vig 1990; Yamada et al. 1999; Russell et al. 2000; Porter and Olson 2003; Uzun et al. 2006; Rosati et al. 2009; Troncoso et al. 2008). Tables 55.1 and 55.2 report a list of the most commonly used nasal landmarks (Fig. 55.1) and measurements.

55.2.1 Asymmetry

Additionally, several investigations reported data on nasal symmetry, using both simple, clinically based, right–left indices (Yamada et al. 1999; Rosati et al. 2009), and more complex mathematical calculations (Russell et al. 2000; White et al. 2004; Baeyens et al. 2006; Daelemans et al. 2006). Asymmetry can be divided into directional and fluctuating: directional asymmetry indicates a differential development favoring one side of the body consistently over the other, while fluctuating asymmetry does not favor one side of the body over the other (Rosati et al. 2009). In morphological contexts, directional asymmetry seems to depend from repeatable effects of environment or genotype on the analyzed structures. In contrast, fluctuating asymmetry seems to reflect developmental stability (Rosati et al. 2009): subjects with a lower level of fluctuating asymmetry should possess a healthier and stronger structure (Ercan et al. 2008).

Therefore, the assessment of asymmetry is of both clinical and theoretical interest: the definition of the level of asymmetry in the normal population can be used to set intervention guidelines and treatment goals (Russell et al. 2000; Ferrario et al. 2003; Schwenzer-Zimmerer et al. 2008a, b). At the same time, facial symmetry is always associated with perceptions of health: present theories of perceptual psychology underline the importance of a reduced fluctuating symmetry for esthetic appraisal (Ercan et al. 2008). In this context, phenotypic symmetry is used as a cue reflecting a better genetic background (Table 55.3).

55.2.2 Methods of Analysis

For a quantitative description of human noses, various methods have been used, both in two (photographs, Porter and Olson 2003; Liou et al. 2004; Baeyens et al. 2006; Daelemans et al. 2006; Troncoso et al. 2008) and three dimensions. In particular, direct facial anthropometry (Farkas et al. 1994; Zankl

Several authors analyzed nasal asymmetry in healthy people, and found that some degree of asymmetry is a common finding at all ages of life

Among the others, considering their position, the assessment of nostril dimensions and shape can often be difficult, when using both direct and indirect anthropometry (Schwenzer-Zimmerer et al. 2008a, b). Therefore, researchers have developed several methods for the reproduction of noses, and their subsequent measurement. The use of stone casts allows the performance of detailed analysis even of the nostrils (Rosati et al. 2009). The casts can be analyzed directly, or they can be reproduced with digital instruments, using reverse engineering methods (Ferrario et al. 2007; Rosati et al. 2009).

55.2.3 Nose Reproduction: Stone Casts and Digital Models

Nasal morphology can be evaluated from 3D reproductions (Ferrario et al. 2007; Rosati et al. 2009). The method developed in our laboratory uses silicon impressions that are cast in dental stone. Subsequently, plaster nasal models are digitized using a computerized electromechanical

digitizer (Microscribe G2, Immersion Corporation, San Jose, CA). Point clouds obtained from the digitization of the plaster casts can subsequently be elaborated to create virtual surfaces using a commercial software for the 3D modeling of solids (Rhinoceros 3.0; Robert McNeel & Associates, Seattle, WA).

All procedures are made with the subject supine in a dental chair.

For each subject, a custom metal mesh is shaped using three 1-mm wires: two horizontal wires, one passing through pronasale and one approximately 1 cm below nasion, and a vertical wire connecting the horizontal wires on the nasal midline. The wires are individually modeled to follow nasal morphology. The mesh needs to be somewhat larger than the actual nose to allow space for the impression material.

The first stratum of impression material (polyvinylsiloxane) is put on the nasal surface, avoiding the formation of bubbles. The entire nasal surface, from glabella (forehead) and endocanthi (medial eye fissure) to subnasale, is gently covered. Some additional impression material is poured at the nostrils. The metal mesh is directly included in the first stratum of impression material. Immediately, a second stratum of polyvinylsiloxane is added, and the metal wires are completely covered.

During the hardening of the impression material (approximately 5 min), the subject breathes through the mouth with no facial movements. The negative cast impression is then gently removed from the skin starting from its uppermost part (nasion), and a positive model is obtained by filling the impression with dental stone. To avoid deformations, stone filling is done in two steps: at first, a thin layer of stone is put in the negative cast; when the layer is hardened, the filling is completed with care. During hardening, the model is kept within a box filled with sawdust that allows a correct positioning of the impression without any local deformation.

Subsequently, the plaster nasal models are digitized using a computerized electromechanical digitizer that provides metric data independent from external reference systems (Ozsoy et al. 2009). The electromechanical digitizer is a multi-joint arm digitizer with a terminal stylus (or tip); within each joint, an optical encoder works with a microchip and instantly sends the joint angle to a host computer; the 3D coordinates of the stylus are therefore provided. The instrument has an accuracy of 0.38 mm within a 50-in. sphere workspace, and its calibration is controlled before each data collection session using 3D objects of known dimensions.

Each stone cast is covered with a grid of lines, and several points on standardized horizontal and vertical lines are digitized. Seven principal horizontal lines are drawn: through landmarks pronasale, nasion, subnasale, columella, at the inferior and superior borders of the nostrils, and at mid-way on the nostrils. Four-to-six additional horizontal lines (according to nasal dimensions) are drawn between nasion and pronasale. Three principal vertical lines are drawn: on the midline through nasion, pronasale, and subnasale; on the right and left sides of the lateral nasal surface through endocanthion, the lateral contour of the nose, and the nasal alar crest. Subsequently, four additional lines for each side are drawn parallel to these three. Overall, each nostril should be crossed by three or four horizontal lines.

Point clouds obtained from the digitization of the nasal casts are subsequently elaborated to create virtual surfaces using the commercial software for the 3D modeling of solids (Rhinoceros 3.0; Robert McNeel & Associates, Seattle, WA).

Non-uniform rational B-spline (NURBS) geometry is used for the digital reproductions. These B-splines are mathematical illustrations of 3D geometry, and can represent geometric objects in two and three dimensions. These surfaces are the mathematical equivalent of elastic sheets, and can be modeled to adapt to any form. Because of their flexibility and accuracy, NURBS models are widely used in several industrial processes from computer-aided design, manufacturing, and engineering, to computerized illustration and virtual animation.

55.3 Nasal Growth, Development, and Aging

Normal growth and development of the nose does not stop in early adulthood. The cartilaginous and skeletal tissues of the face continue to grow and modify during maturity and old age, giving older people longer and larger faces (Zankl et al. 2002; Sforza et al. 2009). This observation is well known even to lay people: for instance, according to a Chinese belief, long ears indicate longevity (Sforza et al. 2009). Indeed, both in cross-sectional and in longitudinal studies, older people tend to possess bigger ears (Zankl et al. 2002; Sforza et al. 2009). Unfortunately, the coexistence of two conditions is not sufficient to demonstrate their association, and we cannot relay on a simple anthropometric measurement to predict health and longevity.

Nasal dimensions and characteristics are currently being measured in utero by ultrasonography: indeed, fetuses with chromosomal alterations (in particular, trisomy 21) tend to have a significantly larger incidence of nasal bone absence (delayed ossification) or hypoplasia than fetuses with a normal karyotype. The intrauterine assessment of nose dimensions is therefore one of the "soft markers" used to detect fetuses with an increased risk of altered karyotype. The matter is further presented and discussed in the chapter "Anthropometric indices of facial features in Down's syndrome subjects" in this book. Nasal alterations are also found in fetuses with cleft lip.

55.3.1 Linear Distances

Postnatal measurements of nasal dimensions were made by several authors; one of the most known cross-sectional databases is that provided by Farkas et al. (1994) for North American white Caucasian persons. In their investigation, they analyzed approximately 1,800 persons from birth to 25 years of age using conventional anthropometry.

In both sexes, nasal height (a vertical distance) had the fastest growth (Fig. 55.2), and it doubled its value from birth to young adulthood. Male values were always larger than female values. A large increment was also observed for the antero-posterior distance prn-sn (nasal tip protrusion); for this measurement, male and female values were very similar at all ages (Fig. 55.3), with female to male ratios all larger than 94% (except in the first age group). The largest sexual dimorphism (males larger than females) and the smallest age-related increments were found for nasal width (al-al), a horizontal measurement (Fig. 55.4).

These growth patterns are well in accord with the general modifications in craniofacial growth: at birth, horizontal dimensions are always more advanced in their development than vertical ones.

Some nasal measurements for the subsequent age groups were provided by Zankl et al. (2002), who analyzed 2,500 white Caucasians of central European descent living in Switzerland. Cross-sectional data were obtained by conventional anthropometry on persons from birth to 97 years. Overall, nasal growth continued also after 20 years of age, but modifications went on with much reduced speed: for instance, nasal protrusion in men changed from 2.2 cm at 20 years of age, to 2.45 cm at 88 years of age. In the same period, the length of the nasal bridge (n-prn) modified from 5.25 cm to 6.8 cm. Modifications were even smaller in women. As expected, the largest modifications were found for vertical measurements: at 88 years of age, philtrum length (sn-ls) was 1.6 (men) and 1.26 (women) times larger than at 20 years of age.

The age-related modifications found in our laboratory were smaller than those reported by Zankl et al. (2002). We analyzed 859 healthy white Caucasians living in northern Italy (519 men, 340

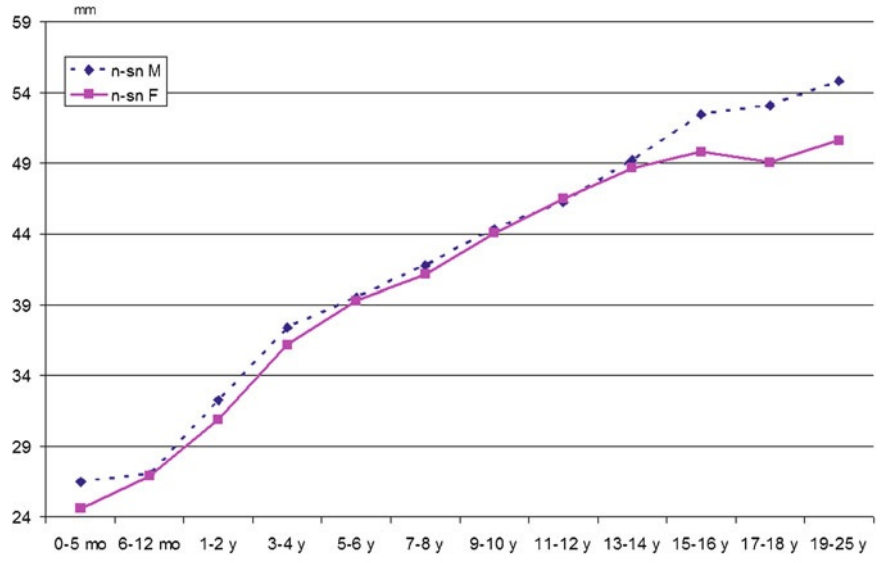

Fig. 55.2 Height of the nose (*n-sn*) in healthy white Caucasians from northern America (Data from Farkas et al. 1994). Continuous line, women (*F*); interrupted line, men (*M*). From birth to young adulthood, nasal vertical dimensions grow in both sexes, with a clear sexual dimorphism

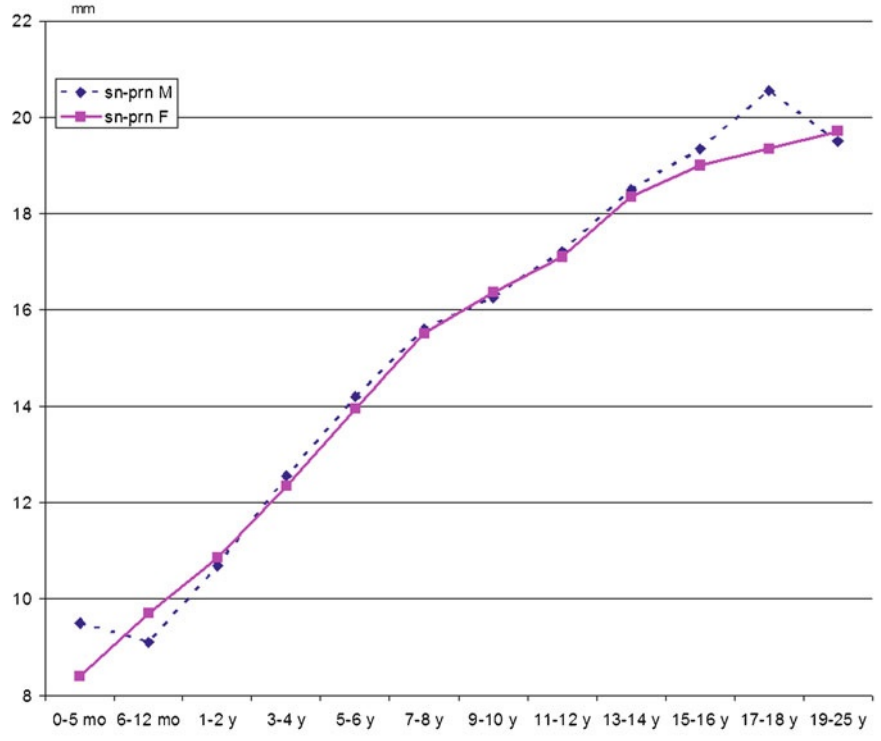

Fig. 55.3 Nasal tip protrusion (*sn-prn*) in healthy white Caucasians from northern America (Data from Farkas et al. 1994). Continuous line, women (*F*); interrupted line, men (*M*). From birth to young adulthood, nasal antero-posterior dimensions grow in both sexes, but male and female data are very similar

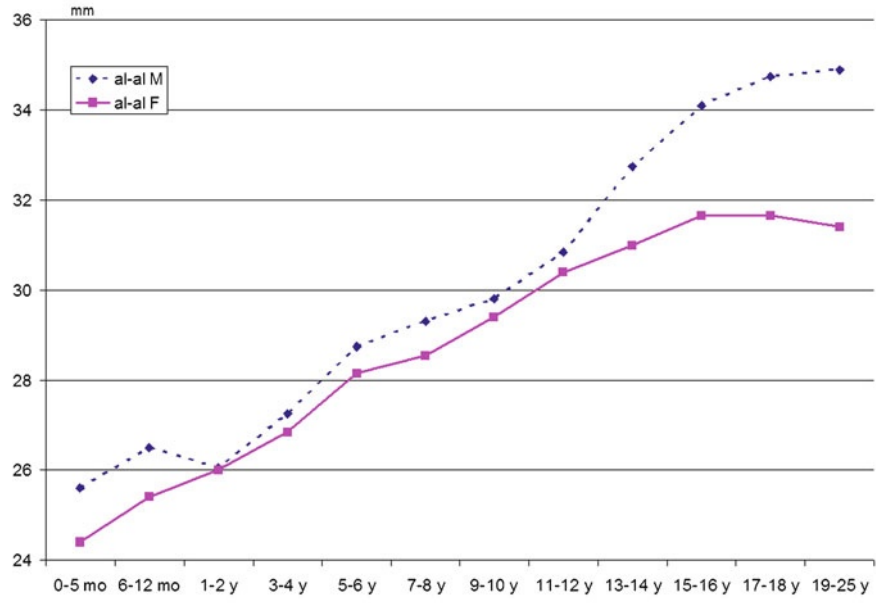

Fig. 55.4 Nasal width (al_r-al_l) in healthy white Caucasians from northern America (Data from Farkas et al. 1994). Continuous line, women (*F*); interrupted line, men (*M*). From birth to young adulthood, nasal horizontal dimensions grow in both sexes; sexual dimorphism becomes larger after adolescence

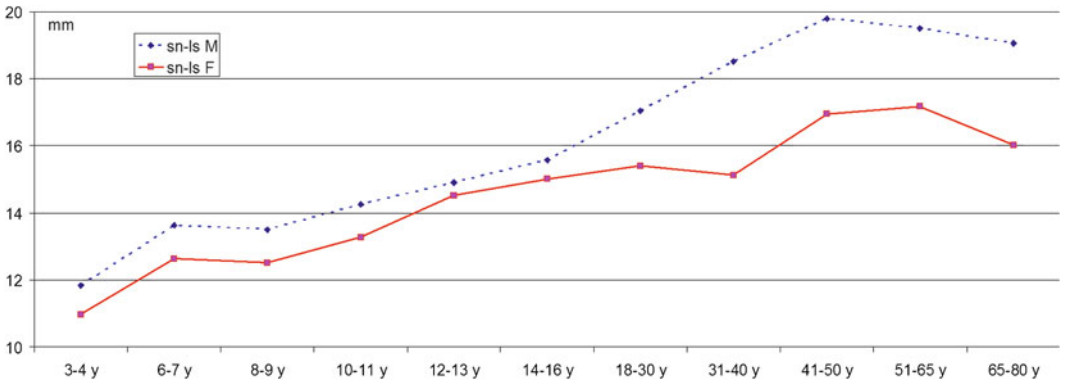

Fig. 55.5 Philtrum length (*sn-ls*) in healthy white Caucasians from northern Italy. Continuous line, women (*F*); interrupted line, men (*M*). From childhood to old age, nasal vertical dimensions grow in both sexes, with a clear sexual dimorphism

women) from 3 to 73 years of age, using digital anthropometry (details are provided in the chapter "Three-dimensional facial morphometry: from anthropometry to digital morphology" in this book). Overall, from young adulthood (18–30 years of age) to old age (65–80 years of age) philtrum length increased 1.12 (men) and 1.04 (women) times (Fig. 55.5). Also, the values reported by Zankl et al. (2002) were somewhat larger than those found in our laboratory.

Data collected in our laboratory were also smaller than those reported by Farkas et al. (1994), even if similar age-related trends were observed: the largest modifications were found for the vertical distance (nasal height, Fig. 55.6), intermediate variations for the antero-posterior dimension (nasal tip protrusion, Fig. 55.7), and the smallest ones for the horizontal nasal width (Fig. 55.8).

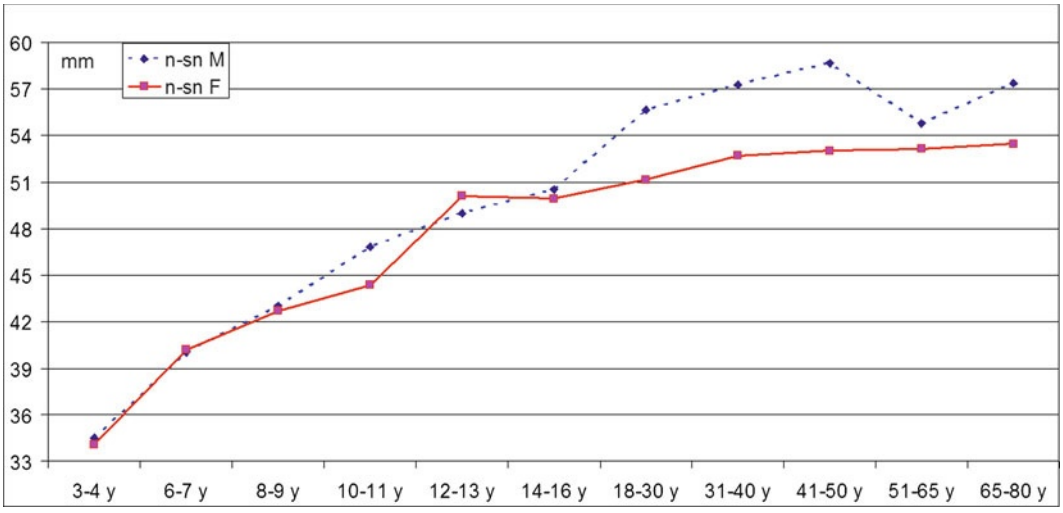

Fig. 55.6 Height of the nose (*n-sn*) in healthy white Caucasians from northern Italy. Continuous line, women (*F*); interrupted line, men (*M*). From childhood to old age, nasal vertical dimensions grow in both sexes; sexual dimorphism is more evident after young adulthood

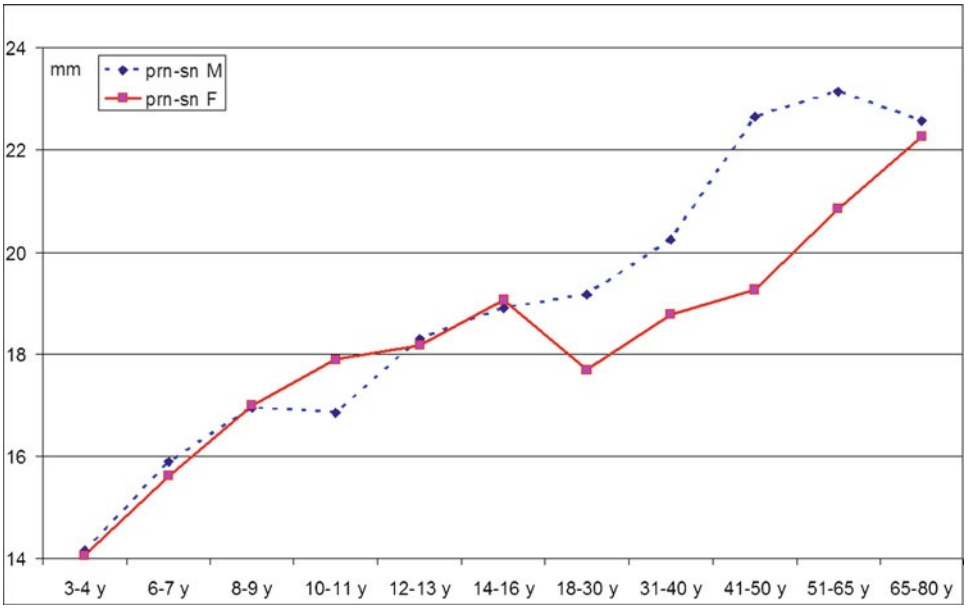

Fig. 55.7 Nasal tip protrusion (prn-sn) in healthy white Caucasians from northern Italy. Continuous line, women (F); interrupted line, men (M). From childhood to old age, nasal antero-posterior dimensions grow in both sexes; sexual dimorphism is more evident after young adulthood

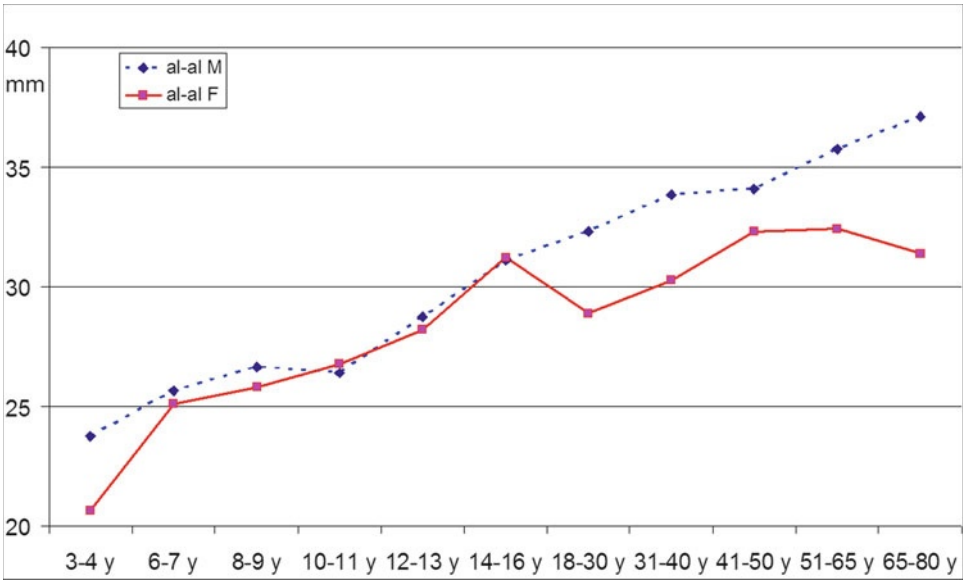

Fig. 55.8 Nasal width (al_r-al_l) in healthy white Caucasians from northern Italy. Continuous line, women (F); interrupted line, men (M). From childhood to old age, nasal horizontal dimensions grow in both sexes; sexual dimorphism is more evident after adolescence

Indeed, differences in the age range, methods, and ethnic origin of the analyzed persons may explain these discrepancies (Aung et al. 2000).

55.3.2 Angles

The largest ethnic variations in the nose are expected in the descriptors of nasal shape, that is, the angles. In young adults, nasal angles were measured both directly by conventional anthropometry, indirectly by digital instruments and photographs, and on stone casts. Direct measurements were made by Farkas et al. (1994) on Northern American white Caucasians (100 men and 200 women), and by Porter and Olson (2003) on 107 African American women. Standardized photographs were taken by Troncoso et al. (2008) in 90 men and 90 women who had at least three generations of Chilean ancestry. Aung et al. (2000) laser scanned the noses of 90 Chinese men and women, while in the current study an electromagnetic digitizer was used on Northern Italian white Caucasians (126 men and 65 women). Rosati et al. (2009) measured the nasal casts of 15 women and 5 men from Northern Italy (Table 55.4).

Overall, the largest nasal tip angle was found in the Italian persons, while the smallest in the Chinese persons. The smallest nasolabial angle was measured in Afro-American women, and the largest in Northern Italian women; intermediate values were reported for Chinese and Northern American persons. In Chinese persons, inter-alar angle was approximately 15° larger than in white Caucasians, while the difference in interaxial angle reached 25–30°. Adult Chileans had the smallest interalar angles.

Table 55.4 Nasal angles in healthy young adults in different ethnic groups

Angles (degrees)		Chinese (Aung et al. 2000)	North America (Farkas et al. 1994)	North Italy (current study)	North Italy (Rosati et al. 2009)	Chilean (Troncoso et al. 2008)	Afro-American (Porter and Olson 2003)
Nasal tip	M	82.55	71.7	93.84	–	–	–
(n-prn-sn)	F	83.87	67.4	94.99	–	–	–
Nasolabial angle	M	99.91	99.8	126.84	–	104.8	86
(prn-sn-ls)	F	97.71	104.2	127.06	–	109.9	–
Inter-alar angle	M	89.07	–	75.43	77.5	67.84	–
(al_r-prn-al_l)	F	90.89	–	74.45	–	68.62	–
Inter-axial angle	M	75.07	–	–	49.6	–	–
(stn_r-itn_r^stn_l-itn_l)	F	80.67	–	–	–	–	–

Each ethnic group possesses a specific nasal shape that can be described by a set of angles. The table reports some examples in several ethnic groups

55.3.3 Volume

Nasal volume was assessed only in a limited number of investigations. Ferrario et al. (1997) reported data collected on 402 children aged 6–14 years, and on 101 young adults, using a simplified mathematical calculation. Starting from the 3D coordinates of five soft-tissue facial landmarks (ac_r, ac_l, prn, n, and sn), they reconstructed nasal morphology using two tetrahedra: the first tetrahedron had the plane ac_r, ac_l, prn as its base and vertex in n, the second had the same base and vertex in sn. Euclidean geometry provided the volumes of the two tetrahedra, and reference data for healthy children and adults were calculated. Data were used to assess the final surgical outcome of a group of patients operated for cleft lip and palate (Ferrario et al. 2003).

Heidari et al. (2009) measured the nose characteristics of 200 Baluch and 200 Sistani adult women from Iran, and estimated nasal volume using the same method proposed by Ferrario et al. (1997). On average, the noses of their women were 1.3–1.4 times larger than those estimated from Northern Italian women (Fig. 55.9).

More recently, Ferrario et al. (2007) compared their simplified calculations with values obtained from a surface-based NURBS approach, as detailed in the section "*Nose reproduction: stone casts and digital models*" of this same chapter. In the simplified landmark-based approach, nasal volumes ranged between 3.2 and 8.1 mm^3, and between 12.6 and 23.8 mm^3 in the surface-based approach. On average, nasal volumes obtained by the surface-based approach gave values that were 3.5 times larger than those computed with the landmark-based approach (ratios ranging between 2.8 and 4.7 mm^3/mm^3). The two measurements were highly related to each other, and a linear regression equation was obtained to convert landmark-based values to surface-based volumes. Indeed, the surface-based nasal volumes should directly correspond to the actual nasal volumes.

During growth, nasal volumes progressively increased from childhood to young adulthood, but their modifications continue even after the attainment of skeletal maturity (Fig. 55.9). In children aged 3–4 years, nasal volume is approximately 36% (boys) and 42% (girls) of the mean value attained in young adulthood (between 18 and 30 years of age). In old adults aged 65–80 years, nasal volume is 120% (men) and 118% (women) of the mean value of the 18–30 age group.

If the equation proposed by Ferrario et al. (2007) for young adults is applied to the all adult groups measured in the current study, mean adult nasal volumes should range between 16.6 mm^3 (18–30 years old women) and 19.17 mm^3 (51–64 years old men). Obviously, this equation was tested

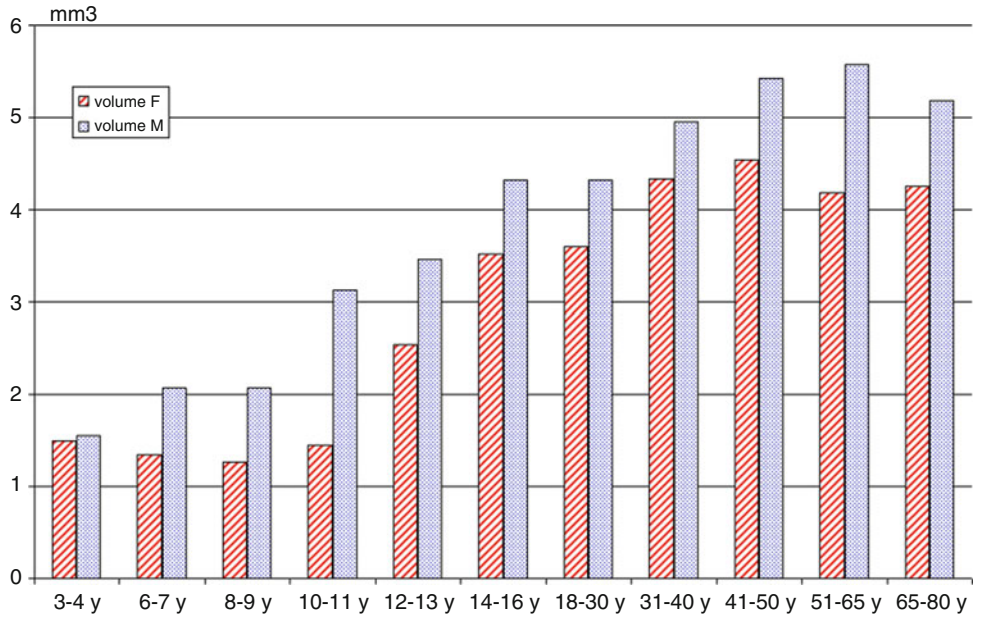

Fig. 55.9 Nasal volume in healthy white Caucasians from northern Italy. Lines, women (F); dots, men (M). From childhood to old age, external nasal volume grows in both sexes; sexual dimorphism is always evident

only in a small group of young adults within a limited age range, and further analyses are necessary to develop conversion algorithms that could provide the actual values of nasal volumes at all ages and in both sexes.

55.4 Applications to Other Areas of Health and Disease

Anatomical and anthropometric descriptions of humans (both living and dead) and clinical applications, both need a quantitative assessment of facial characteristics. The clinical, qualitative description of facial alterations should be supported by well-selected quantitative data that may provide appropriate information for diagnosis, treatment planning, and the evaluation of results (Yamada et al. 1999; Russell et al. 2000; Ferrario et al. 2003; Liou et al. 2004; Baeyens et al. 2006; Daelemans et al. 2006; Honrado et al. 2006; Schwenzer-Zimmerer et al. 2008a, b; Troncoso et al. 2008). In plastic, reconstructive, and cosmetic surgeries, a quantitative approach can be useful to compare the outcome of different surgical procedures or intervention schedules, and it may also assist in the identifications of those facial areas susceptible of surgical intervention (Ferrario et al. 2003).

Nasal size and shape in the different ages and ethnic groups may also be usefully employed for forensic reconstructions (Troncoso et al. 2008). Considering that the nose continue to modify even after the attainment of biological maturity, its age-related variations may help in the aging of both living and dead persons, as well as in personal identification (Rynn and Wilkinson 2006; Sforza et al. 2009). The definition of age-, sex- and ethnic-specific databases may help in the identification of those individual facial features that best discriminate among persons. Facial reconstructions from

skeletal remnants and artificial aging also need data collected from living persons of the widest possible age span, supplying information that may help in simulating the modifications of facial features during normal growth and aging (Troncoso et al. 2008).

55.5 Conclusions

Quantitative data should always come with qualitative anatomical description to allow a deeper understanding of the processes that regulate growth and development, normality, and alterations (Spalding and Vig 1990; Ferrario et al. 1997). In a clinical context, a quantitative description of the outcomes, both immediate and during longitudinal evaluations, gives support to the improvement of surgical procedures, allowing the choice of the best timing of intervention (Honrado et al. 2006; Schwenzer-Zimmerer et al. 2008a, b). In particular, the use of current digital 3D methods adds to linear dimensions and angles (those given by direct anthropometry, Farkas et al. 1994; Zankl et al. 2002), areas, and volumes.

Literature reports several studies about nasal morphology; quantitative investigations underlined that nasal growth does not stop in early adulthood, but it continues even in old age (Zankl et al. 2000). Nasal dimensions do not modify at the same rate: vertical distances tend to increase more and faster than antero-posterior and horizontal ones. These characteristics should be considered when planning plastic, reconstructive, and cosmetic surgeries (Honrado et al. 2006; Schwenzer-Zimmerer et al. 2008a, b), as well as when reconstructing facial characteristics in forensic anthropology (Rynn and Wilkinson 2006; Troncoso et al. 2008).

Most previous studies found a moderate level of asymmetry even in normal, healthy individuals (as reviewed by Rosati et al. 2009). In particular, directional asymmetry may be the effect of possible repeatable environmental factors.

The nostrils had the largest asymmetry (Rosati et al. 2009). This part of the nose was often assessed from nasal stone casts, as described in this same chapter. The principal limit of the method for nose casts was that it requires labor, and a lot of collaboration from the subjects (Ferrario et al. 2007). Alternative procedures that directly digitize nasal morphology using optical devices (Yamada et al. 1999; Aung et al. 2000; White et al. 2004; Mori et al. 2005) have been used by some investigators. It has to be underlined that the nose itself produces a shadow that limits nostril imaging. Additionally, nose hairs (especially in men) produce artifacts, making the final 3D reconstruction inaccurate (see the chapter "Three-dimensional facial morphometry: from anthropometry to digital morphology" in this same book). Indeed, a recent study where the faces of patients with cleft lip were imaged using portable laser scans, found that only two thirds of the scans were free from imaging artifacts in the nasolabial area (Schwenzer-Zimmerer et al. 2008b). Therefore, the use of plaster models still maintains its validity when a detailed analysis of nostrils is needed.

Nonetheless, direct contact with calipers, as well as the effect of the impression material during the production of a nasal cast, may artificially increase nasal asymmetry, especially in the nostril area, where the cartilaginous support is more limited, and deformations may become larger.

Additionally, the use of less invasive optical instruments may provide the best patient compliance, especially when repeated, longitudinal measurement should be made (Yamada et al. 1999; Baeyens et al. 2006; Daelemans et al. 2006; Honrado et al. 2006; Schwenzer-Zimmerer et al. 2008a, b). Unfortunately, their actual performance for selected nasal base measurements is still unknown.

A further question is the effect of race/ethnicity on nasal dimensions and shape. Surgeons and forensic anthropologists should use reference, normative data collected on the population most similar to the individual patient (Table 55.5).

Table 55.5 Key points in age-, sex- and ethnic-related variations in nasal dimensions

	Adult dimensions at	Old age increment	Sexual dimorphism	Ethnic/racial variations
Vertical dimensions	13–14 years (females) 18 years (males)	104–126% (women), 110–160% (men)	✓	✓
Horizontal dimensions	15 years (females), 20 years (males)	109% (women), 115% (men)	✓	✓
Antero-posterior dimensions	15–16 years	115%	=	✓
Angles	12–13 years	Variable	Variable	✓
Volume	14–16 years (females), 16–18 years (males)	118–120%	✓	?

The various nasal dimensions modify in different ages of life, with different patterns in the two sexes and in the various ethnic groups

Summary Points and Practical Methods

- Together with conventional anthropometry, digital anthropometry as well as plaster casts can be used to investigate nasal morphology from a quantitative point of view.
- Less invasive optical instruments may provide the best results, but their actual performance for selected nasal base measurements is still unknown.
- To provide a complete evaluation of any patient, individual values should be compared to those collected in healthy subjects of the same age, sex, race, and ethnic group.
- Surgical reconstructions should attentively consider the different growth potentials and timing of the various nasal structures.
- Three-dimensional nasal reconstructions can be profitably used in several medical and forensic fields.

Chapter 56
Imaging Techniques for the Measurement of Liver Volume

Ferruccio Santini, Monica Giannetti, and Aldo Pinchera

Abstract Assessment of liver volume may be of great relevance in the clinical management of several hepatic diseases as well as systemic disorders associated with liver involvement. With the increasing use of innovative strategies in liver resection and partial transplantation, in vivo measurement of liver volume has become of major interest. Liver volume has also been proposed as a sensitive indicator of ectopic adiposity and associated metabolic disorders in obese subjects. Several formulae have been developed for the estimation of standard liver size, based on anthropometric measures. Most data have been generated in the research areas of liver transplantation and computation of the body surface area, body weight, age, and/or gender. Several methods for measuring liver volume using Computerized Tomography (CT) or Magnetic Resonance (MR) have been described, which apply automatic or semiautomatic segmentation and subsequent reconstruction by the summation of the products of section thickness and area of the segmented liver in each section. Ultrasonography has also been employed for the estimation of liver volume. The left lateral segment of the liver can be easily visualized in its entirety by ultrasound examination, and measurement of the hepatic left lobe volume has been employed to objectively evaluate the extent of liver involvement in nonalcoholic fatty liver disease of obese subjects.

56.1 Introduction

The liver is a large organ located in the upper right-hand portion of the abdominal cavity, extending from the right lateral aspect of the abdomen transversely toward the xiphoid. The weight of the adult liver varies from 1,200 to 1,800 g, depending on the body size, and constitutes about 2–3% of the total body weight of an adult. Based on external appearance, four lobes are traditionally described: right, left, quadrate, and caudate. The 2 main lobes (right and left) are anatomically divided by the falciform ligament on the anterosuperior surface and by the fissures for the ligamentum venosum and ligamentum teres on the visceral surface (Skandalakis et al. 2004). Liver weight increases with age, reaching the highest values in the fifth to sixth decades, with males showing greater volumes (Choukèr et al. 2004).

Assessment of liver volume may be of great relevance in the clinical management of several hepatic diseases as well as systemic disorders associated with liver involvement. It may be useful to evaluate the progress of hepatic failure, to plan radiotherapy dosimetry, and to assess the responses to treatments. With the increasing use of innovative strategies in liver resection and partial transplantation, in vivo measurement of liver volume has become of major interest (Reiner et al. 2009). Successful liver transplantation is the result of several factors, including reliable volumetric estimation of the hepatic segments of living donors. This is crucial to provide suitably sized grafts for the recipient, without compromising liver function of the donor after resection. Sedentary lifestyle and poor dietary choices have led to an obesity epidemic associated with the risk for developing metabolic syndrome and nonalcoholic fatty liver disease (NAFLD) (Table 56.1). Liver disease of metabolic origin, associated with obesity, is now recognized as the most prevalent liver disease in Western countries. The histological spectrum of NAFLD ranges from simple steatosis, which in general

Table 56.1 Key features of Nonalcoholic fatty liver disease (NAFLD)

1. The term Nonalcoholic fatty liver disease (NAFLD) has been introduced to indicate a clinicopathologic syndrome that encompasses a broad spectrum of hepatic lesions, ranging from simple steatosis to necroinflammatory lesions and fibrosis
2. NAFLD is a common finding in obese subjects.
3. Among obese subjects, NAFLD is frequently observed in patients with the metabolic syndrome.
4. Visceral adiposity and insulin resistance are viewed as the key factors in the development of the metabolic syndrome.
5. The metabolic syndrome represents a clustering of risk factors for cardiovascular diseases.
6. Increasing evidence has been provided suggesting that NAFLD represents the hepatic component of the metabolic syndrome.

This table lists the key facts of NAFLD. Liver enlargement due to diffuse accumulation of triglycerides in hepatocytes is a common finding in obese subjects. NAFLD is the result of a multi-factorial process, and there is increasing evidence that NAFLD represents the hepatic component of the metabolic syndrome

follows a benign nonprogressive clinical course, to nonalcoholic steatohepatitis (NASH), which is a more aggressive form of liver injury that may progress to cirrhosis and end-stage liver disease (Marchesini et al. 2008; Myers 2009). At present, liver biopsy represents the most reliable tool to establish the severity of hepatic involvement. However, due to the complexity of this procedure and the growing prevalence of NAFLD, the identification of effective noninvasive tools for the diagnosis and staging of this liver disease has emerged as a major clinical and research priority. Furthermore, liver enlargement appears related to the extent of the metabolic derangement that is associated with visceral obesity, and liver volume has been proposed as a sensitive indicator of ectopic adiposity and related metabolic disorders in obese subjects (Santini et al. 2007).

Manual assessment of liver volume by palpation and percussion lacks both accuracy and reliability, especially in obese subjects. Formulae based on anthropometric measures can calculate the expected normal liver volume, which can be taken as a standard reference to assess adequacies of graft size in living donor before liver transplantation or remnant liver after major hepatectomy. An accurate noninvasive in vivo volumetry of individual livers may be performed by imaging techniques.

56.2 Estimation of the Standard Liver Volume by Formulae Based on Anthropometric Measures

Several formulae have been developed to estimate normal liver size, the ultimate goal being to find the method that most often leads to appropriate clinical decision-making. Most data have been generated in the research area on liver transplantation. An accurate pretransplant estimation of standard liver volume is indeed crucial to provide an adequate hepatic mass to the recipient while ensuring donor safety. Most formulae include the body surface area (BSA), as the best index that correlates with liver volume. Other formulae compute the body weight, age, and/or the gender (Table 56.2). Yet, several differences have been observed among formulae derived from various ethnic groups, thus suggesting that a formula may be necessary for each local population.

Table 56.2 Reported formulae for the estimation of standard liver volume (LV), based on anthropometric measures

Author	Formula	LV (mL) ± SD
DeLand and North (1968)	LV = 1,020 × BSA - 220	1400.41
Urata et al. (1995)	LV =706.2 × BSA + 2.4	1195.34 ± 112.64
Lin et al. (1998)	LV = 13 × BH + 12 × BW – 1,530	1364.41 ± 212.94
Heinemann et al. (1999)	LV =1072.8 × BSA – 345.7	1466.52 ± 171.11
Lee et al. (2002)	LV = 691 × BSA + 95	1022.95
Vauthey et al. (2002)	LV = 1267.28 × BSA - 794.4	1355.77 ± 200.95
Choukèr et al. (2004)	LV = 16.98 × BW + 591.82	1666.55 ± 152.09
Yu et al. (2004)	$LV = 21.585 \times BW^{0.732} \times BH^{0.225}$	1414.67 ± 160.17
Chan et al. (2006)	LV = 218.32 + BW × 12.3 + gender × 51 (M = 1; F = 0)	927.54 ± 168.78
Hashimoto et al. (2006)	LV = 961.3 × BSA - 404.8	1219.07 ± 153.33
Yuan et al. (2008)	LV = 949.7 × BSA - 48.3 × age-247.4 (<40 years = 1; 41–60 years = 2; >61 years = 3)	1290.18 ± 156.40
Yoshizumi et al. (2008)	LV = 772 × BSA	1308.84 ± 122.41

Several formulae have been developed for the estimation of the normal liver size. Most formulae include the BSA as the best index that correlates with liver volume. Other formulae compute the body weight, age, and/or the gender. Yet, several differences have been observed among formulae derived from various ethnic groups, thus suggesting that a formula should be created for each local population

56.3 Measurement of Liver Volume by Computed Tomography (CT)

Several methods for measuring liver volume using CT have been described. Early methods require manual tracing of the entire liver contour on every CT slice. The area of each slice is calculated by a computer using mathematical algorithms and the volume is reconstructed by summation of the products of the section thickness and area of the segmented liver in each section (Heymsfield et al. 1979; Fritschy et al. 1983; Emiroglu et al. 2006). While yielding very accurate results, manual methods are time-consuming processes that require considerable user involvement in the segmentation of the liver on each section.

More recent methods apply automatic or semiautomatic segmentation (Gao et al. 1996; Sandrasegaran et al. 1999; Schroeder et al. 2002; Hermoye et al. 2005; Nakayama et al. 2006). These systems use mathematical computerized models that provide an estimation of CT value of the liver to determine the boundaries of liver in each section. The results of liver volumetry are dependent on the slice thickness, and a 6-mm slice has been proposed as the preferred slice thickness for CT imaging (Reiner et al. 2009). Because the liver density is similar to the density of surrounding tissues, automatic techniques have been developed after intravenous or intra-arterial infusion-iodinated contrast material to provide better delineation of the liver edge.

56.4 Measurement of the Liver Volume by Magnetic Resonance (MR)

As for CT, MR imaging offers an accurate means of determining adult liver volume, and it now plays a major role in the evaluation of the living donor before liver transplantation. MR imaging of the liver has evolved in recent years mainly due to the development of fast imaging techniques that provide superior-quality, high-resolution images in a breath hold. By using the generated data, 3D reconstructed images of the liver and its vascular anatomy can be created (Marcos et al. 2000; Bassignani et al. 2001; Cheng et al. 2001, Fulcher et al. 2001, Lee et al. 2001; Sahani et al. 2004). A comprehensive MR imaging examination includes parenchymal assessment for focal or diffuse abnormalities; MR angiography for delineation of vascular anatomy; MR cholangiography for biliary branching anomalies. Diffuse liver diseases like fatty infiltration and hemochromatosis can be diagnosed at MR imaging due to the signal intensity changes they produce with the different pulse sequences.

A simple, diameter-based formula, applied to CT and MR cross-sectional images has recently been proposed for calculation of total liver volume (Muggli et al. 2009). The volume formula for a tetrahedron was used as a starting point to define a new formula. The ground area was defined as the product of the maximal craniocaudal (CC), ventrodorsal (VD), and coronal (COR) liver diameters. A quotient was calculated and the following formula was obtained: Liver volume = CC × VD × COR × 0.31. The estimated volumes showed a highly significant correlation with the virtual volumetric measurement obtained by a dedicated computer software.

56.5 Measurement of the Liver Volume by Ultrasound (US)

Ultrasonography represents an easy and reliable tool for the estimation of visceral adiposity through measurement of visceral fat thickness. Ultrasonography may also provide semi-quantitative information on the degree of liver steatosis (Joseph et al. 1991; Mathiesen et al. 2002), and it has been

Table 56.3 Key features of liver ultrasonography

1. Liver ultrasonography may be of great relevance in the clinical management of several hepatic diseases as well as systemic disorders associated with liver involvement.
2. Ultrasonography may provide semi-quantitative information on the degree of liver steatosis.
3. Ultrasonography can be employed for the detection of liver masses.
4. Ultrasonography can be employed for the estimation of liver volume.
5. The left lateral segment of the liver can be easily visualized in its entirety by ultrasound examination.
6. Measurement of the hepatic left lobe volume (HLLV) has been employed to objectively evaluate the extent of liver involvement in nonalcoholic fatty liver disease of obese subjects.
7. HLLV can be used as an anthropometric marker of visceral obesity and related co-morbidities.
8. Ultrasonography is handy, little expensive, and easily feasible in an ambulatory setting.
9. Ultrasound measurement of HLLV is a reliable and simple tool for the estimation of liver enlargement in several clinical circumstances.

This table lists the key facts of liver ultrasonography. Ultrasonography represents an easy and reliable tool for the estimation of visceral adiposity through the measurement of visceral fat thickness, may provide semi-quantitative information on the degree of liver steatosis and it has been employed for the estimation of liver volume

employed for the estimation of liver volume (Carr and Duncan 1976; Fritschy et al. 1983; Van Thiel et al. 1985; Leung et al. 1986) (Table 56.3). Sonographic preoperative assessment of liver volume before major liver resection has been recently performed (Kitajima et al. 2008). In that study, liver was divided into three main compartments: segments II–III (left lateral segment) were configured as a quarter of an ellipsoid, segments V–VIII (right lobe) were configured as an ellipsoid, and segment IV was configured as a section of a cylinder. The volume of each compartment was calculated from three measures obtained by ultrasound examination. A fair correlation was observed between estimated volumes and the volume of actual specimens after hepatectomy. However, ultrasonographic measurement of liver volume presents objective difficulties. Indeed, the liver shows wide individual variation, and the scanning fields may be hindered by the bowels or the lungs, particularly in obese subjects. The left lateral segment of the liver can be easily visualized in its entirety by ultrasound examination, even in subjects with severe abdominal obesity. Measurement of the hepatic left lobe volume (HLLV) has been employed in patients scheduled for liver transplantation (Hatsuno et al. 2002). In a recent study (Santini et al. 2007), the ellipsoid formula (width × height × length × 0.52) was applied to calculate the hepatic left lobe volume in obese subjects. The height (longitudinal diameter) of the lobe was obtained on an epigastric-longitudinal scan, considering the distance between the diaphragm and the lower margin of the left lobe. The length of the lobe (lateral–lateral diameter) was calculated on the axial scan by drawing a line between the round ligament and the lateral margin of the hepatic lobe. Thickness was obtained on both the axial and the longitudinal scans, measuring the distance between the anterior and the posterior borders of the liver. To validate the ultrasound procedure, sonographically measured HLLV was compared with the total liver volume as measured by MR and dedicated software. A highly significant positive association was demonstrated. The mean ± SD value of HLLV in obese women was 431 ± 214 mL (range = 46–1,019 mL) while it was 187 ± 31 mL (range 143–258 mL) in the normal weight group. A close association between HLLV and several anthropometric and serologic parameters that may be altered in obese subjects was demonstrated. In particular, in a multiple logistic regression analysis, intra-abdominal fat was the only anthropometric measure independently associated with HLLV (Fig. 56.1). Furthermore, a significant association was observed between HLLV and serum liver enzymes, fasting glucose, insulin, uric acid, CRP, triglycerides, and HDL-cholesterol (Fig. 56.2). Finally, a positive association between HLLV and systolic or diastolic blood pressure was observed. For all these parameters, the association with HLLV was stronger than that observed with ultrasound measured intra-abdominal fat. Using the linear regression formulas, the values of HLLV corresponding to the

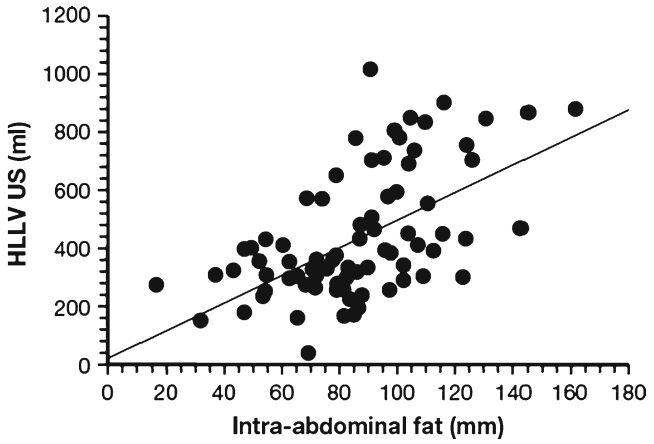

Fig. 56.1 Correlation between hepatic left lobe volume (*HLLV*) and intra-abdominal fat in obese women. A highly significant ($p < 0.0001$, $R = 0.572$) positive association between HLLV and intra-abdominal fat was observed. In a multiple logistic regression analysis including BMI, weight, and intra-abdominal fat, the latter was the only anthropometric measure independently associated with HLLV (From Santini et al. (2007). With permission)

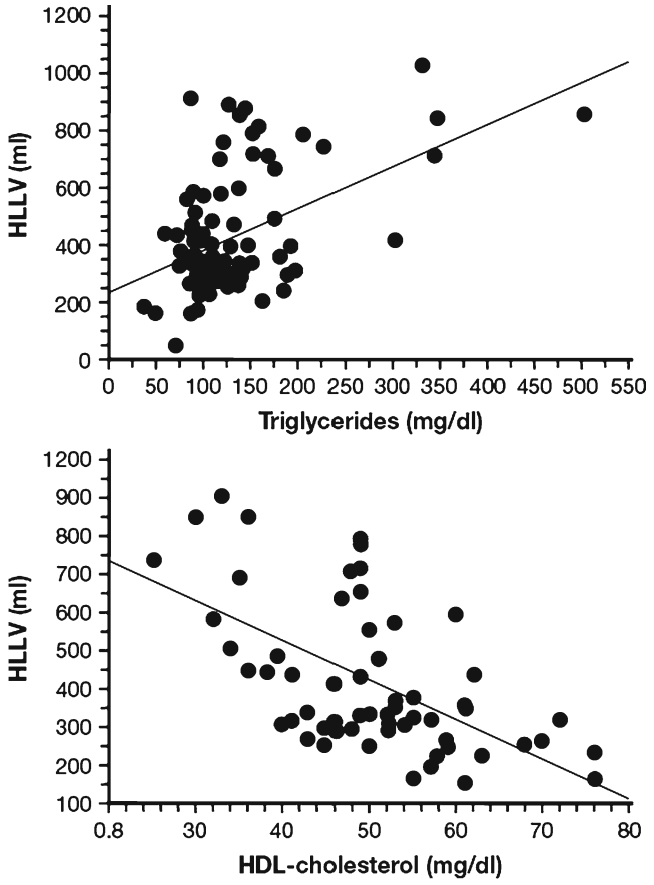

Fig. 56.2 Correlations between hepatic left lobe volume (*HLLV*) and serum indexes of lipid metabolism in obese women. A positive correlation between HLLV and triglycerides ($p < 0.0001$, $R = 0.485$) and a negative correlation between HLLV and HDL-cholesterol ($p < 0.0001$, $R = -0.583$) were observed (From Santini et al. (2007). With permission)

Table 56.4 Cut-off values of the risk factors for the metabolic syndrome and HLLV

Risk factors for the metabolic syndrome (cut-off value)	HLLV (mL)
Triglycerides (≥150 mg/dL)	452
High Density Lipoprotein Cholesterol (≤50 mg/dL)	422
Glucose ATP III (≥110 mg/dL)	549
Glucose IDF criteria (≥100 mg/dL)	478
Systolic blood pressure (≥130 mmHg)	443
Diastolic blood pressure (≥85 mmHg)	457
Mean HLLV ± standard deviation (ATP III)	465 ± 49
Mean HLLV ± standard deviation (IDF)	450 ± 20

Modified from Santini et al. (2007)
This table shows the estimated hepatic left lobe volume (HLLV), as assessed by linear regression, at each cut-off point of various risk factors for the diagnosis of the metabolic syndrome, defined according to the criteria of the Adult Treatment Panel III (ATP III) or the International Diabetes Federation (IDF)

cut-off values of various risk factors for the diagnosis of the metabolic syndrome, as proposed by the National Cholesterol Education Program Adult Treatment Panel III or the International Diabetes Federation, were calculated. A mean value of 465 mL (450 mL according to the criteria of the International Diabetes Federation) as the threshold volume matching the outbreak of the syndrome was calculated (Table 56.4). These results suggest that HLLV can be used as an anthropometric marker of visceral obesity and related co-morbidities. While CT and MR are sophisticated techniques unlikely accessible for routine management of obese subjects and, due to technical limitations, they may not be available for the most severely obese patients, ultrasonography is handy, little expensive, and easily feasible in an ambulatory setting. This makes ultrasound measurement of HLLV a reliable and simple tool for the estimation of liver enlargement in several clinical circumstances (e.g. preoperative evaluation of obese candidates to laparoscopic bariatric surgery, follow-up of patients undergoing weight-loss programs).

Summary Points

- The liver is a large organ located in the upper right-hand portion of the abdominal cavity, extending from the right lateral aspect of the abdomen transversely toward the xiphoid.
- The weight of the adult liver varies from 1,200 to 1,800 g, depending on the body size.
- Assessment of liver volume is of great relevance in the clinical management of several hepatic diseases as well as systemic disorders associated with liver involvement.
- Sedentary lifestyle and poor dietary choices have led to an obesity epidemic associated with the risk for developing metabolic syndrome and nonalcoholic fatty liver disease (NAFLD).
- At present, liver biopsy represents the most reliable tool to establish the severity of NAFLD.
- With the increasing use of innovative strategies in liver resection and partial transplantation, in vivo measurement of liver volume has become of major interest.
- Manual assessment of liver volume by palpation and percussion lacks both accuracy and reliability, especially in obese subjects.
- Formulae based on anthropometric measures can calculate the expected normal liver volume.
- An accurate noninvasive in vivo volumetry of individual livers may be performed by imaging techniques.
- Several methods for measuring liver volume using CT have been described.

- MR imaging offers an accurate means of determining adult liver volume, and it now plays a major role in the evaluation of the living donor before liver transplantation.
- Ultrasonography represents an easy and reliable tool for the estimation of visceral adiposity, may also provide semi-quantitative information on the degree of liver steatosis and it has been employed for the estimation of liver volume.

Chapter 57
Epicardial Adipose Tissue Measured by Multidetector Computed Tomography: Practical Tips and Clinical Implications

Tzung-Dau Wang and Wen-Jeng Lee

Abstract Epicardial adipose tissue (EAT) is the fat depot surrounding the heart and is confined within the pericardial sac. It accounts for approximately 20% of the total heart weight and covers 80% of the cardiac surface, mostly in the grooved segments along the paths of the coronary arteries. To clearly delineate the asymmetric distribution of EAT and explore its pathophysiological significance, EAT should be measured in three dimensions using multidetector computed tomography (MDCT): regional thickness, cross-sectional areas, and total volume. Details regarding MDCT measurements of EAT are introduced in this chapter. Regardless of differences in ethnicity and body habitus, EAT thickness in the grooved segments is greater than in the non-grooved segments. Among the grooved segments, the right atrio-ventricular groove (where the right coronary artery is located) has the thickest fat, followed by the left atrio-ventricular groove (where the left circumflex artery and great cardiac vein are located). The maximal EAT thickness surrounding the left anterior descending coronary artery, measured in the superior inter-ventricular groove in the basal short-axis plane, is less than that surrounding the right coronary artery or the left circumflex artery. The average volume of EAT is generally between 110 and 125 cm^3.

Although EAT constitutes only 1% of the total fat mass, several clinical studies have shown that the amount of EAT is associated with obesity, the amount of intra-abdominal visceral fat, cardiometabolic risk factors, cardiac structural changes, coronary atherosclerosis, and the incidence of coronary heart disease events. However, it is still a matter of debate as to whether these associations with EAT are direct or indirect, and which EAT measurement provides the best correlate. It appears that EAT thickness in the left atrio-ventricular groove provides a more accurate assessment of its metabolic and atherogenic risks and is therefore a better indicator of its metabolic risk and a stronger coronary risk factor than total EAT volume. Future studies are critical to elucidate whether there is indeed regional variation in the molecular characteristics of EAT and whether this variation confers any clinical, prognostic, and therapeutic implications.

57.1 Introduction

Fat surrounding the heart resides in two distinct depots separated by the parietal pericardium: the epicardial and paracardial adipose tissues (Rabkin 2007; Sacks and Fain 2007). Epicardial adipose tissue (EAT) is situated on the surface of the heart, especially around the epicardial coronary vessels, and it is confined within the pericardial sac. Paracardial adipose tissue is located on the external surface of the parietal pericardium within the mediastinum and has alternatively been termed mediastinal fat. Pericardial adipose tissue is defined as EAT plus paracardial adipose tissue (Fig. 57.1).

Epicardial and paracardial adipose tissues have different embryological origins (Ho and Shimada 1978). EAT shares a common embryological origin, the splanchnopleuric mesoderm, with intra-abdominal visceral fat depots (mesenteric and omental fat depots). Paracardial adipose tissue originates from the primitive thoracic mesenchyme, which then forms the parietal pericardium and the outer thoracic wall. The vascular supplies of both depots are also different. EAT obtains its vascular supply from the coronary arteries, which together with the epicardium (visceral pericardium) originate from mesothelial cells migrating from the septum transversum (the embryological source of the diaphragm). Paracardial adipose tissue derives its blood supply from non-coronary vessels such as the pericardiacophrenic branch of the internal mammary artery.

Unlike the isolation of paracardial adipose tissue from the heart by the parietal pericardium, there are no fascia-like structures separating EAT and the underlying myocardium (Iacobellis et al. 2005). It is commonly observed that a small amount of EAT extends from the epicardial surface into the myocardium, often following the adventitia of the coronary arteries. This close anatomical relationship between EAT and the myocardium suggests that it may play a role in the development of coronary atherosclerosis and the functional alterations of cardiac structures. Moreover, a growing body of evidence indicates that EAT is a metabolically active visceral fat depot, like intra-abdominal visceral fat. The rate of fatty acid breakdown and the secretion of pro-inflammatory cytokines are even higher in EAT compared with subcutaneous and omental fats (Marchington and Pond 1990; Mazurek et al. 2003; Kremen et al. 2006; Baker et al. 2009). These observations have prompted a resurgence of interest in EAT and its pathophysiological significance.

Several clinical studies have explored the association of EAT with anthropometric indices, the amount of intra-abdominal fat, cardio-metabolic risk factors, and coronary atherosclerosis (Chaowalit et al. 2006; Ahn et al. 2008; de Vos et al. 2008; Gorter et al. 2008a; Rosito et al. 2008; Sarin et al. 2008; Wang et al. 2009a, b). In most of these studies, they either measured the local thickness of EAT over the right ventricular free wall using echocardiography or the total volume of EAT using multidetector computed tomography (MDCT). As the distribution of EAT is asymmetric and mostly localized in the perivascular atrio-ventricular and inter-ventricular grooves (Abbara et al. 2006; Gorter et al. 2008b; Wang et al. 2009b), it is reasonable to question whether global or focal EAT measurements are more appropriate to assess the clinical significance of EAT. Furthermore, how many and which focal EAT measurements should be obtained is still controversial. Among the three imaging modalities (echocardiography, magnetic resonance imaging, and MDCT) used to assess EAT, MDCT offers a novel opportunity to assess the in vivo distribution of EAT in high-resolution three-dimensional

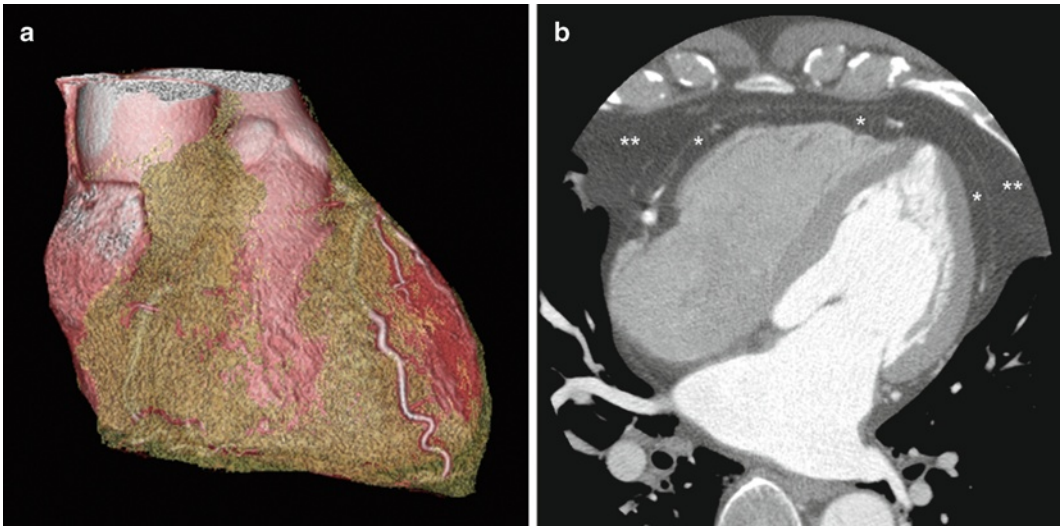

Fig. 57.1 Computed tomographic images of epicardial adipose tissue. (**a**) A three-dimensional volume-rendered computed tomographic image showing the distribution of epicardial adipose tissue around the heart. Epicardial adipose tissue is primarily concentrated in the atrio-ventricular and inter-ventricular grooves along the major branches of the coronary arteries. (**b**) Epicardial and paracardial adipose tissues are separated by the parietal pericardium. *Single asterisk mark* (*) denotes epicardial adipose tissue and *double asterisk mark* (**) denotes paracardial adipose tissue

views. Echocardiogram is dependent on acoustic windows and cannot provide an adequate window to assess all of the cardiac segments, whereas magnetic resonance imaging has spatial resolution limitations in the through plane dimension.

In this chapter, we first introduce the anatomical and physiological characteristics of EAT. Second, we describe how to measure EAT and which measurements should be made by MDCT, together with various EAT topographic data reported in subjects of different ethnic backgrounds. Third, we discuss the clinical significance of EAT by describing the association of various MDCT measurements of EAT with anthropometric indices, metabolic risk factors, coronary atherosclerosis and prevalent cardiovascular diseases, and cardiac structural changes. Finally, we delineate the future perspectives of EAT topographic measurements in different medical research fields.

57.2 Anatomical and Physiological Characteristics of Epicardial Adipose Tissue

Autopsy studies have shown that EAT accounts for approximately 20% of the total heart weight (Corradi et al. 2004). Although left ventricular mass far exceeds that of the right ventricle, the amount of EAT is equally distributed on the surface of the right and left ventricles. As a result, the ratio of EAT to the weight of the myocardium for the right ventricle is more than 3 times that of the left ventricle: 0.54 for the right ventricle and 0.16 for the left ventricle.

The low specific gravity of adipose tissue compared with myocardium indicates that EAT comprises an even higher percentage of the mass volume of the heart. It covers approximately 80% of the cardiac surface area and is primarily present in the grooved segments (Shirani et al. 1995). In normal adults, EAT is concentrated in the atrio-ventricular and inter-ventricular grooves and along the major

Table 57.1 Key features of epicardial adipose tissue

1. EAT is the fat surrounding the heart and within the pericardial sac.
2. EAT accounts for approximately 20% of total heart weight and covers 80% of the cardiac surface, mostly in the grooved segments along the paths of the coronary arteries.
3. The volume of EAT (~120 cm^3) accounts for approximately 20% of total cardiac volume, including the chambers.
4. EAT often extends from the epicardial surface into the myocardium and the adventitia of coronary arteries since there are no fascia-like structures separating EAT and the underlying myocardium.
5. EAT constitutes only 1% of the total body fat mass.
6. EAT shares a common embryological origin, the splanchnopleuric mesoderm, with intra-abdominal fat depots (mesenteric and omental fat) and is also a metabolically active visceral fat depot.
7. The putative physiological functions of EAT include:
   (a) A cushion to buffer the coronary artery against the torsion induced by the arterial pulse wave and cardiac contraction
   (b) A buffering system against toxic levels of fatty acids between the myocardium and the local vascular bed by its ability to rapidly scavenge excess fatty acids
   (c) A local energy source by providing free fatty acids to meet increased myocardial demands, especially under ischemic conditions
   (d) Protecting the ganglia of the intrinsic cardiac nervous system residing in EAT

This table lists the anatomical, embryological, and physiological properties of epicardial adipose tissue. *EAT* epicardial adipose tissue

branches of the coronary arteries, and, to a lesser extent, around the atria, over the free wall of the right ventricle and over the apex of the left ventricle (Fig. 57.1).

The putative physiological functions of EAT are listed in Table 57.1. First, because the coronary arteries and their major branches are embedded in EAT, it has been proposed that EAT functions as a cushion to buffer the coronary artery against the torsion induced by the arterial pulse wave and cardiac contraction. Second, high circulating levels of fatty acids in the coronary microcirculation can interfere with the generation and propagation of the contractile cycle of the heart, causing ventricular arrhythmia and alterations in repolarization. In young adult guinea pigs, the rate of fatty acid synthesis, release, and breakdown in response to catecholamines by EAT is markedly higher than in other adipose depots (Marchington and Pond 1990). Therefore, the second putative function of EAT is that it may act as a buffering system against toxic levels of fatty acids between the myocardium and the local vascular bed by its ability to rapidly scavenge excess fatty acids. Third, the increased lipolytic activity of EAT suggests that this fat depot may serve as a local energy source by providing free fatty acids to meet increased myocardial demands, especially under ischemic conditions. Fourth, EAT is the anatomical site where the intrinsic cardiac nervous system, including numerous ganglia and interconnecting plexuses, are located. Stimuli, such as transient coronary artery occlusion, can modify the activity generated by the intrinsic cardiac nervous system and thereby mediate the pain of angina pectoris. EAT may have a protective role for these ganglia (Rabkin 2007).

57.3 Practical Methods and Techniques: Measurements of Epicardial Adipose Tissue by Multidetector Computed Tomography

Before introducing how to measure EAT by MDCT, the geographical characteristics of EAT should first be reiterated. The distribution of EAT is characterized by its asymmetric distribution and its primary accumulation around the base of both ventricles, especially in the perivascular atrio-ventricular and inter-ventricular grooves, rather than in the non-grooved cardiac surfaces (Abbara et al. 2006; Sacks and Fain 2007). It is obvious that the measurement of total EAT volume alone cannot provide

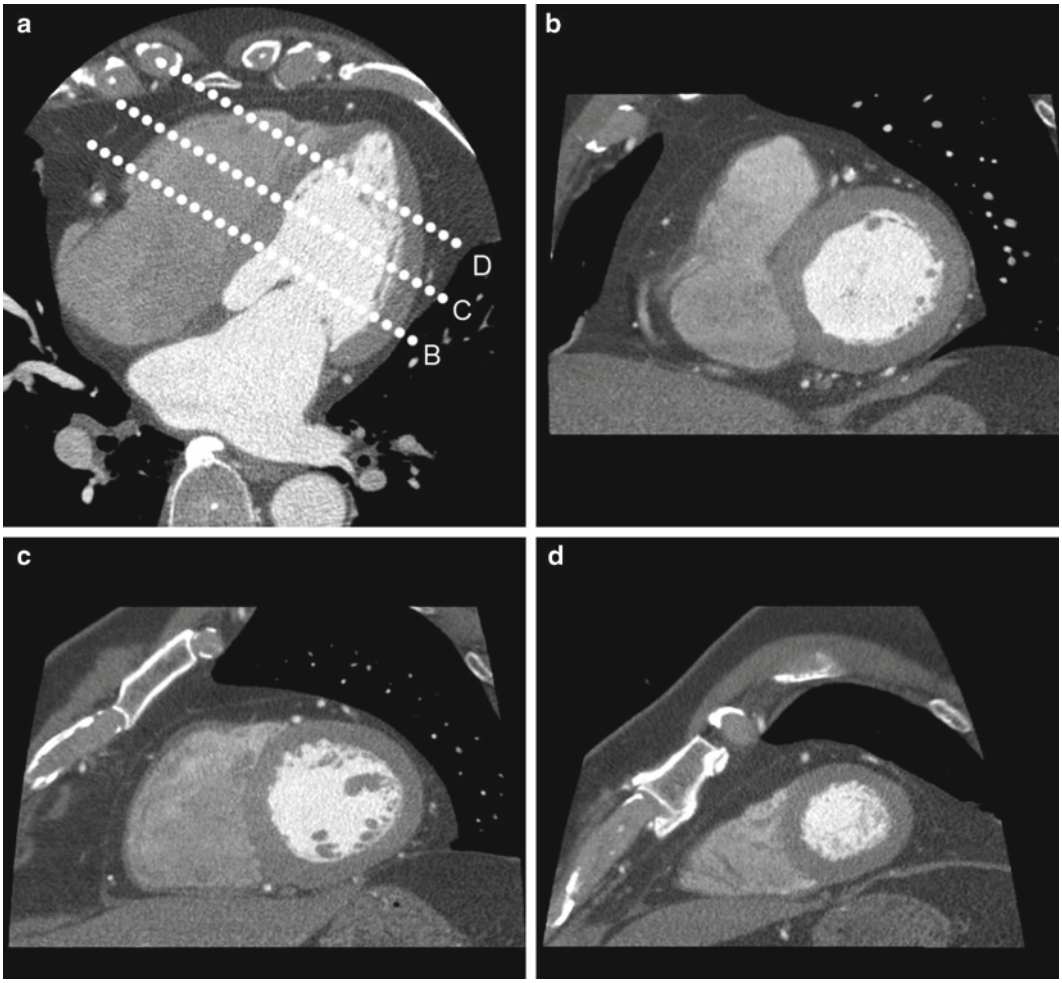

Fig. 57.2 Multiplanar reconstructions of multidetector computed tomographic images of epicardial adipose tissue. Multiplanar reconstructions of multidetector computed tomographic images in the horizontal long-axis (**a**) and short-axis (**b**–**d**) planes are shown. Anatomical landmarks for the selection of the basal (**b**, tips of the mitral valve leaflets), mid-cavity (**c**, papillary muscles), and apical (**d**, beyond the papillary muscles but before the end of the cavity) short-axis slices are displayed. The horizontal long- and short-axis planes are at 90º relative to the long-axis of the left ventricle

relevant information. To clearly delineate the asymmetric distribution of EAT and explore its pathophysiological significance, we propose that EAT should be measured in three dimensions: regional thickness, cross-sectional areas, and total volume (Wang et al. 2009b). Details of how to measure EAT in these three dimensions are described accordingly.

57.3.1 Regional Thickness of Epicardial Adipose Tissue

In order to measure the regional thickness of EAT, the first step is to obtain multiplanar reconstructions of the MDCT data in the standardized ventricular short-axis planes at the basal, mid-cavity, and apical levels, and in the horizontal long-axis plane, as defined by the Cardiac Imaging Committee of the Council on Clinical Cardiology of the American Heart Association (Fig. 57.2) (Cerqueira et al. 2002).

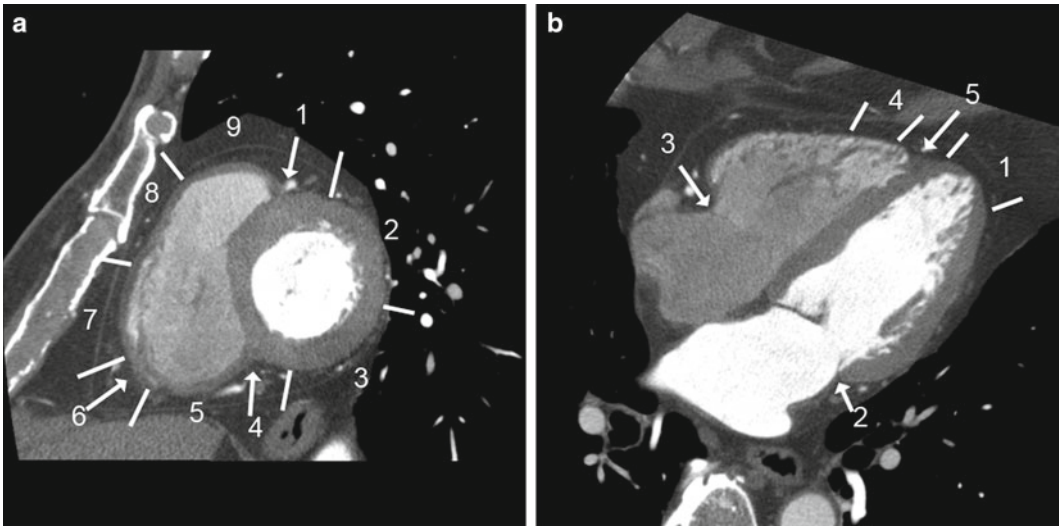

Fig. 57.3 Comprehensive segmentation system for the measurement of regional thickness of epicardial adipose tissue. The segmentation system, proposed by Abbara et al., for the measurement of the regional thickness of epicardial adipose tissue in the short-axis (**a**) and horizontal long-axis (**b**) planes are shown. The 9 short-axis segments are: *1* superior inter-ventricular groove, *2* left ventricular superior lateral wall, *3* left ventricular inferior lateral wall, *4* inferior inter-ventricular groove, *5* right ventricular diaphragmatic wall, *6* acute margin, *7* right ventricular free wall inferior, *8* right ventricular free wall superior, and *9* right ventricular superior wall. The 5 segments in the horizontal long-axis plane are: *1* left ventricular apex, *2* left atrio-ventricular groove, *3* right atrio-ventricular groove, *4* right ventricular apex, and *5* anterior inter-ventricular groove

The short-axis and horizontal long-axis planes are at 90º relative to the long axis of the left ventricle that transects the apex and the center of the mitral valve plane. The MDCT short-axis plane corresponds to the parasternal short-axis plane traditionally used in echocardiography, whereas the horizontal long-axis plane corresponds to the echocardiographic apical 4-chamber plane. The basal level of the short-axis plane is acquired from between the mitral annulus and the tips of the papillary muscles at end-diastole. The mid-cavity level is selected from the middle of the entire length of the papillary muscles. The apical level is selected from the area beyond the papillary muscles to just before the end of the cavity. The slice thickness is set to be 3 mm in our protocol. Image reconstructions are performed at 75% RR intervals (Lee et al. 2008).

The second step is to divide the cardiac surfaces, as shown in the above-mentioned reconstructed MDCT images, into segments. Abbara et al first reported their segmentation system for mapping EAT to facilitate transepicardial arrhythmia ablation (Fig. 57.3) (Abbara et al. 2006). In their system, 9 segments were made at each level of the short-axis slices (27 segments overall), including the superior inter-ventricular groove, left ventricular superior lateral wall, left ventricular inferior lateral wall, inferior inter-ventricular groove, right ventricular diaphragmatic wall, acute margin, right ventricular anterior free wall inferior, right ventricular anterior free wall superior, and right ventricular superior wall. In the horizontal long-axis plane, five segments, including the left ventricular apex, left atrio-ventricular groove, right atrio-ventricular groove, right ventricular apex, and anterior inter-ventricular groove, were obtained. This segmentation system is comprehensive but relatively complex and may exceed practical clinical application. To simplify the segmentation system without sacrificing essential information about the distribution of EAT, we designed a modified segmentation system as described below (Fig. 57.4) (Wang et al. 2009b). As EAT is mostly distributed around the base of both

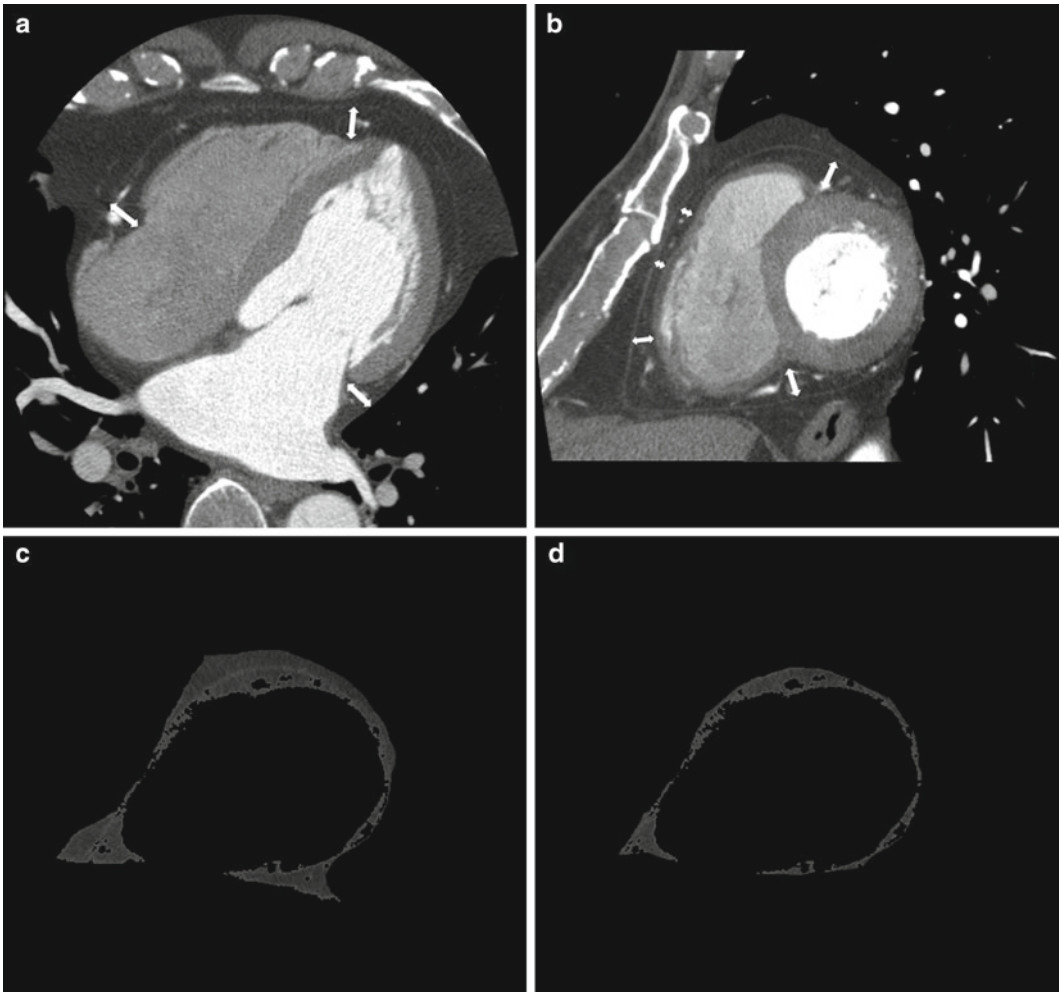

Fig. 57.4 Simplified segmentation system for the measurement of regional thickness of epicardial adipose tissue. Simplified segmentation system for the measurement of the regional thickness of epicardial adipose tissue (**a**, **b**) and cross-sectional areas of intra-thoracic adipose tissues (**c**, **d**) are shown. (**a**) Epicardial adipose tissue thickness in the grooved segments is measured at three sites in the horizontal long-axis plane (right atrio-ventricular groove, left atrio-ventricular groove, and anterior inter-ventricular groove). (**b**) Epicardial adipose tissue thickness in the superior inter-ventricular groove and the inferior inter-ventricular groove and over the right ventricular free wall is measured in the basal short-axis plane. Epicardial fat over the right ventricular free wall is measured at three equally spaced points along the right ventricular free wall (25%, 50%, and 75% of the full length). (**c**) Measurement of the cross-sectional area of pericardial (paracardial plus epicardial) adipose tissue is made by tracing the mediastinum boundary in the short-axis plane. A density range between –30 and –190 Hounsfield Units is used to identify adipose tissue. (**d**) Measurement of the cross-sectional area of epicardial adipose tissue is made by tracing the pericardium

ventricles, only the basal short-axis plane, rather than all three short-axis levels, is used for the measurement of regional EAT. Segmentation is simplified to include only the right ventricular free wall and two grooved segments (superior inter-ventricular groove and inferior inter-ventricular groove), where EAT primarily accumulates. Likewise, three grooved segments in the horizontal long-axis plane (right atrio-ventricular groove, left atrio-ventricular groove, and anterior inter-ventricular groove), rather than non-grooved cardiac surfaces, are chosen. Overall, six segments (five grooved

segments and the right ventricular free wall) are measured in our system. The segment of the right ventricular free wall is selected because this is the only EAT segment that can be assessed reliably using echocardiography, and all previous echocardiographic assessments of EAT were made in this specific location (Iacobellis et al. 2003; Ahn et al. 2008). Given that all coronary vessels are present in the grooved segments and EAT primarily accumulates at the base of both ventricles, the "maximal" pericoronary EAT thickness could be obtained from measurements in the five grooved segments selected in our simplified segmentation system (Fig. 57.5). According to our MDCT findings and those of Abbara et al., the maximal EAT thickness around the left anterior descending artery is found at the superior inter-ventricular groove in the basal short-axis plane, the maximal EAT thickness around the left circumflex artery approximates the thickness measured in the left atrio-ventricular groove in the horizontal long-axis plane, and the maximal EAT thickness around the right coronary artery is close to the thickness measured in the right atrio-ventricular groove in the horizontal long-axis plane (Abbara et al. 2006; Wang et al. 2009b), further ensuring the clinical applicability of our simplified segmentation system. In the report of de Vos et al., maximal EAT thickness surrounding each individual coronary artery was measured in the axial cut that is not perpendicular to the long-axis of the left ventricle and may therefore overestimate EAT thickness by obliquity (de Vos et al. 2008).

The third step is to measure EAT thickness in the pre-defined segments. Maximal EAT thickness perpendicular to the pericardium is recorded in the grooved segments. In the only non-grooved segment chosen in our system (the right ventricular free wall), the averaged thickness orthogonal to the myocardial surface at three equally spaced points is recorded (Fig. 57.4).

Regardless of differences in ethnicity and body habitus, it is consistently observed that EAT thickness in the grooved segments is greater than in the non-grooved segments, including the right ventricular free wall (Table 57.2). Among the grooved segments, the right atrio-ventricular groove has the thickest fat where the right coronary artery is located, followed by the left atrio-ventricular groove where the left circumflex artery and great cardiac vein are found. The maximal EAT thickness surrounding the left anterior descending coronary artery, measured in the superior inter-ventricular groove in the basal short-axis plane, is less than that surrounding the right coronary artery or the left circumflex artery.

57.3.2 Cross-Sectional Areas of Epicardial Adipose Tissue

Measurements of abdominal fat depots usually take the form of cross-sectional areas. Likewise, measurements of EAT cross-sectional areas could be of clinical value. We propose that cross-sectional areas of EAT should be measured in all four MDCT planes (the short-axis planes at the basal, mid-cavity, and apical levels, and the horizontal long-axis plane) for regional EAT thickness measurements.

To obtain EAT cross-sectional areas, measurements of a thin slab volume of EAT from two contiguous images are made by tracing the pericardium. A density range between –30 and –190 Hounsfield Units is employed to identify adipose tissue. The cross-sectional area is determined by dividing the thin-slab volume by the slab thickness (4 mm in our protocol).

Aside from the EAT cross-sectional areas, cross-sectional areas of the pericardial and paracardial adipose tissues can be obtained in the same way (Fig. 57.4). the thin-slab volume of pericardial (epicardial and paracardial) adipose tissue from two contiguous images can be measured by tracing the mediastinum boundary. The thin-slab volume of paracardial adipose tissue is obtained by subtracting the volume of EAT from that of pericardial adipose tissue. Dividing the thin-slab volume by the slab thickness produces the cross-sectional area.

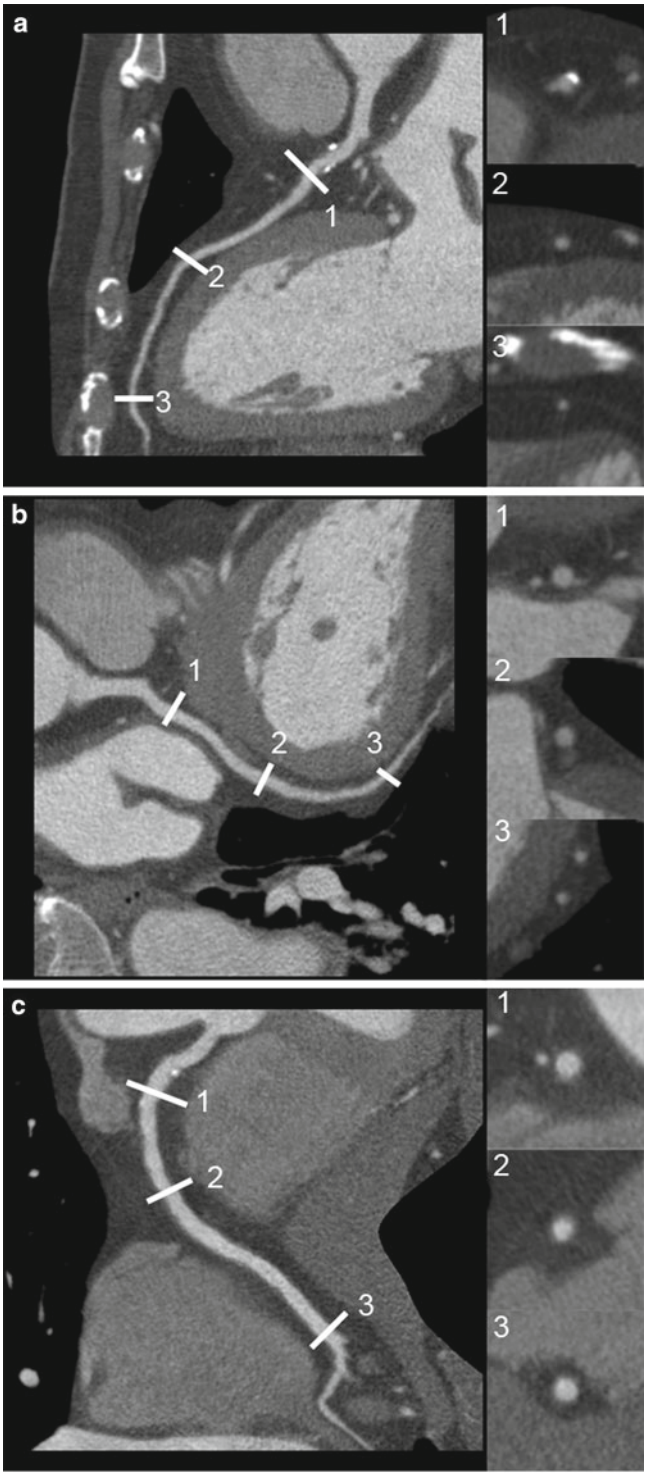

Fig. 57.5 Thickness of epicardial adipose tissue around the coronary arteries at different segments. Thickness of epicardial adipose tissue surrounding the left anterior descending (**a**), left circumflex (**b**), and right (**c**) coronary arteries at the arbitrarily defined proximal (*1*), mid (*2*), and distal (*3*) segments are shown. The maximal epicardial adipose tissue thickness around the left anterior descending artery is in the proximal segment located at the superior inter-ventricular groove in the basal short-axis plane (**a**). The maximal epicardial adipose tissue thickness around the left circumflex artery is also in the proximal segment, approximating the thickness measured in the left atrio-ventricular groove in the horizontal long-axis plane (**b**). The maximal epicardial adipose tissue thickness around the right coronary artery is in the proximal segment, close to the thickness measured in the right atrio-ventricular groove in the horizontal long-axis plane (**c**)

Regardless of differences in ethnicity and body habitus, the thickness of epicardial adipose tissue in the grooved segments is greater than in the non-grooved right ventricular free wall. Values are mean ± SD for quantitative variables and *n* or % for qualitative variables

The cross-sectional areas of epicardial, paracardial, and pericardial adipose tissues have been reported only by our group. We demonstrated that the distribution of EAT is primarily located at the base of both ventricles, with the greatest area obtained in the basal short-axis plane. The distribution of paracardial adipose tissue is similar to that of EAT. However, the amount of paracardial adipose tissue is slightly greater than that of EAT in the parasternal short-axis plane (Table 57.2).

57.3.3 Total Volume of Epicardial Adipose Tissue

To calculate the entire volume of EAT, as well as the other intra-thoracic adipose tissues, all the axial images should be loaded into a workstation, with the pericardium manually traced in these images.

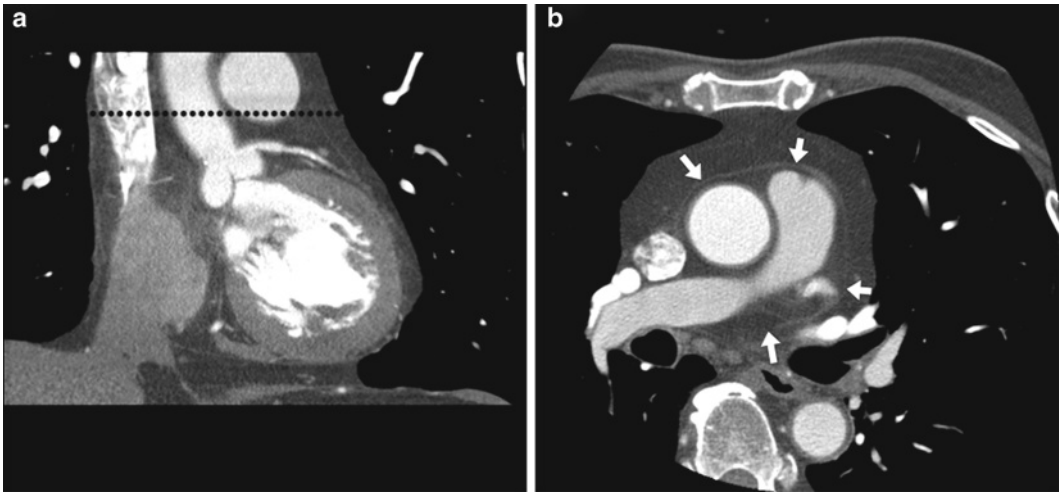

Fig. 57.6 The top boundary for the measurement of total epicardial adipose tissue volume. Method of selection of the top boundary for the measurement of total epicardial adipose tissue volume is shown. (**a**) The top boundary is set to 1 cm above the superior extent of the left coronary artery (*dotted line*). (**b**) The axial cut of the top boundary shows the presence of the right pulmonary artery. The surrounding pericardium is identified by four *white arrows*.

To measure the volume of EAT, the selected top boundary is somewhat different between studies. We set the top boundary at 1 cm above the superior extent of the left coronary artery, and others chose the level of the right pulmonary artery or the bifurcation of the main pulmonary artery (Greif et al. 2009; Mahabadi et al. 2009). In fact, the level we set was approximately at the level of the right pulmonary artery (Fig. 57.6). Conversely, the "exact" level of the right pulmonary artery or the bifurcation of the main pulmonary artery is ambiguous and may vary within the width of the pulmonary artery (~2 cm). The visceral pericardium reflects back near the origins of the great vessels and a few centimeters proximal to the junctions of the caval vessels with the right atrium. Therefore, the top boundary we selected is close to the uppermost level of the pericardium. In the areas above our top boundary, the volume of EAT between the great arteries is minimal and almost negligible. We thus suggest setting the top boundary to 1 cm above the superior extent of the left coronary artery to simplify the measurement procedure and to retain accuracy. The diaphragm is generally set as the lower boundary.

To measure the pericardial adipose tissue volume, the anterior border is defined by the sternum and the ribs, whereas the posterior border is defined by the esophagus and the descending aorta. The volume of paracardial adipose tissue is then derived by subtracting the volume of EAT from that of pericardial adipose tissue.

The average volume of EAT is generally between 110 and 125 cm^3 (ml), despite tremendous heterogeneity in ethnic background, anthropometric features, and underlying medical conditions (Table 57.3). Despite the low specific gravity of adipose tissue and the widespread coverage (~80%) of the cardiac surface, the volume of EAT accounts for approximately 15–20% of the total cardiac volume, including the chambers (Sarin et al. 2008). Intriguingly, this number is close to the ratio of total EAT weight to total heart weight (~20%).

On the basis of a random sample of 60 images evaluated by 2 investigators, we previously demonstrated that intra- and inter-observer reproducibility for all adipose tissue measurements were >0.95 (Wang et al. 2009b).

It is worth mentioning that although the total volume is an overall measure of EAT, the volume of EAT is only moderately correlated with various regional EAT thicknesses. This phenomenon is

Epicardial adipose tissue volume (cm^3)	107 ± 43	140 ± 49	124 ± 50	121 ± 47	110 ± 44

Values are mean ± SD for quantitative variables and *n* or % for qualitative variables

consistent with the fact that EAT is asymmetrically distributed. Moreover, it indicates that the measurement of regional thicknesses could not be replaced by the total EAT volume since it reflects the region-specific characteristics of EAT that might have particular clinical significance.

57.4 Applications to Other Areas of Health and Disease

Although EAT constitutes only 1% of the total fat mass (Rabkin 2007), several clinical studies have shown that the amount of EAT is associated with obesity (generalized and abdominal), cardiometabolic risk factors, cardiac structural changes, coronary atherosclerosis, prevalent cardiovascular diseases, and the incidence of coronary heart disease events. However, it is still under debate as to whether these clinical associations of EAT are direct or indirect. We discuss each of these associations in this section.

57.4.1 Association with Obesity (Generalized and Abdominal)

It has been consistently observed that the volume of EAT is positively related to the extent of obesity. However, the strengths of the associations of total EAT volume with different measures of obesity are varied. Most MDCT studies show that total EAT volume is highly correlated with the amount of intra-abdominal visceral fat (correlation coefficient 0.6–0.8) and is moderately correlated with body-mass index (BMI) – the index of general adiposity – waist circumference – the index of abdominal adiposity (correlation coefficient 0.4–0.6) (de Vos et al. 2008; Rosito et al. 2008; Wang et al. 2009b) (Fig. 57.7). Compared to BMI, total EAT volume is more closely related to waist circumference. These observations are in line with the fact that EAT and intra-abdominal visceral fat depots, but not subcutaneous fat, share a common embryological origin, and therefore a closer quantitative relationship. Among all MDCT measurements of EAT, total EAT volume is most closely related to various obesity measures and is therefore the best indicator of visceral obesity.

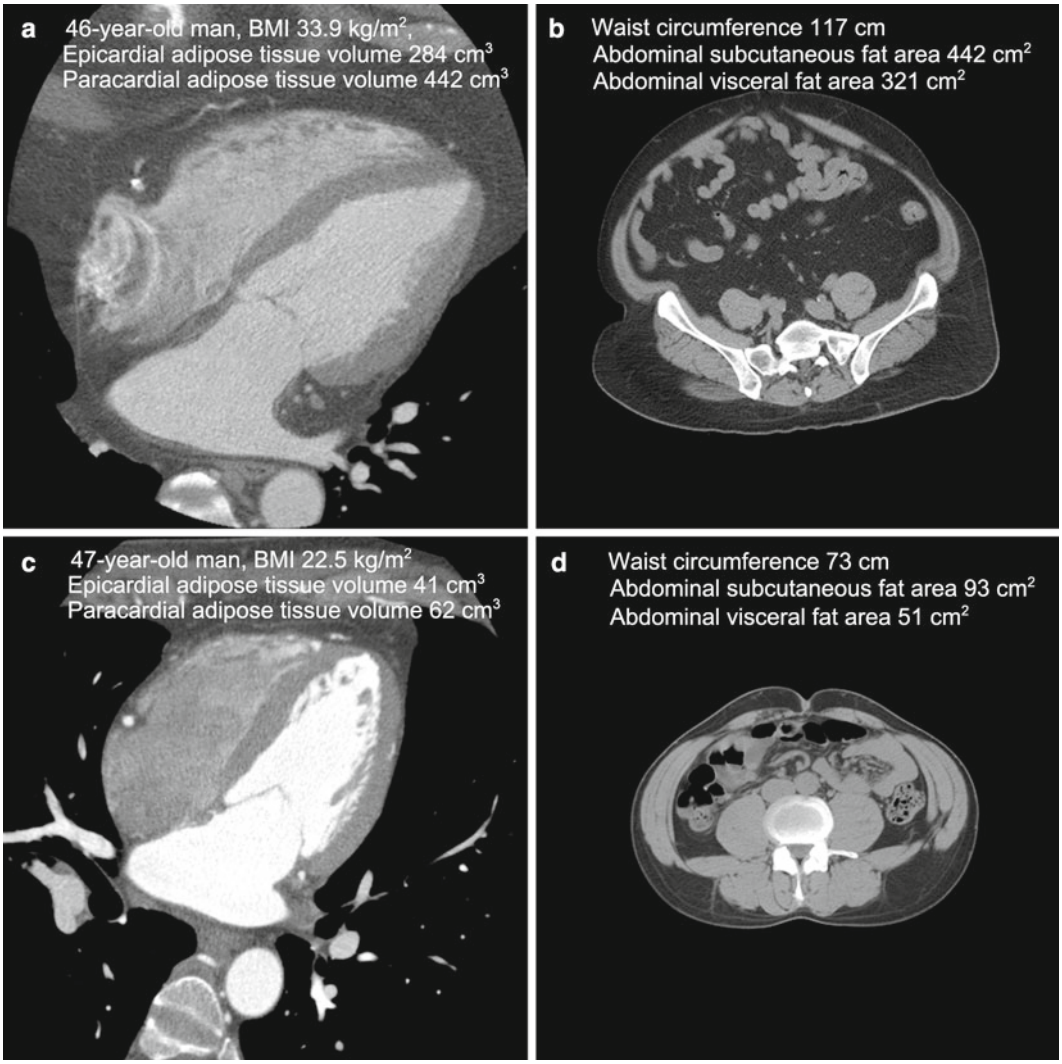

Fig. 57.7 Cases demonstrating the positive association of the total volume of epicardial adipose tissue with other anthropometric indices and intra-abdominal adiposity. (**a**, **b**) are the axial cuts at levels of the mitral valve and the umbilicus, respectively, in a 46-year-old man with hypertension, diabetes mellitus, and coronary artery disease. (**c**, **d**) are the axial cuts at levels of the mitral valve and the umbilicus, respectively, in a 47-year-old man with no coronary risk factors or prior history of coronary artery disease. The positive association of the total volume of epicardial adipose tissue with other anthropometric indices and the amount of intra-abdominal visceral fat is clearly exemplified in this figure. *BMI* body-mass index

57.4.2 Association with Cardio-Metabolic Risk Factors

Obesity often coexists with a number of cardio-metabolic risk factors, including hypertension, atherogenic dyslipidemia, insulin resistance, and impaired glucose tolerance, which are collectively referred to as the metabolic syndrome. Adipocytes and the surrounding adipose tissue, especially intra-abdominal visceral fat depots, have been ascribed to be the underlying pathogenic factor mediating the links between obesity, insulin resistance, and other components of the metabolic syndrome

(Van Gaal et al. 2006). Given the shared embryological origin of EAT and intra-abdominal visceral fat, several recent studies have demonstrated that the amount of EAT is quantitatively associated with various cardio-metabolic risk factors, even after adjustment for intra-abdominal visceral adiposity (Iacobellis et al. 2003; de Vos et al. 2008; Gorter et al. 2008b; Rosito et al. 2008; Wang et al. 2009a, b). Intriguingly, the strengths of associations between peri-coronary EAT thickness (averaged EAT thickness in the grooved segments) and total EAT volume with three different components (blood pressure, lipid, and glucose parameters) of the metabolic syndrome are varied. For peri-coronary EAT thickness, the correlation is strongest with the glucose parameters, then with the lipid parameters, and less strongly with the blood pressure parameters (de Vos et al. 2008; Wang et al. 2009b). For total EAT volume, the significant association is often observed only with the lipid parameters, but not with the other two parameters (Rosito et al. 2008). Consistent with these observations, a stronger correlation between peri-coronary EAT thickness and clustering of metabolic syndrome components than with total EAT volume has been demonstrated (Gorter et al. 2008b). We further clarify this by demonstrating that the association between the increasing number of metabolic syndrome components and EAT is primarily related to regional EAT thickness in the left atrio-ventricular groove, with a moderate magnitude of correlation (correlation coefficient ~0.4) (Wang et al. 2009b). The underlying mechanisms for this region-specific association of EAT and cardio-metabolic risk factors remain elusive. However, it has been speculated that this association might be related to the well-developed venous drainage system and great cardiac vein traversing the left atrio-ventricular groove, and its role as an arena for communications between EAT and systemic circulation. Moreover, although echocardiographic EAT thickness over the right ventricular free wall correlates with the circulating levels of C-reactive protein and several adipokines (Iacobellis et al. 2003; Malavazos et al. 2008), we demonstrated that the correlations between EAT and inflammatory markers and adipokines are also specifically related to the thickness of EAT in the left atrio-ventricular groove, thereby providing a mechanistic link. By using receiver-operating-characteristic analysis, the optimal cutoff point for left atrio-ventricular groove thickness to predict the metabolic syndrome was determined to be 12.4 mm for men and women of Chinese ethnic origin (Wang et al. 2009b). Whether this cut-off point can be applied to other ethnic groups still awaits confirmation.

In summary, EAT thickness in the left atrio-ventricular groove, but not total EAT volume, is the best indicator of metabolic risk.

57.4.3 Association with Cardiac Structural Changes

Several echocardiographic studies have shown that the thickness of EAT over the right ventricular free wall is associated with measures of the left ventricular mass, left atrial size, and impaired right and left ventricular diastolic filling (Iacobellis and Willens 2009). However, these associations are not independent of other ectopic fat stores, the only exception is the left atrial size. In the Framingham Offspring Study, total EAT volume was also independently associated with increased left atrial dimension, measured in the anteroposterior direction from an axially oriented image, in white men (Fox et al. 2009). Generally speaking, for cardiac structures and functions, the effects of EAT are mostly outweighed by the systemic effects of obesity.

57.4.4 Association with Coronary Artery Disease

A number of clinical studies have shown that the amount of EAT, measured by either echocardiography or MDCT, was correlated with coronary atherosclerosis and the prevalence of cardiovascular

disease (Chaowalit et al. 2006; Ahn et al. 2008; de Vos et al. 2008; Gorter et al. 2008a; Rosito et al. 2008; Sarin et al. 2008; Greif et al. 2009; Wang et al. 2009a). However, in studies showing a positive association between total EAT volume and the "presence" of coronary artery calcification or atherosclerotic plaques, the EAT volume was paradoxically not related to the severity of coronary atherosclerosis or plaque burden in a dose-dependent manner (Gorter et al. 2008a; Rosito et al. 2008; Greif et al. 2009). Additionally, the positive association between averaged peri-coronary EAT thickness and coronary artery calcification is not significant after adjustment for waist circumference in healthy post-menopausal women (de Vos et al. 2008). As observed for the relationship between EAT and the metabolic syndrome, we found that the quantitative association between EAT and coronary atherosclerosis primarily stems from EAT thickness in the left atrio-ventricular groove, which is the only EAT measurement unanimously associated with all different measurements and definitions of coronary atherosclerosis (correlation coefficient ~0.3). This association remains significant even after adjustments for conventional risk factors, such as BMI, waist circumference, C-reactive protein, and intra-abdominal visceral adiposity. Therefore, it is conceivable why only modest associations are observed between "global" EAT measurements (total EAT volume and averaged peri-coronary EAT thickness) and coronary atherosclerosis. The consistent region-specific associations of EAT thickness in the left atrio-ventricular groove with the metabolic syndrome, inflammatory markers, and coronary atherosclerosis further strengthen the reliability of this intriguing finding. Moreover, there is a preferential association between EAT thickness in the left atrio-ventricular groove and atherosclerosis in the embedded left circumflex artery, indicating a local atherogenic role of EAT accumulated in the left atrio-ventricular groove. Using receiver-operating-characteristic analysis, 12.2 mm was determined to be the optimal cutoff point for left atrio-ventricular groove thickness to predict the presence of significant coronary stenosis (≥50% diameter stenosis) for men and women of Chinese ethnic origin.

Apart from the cross-sectional association between EAT and coronary atherosclerosis, it has been shown that "pericardial" adipose tissue volume predicts the occurrence of coronary heart disease in white adults who participated in the Multi-Ethnic Study of Atherosclerosis (Ding et al. 2009). However, it has not been determined whether this association is independent of other ectopic fat depots. Moreover, it is not known whether EAT thickness in the left atrio-ventricular groove has a greater power to predict coronary heart disease than pericardial or epicardial fat volume. To date, it appears that the thickness of EAT in the left atrio-ventricular groove provides a more accurate assessment of its atherogenic risk and is therefore a better coronary risk factor than total EAT or pericardial adipose tissue volume.

57.5 Future Perspectives

In recent years, EAT has attracted wide attention from clinicians and medical researchers, and is no longer regarded as an indolent bystander in the human body. EAT as a whole has generally been viewed as an integral ectopic fat depot and assumed to behave similarly, although the distribution of EAT around the heart is obviously asymmetric and mostly concentrated in the grooved segments around the epicardial vessels. However, our recent cross-sectional association studies demonstrated that there are substantial variations in the metabolic and atherogenic risks of EAT in different locations. Therefore, it is mandatory to examine whether there is indeed regional variation in the molecular characteristics (adipokine secretion, inflammatory activity, brown/white adipose tissue distribution, etc.) of EAT, whether this variation is a primary or secondary (responsive to coronary atherosclerosis) event, and whether it confers any clinical significance, such as contributing to the systemic levels of inflammatory markers, clustering of metabolic risk factors, and local coronary atherogenesis.

Although a number of cross-sectional association studies demonstrated that EAT, using either regional or global measurements, is correlated with measures of obesity, cardio-metabolic risk factors, and coronary atherosclerosis, larger studies are still needed to verify these findings and further examine: (1) whether these EAT measurements provide incremental information compared to conventional risk factors, other anthropometric indices, and ectopic fat measurements; (2) the threshold values of EAT measurements to predict the presence of various pathological conditions; and (3) whether there are any ethnic and gender differences in the clinical significance and threshold values of EAT. More importantly, information regarding the prognostic significance of various EAT measurements is still lacking and desperately needed.

After obtaining the above-mentioned information, it would be worthwhile to evaluate the effects of non-pharmacological (weight reduction, caloric restriction, exercise training, etc.) and pharmacological interventions on EAT measurements. Moreover, it would be interesting to assess whether local treatment for specific EAT regions may provide any benefits in stabilizing the progression of coronary artery disease.

Summary Points

- Epicardial adipose tissue (EAT) is situated on the surface of the heart and confined within the pericardial sac.
- The distribution of EAT is characterized by its asymmetric distribution and its primary accumulation around the base of both ventricles, especially in the perivascular atrio-ventricular and inter-ventricular grooves, rather than in the non-grooved cardiac surfaces.
- To clearly delineate the asymmetric distribution of EAT and explore its pathophysiological significance, EAT should be measured using multidetector computed tomography (MDCT) in three dimensions: regional thickness, cross-sectional areas, and total volume.
- The first step to measure the regional EAT thickness is to obtain multiplanar reconstructions of MDCT data in the standardized ventricular short-axis planes at the basal, mid-cavity, and apical levels, and in the horizontal long-axis plane. The second step is to divide the cardiac surfaces in the reconstructed MDCT images into segments. The final step is to measure EAT thickness in the pre-defined segments. In grooved segments, maximal EAT thickness perpendicular to the pericardium is recorded, whereas in non-grooved segments, EAT thickness orthogonal to the myocardial surface is recorded.
- Regardless of differences in ethnicity and body habitus, EAT thickness in the grooved segments is greater than in the non-grooved segments, including the right ventricular free wall.
- Among the grooved segments, the right atrio-ventricular groove has the thickest deposits of fat where the right coronary artery is located, followed by the left atrio-ventricular groove where the left circumflex artery and great cardiac vein are located. The maximal EAT thickness surrounding the left anterior descending coronary artery, measured in the superior inter-ventricular groove in the basal short-axis plane, is less than that surrounding the right coronary artery or the left circumflex artery.
- The average volume of EAT is generally between 110 and 125 cm^3 (ml), despite high levels of heterogeneity in the ethnic background, anthropometric features, and underlying, associated medical conditions.
- Although EAT constitutes only 1% of the total fat mass, several clinical studies have shown that the amount of EAT is associated with obesity, cardio-metabolic risk factors, cardiac structural changes, coronary atherosclerosis, and the incidence of coronary heart disease events. However,

it is a matter of debate as to whether these associations of EAT are direct or indirect and which EAT measurement represents the best correlate.

- Among all MDCT measurements of EAT, total EAT volume is most closely related to various obesity measures and is the best indicator of visceral obesity.
- To date, it appears that EAT thickness in the left atrio-ventricular groove provides a more accurate assessment of its metabolic and atherogenic risks, and is therefore a better indicator of its metabolic risk and a better coronary risk factor than total EAT volume.
- Further studies are desperately needed to elucidate whether there are indeed regional variations in the molecular characteristics (adipokine secretions, inflammatory activities, brown/white adipose tissue distributions, etc.) of EAT and whether this regional variation confers any clinical, prognostic, or therapeutic implications.

Chapter 58
Breast Volume Determination in Breast Hypertrophy

Laszlo Kovacs and Maximilian Eder

Abstract In the last few decades, several surgical techniques have been presented to decrease the symptoms of breast hypertrophy by removing a specific amount of breast tissue and reshaping the breast. Reliable and objective breast volume determination could be a helpful pre- and intraoperative assistance for the surgeon to achieve an aesthetic result, especially in breast asymmetry. But thus far no generally accepted method exists. In this paper, the advantages and disadvantages of classical techniques for breast volume determination (anthropomorphic measurements, conventional 2D radiological imaging, Archimedean methods, moulding techniques, measuring devices, modern radiological imaging) are critically analyzed and compared to an innovative alternative technique using 3D surface imaging. The technical background of 3D surface imaging is presented, underlining the reliability and accuracy of this innovative breast volume determination technique. Furthermore, a comparison of 3D surface imaging with the classical techniques of breast volume determination reveals the more comprehensible and transparent character of the 3D surface imaging method that permits a non-invasive, risk-free, non-contact, non-deformable patient assessment and delivers high-resolution 3D virtual, colored models of the breast region. Precise and accurate pre- and postoperative 3D quantitative calculations of shape, volume, surface changes, symmetry, projection, swelling tendency, contour and deformation are feasible. Finally, postoperative follow-up examinations at close intervals and optimizations of the preoperative surgical planning are possible. The clinical applications in the field of plastic, reconstructive and aesthetic breast surgery show promising results, but further implementations in other related fields should be performed.

58.1 Introduction

Breast hypertrophy patients often suffer from physical and psychological discomfort because of their heavy breasts. Physical symptoms of mammary hypertrophy (neck and shoulder strain, headaches, back and breast pain, persistent rashes in the intertrigo areas and sometimes musculoskeletal degenerations) combined with psychological disorders (minor self-esteem and self-confidence because of their breast or rather shame and aversion against their breast) aggravates the desire of these women for breast reduction surgery (Birtchnell et al. 1990). Different studies have demonstrated the medical benefits with regardto the improvement in physical and psychological well being after breast reduction (Blomqvist et al. 2000). In the last few decades, several surgical techniques have been presented to decrease the symptoms of breast hypertrophy by removing a specific amount of breast tissue and reshaping the breast (Bostwick 1999). Besides improvement in clinical symptoms, the aesthetic appearance (shape, volume, and symmetry) of the breast is also a decisive reason for patient's satisfaction and quality of life after surgery. The correlation between breast shape and breast volume for achieving postoperative symmetry is essential (Hudson 2004; Kovacs et al. 2004). Especially, breast volume estimation in mamma hypertrophy patients with large and pendulous breasts is challenging and purely intuitive. Reliable and objective breast volume determination could provide helpful pre- and intraoperative assistance for the surgeon to achieve an aesthetic, pleasing result, especially in breast asymmetry (Eder et al. 2007). Further, a reliable method of determining postoperative volume, shape and resulting symmetry in sense of an outcome analysis or quality assurance could guarantee a more transparent and objective evaluation (Kovacs et al. 2006a, b, 2007).

Therefore, this contribution will give an overview of the existing classical techniques of breast volume determination and will provide a critical analysis of the advantages and disadvantages of each method. Further, we will present an innovative alternative technique using 3D surface imaging and its potential clinical application in comparison with the established breast volume determination techniques.

58.2 Main

Breast volume determinations are not regularly performed in a clinical routine because thus far no generally accepted method exists (Bulstrode 2001). The classical techniques for breast volume determination can be assigned to one of the following presented categories.

58.2.1 Classical Breast Volume Determination Techniques

58.2.1.1 Anthropomorphic Measurements

Anthropomorphic measurements in plastic surgery were primarily used to describe anatomical relations between specific landmarks of the thoracic region to support the surgeon in optimal breast shaping (Penn 1955; Smith et al. 1986). Later, anthropomorphic methods were followed to derive correlations between breast volume calculations and standardized direct end-to-end measurements of the thoracic region (Westreich 1997). With regard to statistically relevant conformity, specific formulas mainly based on geometrical bodies have been developed to determine the breast volume. A modified anthropomorphic method, for example, equates breast volume to a half-ellipse. The

parameters of the mathematical formula of a half-ellipse are measured directly on the patient or indirectly using two-dimensional (2D) photographs of the breast region (Qiao et al. 1997).

Calculated breast volumes using anthropomorphic methods are based only on individually determined values (end-to-end measurements) and a predefined geometrical breast shape which hardly corresponds to the individual anatomical breast conditions. The reported mean breast volume measurement deviations of 3.61 percentage by Westreich et al. and 3.89 percentage by Qiao et al. are surprisingly small taking into account the known uncertainties caused by individual uneasiness during an investigation and compared to Kovacs et al. with a mean deviation of 6.26 percentage (Kovacs et al. 2007).

Anthropomorphic methods are relatively easy and inexpensive (tape measure, calculator, and working time) and can be used with the patient standing. But calculation of the formulas is quite cumbersome and the methods require subjective determinations because breast landmarks are extremely arbitrary and not well defined. Variability of manual measurement increases with less anatomically well-defined landmarks or those which are located in the submammary region (Kovacs et al. 2006a). Additionally, manual interaction of the observer with the patient can cause decreased acceptance of this method. The abovementioned individual feeling of uneasiness related to anthropomorphic methods affects reproducibility, and clearly shows observer dependency of volume determination.

58.2.1.2 Conventional 2D Radiological Imaging

Breast volume determination methods using conventional 2D radiological imaging such as mammography and ultrasound are comparable to the abovementioned modified anthropomorphic measurement using 2D photographs (Malini et al. 1985; Kalbhen et al. 1999). Different geometric parameters (e.g. partial ellipse) are projected onto the 2D image or ultrasonic layers and the volume is calculated according to the applied mathematical formulas. A major disadvantage is caused by the compression of the breast during the assessment. The resulting images do not provide the natural shape and appearance of the breast. Therefore, the calculations are questionable and, in addition, the patient's acceptance due to personal discomfort is very low (Bulstrode et al. 2001).

58.2.1.3 Archimedean Methods

The technique is based on the Archimedes' principle of water displacement. The patient bends over a water-filled vessel, lowering her breast into the water and the breast volume is calculated based on the displaced water (Bouman 1970). Modified methods use calibrated cylinders placed against the thoracic wall. The rigid thoracic wall forms the dorsal border of the breast and the ventral soft-tissue portion is measured as the displaced breast volume (Wilkie 1977). Patient's acceptance is poor because of cumbersome feasibility and impracticable measurement systems with low reliability (Bulstrode et al. 2001).

58.2.1.4 Moulding Techniques

Moulding materials (plaster or thermoplast) are placed on the upright seated patient and generate a negative cast of the breast. The cast model is filled with water or sand in order to determine the breast volume (Campaigne et al. 1979). During the assessment the breast is deformed and compressed against the thoracic wall. The relatively inflexible moulding material cannot perfectly model the breast shape and is distorted under the manual pressure of the examiner (Kovacs et al. 2007). By

filling up the casts with water or sand, the rear demarcation of the chest is defined as a flat level. Breast portions above this flat rear wall are not included into volume calculations and therefore smaller volumes are computed (Kovacs et al. 2007). Moreover, manual evaluation is quite subjective, arbitrary and extremely difficult to perform because of not clearly defined breast boundaries. The precision of the breast volume calculation using thermoplastic casts has been reported as relatively constant with a mean deviation of 6 percentage (Edsander-Nord et al. 1996) and 7.97 percentage (Kovacs et al. 2007). Besides high material costs of approximately US$ 150 per breast, inflexible moulding, resulting breast tissue deformation and cumbersome manual volume assessment affect reproducibility. Therefore, thermoplastic casts should be used with caution for breast volume assessment (Bulstrode et al. 2001; Kovacs et al. 2007).

58.2.1.5 Specific Measuring Devices

Strömbeck et al. used transparent, non-deformable containers of different sizes to cover the breast and to measure the volume before surgery (Strömbeck and Malm 1986). The method is fast, practicable and not expensive. But by using rigid containers the breast is deformed and compressed. The proper breast shape is not taken into consideration. Grossmann and Roudner developed a cone shaped, adaptable device which shows the corresponding volume on a lateral placed scale (Grossman and Roudner 1980). But according to Palin et al. the "Grossmann-Roudner-Device" delivers only acceptable reproducibility in a certain breast volume range and is therefore limited in its clinical functionality (Palin et al. 1986).

58.2.1.6 Modern Radiological Imaging

Computer tomography (CT) and nuclear magnetic resonance imaging (MRI) offer an alternative to visualize and to calculate breast volumes in 3D (Kovacs et al. 2006b). The patient is placed in the scanner in a prone or supine position. The breast volume is calculated by the summation of segmented mono-layers.

Breast volume calculation is based on clear, visible anatomical structures and landmarks. Therefore, manual segmentation is easy and precise. MRI provides the most precise volume assessment method with a mean deviation varying from 4.3 percentage (Fowler et al. 1990) to 1.56 ± 0.52 percentage (Kovacs et al. 2007). Because of its time and cost-intensive acquisition ($1.400 per assessment) and its invasive character, MRI is not suitable for routine preoperative breast volume measurements (Caruso et al. 2006). Another disadvantage of the MRI is the resulting deformation of the breast tissue in the supine or prone position. The reconstructed 3D models do not correspond to the real anatomical shape of the breast and are of little help to clinicians (Eder et al. 2008).

58.2.1.7 Intermediate Review

The hitherto presented various breast volume determination techniques exhibit variable reliability. Furthermore, these techniques are sometimes difficult to perform because of cumbersome feasibility or even limited practicability, of low patient acceptance and are often cost-intensive (Table 58.1). These reasons limit the application in daily clinical routine and, therefore, breast volume determination is used for preoperative surgical planning only in some exceptional cases (Kovacs et al. 2007).

Table 58.1 Key facts of different breast volume determination techniques

	Reliability	Practicability	Costs	Patients acceptance	Overall rating

58.2.2 Innovative Breast Volume Determination in Three Dimensions

These insufficient breast volume determination methods show the necessity to supply clinicians with additional comfortable evaluation methods that guarantee fast, noninvasive, routine clinical follow-up examinations at close intervals and objective and patient-specific quantification of the breast geometry. Optical measurement systems for three-dimensional (3D) body surface imaging fulfill these requirements. Their potential applications in the field of breast surgery have been presented (Eder et al. 2007, 2008, Kovacs et al. 2006a, b, 2007). Three-dimensional surface imaging permits a noninvasive, risk-free, noncontact, nondeformable patient assessment and delivers high-resolution 3D virtual color models of the breast region. Precise and accurate pre- and postoperative 3D quantification of shape, volume, surface changes, symmetry, projection, swelling tendency, contour and deformation are possible. Furthermore, 3D surface imaging enables postoperative follow-up examinations at close intervals and optimizes specific steps in preoperative surgical planning (Eder et al. 2007). The stored digitalized 3D data guarantee reliable, well-structured patient documentation that allows a computer-aided detailed evaluation even in the absence of the patient. Time-consuming patient measurements are not needed any longer, and the possibility to work with different data sets concerning different clinical questions applying different software solutions pre-, intra- and postoperatively is provided as well (Kovacs et al. 2004, 2006).

58.2.2.1 Technical Background

The technical principle of 3D optical measurement systems is based on triangulation and consists of a transmitter unit (light source) and a receiver unit (camera). The transmitter unit projects a point upon the object to be assessed whereas the receiver unit detects the reflected light. The geometric shape and the measured angle between the light source and the camera enable the precise definition of the accurate object point in space and the resulting surface geometry (Breuckmann 1993). The captured surface is accumulated as a point cloud (different single points). Each point has a respective *x*-, *y*-, and *z*-coordinate, and precise visualization of the whole body surface is possible (Kovacs et al. 2006a, b). The mathematically precise 3D quantification of the body region in a Cartesian coordinate system allows the creation of a virtual 3D surface computer model using different algorithms and software. This virtual 3D model offers several advantages compared to conventional 2D photography: apart from color information, spatial computation of individual points on the basis of the respective *x*-, *y*-, and *z*-coordinates and rotation of the 3D model in all three dimensions is possible.

A large variety of 3D surface geometry acquisition systems exist and are based on varying physical principles (stereo (-photo) grammetry, Moiré topography, pattern/structured light, linear laser scanner, etc.). They all have in common that a virtual digitalized 3D model of the body surface is created in a short time without any deformable body contact. Different body surface imaging systems were tested in our preliminary studies with regard to their potential medical application, and we concluded that the 3D linear laser scanner was the most suitable method (Brockmann et al. 2006).

Before applying this 3D technology to clinical routine it is necessary to standardize the 3D capturing process of the breast region in a normal standing position and to evaluate the precision and accuracy of the method in order to optimize the data reproducibility (Kovacs et al. 2006a). Accuracy of existing scanning systems depends on the capturing speed and their capability to assess larger body regions in one or more steps (Brockmann et al. 2006). Current 3D imaging systems vary enormously in fulfilling these requirements. It is often necessary to accomplish multiple surface scans from different angles to capture the whole breast region. The capturing process for one single shot takes 1–2 s. More complex scanning systems with multiple combined scanning modules are expensive but allow a 360° assessment with one single shot. Depending on the scanning system and the region of interest, the whole capturing process takes from seconds until several minutes.

In a test series, scanner-related factors (scanner position, number of scanners and single shots), as well as the influence of the breast region (variable breast shapes) were investigated. The accuracy of measurements on the virtual models was compared with manual measurements through a coincidence analysis (Kovacs et al. 2006a). By respecting standardized settings for 3D imaging of the breast region with a laser scanner, an acceptable degree of accuracy and reproducibility can be achieved, and is therefore clinically applicable (Kovacs et al. 2006a).

58.2.2.2 Three-Dimensional Breast Volume Determination: Reliability and Accuracy

The pre- and postoperative assessment of the breast and thoracic regions can be accomplished sufficiently precisely and accurately using a 3D linear laser scanner according to a standardized scanning protocol (Kovacs et al. 2006) and presented as a virtual 3D model for further computer-aided evaluation with appropriate software (Fig. 58.1). To establish an easily reproducible investigation protocol for reliable breast volume determination, a standardized procedure was defined and evaluated (Fig. 58.1). The breast volume of interest was labeled on the virtual 3D model (Fig. 58.1a and b). The labeled area was deleted and by applying specific software algorithms the defective curvature surrounding the deleted area (Fig. 58.1c) was used to compute the surface to be filled. The mean curvature of the thoracic wall at skin level was interpolated (Fig. 58.1d). The overlaid congruent areas were subtracted to obtain a closed volume corresponding to the breast volume (Fig. 58.1e and f).

The standardization of this 3D breast volume determination method showed a mean deviation of breast volume measurements (reliability) expressed as a percentage of volume over 2,420 measurements of 2.86 ± 0.98%. The highest measurement reliability was found between a breast volume range from over 250 cm^3 to 1,600 cm^3 (Fig. 58.2). Reasons for decreased reliability outside this range are on the one hand large and ptotic breasts, and on the other hand smaller breasts which are not clearly visible on the thoracic wall (Kovacs et al. 2006b). For further validation these 3D breast volume determinations were compared with reference MRI volume measurements obtained from test subjects; they showed significant ($r = 0.995$, $p < 0.001$) correlation (Kovacs et al. 2006b).

In addition to the evaluation of reliability, studies were performed focusing on the precision of measurement. In order to examine the accuracy of the 3D method, Losken et al. analyzed the mean

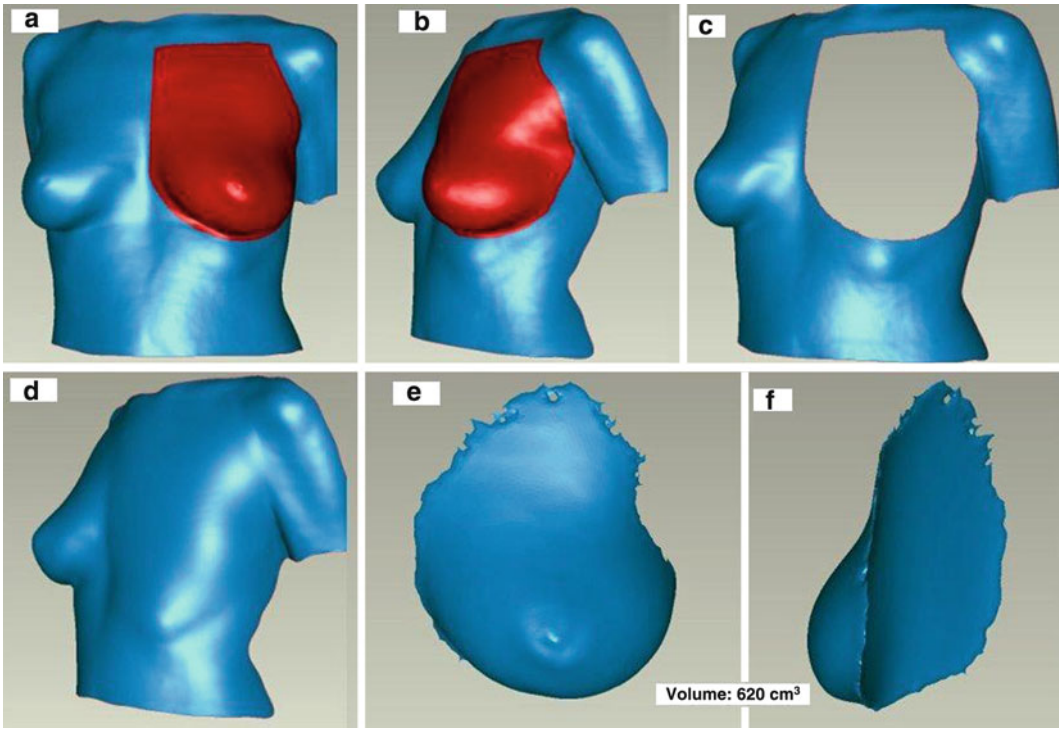

Fig. 58.1 Standardization of 3D breast volume determination. Procedure for standardized breast volume measurements: (**a**, **b**) labeled breast region; (**c**) erased breast region; (**d**) interpolated chest wall curvature as dorsal boundary of the breast volume; (**e**) measured breast volume: ventral and (**f**) dorsal aspect

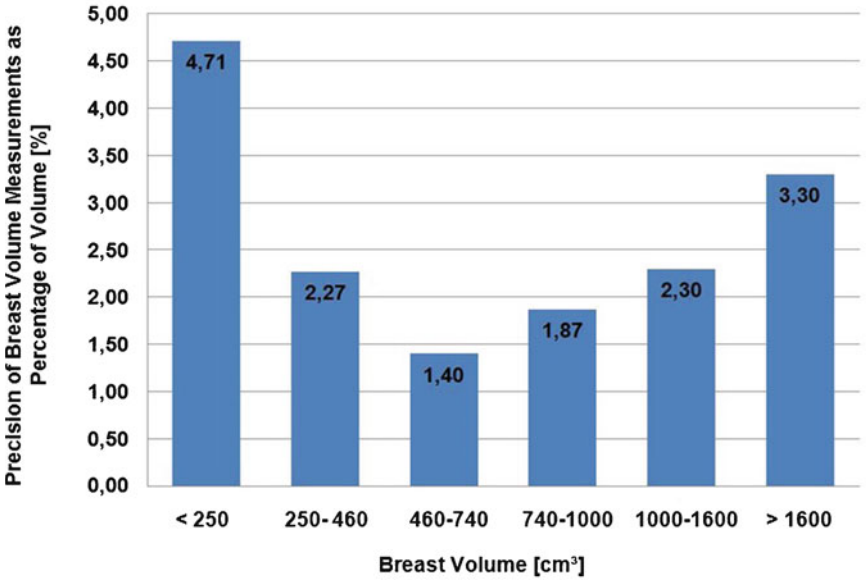

Fig. 58.2 Reliability of 3D breast volume determination. Reliability (precision) of 3D breast volume determination according to breast volume (mean deviation of the breast volume measurements expressed as percentage of volume over n = 2,420 measurements of 2.86 ± 0.98 percentage)

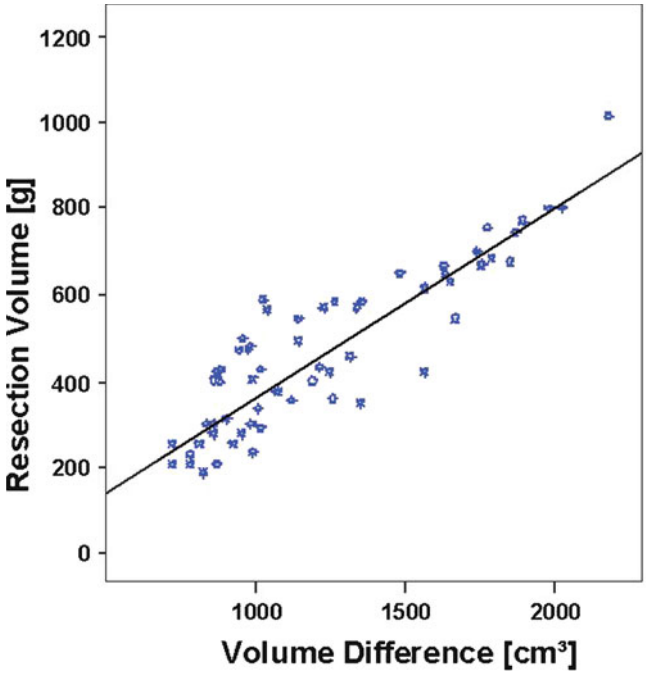

Fig. 58.3 Accuracy of 3D breast volume determination. Correlation ($r = 0.804$, $p < 0.001$) between the breast resection weight [g] and measured difference between pre- and postoperative breast volumes [cm^3]

relative difference between the breast resection weight and the measured difference between pre- and postoperative calculated breast volumes using 3D surface imaging in breast reduction patients: a mean relative difference of –2 ± 13–16 percentage is described (Losken et al. 2005). In our preliminary findings we described a mean relative difference of –1.80 ± 5.92 percentage (Kovacs et al. 2006b). Our actual findings show a significant, high correlation between the resection weight and the measured difference between pre- and postoperative volumes ($r = 0.804$, $p < 0.001$); it delivers a mean relative difference of 0.75 ± 6.75 percentage (Fig. 58.3).

58.2.2.3 Comparison to Classical Techniques

Breast volume determination using 3D surface imaging is sufficiently precise and accurate, but to what extent are these findings comparable to other determination techniques? Until today, only one comparison has been made between breast volume calculations using 3D imaging versus classical techniques (Kovacs et al. 2007) and only two cross-comparisons of the classical volume computation methods were performed (Palin et al. 1986; Bulstrode et al. 2001). These analyses have shown that the different breast volume calculation methods include different areas of breast tissue (Kovacs et al. 2007). Therefore, differences in the measured absolute volume values across the analyzed methods were found. Because different methods measure different breast volume areas, a meaningful comparison can be made only by applying the precise level of measurement (Kovacs et al. 2007).

We compared the most common techniques of anthropomorphic measurements, MRI, and thermoplastic casts with 3D surface imaging (Kovacs et al. 2007), and MRI showed the best agreement

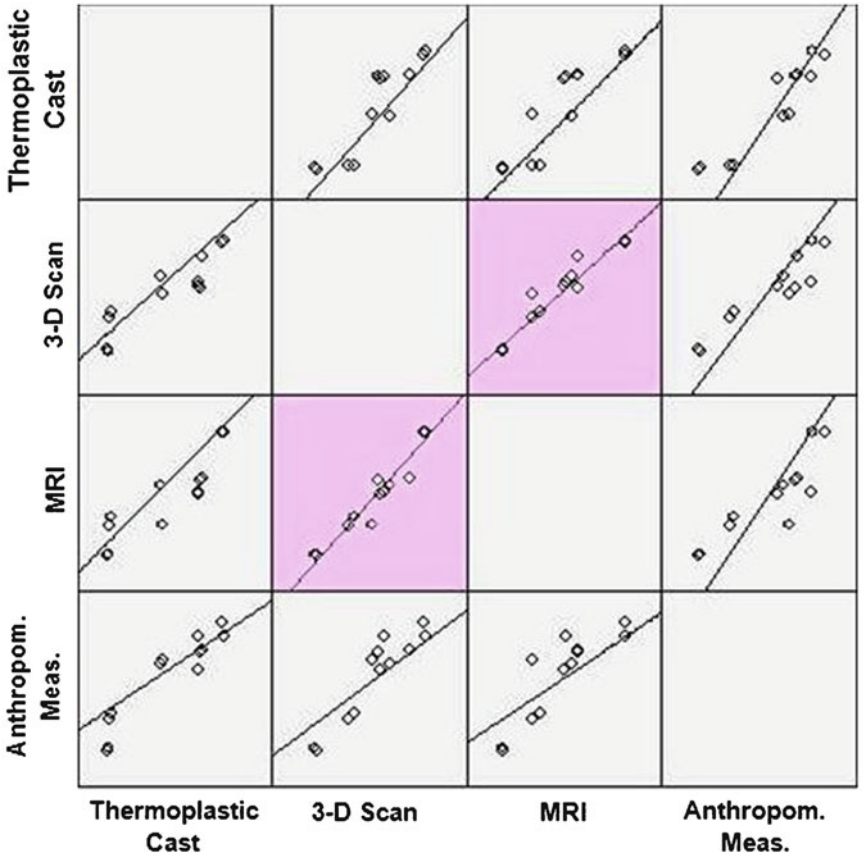

Fig. 58.4 Comparison of different breast volume determination techniques. Regression lines between breast volume determinations from 3D scanning, MRI, anthropomorphic measurements and thermoplastic casts

with 3D surface imaging ($r = 0.990$, $p < 0.001$), followed by the anthropomorphic method ($r = 0.947$, $p < 0.001$) and thermoplastic casts ($r = 0.727$, $p = 0.017$). To compare classical breast volume determination with 3D surface imaging, regression equations were calculated which enabled conversion of all determination units into those of 3D surface imaging (Fig. 58.4). The regression equations showed the following relations: (a) 3D scan = 9.83 + 0.75 × MRI, (b) 3D scan = –47.69 + 1.22 × thermoplastic casts, and (c) 3D scan = 141.03 + 0.70 × anthropomorphic measurement (all units in cm^3). The regression equations can compare absolute values of the specific volume calculation methods and permit comparison of the innovative 3D surface imaging technique with other classical techniques (Fig. 58.4).

58.2.2.4 Objective Breast Region Evaluation

In contrast to conventional 2D photographs, direct linear measurements can be performed directly on the surface using virtual 3D models. Breast projection, degree of ptotic breasts, thoracic circumference, etc. can be documented and visualized precisely (Fig. 58.5a). Objective breast volume and breast surface determinations (Fig. 58.5b and c) are fast, noninvasive and precisely quantifiable (Kovacs et al. 2006a, b; Eder et al. 2007, 2008). It is possible to compare the whole breast region

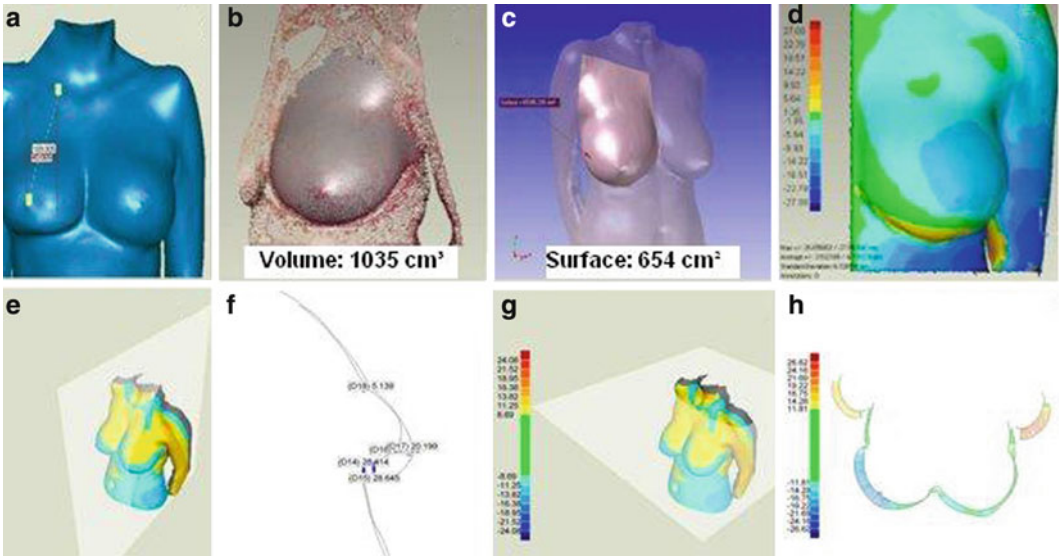

Fig. 58.5 Objective breast region evaluation. Different 3D quantification methods of the breast region: (**a**) linear on surface measurements [cm]; (**b**) volume measurements [cm^3]; (**c**) surface measurements [cm^2]; (**d**) placing symmetric mirror plane and color-coded quantification of breast asymmetry by superimposed mirrored 3D model on the non-mirrored 3D model; (**e**) and (**g**) superimposed preoperative 3D model and the postoperative 3D model and color-coded deviation visualization [cm]; (**f**) vertical and (**h**) horizontal slice at nipple–areola-complex height with color-coded 2D deviation between the pre- and postoperative 3D model [cm]

surface by mirroring the region of interest and to evaluate the symmetry (Fig. 58.5d). By superimposing the preoperative 3D model onto the postoperative 3D model, precise color-coded quantification of surgically induced breast shape changes is possible in horizontal (Fig. 58.5e and f) and vertical (Fig. 58.5g und h) axes. The noninvasive and fast technique of 3D surface imaging provides the possibility for routine follow-up examination at close intervals. 3D surface imaging permits postoperative long-time analysis regarding swelling and soft tissue shape changes over time. By superimposing standardized 3D surface scans accomplished at different postoperative examination dates and by applying the above-described analyzing tools, the results can be automatically generated in an evaluation report which allows objective breast region quantification to optimize surgical procedures. It also allows an objective quality assurance of postoperative results and long-term postoperative follow-up studies.

58.2.3 Application to Other Areas of Health and Disease

Efforts in the field of cranio-maxillo-facial surgery enabled the expansion to related medical fields (Brockmann et al. 2006; Kovacs et al. 2004, 2006b). Clinical applications in the field of plastic, reconstructive and aesthetic breast surgery are well known and show promising results (Kovacs et al. 2004; Losken et al. 2005). Further promising implementations in other related fields, especially in breast surgery, is feasible in the future. One potential future application should be the implementation of noninvasive 3D surface technologies in the field of oncologic breast surgery. In particular, oncologic breast surgery pursues the challenge of operating being as minimally invasive as possible

and performing breast-preserving surgery. Current surgical planning regarding the quantification of tumor size and the correlation between tumor size and breast volume/breast shape are based on 2D radiographic diagnosis (mammography and ultrasound) or MRI/CT, which do not take the normal breast shape into account. By combining tumor location, size and expansion using current diagnosis systems with 3D surface imaging while respecting the normal breast geometry, it would be potentially possible to reduce soft tissue resection in tumor surgery to a minimum, with the result that the original breast shape is preserved. Another application could be in the field of breast reconstruction with patient-specific designed implants. For the non-operated, healthy breast, a virtual 3D breast implant could be designed on the basis of 3D surface imaging data and be produced using modern manufacturing techniques like rapid prototyping. In combination with other innovative techniques, it would be possible to introduce 3D surface imaging as an objective technique for quality assurance in oncologic breast surgery.

Besides surgical application, efforts have been undertaken in the clothing industry (Lee et al. 2004). Every kind of brassiere (underwire, jogging, sport or nursing) can be produced according to the patient's specific breast geometry. The individual anatomical measurements of the 3D surface model can be transferred to specific CAD (Computer Aided Design) software and variable kinds of brassieres could be virtually designed. In the future, as soft tissue research develops, the stiffness of the used brassiere components could be included and bra firmness could be simulated.

Summary Points

- Correlation between breast shape and breast volume for achieving postoperative symmetry is essential.
- Reliable and objective breast volume determination could be helpful in providing pre- and intraoperative assistance to the surgeon to achieve an aesthetically pleasing result, particularly for patients with asymmetric breasts.
- Breast volume determinations are not yet performed as clinical routine because so far no generally recognized method exists.
- Classical breast volume determination techniques exhibit variable reliability, are sometimes difficult to perform because of cumbersome feasibility or even limited practicability, have low patient acceptance and are often cost-intensive.
- There is a need to supplement clinicians with additional evaluation methods to guarantee fast, non-invasive, routine clinical follow-up examinations at close intervals and objective and patient-specific quantification of the breast geometry.
- Three-dimensional surface imaging permits a noninvasive, risk-free, noncontact, nondeformable patient assessment and delivers a high-resolution 3D virtual colored model of the breast region. Precise and accurate pre- and postoperative 3D quantification of shape, volume, surface changes, symmetry, projection, swelling tendency, contour and deformation are enabled.

Chapter 59
Numerical Modelling of Human Breast Deformation

A. Pérez del Palomar, B. Calvo, and A. Lapuebla-Ferri

Abstract Most surgical procedures in breast plastic surgery are either reconstructive procedures following oncologic interventions (tumorectomy, quadrantectomy, mastectomy…) or aesthetic ones, including both augmentation and reduction. With current techniques, the results of such procedures cannot be fully guaranteed. Usually, surgical planning is based on a photographic and anthropometric study of only the breast. Among others, one of the difficulties that plastic surgeons have is the noticeable change of the breast shape with the position of the patient. Thus, it is more and more necessary to plan a presurgical methodology to help the plastic surgeon and guarantee the patient a successful result of the intervention.

Numerical methods such as finite element simulations can help in predicting the deformations of a specific tissue if a suitable definition of the tissue is introduced. These models take into account the constitutive behaviour of the involved materials, the boundary conditions and the externally applied loads. Thus, numerical modelling can be used as a powerful tool to provide accurate and useful information to the surgeon planning such surgical procedures.

59.1 Introduction

Plastic surgery has suffered a great expansion in the last few decades, with patients demanding accurate and satisfactory outcomes. Medical students and residents who typically learn surgical procedures by performing them on real patients under close supervision, as well as experienced surgeons, may take advantage of virtual simulations of surgery. They can plan and rehearse complex procedures, predict

their outcomes and design and evaluate new methods and equipment. However, the majority of the simulation and manipulation systems for surgery have been built using largely phenomenological and heuristic models that have not been validated. This is why modelling the post surgery deformation of human organs for surgery planning systems has turned out to be a very important subject of research, one continuously in development.

With regard to breast morphology, this tissue lies on a mobile and irregular muscular bed and is composed of skin, fat and gland which have different mechanical properties that vary according to genetic factors and age (Pérez del Palomar et al. 2008). One of the difficulties that plastic surgeons have is the noticeable change of the breast shape with the position of the patient. Moreover, the plastic surgeon performs the surgical procedure with the patient in the lying position but needs to move the patient to the standing up position up to 5 times to check the shape of the breast.

Biomechanics is defined as the development, extension and application of mechanics with the purpose of acquiring a better understanding of physiology and pathophysiology and helping in the diagnosis and treatment of disease and injury. That is, the overall goal of biomechanics is, and must remain, the general improvement of the human condition (Humphrey 2002).

Despite the many investigations developed in this field, the exact mechanical behaviour of the different human tissues and organs and the causes of many of their diseases are not completely known yet. This is partially due to the inherent limitations of experimental studies such as their high cost, difficulties associated with the obtaining of accurate measures of strain and stress and, especially, the difficult and sometimes impossible reproduction of certain natural, pathological or degenerative situations. Computational models also provide a standardized framework for parameter studies, such as evaluation of clinical treatments, stress distributions for different geometries and kinematics, evaluation of surgical procedures, injury assessment, surgery planning and the effects of ageing, disease and drugs.

It is important to note that reliability of these models strongly depends on a precise geometrical reconstruction and on an accurate mathematical description of the behaviour of the biological tissues involved, and their interactions with the surrounding environment (Ning et al. 2006).

Biomechanical breast models mainly employing finite element methods have been explored to predict breast deformations in different situations. Applications include guiding clinical biopsy (Azar et al. 2001), modelling compressions similar to X-ray mammography (Ruiter et al. 2002), registering X-ray and MR mammography (Poplack et al. 2004), validating nonrigid registration algorithms (Tanner et al. 2006) and testing reconstruction algorithms for elastography (Washington and Miga 2004; Schnabel et al. 2003). The use of mechanical models in these applications is responsible for providing information about the expected deformations. This prior information helps to constrain possible solutions and thus provides a physical basis for interpolation, reconstruction and prediction for those cases in which there is insufficient information in the image data. These biomechanical breast models have been assessed based on the predicted location of anatomical landmarks selected in breast images acquired before and after *in vivo* compression by visual comparison of the simulated compressed breast image with the uncompressed breast (Azar et al. 2001). However, the small number of landmarks available in a single dataset makes these evaluations limited.

A wide range of values for the material properties of the different tissue types involved has been used in previously cited papers. The constitutive material parameters for fibroglandular and fatty tissues are generally obtained from ex vivo indentation tests (Bakic 2000). Azar et al. (2001, 2002), Wellman (1999) and Krouskop et al. (1998) assumed exponential, Samani et al. (2001) hyperelastic and Bakic (1999) linear elastic stress–strain relationships and used different material parameters. Samani used a hyperelastic material model to approximate Wellman's stress–strain properties. Azar et al. (2001, 2002) applied the same material model as Wellman, but used a corrected stress–strain relationship for fat tissue. All authors considered quasi incompressible materials with a Poisson ratio close to 0.5. Ruiter et al. (2002) concluded that the results do not vary within a significant range of

stiffness ratios of gland and fat regarding the required simulation accuracy. The exponential and Neo-hookean models can be used as approximations, whereas the linear elastic approaches do not perform that well. They argued that the simplest tissue model for breast simulation was the Neo-hookean one, ignoring the differences between the material properties of gland and fat. With regard to the skin, Samani et al. (2001) made the assumption that it can be considered as linear elastic and isotropic for strains lower than 50%. Reishner et al. (1995) examined the two-dimensional mechanical behaviour of human skin samples obtained from different anatomical sites, noting that the skin had varying degrees of anisotropy in different regions of the body. By comparing different biomechanical breast models Tanner et al. (2006) found that, for a compression of 20%, the effect on accuracy caused by the modification of the material properties was however less significant than the application of correct boundary conditions. Using the displacements of the surface of the breast as boundary conditions, they were able to recover the displacement of validation landmarks to a mean error of less than 2.5 mm.

In this chapter a virtual deformable breast model is presented to be used as a tool to predict breast deformations under different conditions.

59.2 Breast Computational Model

To construct a virtual deformable breast model medical data are necessary. The morphology of the patient breast is obtained by means of CT images. This data acquisition allows distinguishing not only the external shape of the breast but also its internal composition (glandular tissue and fat). Here, two datasets corresponding to two women are processed. The first patient (Patient A), a 52-year-old female requiring breast reduction, presents a high proportion of fat with respect to gland tissue; the second one (Patient B), a 36-year-old female requiring breast augmentation, presents a lower proportion of fat with respect to gland tissue. From the CT images, each volumetric model was constructed using the different material density (Fig. 59.1). Then, a surface mesh with triangles (STL) was created for each of the tissues (gland, fat, muscle and bone). Once the models

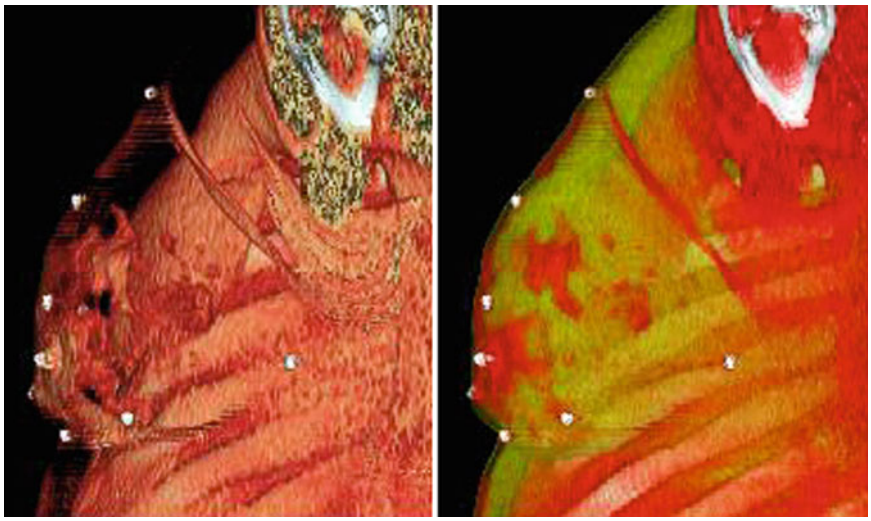

Fig. 59.1 Segmentation of the breast. Segmentation of the breast, distinguishing the different tissues (Patient A). The *white dots* correspond to plumb balls located on the patient to be used as anthropometric measures

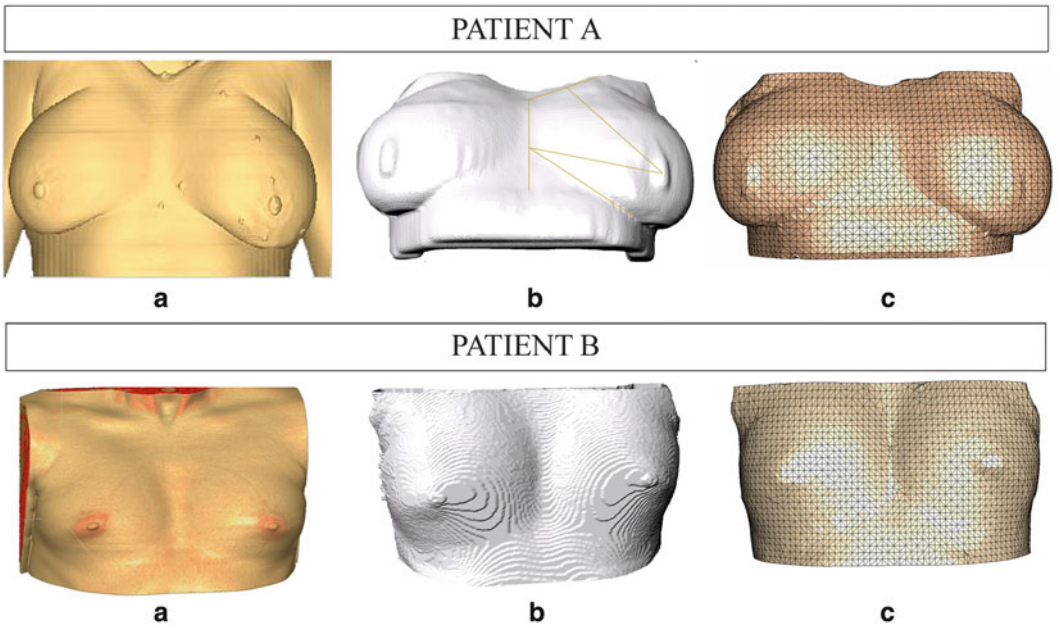

Fig. 59.2 Finite element models of both patients. Geometry reconstruction and finite element mesh of both Patients A and B; (**a**) computed tomography data, (**b**) surface mesh with triangles (STL), (**c**) finite element mesh (FEM)

were constructed, the bones and muscles were removed, obtaining the models shown in Fig. 59.2. These volumes were meshed for their numerical treatment. For further description of this method see Pérez del Palomar et al. (2008).

Once the computational model represents the actual geometry of the breast, a suitable characterization of the tissues involved has to be made. The main constitutive components for breast that are related with its mechanical behaviour are the glandular tissue, the fat and the skin. These tissues can be distinguished using CT images (see Fig. 59.1) and therefore can be separately treated. For the studied cases, Patient A has a similar proportion of glandular tissue and fat (60% glandular tissue/40% fat tissue), while for Patient B this proportion is totally different (90% glandular tissue/10% fat tissue). Therefore, the overall behaviour of the breast will be determined by the mechanical behaviour of each component.

As mentioned before, there is a great dispersion in the material properties used to simulate breast deformation. One thing that is certain is that constitutive models for large deformations have to be used to represent breast behaviour (see Tanner et al. (2006); Azar et al. (2001); Roose et al. (2005); Samani et al. (2001); Pérez del Palomar et al. (2008)). A suitable definition of this material behaviour allows predicting the change of breast shape from a patient lying in a prone position and a patient in a standing position (Figs. 59.3 and 59. 4).

In Fig. 59.3, the positions of different characteristic points drawn by the plastic surgeon are shown. The distances between these points change when the patient moves from the lying to the standing position. These points can be located also in the finite element model by using small titanium balls during the CT acquisition and therefore the new location of these markers in the deformed breast after loading can be compared with the actual locations on the patient. These measures are shown in Fig. 59.4. The comparison of the predicted numerical and the real distances is shown in Table 59.1 for the different reference markers.

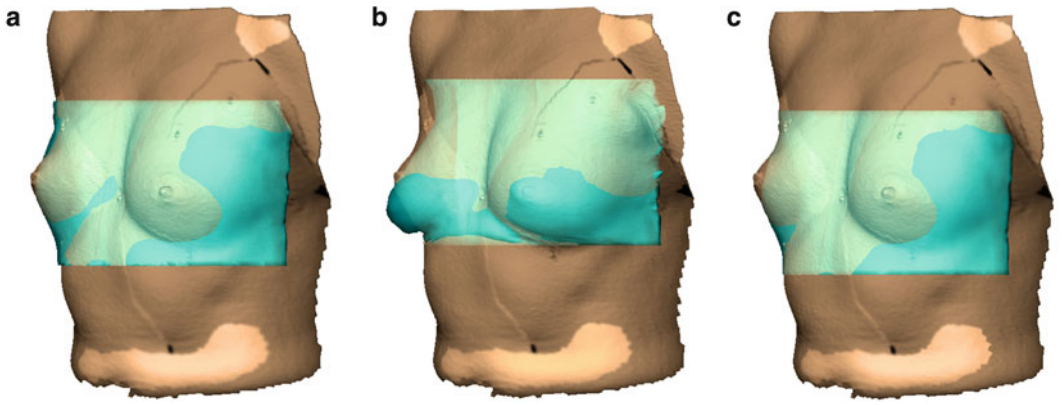

Fig. 59.6 Comparison between finite element simulations and a real patient. Superposition of images. The flesh coloured image corresponds to the reconstruction with the 3D scanner and the blue one with the deformed finite element mesh after different simulations (**a**) 40% fat, 60% gland; (**b**) 80% fat, 20% gland; (**c**) 50% fat, 50% gland

This procedure has proved the ability of the numerical models to predict real deformations of the breast. Finite element deformations represent with high accuracy the real deformations of the patient breast. This method can be improved using digitalized images reconstructed from a 3D scanner. Here, this procedure has been used for Patient B (Fig. 59.5).

The volume ratio of each tissue (gland/fat) can be computed, as has been done for Patient A, using segmentation. The relevance of introducing the correct relation between fat and gland can be seen qualitatively in Fig. 59.6. In this figure the real 3D image of the patient (captured using the

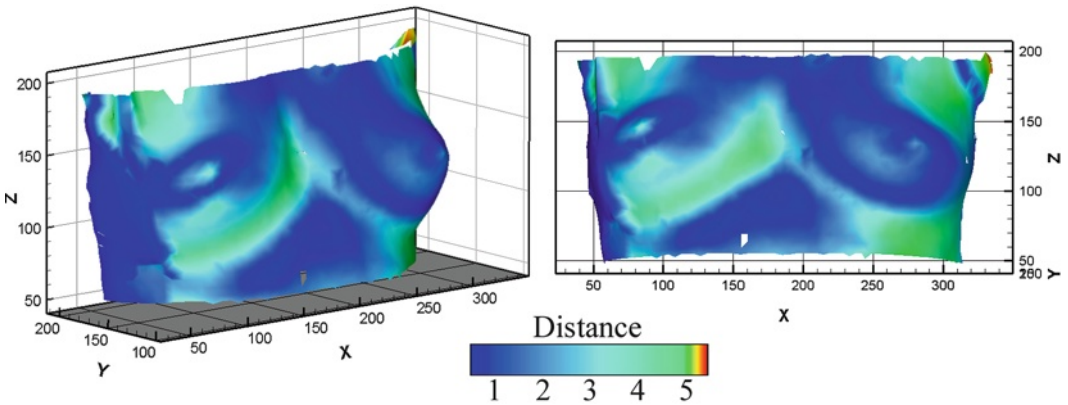

Fig. 59.7 Deviation between the finite element prediction and the real geometry of the patient. The deviation between the prediction of the numerical model and the real shape of Patient B is measured by means of the distance between each geometries. *Blue colour* corresponds to the best fitting between the numerical and the real model. The distance is computed in mm

3D scanner) is superimposed on the deformed mesh of the breast after gravity calculations. This procedure is made modifying the proportion of each tissue, and the qualitative match of the surfaces can be seen. For instance, it can be clearly appreciated that Fig. 59.6a which corresponds to a 40% fat/60% gland breast, fitted much better than Fig. 59.6b in which the fat proportion was increased.

The accuracy of the numerical model can be computed measuring the distance between the finite element solution and the real surface of the woman in the standing position. This can be seen in a colour map of the breast, as shown in Fig. 59.7. In this case, we can see that the mean deviation between both surfaces is 2.4 mm.

59.3 Implications for Breast Simulation

The breast has an inhomogeneous structure containing many layers of different kinds of tissue. However, the two predominant types of tissue within the breast are fat and normal glandular tissue which supports lactation. The proportion of each tissue in a breast depends on the age of the woman, if she is premenopausal or postmenopausal and, in general, on her constitution.

The deformation of soft tissues compromises the accuracy of image-guided surgery based on preoperative images and restricts its applicability. Here, we have presented a numerical model based on biomechanical principles to predict breast tissue deformations, thereby avoiding this limitation. This model can be used as a guideline in numerous clinical applications, such as breast image registration, multimodality data fusion, breast surgery and biopsy. Predicting breast deformations with the reported accuracy will improve the surgical precision for non-palpable lesions and provide plausible breast deformations for validation and teaching purposes. However, the feasibility of the method depends on suitable material characterization.

In this study we propose a method to predict deformations of the breast for presurgical planning. Two different tools are presented to evaluate the accuracy of the models. The first one consists in the validation of the position using landmarks and the second in the registration of the patient in standing

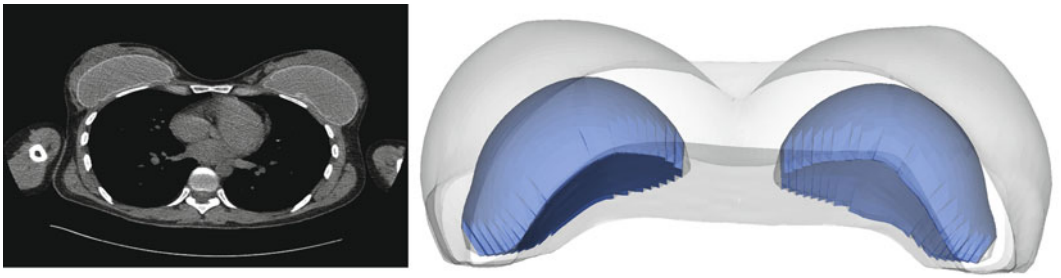

Fig. 59.8 Patient with prostheses and the equivalent finite element model. On the *left*, computed tomography images of a patient after insertion of silicone implants. On the *right*, finite element model of the patient incorporating the meshes of the prostheses

position, comparing the resultant image with the finite element results. These techniques are applied for two different breast models, the first one with a high proportion of fat tissue and the second one with a lower proportion of this tissue. In addition, the reconstruction of the real shape of the breast using a 3D scanner gives more information than using landmarks (Tanner et al. 2006) and can be used as an additional tool for the plastic surgeon to construct an anthropometric study.

Although incorporating other important structures such as the Cooper's ligaments or the effect of the pectoral muscle would also improve the accuracy of the model (Gambarotta et al. 2005), it would involve a loss in simplicity to easily construct breast finite element models.

To conclude, we are interested in finding the best way of presurgically estimating the morphological modifications of the breast depending on a specific intervention (reduction or augmentation). For instance, for augmentation mammoplasties and according to statistical data from American Society of Plastic Surgeons, more than 300,000 augmentation procedures were performed in USA during 2008. Using numerical methods, these surgical techniques can be planned in advance. Thus, a preoperative planning can be traced, including the location, type, size and shape of the implants (Fig. 59.8).

The techniques can also be evaluated by comparing the final deformed shape of the model with the one of the real patient, as shown in Fig. 59.9. The final shape of the FE model should be compared with the one of the real patient in standing position (i.e., with gravity acting on both breasts), as is done in clinical practice to verify the outcomes of surgical interventions.

59.4 Conclusions

Currently, the outcomes of breast surgeries can be predicted within a certain degree of accuracy, but they mostly rely on the surgeon's ability. Many difficulties arise from the intrinsic anatomy of the breast. This organ is heterogeneous, is composed of several tissues (fat, gland and skin) and its mechanical properties vary according to factors such as age or pregnancy. The breast is also an organ that provides support for lactation, and does not sustain external loads in the physiologic situation. Because of this, and because it lies on a mobile myofascial unit over rib cage, breast shape undergoes high changes under applied forces.

For such reasons, plastic surgeons may benefit by virtual surgery simulations. They can provide insight into the mechanical behaviour of the breast and help in surgery planning, to minimize the uncertainty of the results. So a widespread tool in the field of biomechanics such as Finite Element (FE) models is a suitable choice.

Matching of the deformed shape of the FE model with the one of the real patients after a prosthesis augmentation surgery. (**a**–**c**) Before simulation. (**d**–**f**) After simulation

59.5 Applications to Other Areas of Health and Disease

Finite element simulations can be used in the field of biomechanics to be used as a tool to help clinicians in their normal activity. There are many areas in which this tool can be useful. The ability of these numerical techniques to recreate surgical intervention allows the design of prostheses that can minimize damage to the surrounding tissues. Furthermore, the numerical methods can also include not only the mechanical environment of a specific organ but also chemical interactions regarding the use of drugs, for instance.

Summary Points

- Biomechanical breast models mainly employing finite element methods have been explored to predict breast deformations in different situations.
- To construct a reliable finite element model, the morphology of the patient breast has to be constructed using medical data (CT and MR images). Moreover, accurate constitutive properties for the different involved tissues are essential to guarantee the validity of the results.
- The deformation of soft tissues compromises the accuracy of image-guided surgery based on preoperative images and restricts its applicability. Here, we have presented a numerical model,

based on biomechanical principles, to predict breast tissue deformations, thereby avoiding this limitation.
- Predicting breast deformations with the reported accuracy will improve the surgical precision for non-palpable lesions, and provide plausible breast deformations for validation and teaching purposes.
- Plastic surgeons may benefit by virtual surgery simulation. They can provide insight into the mechanical behaviour of the breast and help in surgery planning to minimize the uncertainty of the results.

Key Facts of the Finite Element Method

The finite element method (FEM) (its practical application often known as finite element analysis (FEA)) is a numerical technique for finding approximate solutions of partial differential equations (PDE) as well as of integral equations.

The finite-element method originated from the need to solve complex elasticity and structural analysis problems in civil and aeronautical engineering. Its development can be traced back to the work by Alexander Hrennikoff (1941). Development of the finite element method began in earnest in the middle to late 1950s for airframe and structural analysis and gathered momentum at the University of Stuttgart through the work of John Argyris and at Berkeley through the work of Ray W. Clough in the 1960s for use in civil engineering. A variety of specializations under the umbrella of the mechanical engineering discipline (such as aeronautical, biomechanical, and automotive industries) commonly use integrated FEM in design and development of their products.

Key Facts of Breast Deformities

The breast is a heterogeneous organ, composed of several tissues (fat, gland and skin) and whose mechanical properties vary according to factors such as age or pregnancy. The breast provides support for lactation but does not sustain external loads in the physiologic situation except for the bodyweight. Because of these characteristics, and because it lies on a mobile myofascial unit over the rib cage, its shape undergoes large changes under applied forces. The interaction of the breast implant with the host tissues, the effect of the different prosthetic materials and the surgical procedure itself impose additional difficulties to the surgical procedure, stressing the need for a better understanding and management of the breast reconstruction surgery. Surgeons would greatly benefit from realistic surgical simulations and virtual tools, which could provide insight into the mechanical behaviour of the breast and the implant and, at the same time, help in preoperative planning, thus minimizing the uncertainty of the results.

Anthropometry of Pregnancy: Prenatal and Postnatal Aspects

Chapter 60
Reference Charts for Anthropometric Changes During Pregnancy

Elvira Beatriz Calvo and Laura Beatriz López

Abstract Maternal nutritional status should be viewed as the result of a very long process beginning in the mother's own intrauterine life, and constitutes a critical determinant of pregnancy outcomes for both the mother and her infant.

Strong evidence supports the association between gestational weight gain (GWG) and preterm birth, total birth weight, low birth weight, large and small for gestational age infants, and macrosomia. Moderate evidence relates GWG to cesarean delivery and intermediate-term postpartum weight retention.

In this chapter, the anthropometric indicators used to assess pregnant women nutritional status are reviewed, considering their predictive ability for detrimental pregnancy outcomes.

Criteria for evaluating normality of these indicators and the different instruments used as references in many settings are considered in relation to the epidemiological characteristics and health care facilities of diverse populations.

Evolution of weight gain charts in the last few decades reflects changes in recommendations and better understanding of the role of weight gain in pregnancy management. Nevertheless, there is no standardization across instruments.

Recognizing the importance of adequate weight gain during pregnancy for the mother and newborn health based on prepregnancy nutritional status, as well as the different situation in developed countries – concerned with the increasing prevalence of obesity in women – versus developing countries – where rates of low birth weight in infants are still unacceptable – are among the lessons learned.

60.1 Introduction

Maternal nutritional status should be viewed as the result of a very long process beginning in the mother's own intrauterine life, and not only in terms of the comparatively short pregnancy period.

Gestational weight gain (GWG) is a unique and complex biological phenomenon that supports the functions of growth and development of the fetus, influenced by changes in maternal physiology and metabolism, and also by placental metabolism.

The biological mechanism that underlies the relationship between women's nutritional status and reproductive outcomes is not fully understood. The two negative outcomes of principal interest, i.e. intrauterine growth retardation and prematurity, are heterogeneous syndromes, with maternal malnutrition being only one of the causative factors. Improving maternal nutrition has a significant impact on birth weight only in unfavorable conditions.

60.1.1 Gestational Weight Gain Components

Gain components are of two different natures: the products of conception and the maternal tissue accretion (Fig. 60.1). The products of conception comprise the fetus, placenta and amniotic fluid, representing 35% of the total gain on the average. Cross-sectional data indicate that fetal growth follows a sigmoid curve, with growth slowing in the final week of gestation. The rate of placental growth declines toward the end of pregnancy.

Expansion of maternal tissues accounts for approximately two-thirds of the total gain. There are increases in uterine and mammary tissue mass, along with expansion of maternal blood volume, extracellular fluid, and fat stores.

Expansion of the blood volume accounts for 10% of the total gain, and is related to fetal size. Most of the increase in plasma volume occurs before week 34 of gestation; the increase in red blood cell mass is believed to be linear from the end of the first trimester to term. The expansion of the extracellular, extravascular fluid volume accounts for approximately 13% of the total gain in women without generalized edema or with only leg edema. The retention of extracellular fluid can be highly variable; some women accumulate more than 5 L (5 kg).

Several models of body composition have been used to estimate gains in different tissues during pregnancy (Butte et al. 2003, Lederman et al. 1997). Fat tissue is normally accumulated during pregnancy and a great portion of the variance in total weight gain is accounted by this increase in fat mass. It has been estimated that pregnant women who gain 12.5 kg without edema acquire about 3.5 kg of fat. Fat accretion shows a high correlation with total increase in body weight, but no correlation with birth weight. Fat stores have been suggested as a maternal energy reserve for use when the food supply is limited during pregnancy or for further lactation.

Fat free mass can account for up to 58% of total weight gain; protein deposition also occurs predominantly in late pregnancy and it is accrued mostly in the fetus and placenta but also in the uterus, breast and other maternal tissues. Unlike fat stores, increments in total body water, total

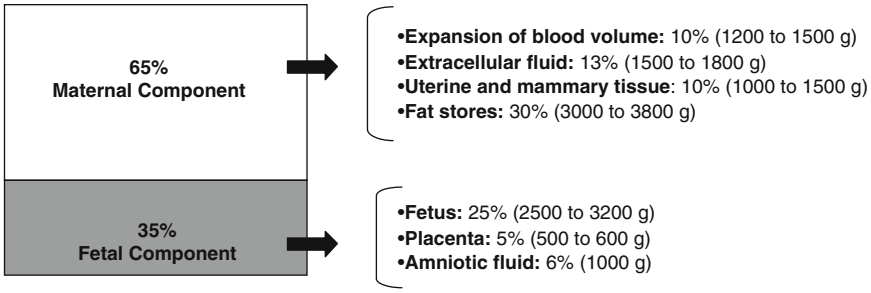

Fig. 60.1 Schematic representation of maternal and fetal components of gestational weight gain (GWG). During normal pregnancy the fetus and placenta account for one-third of total weight gain, while the expansion of blood volume and other maternal tissues for the remaining two-thirds

body potassium, protein and fat-free mass are positively correlated to birth weight across all prepregnancy BMI categories (Butte et al. 2003).

60.1.2 What Measurements Are Appropriate?

60.1.2.1 Height

Maternal height is one of the biologically acceptable predictors of birth weight. Many studies have demonstrated that short maternal stature is associated with low birth weight and stunting in the offspring. A controversial issue is the definition of short stature; the Institute of Medicine (IOM 2009) recommended that women with a height lower than 157 cm should gain weight at the lower range of the proposed standard; studies coming from Africa (Gebremariam 2005) and Asia (Mavalankar et al. 1994) suggest that women shorter than 145 or 150 cm are at higher risk of having a low birth weight (LBW) infant, while data from Latin America (Ferreira et al. 2009) propose a height of less than 152 cm as a risk factor.

There are several kinds of information that height may convey. Height may predict overall maternal body stores and may also reflect socioeconomic conditions. Maternal height is a phenotypic expression of the genetic endowment and the environment during the mother's own childhood.

Finally, maternal height is commonly accepted as a proxy for pelvic size and in turn as a clinical indicator for risk of obstetric complications, particularly cephalopelvic disproportion, prolonged labor, and/or delivery by operative means such as cesarean section. Age is an additional consideration here because pelvic measurements reach final dimensions late in adolescence.

Therefore, use of maternal height as an indicator of nutritional status should take into account the environment in which that woman has grown. A short woman from a developed country may be at risk of obstetric complications because her relatively small pelvis may constraint a vaginal delivery of a normal weight infant.

Measurement of height is best performed in the first weeks in order to avoid errors related to the normal lordosis of pregnancy, which reduces maternal height as pregnancy progresses. In young adolescent mothers, some increase in height may be observed during pregnancy.

Country- or region-specific maternal height cut-off points, which maximize sensitivity and specificity, need to be established for predicting risk of LBW and cephalopelvic disproportion. This range is likely to fall between 140 and 150 cm.

60.1.2.2 Prepregnancy/Early Pregnancy Weight or Body Mass Index (BMI)

Prepregnancy weight or prepregnancy BMI is one of the strongest anthropometric measurements associated with maternal and fetal outcomes.

Measurement of prepregnancy weight is used to assess initial risk of poor pregnancy outcomes, to determine appropriate weight gain goals for women of different nutritional risk status, and to target nutritional interventions for those most in need and those most likely to benefit from them.

The large variation in weight within a specific height category has given rise to various expressions of weight-for-height (referred to tables of desirable weight-for-height) or body mass index (BMI) calculated as weight/height^2. All these measures are primarily weighted for weight (BMI correlates above 0.9 with weight in adult women), and can be substituted.

Unfavorable outcomes of pregnancy demonstrated a U-shaped relationship with prepregnancy weight. Low prepregnancy BMI has been identified as a risk factor of having an infant of LBW or small for gestational age (SGA); on the other hand, a high prepregnancy BMI is linked to a number of fetal and maternal complications, including fetal death, preeclampsia, gestational diabetes, macrosomia, and complicated deliveries.

Prepregnancy weight is also related with the pattern of GWG. Many epidemiological studies around the world suggest that GWG is influenced by maternal weight or BMI. In general, GWG decreases as prepregnancy BMI increases.

In developing countries, many women do not remember their prepregnancy weight. In such cases, weight at gestational ages lower than 12 weeks can be used as an equivalent of prepregnancy weight because during the first trimester weight accretion is minimal.

A low cut-off point of 40 kg is the most cited figure of risk in developing countries' literature for populations with average heights of 150 cm or less.

60.1.2.3 Weight Gain During Pregnancy

Maternal weight gain during pregnancy is a key component of prenatal care, and reflects maternal and fetal health. Both total weight gain and the rate of weight gain are associated with infant and maternal health outcomes.

Many factors determine the total amount of weight gain during pregnancy. Among the physiological factors, the three main components are changes in maternal physiology and metabolism, placenta functions, and fetus growth. Non-physiological factors include psychological, behavioral, family, social, cultural and environmental aspects.

During prenatal care, maternal weight gain at different gestational ages should be used to guide pregnant women in order to achieve an optimal weight which minimizes the risk of adverse fetal and maternal outcomes. For this purpose, charts, curves or guidelines are useful instruments that can be applied at individual level or for epidemiological evaluation.

60.1.2.4 Mid-Upper Arm Circumference (MUAC)

Mid-upper arm circumference is a simple and objective method of assessing nutritional status, widely recognized as an effective tool for screening purposes. Like body weight, it also reflects past and current status, but is less responsive to short-term changes in health and nutrition.

Many studies have evaluated its use as an alternative or complementary measurement during prenatal care. There is a consensus that it has a strong correlation with maternal weight and BMI, and also a positive relationship between MUAC and birth weight has been reported.

In developing countries, pregnant women usually start prenatal control after the first months of pregnancy and thus prepregnancy weight could be unknown; in such cases, total weight gain by gestational age is difficult to determine and MUAC becomes an alternative tool for anthropometric evaluation.

Nevertheless, there is no consensus about the cut-off point that can be associated with an increased risk of LBW, prematurity or insufficient maternal weight gain. The proposed figures vary according to socioeconomic and demographic characteristics of the populations studied. Data from Africa and Asia (Kruger 2005; Ojha and Malla 2007) suggest that, during pregnancy, MUAC below 25 cm can be used as a warning of malnutrition, below 23 cm as a strong indicator of malnutrition, and figures lower than 22 cm are highly associated with an increased risk of adverse pregnancy outcomes, specially LBW. However, there is lack of information about reference figures for MUAC to be applied in pregnant women from other regions of the world.

Different patterns of MUAC change have been described in well-nourished European or U.S. women (with average increments between 0.3 and 0.5 cm), and consistent losses in arm circumference have been reported in studies from developing countries. It seems that subcutaneous fat is used to fulfill fetus requirements when weight gains are in the range of 4–6 kg in thin or normal weight women. With intermediate gains, MUAC could remain unchanged.

Taking into account the abovementioned data, MUAC is not recommended for monitoring, but it is a useful tool for screening purposes.

60.1.2.5 Skinfold Thickness

Skinfold thickness reflects subcutaneous fat stores, which are used to fulfill the fetus and the mother's energy needs during pregnancy and lactation. Bicipital, tricipital and subscapular skinfolds are the most frequently used. Changes in these measurements could also be appropriate to assess maternal nutrition status, but as in the case of MUAC, few studies have evaluated the pattern of their variation at different gestational ages and no cut-off points are available to be applied during prenatal control.

A more extensive description of skinfold use during pregnancy will be addressed by Professor S. Rao in other chapter of this book.

60.1.3 Conditions for a Reference

"A reference is defined as a tool for grouping and analyzing data and provides a common basis for comparing populations; no inferences should be made about the meaning of observed differences. A standard, on the other hand, embraces the notion of a norm or desirable target, and thus involves a value judgment" (WHO 1995a).

Current reference data describe the distribution of anthropometric indices in ostensibly healthy and well-nourished populations with favorable pregnancy outcomes. This is known as the specificity distribution for anthropometric characteristics.

In turn, there are several definitions of what constitutes a healthy population:

- The population lives in a healthy environment.
- The population lives in a healthy environment and contains no overtly sick or very few clinically sick individuals.

- The population lives in a healthy environment and contains only individuals whose present good health will be demonstrated by survival after measurements are taken.
- The population lives in a healthy environment and contains only individuals who live healthily according to present prescriptions.

It should be emphasized that the specificity distribution indicates only the extent to which a particular woman deviates from the median of a healthy population; it does not indicate the probability of suffering an adverse outcome in the future. The latter requires empirical data on the sensitivity distribution, which is the probability of suffering a given adverse outcome, which in turn depends on the prevalence of that outcome in the population. The distance between these two distributions can only be determined empirically.

From the above, it is derived that some conventional cut-off value based on the specificity distribution (e.g. the 3rd centile) has no intrinsic meaning for predicting the risk of adverse outcomes as obstetric complications, LBW, or others. The risk of adverse outcomes increases as distance from the median increases, but the particular point where the risk steps up requires knowledge of the sensitivity distribution and the prevalence of the outcome under study. Most of the empirical evidence of weight gain during pregnancy is not sufficient for constructing reference data based on risk or benefit.

In the case of individual screening, the ability of the standard to appropriately select individuals at risk largely depends on the prevalence and variability of the condition being screened.

When used for categorizing populations, a common reference allows comparison of the nutritional status of populations in different regions of the world.

There is a controversy about the utilization of universal references, even when it could be considered that physiological processes in healthy individuals (growth in the first years of life, gestation) evolve in the same way independently of geography or even ethnicity.

On the other hand, different standards have been proposed for diverse populations, considering variation in genetics, phenotypes or environmental exposures; for example, growth data according to parental size or pregnancy weight gain according to ethnicity, or mean birth weight according to maternal smoking habits.

However, when reference data are used to make decisions about populations, it is better to use statistical methods to control for differences within or across populations than to use different standards.

The relatively lower use of "growth" or nutritional status reference data in prenatal care as compared with pediatric care is noteworthy.

Worldwide, the references accepted and used for monitoring infants' and children's growth are basically normative; that is, they are derived from samples of a "healthy population". Taking the most stringent criteria – such as the WHO multicenter growth reference (de Onis et al. 2004) for children of 0–5 years of age – does not necessarily imply that the sensitivity and specificity of these indicators and their usual cut-offs for predicting several functional outcomes will be optimal. Nonetheless, their usefulness is beyond discussion.

Why, then, are similar criteria not considered sufficiently appropriate to develop references for GWG or other parameters of pregnant women nutritional status?

60.1.4 Relationship Between Reference Data and Functional Outcomes

There is no standard definition of what constitutes a "good pregnancy outcome". The IOM Committee defined a favorable pregnancy outcome as the delivery of a live-born infant with a birth weight

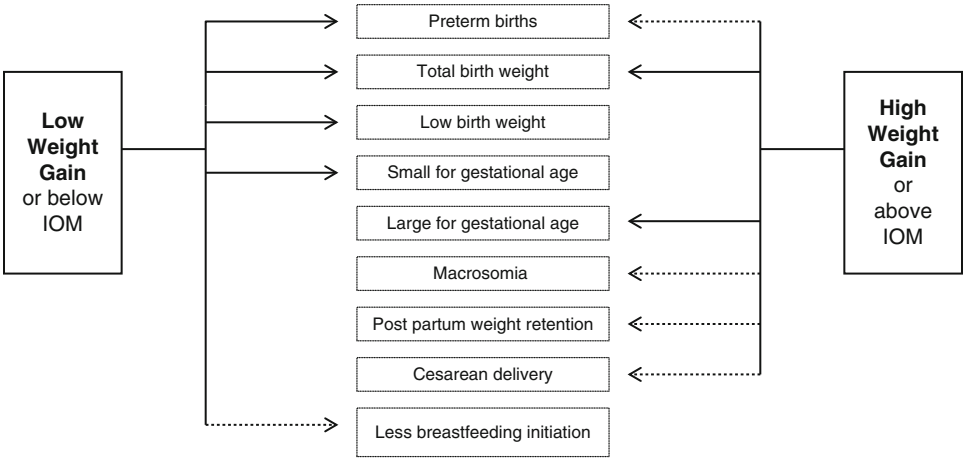

Fig. 60.2 Evidence-based association between GWG and several outcomes. This scheme represents the association between GWG and the most important newborn and maternal outcomes, based on observations from different studies. Strong evidence is shown with *solid arrows* and moderate evidence with *dotted arrows*. IOM = Institute of Medicine recommendations

between 3 and 4 kg at 39–41 weeks of gestation (IOM 1990). Carmichael et al. (1997) defined a good outcome as a vaginal, term delivery of a live infant of average size for gestational age (between the 10th and 90th percentiles of gestation-specific birth weight) from a mother without diabetes or hypertension.

Other outcomes would potentially be included, such as absence of medical complications during labor and delivery, or absence of postpartum weight retention or breast-feeding initiation.

Previous observational research has shown that weight gain monitoring is not highly sensitive when used in isolation to predict pregnancy problems. Because the amount of total weight gain is widely variable among women with good pregnancy outcomes, and as perinatal outcomes of interest are multifactorial in origin, no one should expect that weight gain alone is a perfect diagnostic or screening tool.

On the other hand, there are several consequences for the health of the mother and the child that are potentially causally related to GWG. It is important to consider their incidence, long-term sequelae and baseline risk (concept that can be summarized as the population attributable risk) in order to prioritize its inclusion in the development of a normative instrument or recommendation.

Recently, a systematic review of the literature on outcomes of GWG has been published (Viswanathan et al. 2008). It comprises studies published in English from 1990 through October 2007 and assesses the evidence about five key questions, among which the following are included:

1. Association between total weight gain (or rate of weight gain) during pregnancy and birth outcomes, infant health outcomes, and maternal health outcomes.
2. Evidence that weight gain above or below IOM (1990) recommendations on BMI or weight loss in pregnancy contribute to antepartum or postpartum complications or longer term maternal and fetal complications.
3. Harms or benefits of offering the same weight gain recommendations to all pregnant women, irrespective of age and body weight.

Figure 60.2 summarizes results for major outcomes. Other maternal and infant or children health outcomes had weak or nil evidence of association. The authors also concluded there is inadequate

evidence for the objective assessment of harms and benefits of providing all women (irrespective of age, ethnicity or prepregnancy BMI) with the same recommendations for weight gain in pregnancy.

The majority of studies found an effect of low GWG on preterm birth; high GWG was less consistently associated with this outcome. The association between low GWG and preterm birth was stronger for underweight women than for any other category of pregravid weight status.

Low GWG is significantly associated with lower birthweights across all pregravid weight status groups. High GWG resulting in higher birthweight appears to be limited to underweight and normal-weight women.

The evidence linking low GWG and LBW (<2,500 g) appears to be stronger among women who, before pregnancy, had underweight or normal weight than among women who had overweight or were obese. In general, risks for LBW began to decrease for GWGs above 11.3–13.6 kg.

Several studies evaluated the relationship between continuous total weight gain and birthweight using linear regression techniques, and reported that birthweight increased between 16.7 and 22.6 g for every 1 kg of increase in weight gain.

A large body of literature yielded strong evidence of an association between low GWG and the risk of having an SGA infant. This association is seen whether weight gain is examined in categories or in absolute terms and despite some inconsistencies regarding what variables were controlled for in the analysis.

The increased risk of delivering a large for gestational age (LGA) infant was consistently seen in women with higher absolute weight gains and in women with gains over the IOM 1990 recommendations. The body of evidence is large and strong for this association, despite differences in the definition of LGA and factors that were controlled for confounding.

On the other hand, the evidence suggests that a high gestational weight gain has no effect on macrosomia for underweight women.

The majority of studies suggested an association between high gestational weight gain and cesarean delivery. This association appeared to be stronger for overweight and obese women, and when weight gains were above IOM 1990 recommendations for underweight and normal-weight women.

Gestational weight gain was positively associated with weight retention within 1 year postpartum and with interpregnancy weight gains. In the long term, the effect of GWG on weight retention was less conclusive.

Additionally, weight retention differed across pregravid BMI strata: overweight and obese women retained more weight compared to normal weight women. Postpartum weight retention could be especially problematic for obese women, who may be at risk of increases in fat mass and central adiposity in the postpartum period.

Even when the review found few studies that collected or analyzed data in a manner that allowed compilation and synthesis, the authors concluded that:

Weight loss is not considered appropriate during pregnancy for any weight status.

The review found no evidence for other maternal outcomes such as hyperemesis, abnormal glucose metabolism, hypertensive disorders, gallstones and maternal discomforts of pregnancy.

The Committee of Weight Gain during Pregnancy: Re-examining the Guidelines (IOM 2009) has finally retained measures of birth size (SGA and LGA), preterm birth and childhood obesity as the most important infant health outcomes. In the case of mother health outcomes, only postpartum weight retention and unscheduled primary cesarean delivery were considered, after removing preeclampsia and gestational diabetes mellitus due to lack of sufficient evidence that GWG was a cause.

The Committee based its guidelines "on the presumption that the extensive, consistent observational data that link GWG to fetal growth, as measured by SGA and LGA, as well as those that link GWG to postpartum weight retention are *causal*."

Universality of a reference for clinical use precludes in some way its linkage with a particular outcome. Moreover, indicators and cut-off points for different outcomes in different population settings should be different.

Weight gain during pregnancy should continue to be monitored, given the ease of measuring and due to consistent findings in diverse populations that women who gain above or below the current recommended amounts have worse pregnancy outcomes.

There is enough evidence in the developed countries' literature that pregnancy weight gains within the limits of the IOM 1990 recommendations are related to better outcomes.

60.1.5 Most Used Instruments for Measuring Gestational Weight Gain

60.1.5.1 A Historical Perspective

Gestational weight gain (GWG) charts are useful instruments to monitor GWG in clinical practice. Table 60.1 summarizes some of these curves developed in different geographical areas of the world.

Many approaches have been used for making recommendations about GWG. From the extreme of the National Center for Clinical Excellence in the UK that women should not be weighted at all during pregnancy to avoid anxiety, to a single average weight gain target for all women irrespective of their previous nutritional status, such as the US recommendation in the first half of the twentieth century of ideally no more than 9.1 kg. At that time, a common practice was to restrict weight gain during pregnancy with the aim of preventing toxemia, difficult births and maternal obesity. This policy started to change during the 1970s when experts began to associate LBW with the relatively high rates of infant mortality, disability and mental retardation at that moment. A new target of 10.9 kg with a range of 9.1–11.3 kg was then proposed, based on the amount of obligatory weight gain to meet the physiologic needs of the product of conception, plus the expansion of plasma volume and fat stores during pregnancy (NRC 1970).

The first proposed instruments were developed based on the average GWG observed in samples of healthy pregnant women; many of them have the disadvantage of the small sample size or the theoretical approach in the design. Proposals from the beginning of the twenty-first century are mostly based on longitudinal studies, applying new statistical methods, and/or considering the prepregnancy BMI category for making different recommendations.

60.1.6 Charts Versus Recommendations for Total Weight Gain

Even when GWG charts have been used in clinical practice for many years, there is no standardization across instruments because of lack of appropriate primary data. Different kinds of references have been published, basically those that recommend ranges of weight gain and charts of attained weight or BMI for gestational age.

Table 60.1 Characteristics of main GWG charts and tables

Author and year	Country (*n*)	Study characteristics
Tompkins and Wiehl (1951)	Unites States (*n* = 60)	The mean total GWG in the sample was 10.9 kg, but no ranges, standard deviations or percentiles were reported. The curve developed has been used to generate different charts mostly in the USA
Hytten and Leitch (1971)	England (*n* = 2870)	Average weight gain of healthy, primiparous, normotensive British women with favorable pregnancy outcomes
Gueri et al. (1982)	Dominica (*n* = 340)	A reference table of weight-for-height by week of pregnancy was devised on theoretical grounds, based on the premises that the average weight increase during pregnancy is 20% of the prepregnancy weight and that almost all the increase takes place linearly during the 2nd and 3rd trimesters of pregnancy
Fescina (1983)	Uruguay (*n* = 43)	A chart was developed on the basis of longitudinal follow-up of pregnant women without pathologies. A second chart was proposed to evaluate GWG when prepregnancy weight is unknown
Rosso (1985) Mardones and Rosso (2005)	Chile (*n* = 1745)	The instrument diagnoses, from gestational week 10 onwards, mothers at risk of delivering babies with birth weight under 3,000 g and set weight gain goals for each individual mother based on her nutritional status. For underweight women, weight recommendation was derived from the obtained data, while for overweight and obese women it was based on data extrapolations. The chart has been used in many Latin American countries
WHO Collaborative Study (1995b)	25 population groups throughout the world (*n* = 111,000)	Height, weight, BMI and MUAC in early pregnancy, and weight and BMI attained at 20th, 28th, and 36th weeks were determined. Odds ratios for low birth weight (LBW), preterm delivery, SGA and other outcomes were calculated by each indicator. Weight gain charts for four different country groups were developed
Wong et al. (2000)	China (*n* = 504)	Target weight gains associated with reduced risk of adverse pregnancy outcomes for underweight, average and overweight women were developed
Mahaba et al. (2001)	Egypt (*n* = 830)	A prospective study was conducted to develop weight gain charts for healthy Egyptian pregnant women. The mean total weight gain was 9.3 kg. The velocity growth chart developed for weight gain showed that weight increase was about 1 kg up to the 4th gestational month, then, a steady increase of 0.37 kg/week was observed till the end of pregnancy
Ochsenbein-Kolble et al. (2007)	Switzerland (*n* = 4,034)	Fifth, 50th and 95th centiles of weight and BMI were presented for Caucasian, Asian, and black women. Mean total weight gain was 15.5 ± 5.9 kg
Casanueva et al. (2008)	Mexico (*n* = 438)	Four equations for maternal predicted weight across categories of pregestational BMI (underweight, normal, overweight and obese) and gestational ages were developed and synthesized in a table of reference values
Calvo et al. (2009)	Argentine (*n* = 1,439)	A prospective multi center cohort study was conducted to develop weight gain charts for healthy Argentinean pregnant women. Centile curves of body weight and BMI by gestational age were developed using the LMS method. Mean total weight gain was 11.9 ± 4.4 kg

This table summarizes the authors, year of publication, country, number (*n*) of subjects studied, and the main characteristics of some of the relevant publications which developed charts for evaluate GWG

The evolution of weight gain charts reflects changing recommendations over time and the greater understanding of the role of weight gain in managing pregnancy.

60.1.6.1 Weight Gain Recommendations

The IOM (1990) report recommended different weight gain targets according to prepregnancy BMI groups. The rationale was to achieve birth weights in the range of 3–4 kg for all prepregnant

Table 60.2 IOM recommendations for total gain and rate of weight gain during pregnancy, by prepregnancy BMI (IOM, USA 2009)

Prepregnancy BMI	Total weight gain (range in kg)	Rates of weight gain 2nd and 3rd trimester Mean (range) in kg/week
Underweight (<18.5 kg/m^2)	12.5–18	0.51 (0.44–0.58)
Normal weight (18.5–24.9 kg/m^2)	11.5–16	0.42 (0.35–0.50)
Overweight (25–29.9 kg/m^2)	7–11.5	0.28 (0.23–0.33)
Obese (≥30.0 kg/m^2)	5–9	0.22 (0.17–0.27)

The first column shows the usual classification of prepregnancy BMI; the range of total recommended weight gain for each category and the rate of gain in kilogram per week are shown in the second and third columns, respectively

BMI groups while avoiding LGA infants and other possible risks to the mother and newborn. These recommendations were the first to account for pregravid weight status and to encourage obese women to gain weight during pregnancy in recognition of the needs of the fetus. This report used BMI values of 19.8–26.0 as the definition of normal prepregnancy weight, which corresponds to 90% and 120% of the desirable weight-for-height of the 1959 Metropolitan Life Tables. Since the publication of the IOM report, many studies have intended to determine the optimal GWG that represents a reasonable trade-off between adequate fetal growth and maternal weight retention.

The prepublication copy of IOM (2009) Guidelines, after reviewing main publications during the preceding period, finally modified the previous recommendation by changing the values of prepregnant BMI categories and the recommended weight gain for obese women. BMI values for adults proposed by the World Health Organization (WHO 1995) have been substituted for prepregnant BMI categories.

The Committee formulated the new Guidelines with a range of recommended weight gain for each category of prepregnant BMI. Ranges reflect the imprecision of the estimates, and the reality that good pregnancy outcomes are achieved with different gains and are influenced by many other factors. Ranges were chosen on the basis of values associated with the lowest prevalence of adverse outcomes of greatest interest – cesarean delivery, postpartum weight retention, preterm birth, small or large for gestational age newborn – and according to the quality of available data.

The range of total weight gain was modified only for the obese group and set at 5–9 kg, with respect to the 7 kg of 1990 IOM recommendations. These new guidelines are shown in Table 60.2.

Average pregnancy weight gains in developing countries are much lower than those reported in industrialized countries. Figures in the literature are between 5 and 9 kg for the former ones, compared to 10–15 kg for the latter (Krasovec and Anderson 1991). The extent to which the USA or European standards of pregnancy weight gain are appropriate for undernourished women in developing countries needs to be assessed. These differences in weight gains parallel the differences in the incidence of LBW.

60.1.6.2 Distance and Velocity Curves

Distance is the current value of an anthropometric measurement, and velocity is the rate of change of that measurement.

Height, prepregnant weight, weight at any point during pregnancy, MUAC, and skinfold thickness are distance measurements. Most weight gain charts are actually distance curves, representing attained weight at a given point in pregnancy.

Velocity of weight gain has been described in Tables or Charts in different time intervals: by week, by month or by trimester. It should be adjusted for gestational age, since it is not linear throughout pregnancy.

An alternative to those is a conditional standard, usually regression-adjusted, like the one proposed by Rosso, which takes into consideration the expected weight gain at the end of pregnancy as a function of prepregnant weight.

The chart published by Rosso (1985) and Mardones and Rosso (2005) is based on a single target of weight gain but is expressed in a relative value of standard weight-for-height, from 95% of the standard at the beginning of pregnancy to 120% of the standard at term. This represents different patterns of recommended weight gain for underweight, normal weight and overweight women. The instrument was based on empirical data and intended to increase average birth weight among underweight women. Rosso's chart, like that of Gueri et al. (1982), suggests that underweight women should gain all their weight deficit up to the prepregnancy reference weight as well as the additional weight due to pregnancy needs.

Anderson, in Krasovec and Anderson (1991), pointed out that a 110% increase in weight-for-height could be a more realistic target for developing countries' women, based on her findings in India.

60.1.6.3 Advantages and Disadvantages of Charts

The WHO (1995) recommends that GWG charts should be based on longitudinal studies in selected populations with low prevalences of maternal and fetal complications, with anthropometric measurements being performed before and during the course of pregnancy. Ideally, upper and lower limits around the average curves should be set.

Most recommendations, including those from the IOM, are based on cross-sectional studies and this precludes the analysis of the shape of weight gain curves.

It is sensible to study changes during pregnancy in longitudinal designs in order to develop reference patterns to be used in clinical practice. We have identified only a few cohort studies of prospective nature with an adequate sample size in the literature: Mahaba et al. (2001) in Egypt, Mardones and Rosso (2005) in Chile, Casanueva et al. (2008) in Mexico, and Calvo et al. (2009) in Argentina.

Expressing weight gain in absolute values does not consider proportionality of suggested weight gain for short and tall women. The use of BMI is a practical way to solve this problem, taking into account a woman's height during the whole course of pregnancy, along with keeping to the current recommendations of expressing body size in adults in terms of BMI. Moreover, BMI is not based on the concept of "ideal".

Other aspect to be considered is the reliability of the recalled prepregnancy weight (Brown et al. 2002), which is essential for the calculation of weight gain. When using charts, even if women initiate prenatal care late in pregnancy, their current weight or BMI can be plotted in the appropriate risk area for their gestational age in the chart.

In turn, most charts require accurate estimations of gestational age for proper interpretation of adequacy of achieved weight or BMI. This can be difficult in certain environments.

In the design of weight gain charts, it is necessary to be clear about the outcomes they are intended to predict or prevent: infant outcomes, pregnancy complications, or maternal stores postpartum. Charts need to be interpreted accordingly, and one chart could serve various purposes.

To a certain degree, the curve of average gain in the normative population provides guidance to the health team. However, it is advisable to validate upper and lower limits of the instruments as empirically derived cut-off values to discriminate at least one favorable outcome. Most references (Rosso 1985; Calvo et al. 2009) use birth weight as the outcome.

60.1.6.4 Weight Gain Patterns

Several studies reported on the effects of GWG, by trimester, on infant birthweights. They were consistent in demonstrating that weight gain in the third trimester had the least effect.

One US study (Brown et al. 2002) reported that weight gain during the first trimester was associated with a 31 g increase in birthweight per kilogram of GWG. Comparable gains in infant birthweight for each kilogram of GWG in the second and third trimesters were 26 and 7 g. This study also found that infant birthweight decreased by 211 g among mothers who lost weight during the first trimester.

A Canadian study (Muscati et al. 1996) found similar results: for each 1 kg increase in weight gain up to week 20, birthweight increased by 22 g; increases from week 21 to 30 increased birthweight by 31 g; and weight gain from week 31 to term increased birthweight by 12 g.

Lastly, another US study (Abrams and Selvin 1995) reported an 18 g increase in birthweight for each kilogram gained by the mother in the first trimester. Corresponding increases in the second and third trimesters were 32.8 and 17.0 g, respectively.

Our own study (Calvo et al. 2009) showed differential patterns of weight velocity by trimester in women who gave birth to infants of less than 3 kg and infants of 3 kg or more, particularly between weeks 20 and 24 (0.45 vs. 0.52 kg/week).

60.1.7 Special Pregnancies

60.1.7.1 Multiple Pregnancies

In multiple pregnancies, average weight gain is higher than in singleton pregnancies and it is also positively related to birth weight.

Over the last years, a number of studies have evaluated total weight gain, the rate of weight gain, and their relationship with fetal outcomes in twin pregnancies. One of the most relevant comes from the historical cohort of twin births based on 2,324 pregnancies with non-anomalous, liveborn twins (4,684 infants) from Ann Arbor, Charleston, Baltimore and Miami in the USA (Luke et al. 2003). Data from this cohort have been taken into account by the IOM to set up the cumulative gains and rates of weight gain stratified by maternal prepregnancy BMI (Table 60.3). In mothers with normal prepregnancy BMI, average total weight gain was around 20 kg, with a rate of 0.3 kg/week in the first trimester and around 0.7 kg/week in the second and third trimesters. As in singleton pregnancies, there is an inverse relationship between GWG and pregravid BMI.

In twin pregnancies, maternal weight gain during critical periods of gestation significantly influences twin birth weight, and these critical periods vary by maternal pregravid weight status; birth weight is significantly associated with weight gain before 20 weeks in underweight women, after 28 weeks in overweight women, and during the whole pregnancy in normal-weight women.

According to the IOM (2009), mean GWG for triplet pregnancies varied from 20.5 to 23.5 kg at 32–34 weeks and from 20.8 to 31.0 kg at 32 weeks of gestation for quadruplets.

Table 60.3 Cumulative weight gain and rates of weight gain by prepregnancy BMI status of mothers of twins with average birth weight > 2,500 g (Modified from IOM, USA 2009)

	Prepregnancy BMI		
Weight gain by gestational age	Normal weight (18.5–24.9 kg/m^2)	Overweight (25.0–29.9 kg/m^2)	Obese (≥30.0 kg/m^2)
Up to 13 weeks			
Cumulative weight gain (kg)	3.6 ± 0.3	2.1 ± 0.4	2.0 ± 0.5
Rate of weight gain (kg/week)	0.33 ± 0.02	0.20 ± 0.04	0.18 ± 0.04
Up to 26 weeks			
Cumulative weight gain (kg)	13.1 ± 0.3	11.3 ± 0.4	8.5 ± 0.4
Rate of weight gain (kg/week)	0.77 ± 0.02	0.72 ± 0.03	0.45 ± 0.03
27 weeks to delivery			
Cumulative weight gain (kg)	20.9 ± 0.3	18.9 ± 0.5	15.7 ± 0.5
Rate of weight gain (kg/week)	0.67 ± 0.01	0.61 ± 0.02	0.58 ± 0.03

In this table the figures (mean ± standard error of the mean) refer to the estimated weight gain of mothers of twins with adequate birth weights in different trimesters and according to their prepregnancy BMI. First row refers to total accumulated weight gain, and second row shows the rate of weight gain per week

60.1.8 Adolescent Pregnancy

Pregnant adolescents are at particular risk of both inadequate and excessive GWGs. In addition, there is evidence that adolescents, especially young adolescents (≤16 years old), are more likely to deliver LBW infants and have an increased risk of neonatal and postnatal mortality.

No special charts or patterns have been proposed to monitor pregnancy weight gain in adolescents. According to the 1990 IOM recommendations, young adolescents should gain weight at the upper end of the recommendations, while older adolescents (>16–19 years old) should gain weight similarly to adult women. Nevertheless, there is concern regarding the application of adult criteria to categorize pregnant adolescents into prepregnancy BMI categories and subsequent GWG recommendations.

The misclassification of adolescent prepregnancy BMI could lead to inadequate guidance (Groth 2007).

A recent study (Fernandez et al. 2008) has pointed out that, according to the Center for Disease Control BMI cut-offs points, adolescents with healthy weight and those at risk of overweight are at higher risk of misclassification, and they could be recommended to gain too much weight because they would be assigned the GWG ranges corresponding to the low and average IOM categories, respectively.

In adolescents, an unnecessary higher weight gain during the course of pregnancy can be associated with higher postpartum weight retention and could contribute to higher levels of obesity, with minimal improvement of infant birth weight. For these reasons, the last IOM (2009) document states that young adolescents should be advised to stay within the recommended BMI-specific weight gain range, without either restricting weight or encouraging weight gain at the upper end of the range.

60.1.9 Suggestions for Selecting an Anthropometric Reference in Prenatal Care

Monitoring weight gain has been the most common means of assessing the nutritional status of women and their infants during pregnancy. Maternal weight is sensitive to acute nutritional stresses during pregnancy, and it provides the most general impression of fetal growth as compared to other

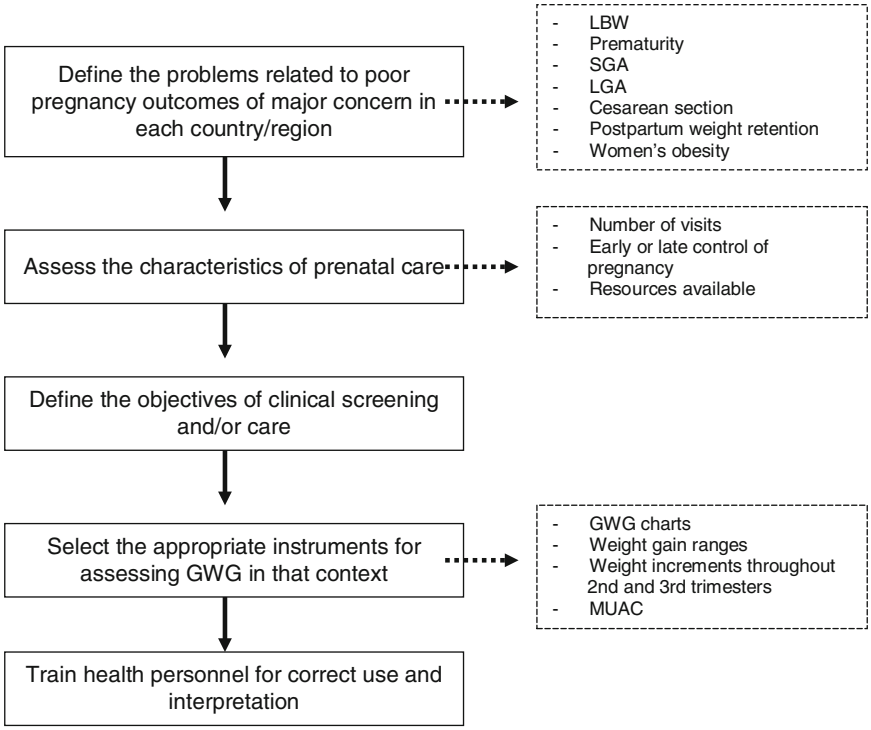

Fig. 60.3 Scheme for selecting the appropriate instruments and processes to evaluate pregnant women nutritional status, according to epidemiology and health care conditions. This figure is thought to guide policy makers and public health agents to select the instruments for maternal nutrition evaluation appropriate for the context

anthropometric measures. Another advantage of weight monitoring for risk assessment is that weight changes are gross enough to detect significant increments during pregnancy.

Figure 60.3 shows a scheme suggested to choose the appropriate instruments and processes to evaluate women's nutritional status during pregnancy, according to the epidemiological and health care conditions for.

Due to the fact that pregnancy is the only common clinical situation where the health provider has at least two patients, the mother and the fetus(es), balancing the amount of weight gain needed to optimize the size of the baby without jeopardizing the health of the mother both in the short and long term is essential. The balance has proven challenging.

While developed countries are concerned about body weight increases in women of childbearing ages combined with a rising trend in weight gain during pregnancy outside the IOM recommendations, in many developing countries prevalence of LBW remains unacceptably high.

Many of the current weight gain charts assume that women initiate prenatal care early in the first trimester and have prenatal visits once a month during pregnancy. The feasibility of this approach is low in developing countries, and it is also matter of debate if such frequency is necessary.

Monitoring weight gain during pregnancy can be difficult in a primary health care setting considering equipment, personnel training, and the need of multiple visits among other obstacles. However, many of these difficulties have been overcome in child growth monitoring, and lessons can be learned from these successful programs.

Define the objectives of care:

- *Adequate resources; mothers seen periodically from early pregnancy*: In countries where more than 60% of women receive regular prenatal care, and equipment as well as trained staff are available,

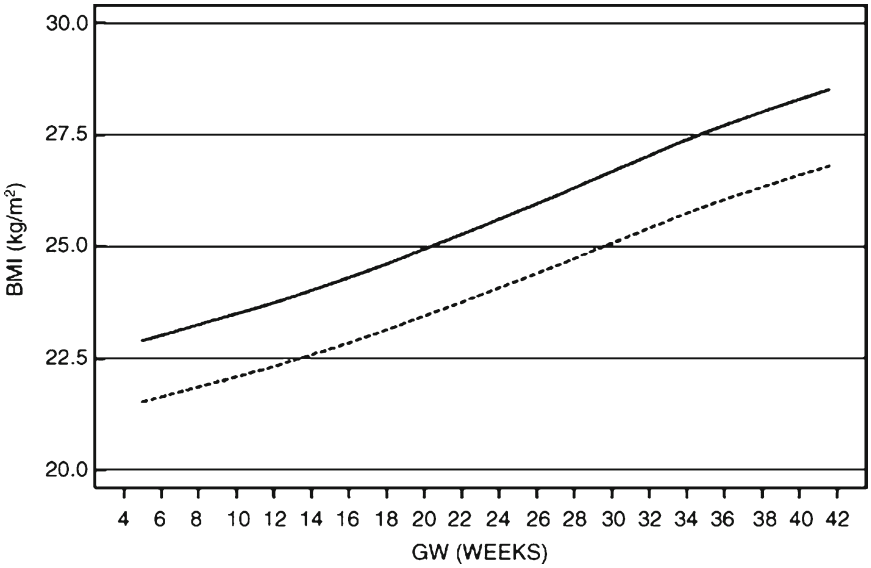

Fig. 60.4 BMI 50th centile curves in European pregnant women. Body mass index (BMI) of European pregnant women along pregnancy. Caucasians and Blacks (*continuous line*) and Asians (*dashed line*). (Reprinted from Ochsenbein-Kölble et al. 2007, Copyright (2007), with permission from Elsevier)

serial weighing during pregnancy should be undertaken (Krasovec and Anderson 1991). Use of charts for individual follow-up is advisable.

- *Adequate resources; at least two measurements from mid-pregnancy*: Assessment of weight increments in the second or third trimester of pregnancy is a simplified means to monitor weight gain. A minimum amount of 1 kg/month throughout the 2nd and 3rd trimesters has been recommended. Taking only two measurements 1 month apart is far more feasible in disadvantaged regions.

  Lack of weight gain or weight loss between two consecutive measurements is very detrimental to the fetus and requires immediate action.

- *Low resources setting*: Where weight gain monitoring is not feasible at all due to limitations in facilities, staff and/or coverage of prenatal care, screening with measurements that require only one contact should still be recommended. Arm circumference or prepregnant weight could be used.

  MUAC can be used as a first screen in order to refer women to facilities for a more complete assessment of nutritional risk.

60.1.10 Select the Instruments

Charts have been developed for screening individuals who may be at risk based on one or more measurements, either for individual treatment or for targeting interventions to groups, and also for monitoring the progress of women between serial visits during pregnancy and for pregnancy management.

Even if women initiate care late in pregnancy, their weight-for-height or BMI can be plotted in the appropriate risk area for their gestational age in a chart. Nevertheless, gestational age must be known.

In Figs. 60.4–60.6 several examples of recently published Charts from different countries are provided.

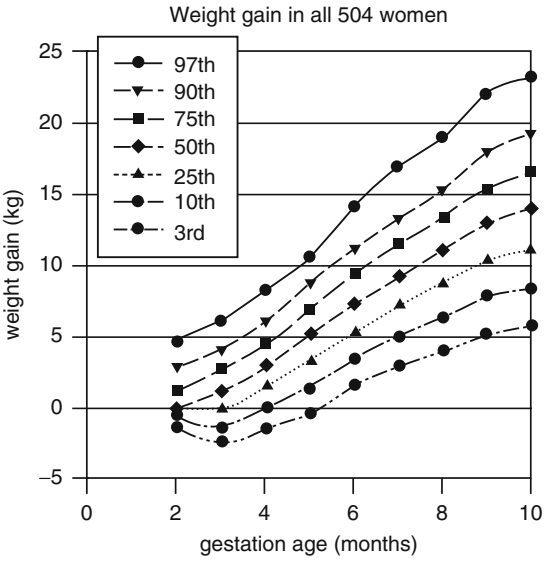

Fig. 60.5 Distribution of weight gain during pregnancy in Chinese women. Percentiles of weight gain during pregnancy in Chinese women with good outcomes. (Reprinted from Wong et al. 2000, Copyright (2000), with permission from Elsevier)

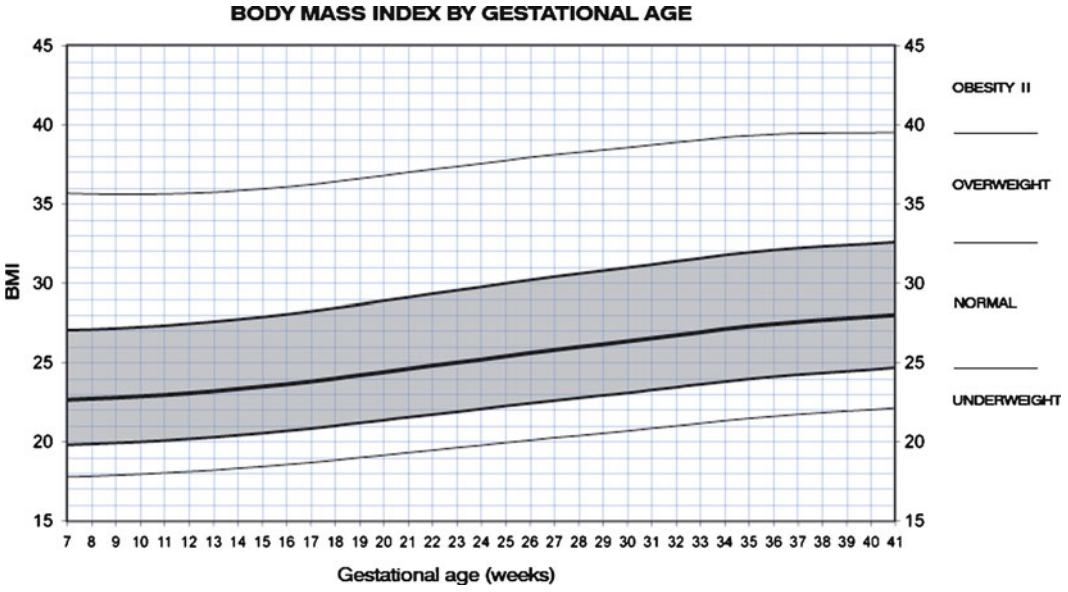

Fig. 60.6 BMI curves by gestational age in Argentine pregnant women with normal weight newborns. The *shadow area* represents the recommended BMI at different gestational ages for women who gave birth to normal weight infants

Anthropometric indicators identify women with nutritional problems, but do not reveal the underlying cause or determinant of the problem, or the best interventions to solve it.

Any guidelines should be used in concert with good clinical judgment as well as discussion between the woman and her prenatal care provider, who should consider other relevant clinical evidence

in addition to the adequacy and consistency of fetal growth, and any available information on the nature of the excess (e.g. fat or edema) or inadequate weight before suggesting that the woman modify her pattern of weight gain.

It is useful to screen reproductive age women either for low or high BMI in order to intervene prior to pregnancy, since prepregnancy weight is highly critical to pregnancy outcome and maternal global health.

The high pregnancy weight gains necessary to ensure favorable pregnancy outcomes for women of low prepregnancy weight may be unrealistic for many women in developing countries. Therefore, equal emphasis should be placed on improving prepregnancy weights.

On the other hand, interventions aimed at treating obesity (modifying dietary habits and physical activity) should be undertaken before pregnancy.

Interventions for undernourished mothers should not be limited to the 9 months of pregnancy or even to the fewer months of acknowledged pregnancy. Supplementation programs can have a greater impact on birth weight in the second pregnancy if intervention is maintained.

Summary Points

Background

- Maternal nutritional status, both prior to and during pregnancy, is a critical determinant of pregnancy outcomes for both the mother and her infant. This is true in industrialized and developing country settings.
- Strong evidence supports the association between GWG and preterm birth, total birthweight, LBW, large and small for gestational age infants, and macrosomia. Moderate evidence relates GWG to cesarean delivery and intermediate-term postpartum weight retention.

Antropometric Indicators

- Maternal height is one of the biologically acceptable predictors of birth weight, along with other indicators. For screening purposes, the range of cut-off points for predicting either LBW or cephalopelvic disproportion is likely to fall between 140 and 150 cm.
- Low prepregnancy BMI has been identified as a risk factor for having an infant of LBW or small for gestational age.
- High prepregnancy BMI is linked to fetal death, macrosomia, preeclampsia, gestational diabetes and complicated deliveries.
- Prepregnancy weight should be interpreted in relation to height to be useful for cross-population comparisons.
- The relationship between prepregnancy weight and pregnancy outcomes is mediated by the amount of weight a woman gains during pregnancy.
- In cases where prepregnancy weight is unknown and total weight gain by gestational age is difficult to determine, MUAC becomes an alternative tool for anthropometric screening.

Reference Charts

- Most reference charts currently available are based on the distribution of weight gains during pregnancy in apparently healthy populations with favorable pregnancy outcomes. Their conventional cut-off values have no intrinsic meaning for predicting the risk of adverse outcomes.
- Weight gain charts' evolution in the last few decades reflects changes in recommendations and a better understanding of the role of weight gain in pregnancy management.

Special Pregnancies

- In twin pregnancies of mothers with normal prepregnancy BMI, average total weight gain is around 20 kg. Mean gestational weight gain (GWG) at the end of pregnancy varies from 20.5 to 23.5 kg for triplet pregnancies and from 20.8 to 31.0 kg for quadruplets.
- No special charts or patterns have been proposed to monitor pregnancy weight gain in adolescents.
- In pregnant adolescents, excessive weight gain can be linked to postpartum weight retention and obesity; thus, they should be advised to gain weight at the same pattern as adult women, without either restricting weight or encouraging weight gain at the upper end of the range.

Prenatal Care

- Anthropometric indicators identify women with nutritional problems, but do not reveal the underlying cause or determinant of the problem, or the best interventions to solve it.
- Monitoring weight gain during pregnancy can be difficult in a primary health care setting considering equipment, personnel training, and the need of multiple visits among other obstacles. However, many of these difficulties have been overcome in child growth monitoring, and lessons can be learned from these successful programs.

Key Features

The criteria commonly used to classify fetal growth are:

Small for gestational age (SGA): birth weight less than the 10th centile for gestational age.
Adequate for gestational age (AGA): birth weight between the 10th and 90th centiles for gestational age.
Large for gestational age (LGA): birth weight greater than the 90th centile for gestational age.
Premature delivery: before 37 weeks of gestation.
Low birth weight: birth weight below 2,500 g. A small infant size at birth is a function of both poor growth and shortened gestation, with most adverse outcomes occurring in the most immature infants.
Macrosomia: is defined as a birth weight higher than 4,000 g.
Cephalopelvic proportion: measurement of fetal head size in relation to maternal pelvic capacity.

Chapter 61
Prenatal Famine Exposure and Long-Term Consequences for Anthropometry and Adult Health

Tessa Roseboom, Rebecca Painter, and Susanne de Rooij

Abstract This paper describes the findings from a cohort study of 2,414 people born around the time of the Dutch famine. We found more coronary heart disease, a more atherogenic lipid profile, disturbed blood coagulation, and increased stress responsiveness among those exposed to famine in early gestation. Women exposed to famine in early gestation were more obese and had an increased risk of breast cancer. People exposed to famine in mid gestation had more microalbuminuria and obstructive airway disease. Exposure to famine during any stage of gestation was associated with glucose intolerance. Also, women who had been exposed to famine prenatally were more reproductively successful: they started reproducing at an earlier age, had more children, more twins, and were less likely to remain childless. The effects of prenatal famine exposure did not appear to be restricted to those exposed to it prenatally: also, their children appeared to be less healthy.

These findings show that maternal undernutrition during gestation has important effects on health in later life, but that the effects on health depend on its timing during gestation. Early gestation seems to be an especially vulnerable period. Adequate dietary advice to women before and during pregnancy seems a promising strategy in preventing chronic diseases in future generations.

61.1 Introduction

Coronary heart disease remains a major burden on public health in the Western world, and is taking on epidemic proportions in developing countries (Murray and Lopez 1997). Small babies go on to develop more coronary heart disease in adult life (Barker 1995). Restricted intrauterine growth has been identified as an important contributor to later coronary heart disease and its biological risk factors. Developing organ systems adapt in response to the reduced availability of nutrients, particularly during periods of rapid development – so-called critical periods (Hoet and Hanson 1999). These adaptations, while advantageous for short-term survival, can be detrimental for health in later life. Animal experiments indicate that substantial changes in cardiovascular function can result from maternal or fetal undernutrition without necessarily affecting birth weight (Harding 2001). In this chapter, we describe the effects of restricted prenatal nutrition during

different periods of gestation on health in later life. In the past 15 years, we have studied the health of people born around the time of the Dutch famine of 1944–1945, this has provided us more insight into fetal origins of adult disease.

61.1.1 Dutch Famine as an Experimental Study Design

While famine is sadly not uncommon in many parts of the world, studying the effects of undernutrition during specific periods of pregnancy is hampered by the fact that undernutrition is usually not restricted to pregnancy alone, and effects of chronic undernutrition and accompanying problems of infection complicate the situation. What is unusual about the Dutch famine is first, that the famine was imposed on a previously well-nourished population; second, that there was a sudden onset and relief from the famine; and third, that despite the adversities of the war, midwives and doctors continued to offer professional obstetric care and kept detailed records of the course of pregnancy, the delivery, and the size and health of the baby at birth. Furthermore, detailed information is available on the weekly rations for the people in Amsterdam, and because birth records were kept we were able to trace those born around the time of the famine allowing us to study the long-term effects of famine. All these characteristics bring about that the Dutch famine is a unique counterpart for animal models that study the effects of restricted maternal nutrition during different stages of gestation.

61.1.2 The Dutch Famine

After weeks of heavy fighting following the invasion on the 6th of June 1944, the Allied forces finally broke through German lines. With lightning speed, the Allied troops took possession of much of France, Luxembourg, and Belgium. By the 4th of September 1944, the Allies had the strategic city of Antwerp in their hands, and on the 14th they entered the Netherlands. Everyone in the Netherlands expected that the German occupation would soon be over. The advance went so quickly that the commanders of the Allied forces too thought it would be only a matter of days before the Germans would surrender. But the advance of the Allies to the north of the Netherlands came to a halt when attempts to get control of the bridge across the river Rhine at Arnhem (operation 'Market Garden') failed.

In order to support the Allied offensive, the Dutch government in exile had called for a strike of the Dutch railways. As a reprisal, the Germans banned all food transports. This embargo on food transports was lifted in early November 1944, when food transport across water was permitted again. By then, it had become impossible to bring in food from the rural east to the urban west of the Netherlands because most canals and waterways were frozen due to the extremely severe winter of 1944–1945, which had started unusually early. Consequently, food stocks in the urban west of the Netherlands ran out rapidly.

As a result, the official daily rations for the general adult population – which had decreased gradually from about 1,800 calories in December 1943 to 1,400 calories in October 1944 – fell abruptly to below 1,000 calories in late November 1944. At the height of the famine from December 1944 to April 1945, the official daily rations varied between 400 and 800 calories. Children younger than 1 year were relatively protected, because their official daily rations never fell below 1,000 calories, and the specific nutrient components were always above the standards used by the Oxford Nutritional Survey (Burger et al. 1948). Pregnant and lactating women were entitled to an extra amount of food, but at the peak of the famine these extra supplies could not be provided anymore.

In addition to the official rations, food came from church organisations, central kitchens, the black market, and foraging trips to the countryside. After the liberation of the Netherlands in early May 1945, the food situation improved swiftly. In June 1945, the rations had risen to more than 2,000 calories (Burger et al. 1948).

There was a serious shortage of fuel during the war which caused a gradual decrease and finally a complete shutting down of the production of gas and electricity, and in several places even the water supply had to be cut off, while the authorities were unable to provide fuel for stoves and furnaces in homes. Throughout the winter of 1944–1945, the population had to live without light, without gas, without heat, laundries ceased operating, soap for personal use was unobtainable, and adequate clothing and shoes were lacking in most families. In hospitals, there was serious overcrowding as well as lack of medicines. Above all, hunger dominated all misery.

The famine had a profound effect on the general health of the population. In Amsterdam, the mortality rate in 1945 had more than doubled compared to 1939, and it is very likely that most of this increase in mortality was attributable to malnutrition (Banning 1946). But, even during this disastrous famine women conceived and gave birth to babies, and it is in these babies that the effects of maternal malnutrition during different periods of gestation on health in adult life can be studied. Because of its unique experimental characteristics, it is not surprising that people born around the time of the Dutch famine have been studied by many investigators.

61.1.3 Dutch Famine Studies

The period of starvation ceased early in May 1945 immediately after the final surrender of the Germans. In addition to the immediate provision of food after the war, medical aid was a top priority for the Netherlands. Doctors from the UK and US were sent to survey medical needs. Clement Smith from Harvard Medical School was among the first to witness the effects of the famine on the health of the Dutch population. He immediately saw the opportunity to obtain information that would help resolve important questions on how poor maternal nutrition affects pregnancy and the development of the fetus before birth. Using obstetric records from Rotterdam and The Hague, he studied effects of prenatal exposure to famine on pregnancy and the fetus (Smith 1947). He found that babies born during the famine (and thus exposed to famine in late gestation) were about 200 g lighter at birth. Later studies focussed on mental performance, following the increasing awareness in the late 1960s that early nutritional deprivation might cause irreversible damage to the brain (Stein et al. 1972). This study among military conscripts did not demonstrate any effect of starvation during pregnancy on the adult mental performance. However, men exposed to famine in early gestation were more likely to be obese, whereas those exposed in late gestation were less likely to be obese (Ravelli et al. 1972). More recently, it has been shown that people conceived during the famine and thus exposed in early gestation had a 2-fold increase in risk of schizophrenia (Hoek et al. 1996) and anti-social personality disorder (Neugebauer et al. 1999). In men, the risk of congenital neural defects was also increased (Stein et al. 1972) which suggests that permanent changes in the central nervous system might be involved. Lumey (1992) studied intergenerational effects of exposure to the Dutch famine and found that women who had spent the first six months of their own fetal life during the famine had slightly smaller babies than women who had not been exposed to famine *in utero*. Later results, however, were inconsistent with these findings and showed that first born babies of women who – as a fetus – had been exposed to the famine in early gestation were somewhat heavier at birth (Lumey et al. 1995).

61.1.4 Methods and Techniques

61.1.4.1 The Dutch Famine Birth Cohort Study

We traced a group of 2,414 term singletons born alive between November 1943 and February 1947 in the Wilhelmina Gasthuis in Amsterdam for whom we had detailed birth records. At ages 50 and 58, we invited the cohort to come to the clinic for detailed investigations. We defined exposure according to the daily official food rations for the general population older than 21 years in Amsterdam. A person was considered to be exposed if the average daily ration during any 13-week period of gestation was below 1,000 calories. The rations for babies never fell below 1,000 calories a day, therefore people born before the famine (as well as those conceived after it) are considered as unexposed.

A person was considered to be prenatally exposed to famine if the average daily ration for adults during any 13-week period of gestation was less than 1,000 calories. Using this definition, all born between January 7th, 1945 and December 8th, 1945 were considered to be exposed *in utero*. All cohort members born between November 1st, 1943 and January 6th, 1945 (born before the famine), and between December 9th, 1945 and February 28th, 1947 (conceived after the famine) were thus unexposed to famine *in utero* and served as the control group. We defined periods of 16 weeks each to differentiate between those who were exposed to famine in late gestation (born between January 7th and April 28th, 1945), mid gestation (born between April 29th and August 18th, 1945) and in early gestation (born between August 19th and December 8th, 1945) (Fig. 5 and Table. 61.1).

61.1.4.2 Results: Long-Term Consequences of Prenatal Exposure to the Dutch Famine

We found that exposure to the Dutch famine in early gestation increased body weight, body mass index, and waist circumference in women but not in men aged 50 years (Table. 61.2a). A poor maternal diet in early gestation which was followed by adequate nutrition during the remaining course of gestation was linked to an increased level of obesity in middle aged women. Exposure to famine in early gestation affected the level of obesity and the distribution of fat differently for men and women. The body mass index and the waist circumference at age 50 were increased in women but not in men (Table. 61.2b). These findings suggest that these women store fat intra-abdominally, because it has been shown that the waist circumference represents intra-abdominal fat mass at least as accurately as the waist-to-hip ratio. Our findings imply that permanent adaptations of central regulatory mechanisms occurred as a result of changes in the mother's body brought about by poor nutrition in early pregnancy followed by rapid improvement later in pregnancy. These adaptations did not restrict linear growth but seemed to have resulted in a disturbed central regulation of the accumulation of body fat in later life.

The Dutch famine study provided the first direct evidence in humans that undernutrition during gestation increases the risk of many diseases that plague our society, such as heart disease, diabetes, airways disease, obesity, renal disease, and cancer (Table. 61.3). The effect size is striking: compared to controls, men and women conceived during the Dutch famine have twice as much cardiovascular disease, and women exposed to famine during gestation even had a 5-fold increase in breast-cancer risk.

The effects of famine appeared to depend on its timing during gestation, and the organs and tissues undergoing critical periods of development at that time. Early gestation appeared to be the most vulnerable period. People who were conceived during the famine – and who had been exposed to famine in early gestation – had a more atherogenic plasma lipid profile (Roseboom et al. 2000a),

breast cancer (Painter et al. 2006c). It is of interest to note that people exposed to famine in early gestation were not small at birth, but did have the most health problems in later life. Although many of these diseases (such as coronary heart disease) were linked to small size at birth, the effects of famine were independent of this. Based on the size of these babies at birth, one would not have predicted these health effects.

We found that undernutrition during any period of gestation was associated with reduced glucose tolerance and raised insulin concentrations at ages 50 and 58. Importantly, this effect was larger than could be explained by the lower birth weights of babies born during the famine and by the low weight gain of their mothers (Ravelli et al. 1998, de Rooij et al. 2006). Also, exposure to famine in mid gestation was linked to a 3.2-fold increase in occurrence of microalbuminuria in adulthood and a 10% increase in creatinine clearance, neither of which can be explained by cardiovascular confounders (Painter et al. 2005). We propose that mid gestational exposure to famine – the period of rapid increase in nephron number – may prevent formation of sufficient glomeruli and thus increase the risk for microalbuminuria and possibly affect renal function in adulthood. This supports the concept that intrauterine conditions during distinct, organ-specific periods of sensitivity may permanently determine health outcome in later life. Another finding in our study also supports this concept: we found that people who had been exposed to famine in mid gestation had an increased prevalence of obstructive airway disease (Lopuhaa et al. 2000). These observations were not paralleled by reduced lung function or increased serum concentrations of IgE. This suggests that the increased prevalence of symptoms and disease may be attributable to increased bronchial reactivity rather than to irreversible airflow obstruction or atopic disease. Because the bronchial tree grows most rapidly in mid gestation, our findings support the hypothesis that fetal undernutrition permanently affects the structure and physiology of the airways during 'critical periods' of development that coincide with periods of rapid growth.

Women – but not men – who were exposed to the Dutch famine of 1944–1945 *in utero* were more reproductively successful than women who were not exposed to famine during their fetal development; they had more offspring, more twins, were less likely to remain childless, and started reproducing at a younger age (Painter et al. 2008a). The increased reproductive success of these women is unlikely to be explained by genes which favor fertility and are passed from mothers to their daughters. *In utero* exposure to famine did not affect the reproductive success of males. These findings suggest that poor nutrition during fetal development, followed by

improved nutrition after birth can give rise to a female phenotype characterized by greater reproductive success.

The constellation of reproductive and metabolic adaptations during fetal development in response to undernutrition *in utero* may be part of a thrifty phenotype which is associated with enhanced reproduction. Post-war Holland provided a postnatal environment of food abundance, which was unlike the conditions anticipated by the environment *in utero*. This disadaptation of a thrifty phenotype may be important in the later occurrence of chronic disease. We have shown that people exposed to famine during gestation have increased risk of cardiovascular disease, metabolic disease, breast cancer, and obesity rates. In conclusion, our findings are consistent with the theory of life history regulation, which proposes that the two traits fertility and body maintenance are mutually balanced, investments in one are traded off by reduction in investment in the other (Stearns 1992). Our findings show that the balance in phenotypic traits underpinning life history regulation may be set by the environmental conditions during fetal development.

We found preliminary evidence that grand-maternal exposure to famine for a brief period during gestation is associated with increased neonatal adiposity and poorer health in the grand-offspring (Painter et al. 2008b). These findings constitute the first direct evidence in humans that the detrimental effects of poor maternal nutrition during gestation on health in later life pass down to subsequent generations. This may imply that improved maternal nutrition during gestation may benefit the health of many generations to come. Also, these findings indicate that the transgenerational effects of famine exposure *in utero* on health in later life differ depending on the exposed parent's sex. Increased neonatal adiposity was only found among the children of prenatally exposed women, whereas poor health was reported among the offspring of both men and women who had been conceived in famine. Importantly, this indicates that effects on health in later life also pass down transgenerationally through the male line. Transgenerational effects of a poor intrauterine environment may thus affect the entire generation parented by exposed individuals.

61.2 Study Limitations

In interpreting our findings, a number of matters need to be considered. Women were less fertile during the famine. The women who did conceive during the famine, whose offspring was exposed to famine in early gestation, may have been of a different constitution. However, correcting for markers of maternal constitution or fertility, such as maternal weight, age and parity and socio economic status did not affect the outcome.

The high rates of infant mortality during the famine affected groups born before the famine and exposed in late gestation most. The two groups with the largest contrast in early mortality (those born before the famine and those conceived after it) are homogeneous in terms of adult health outcomes, indicating that selective survival cannot have a large confounding effect on outcome in later life.

Selective participation of people that were fit enough to attend the clinic, and prior excess mortality among the most seriously affected people may have led to an underestimation of the effect of prenatal famine on subsequent disease.

Finally, there are limitations in pinpointing the exact timing of famine exposure during gestation and associated outcomes in later life, due to the relatively small sample size on the one hand, and partial overlap between the three famine-exposed groups on the other. However, the famine exposure periods do give an estimate of the timing of the focus of effect.

61.3 Interpretation

The findings of the Dutch famine birth cohort study broadly support the fetal origin hypothesis. Chronic diseases originate in the womb through adaptations made by the fetus in response to undernutrition. The effects of undernutrition, however, depend upon its timing during gestation and the organs and systems developing during that critical time window. Furthermore, our findings suggest that maternal malnutrition during gestation may permanently affect adult health without affecting the size of the baby at birth. This gives the fetal origins hypothesis a new dimension. This may imply that adaptations that enable the fetus to continue to grow may nevertheless have adverse consequences for health in later life. Coronary heart disease may be viewed as the price paid for adaptations made to an adverse intrauterine environment. It also implies that the long-term consequences of improved nutrition of pregnant women will be underestimated if these are solely based on the size of the baby at birth.

Little is known about what an adequate diet for pregnant women might be. In general, women are especially receptive to advice about diet and lifestyle before and during a pregnancy. This should be exploited to improve the health of future generations.

61.4 Applications to Other Areas of Health and Disease

The Dutch famine study has highlighted the importance of maternal nutrition during gestation for the health of her offspring in the long term. Although the Dutch famine was a unique situation, the findings of our study may have implications for other situations around the world. Some of these implications will be highlighted below.

We found that people exposed to famine in early gestation were twice as likely to consume a high fat diet and they had a tendency to be less physically active (Lussana et al. 2008). To our knowledge, this is the first report, in humans, that undernutrition during fetal life can influence adult lifestyle choices, such as food preference and sedentary behavior. The combined analysis of our data and animal models suggests that adult lifestyles and metabolic disorders might have a common prenatal background. Therefore, the paradigm that an unhealthy adult lifestyle is the main culprit in the current epidemic of metabolic and cardiovascular diseases may no longer be valid. We must now consider prenatal and perinatal determinants of adverse adult health. Animal models have suggested that the mechanisms underlying the effects of prenatal exposure to undernutrition might be mediated by the induction of leptin resistance and changes in hypothalamic development. At the moment, any pathophysiological consideration in humans is merely speculative, and we need more studies to confirm these intriguing findings.

The Dutch famine study has established the importance of maternal nutrition during early pregnancy for the offspring's cardiovascular risk. The nutritional experience of babies who were exposed to famine in early gestation may resemble not only that of babies in developing countries whose mothers are undernourished in early pregnancy and receive supplementation later on, but also of babies in developed countries whose mothers suffer from severe morning sickness. Morning sickness is common in the first trimester, and severe morning sickness is associated with metabolic changes in the mother which are similar to those seen during starvation. Since the results of our study consistently show that the effects of undernutrition are independent of size at birth, the assumption that the long-term consequences of hyperemesis gravidarum will be limited because of the normal size of the babies at birth no longer holds.

Our findings suggest that maternal nutrition before and during pregnancy play an important role in later disease susceptibility. This suggestion is in line with evidence from animal experiments that identified preconceptional and preimplantation maternal diet as important for the offspring's adult health. Possibly, epigenetic changes, such as imprinting, which takes place before conception and DNA methylation, may be involved. In both animal husbandry and human medicine, the rapid developments in assisted reproduction in the past decades have surpassed the available knowledge about the potential long-term repercussions. These fields could benefit from more knowledge about mechanisms of pathophysiology discussed above. Besides providing insight into the role of prenatal factors in the origins of chronic diseases, this information may also help identify susceptible patient groups and be useful in the development of more appropriate therapies for common chronic diseases in the future. Most importantly, it will contribute to the prevention of chronic disease through the development of adequate dietary advice to women before and during pregnancy.

The issue of generation-spanning effects of poor nutritional conditions during gestation is particularly relevant to populations in transition between traditional and western life styles, because it may shed light on the epidemic of diabetes, obesity, and cardiovascular disease, which is currently rapidly expanding in such countries. In India, currently transitioning to food abundance after generations of poor nutrition, babies are light and small at birth, but have increased neonatal adiposity compared to European babies. Our findings may indicate that increased neonatal adiposity, and possibly increased diabetes risk, is the direct result of poor maternal nutrition which occurred

generations ago. Public health strategies which focus on improved maternal nutrition during gestation may provide a means of promoting cardiovascular and metabolic health which will benefit generations to come.

Summary Points

- Prenatal exposure to the Dutch famine 1944–1945 has lasting consequences for health.
- The effects of famine exposure during gestation depend on its timing during gestation.
- Prenatal exposure to undernutrition of the Dutch famine affects various aspects of health: cardiovascular, and even lifestyle choices.
- The effects of undernutrition are independent of size of the baby at birth.
- The effects of prenatal undernutrition appear to be conveyed to the next generation.

Chapter 62
Parental Determinants of Neonatal Anthropometry

Gareth Hynes, Cyrus Cooper, and Elaine Dennison

Abstract Evidence is accruing that growth early in life has a profound effect on that individual's risk of many chronic diseases in late adulthood. This chapter attempts to unravel the various ways in which parents influence the anthropometry of their offspring. Much research has been undertaken in this area over the years and there is information linking a myriad of factors with foetal growth. It is the following factors, however, that are the most important and will be discussed here: age, race, parental birth anthropometry, parental height, parental weight, maternal weight gain during pregnancy, maternal activity, diet including calorie, protein and micronutrient intake, parity and interpregnancy interval, socioeconomic status, maternal pathology (hypertension, malaria, anaemia and diabetes) and lastly exposure to toxins (cigarette smoke and alcohol). The literature has been reviewed and a summary is presented to the reader. Where possible, conclusions are drawn as to the relative importance of each factor in determining neonatal anthropometry. The sections also include putative biological mechanisms that may underpin any such link where known, and the potential implications the research has on child health, where this is appropriate. The chapter concludes by briefly examining the debate surrounding the evolutionary origins of the parental determinants of neonatal anthropometry.

Abbreviations

SGA	Small for gestational age
IUGR	Intrauterine growth restriction

62.1 Introduction

Not only is size at birth the strongest determinant of perinatal survival, its influence stretches beyond the perinatal period and far into adult life. Weight at birth for instance is a predictor of heart disease, stroke, diabetes, obesity and osteoporosis in late adulthood. Teasing out which factors are important in determining neonatal anthropometric measures is crucial for two reasons. First, it will help us elucidate the mechanisms by which unborn babies grow: if we know that factor A in the parents

causes measure B in the newborn, we can explore the biochemical pathways through which it may be acting, allowing us to advance theories as to why it happens and potentially to develop novel therapeutic targets to aid or hinder the actions of factor A. Secondly, it will help us improve the health of the individuals and the population through targeted clinical and public health measures.

This chapter will attempt to define exactly which parental factors are important in determining neonatal anthropometry. It starts with a note on the term neonatal anthropometry, touches on mechanisms and evolutionary processes underlying any links, and then focuses on the means by which parents exert their influence on the growing child. In each subsection, the posited molecular mechanisms by which these interactions occur are explored, and this is followed where appropriate by reviews of the implications of the research to both individual and public health fields.

62.1.1 Note on Neonatal Anthropometry

There are relatively few anthropometric measures that can be taken from a newborn child. These include birthweight, height, abdominal circumference (measuring primarily the size of the liver), chest circumference, head circumference, ponderal index (paediatric equivalent of BMI) and skinfold thickness (used to measure foetal nutrition). Most studies use birthweight due to the wide availability of relevant data and due to its strong associations with neonatal health.

A small baby may be the result of slow foetal growth, when they would be termed small for gestational age (SGA) due to intrauterine growth restriction (IUGR), or the result of a shortened gestational period, when they would be termed premature. Although premature birth has its own related health problems, this chapter will limit the discussion to factors affecting foetal growth. Where not explicitly mentioned low birthweight can be taken to mean small for gestational age.

62.1.2 Mechanisms and Evolution

Genes and the environment are the ways in which parents influence their unborn child's growth. Genes exert a powerful effect and it could be argued they set the maximal capacity for growth, while it is the surrounding environment that determines whether an individual will reach that maximum potential.

There are several theories in the literature surrounding foetal growth and evolution, and they are generally termed "conflicts." Maternal–offspring conflict emphasises the different needs of mother and baby. Mothers do not wish their child to be too big as this will drain them of needed nutritional resources, so they "constrain" their growth. Unborn babies on the other hand wish to grow bigger to be better able to cope with the outside world. Maternal–paternal conflict is similar, though here while the mother passes on growth-suppression genes, fathers bequeath growth-promoters. These important ideas will be returned to in the conclusion.

62.2 Genetic and Constitutional Factors

62.2.1 Age

Age is undoubtedly associated with neonatal anthropometric measures. Studies consistently show a relationship, which, when examined, would appear to be a U-shape: mothers at the extremes of age tend to have lower birthweight, smaller babies (Karn and Penrose 1951).

Such a link has been discussed in the medical literature since at least the early 1950s, with studies such as that by Karn and Penrose concluding: "Children of the first three parities showed a definite decrease in weight with increasing maternal age, but this effect was not present in higher parities." Most studies to date have replicated such findings, though when the youngest maternal ages have been included they too showed a depressed birthweight (Gage et al. 2009).

There is a multitude of reasons for this, many of which could be described as confounders, and what is less clear is the role age itself plays. Age is clearly associated with parity, and indeed most studies control for this in their analyses. In addition those women at the extreme lower age range tend to be less tall and have a smaller BMI. Cigarette and alcohol consumption may be higher, while educational attainment and socioeconomic status may be lower. By contrast, older mothers tend to have more comorbidities, which may depress the growth of the foetus. In addition, women who become pregnant later in life may do so as a result of ''subfecundity'', or may have accessed infertility therapies that predispose to multiple births.

Another intriguing theory is the weathering hypothesis, proposed by Geronimus in 1992 (Geronimus 1992). It suggests that as women age, the cumulative effect of many years' exposure to adverse events results in irreparable damage that manifests as poor birth outcomes. Geronimus used this to help explain the excess poor birth outcomes experienced by black women in comparison to white women, and in older black women in comparison to younger black women. There has, however, been some criticism that it may be secondary to older white women becoming pregnant after choosing to delay their pregnancies, but older black women becoming pregnant because they have been unable to earlier in life, secondary to the subfecundity mentioned above (Stevens-Simon 2002).

In reality, most studies cannot adequately control for the myriad factors mentioned above, so the role played by age alone remains unclear.

62.2.2 Race

Different population groups have different average birthweights. The mean birthweight in India, for example, is 2,500 g whereas in the UK it is 3,100 g. What is less clear is whether this disparity is the result of true genetic differences between the two populations, or is instead the result of the contrasting cultures of each population. One can easily imagine variation in the average maternal age, height, weight, parity, socioeconomic status, diet, smoking habit, activity and health status between the UK and India. This is of course further complicated by the fact that some of these differences may themselves be due to genetics rather than being true confounders (maternal height or weight for example).

Early studies reported a strong link between race and birthweight, but in retrospect these were often confounded by lack of control for what we now know to be apposite sociodemographic differences. More recent papers have controlled for such factors to a greater or lesser degree, and for the most part find that the link persists. Hulsey, Levkoff and Alexander analysed 10,159 normal spontaneous deliveries, finding that when statistically significant differences in demographic characteristics were controlled, black infants weighed an average of 181 g less than white infants (Hulsey et al. 1991). Around the same time, Goldenberg et al. used a series of regression analyses to determine the effect of black race on various newborn measurements in 1,205 term newborns, adjusting for other known risk factors. "In this model, black race accounted for a mean decrease of 148 g in weight and 0.52 cm in length. There were also significant decreases in mean head (0.44 cm), chest (0.66 cm), and abdominal (0.56 cm) circumferences. Arm and leg lengths were not different, but black arm circumferences (0.14 cm) were significantly larger. Triceps and thigh skin fold measurements were not statistically different… The ponderal index in blacks was significantly less than in whites" (Goldenberg et al. 1991). A recent retrospective study in the US by Tan et al. compared twins' birthweight

in those born to parents of different race. In their study of 121,719 eligible twinsets they controlled for frequency of teenage parents, marriage status, perinatal care service, education, live birth parity, maternal smoking and medical complications. They found infants born to black parents had the lowest average birthweight; white fathers and black mothers had the second lowest means; black fathers and white mothers had the second highest means; and infants born to white parents had the highest mean birthweights. It was concluded both maternal and paternal race were important determinants of birthweight, gestational duration, and foetal growth, that maternal race had larger influence on birthweight than paternal race, and that a proportion of the effect of parents' race on birthweight was the result of its effect on gestational duration rather than foetal growth (Tan et al. 2004). Investigators have argued these findings suggest a genetic basis for the differences.

There is a significant undercurrent of evidence; however, suggesting genetic explanation may be an insufficient interpretation of the link between race and birthweight. Richard David and James Collins Jr have argued for many years that the association can be explained through environmental differences. In their study of Ilinois vital records from 1980 to 1995 involving approximately 80,000 infants, they examined the birthweights of the infants of US-born white mothers, US-born black mothers and African-born black mothers. They realised that the distribution of birthweights among infants of African-born black women approximated that among infants of US-born white women, significantly higher than US-born black women. They state "if genetics played a prominent part in determining black–white differences in birthweight, the infants of the African-born black women should have had lower birthweights than those of the US-born black women. We found the opposite: regardless of socioeconomic status, the infants of black women born in Africa weighed more than the infants of comparable black women born in the United States" (David and Collins 1997). Limitations that they acknowledge include lack of controlling for cigarette-smoking, prepregnancy weight and pregnancy weight gain.

One intriguing phenomenon reported in the literature is known as the epidemiological paradox (also termed the Hispanic paradox or the Mexican paradox). A wealth of data has been advanced that shows South American migrants in the US have babies with greater birthweight than those in similar socioeconomic groups. In fact, according to some measures, they have on average bigger, healthier babies than Caucasians despite the greater wealth and access to healthcare among Caucasian groups. The paradox was first proposed by Markides and Coreil in 1986 (Markides and Coreil 1986). This study found that the mean health status, including infant mortality, of Hispanic individuals in the southwest of the US was broadly comparable to better off white individuals, and far better than the black population with which they share their reduced socioeconomic status. Subsequent studies have questioned this finding. Smith and Bradshaw in 2006, as an example, found that any decrease in mortality was due to the artefact of incorrect identification of Hispanics by the sources used to collect the data for the studies (Smith and Bradshaw 2006).

There are many potential reasons for this paradox, ranging from varying levels of periodontal disease, to an increase in mean height of those migrants that remain in the country in comparison to those that leave. The latter study (Crimmins et al. 2005) was actually using adult height as a marker of poor childhood experiences to suggest that those with worse health and nutrition migrate back to South America, while those who are healthy stay on in their adopted country. This is certainly one potential reason, known as the healthy migrant theory.

62.2.3 Parental Birth Anthropometry

The first evidence that human neonatal birthweight is directly related to maternal birthweight independently of maternal measures such as height and weight emanated from a series of studies by Margaret

Ounsted and colleagues in Oxford. Ounsted used data from the British Perinatal Mortality survery of 1958 to suggest a matrilineal pattern of birthweight inheritance (Ounsted and Ounsted 1968).

Further investigation was undertaken by Klebanoff, who over the following four years published three papers on the subject, concluding in the last that white women with high birthweight (4,000–4,500 g) had a 5.9% risk of having a small for gestational age infant, whereas the rate for white mothers who weighed 2,000–2,499 g at birth was 19.8% (Klebanoff and Yip 1987).

Thoughts that this might have been due to an effect on gestational duration were dismissed by Magnus and others in 1993 (Magnus et al. 1993) – paternal birthweight is inconclusive, with some investigators suggesting it is important, and some reporting it is not. These findings have been corroborated in different populations. In 1999 Ramakrishnan et al. confirmed the maternal link in a developing country. In Guatemala a "child's birthweight increased by 29 g/100 g increase in maternal birthweight which is nearly twice that reported in developed countries. Similarly, child's birth length increased by 0.2 cm for every 1 cm increase in mother's birth length. The effect of maternal birthweight remained significant even after adjusting for maternal adult size" (Ramakrishnan et al. 1999). Agnihotri, in 2008, found for an Indian population: "Both maternal and paternal birthweight are strong determinants of offspring birthweight. The effect of mothers' birthweight on offspring birthweight is weaker than that seen in developed nations" (Agnihotri et al. 2008).

62.2.4 Parental Height

In 1926 Noel Paton and Leonard Findley, professors of physiology and paediatrics respectively at the University of Glasgow, wrote a paper for the Medical Research Council entitled *Poverty, Nutrition and Growth* (Paton and Findlay 1926). Among a number of things they examined they found that parental height was a predictor of a baby's height at two weeks, maternal height more strongly than paternal.

Studies since have put the amount of variation in neonatal birthweight accounted by maternal height at 10% (Magnus et al. 1984), and concluded that approximately for each centimetre increase in maternal height, neonatal weight increases 1.6 g. It has also been shown that a baby born to a shorter mother is symmetrically smaller than a baby born to a taller mother; birthweight and height both decreasing proportionately so that the ponderal index remained the same (Witter and Luke 1991).

Parental height may act through multiple pathways to affect foetal growth. Both genetic inheritance and a shared environment are plausible mechanisms, though the theory of maternal constraint expounded by Margaret Ounsted and discussed elsewhere, may be important in smaller women. The passage through the pelvic canal might be more difficult in smaller women with bigger babies.

62.3 Modifiable Environmental Factors

62.3.1 Parental Weight: Prepregnancy and Pregnancy Weight Gain

There are two aspects to parental weight relevant to this story: one is the mother and father's prepregnancy weight; and the other is maternal weight gain during pregnancy. High pre-pregnancy weight and low pregnancy weight gain generally results in a mean birthweight similar to that of low pre-pregnancy weight and high pregnancy weight gain (Eastman and Jackson 1968). A mother's

prepregnancy weight will influence her baby through genetic inheritance and through the availability of nutritional stores to feed the growing foetus. Her pregnancy weight gain is important in providing nutrients to the unborn baby; and similarly the bigger the baby gets, the more the mother will weigh. So while maternal weight is intuitively linked to neonatal anthropometry, paternal weight is much less so: it can act through genetics alone. And recent studies have confirmed that though paternal height is important, paternal weight is far less so when determining foetal growth (Griffiths et al. 2007).

62.3.2 Maternal Activity

There is some evidence that excess maternal activity is associated with smaller babies. In the Pune maternal nutrition study in India heavy activity levels linked with lower mean birthweight, and smaller neonatal head circumference and mid-arm circumference (Rao et al. 2003). And in a recent study in the UK, maternal self-reported high walking speed was associated with lower birthweight; it increased lean mass but decreased fat mass. This is likely to act via its effect on the amount of nutrition available to the growing baby: activity will burn energy that could otherwise be used by the foetus for growth (Harvey et al. 2007).

62.3.3 Diet

As noted above, prepregnancy weight and weight gain during pregnancy are correlated with the growth of the foetus. In addition to genes and activity levels there is a significant role for calorie intake in determining both these measures. Further to the calorie intake levels, there is a plethora of evidence to support the view that multiple components of the maternal diet are important in determining foetal growth and subsequent neonatal anthropometry, including protein intake and micronutrient levels.

62.4 Caloric Intake

Maternal stores (prepregnancy weight) and intake throughout pregnancy (weight gain during pregnancy) are the sole sources of energy for the growing foetus. The adjudged importance of caloric intake during pregnancy is unsurprisingly similar to pregnancy weight gain: it is important, especially so for mothers with a low weight pre-pregnancy. The reasons for this are outlined in the above section, but it is interesting to note some of the underpinning biological mechanisms. We know that diabetic women have large, macrosomic babies. It is also known that women who are not overtly clinically diabetic but when tested are at a level, we now term subclinical diabetes are at increased risk of having large babies too. The mechanism for this is high levels of circulating maternal glucose, occurring as a result of the diabetes, spill over into the foetal circulation. Here the glucose provokes the release of insulin, insulin-like growth factors and growth hormone, all of which encourage the growth of the foetus. It is logical to suppose that excessive maternal calorie intake would have the same effect on maternal glucose levels and hence foetal growth.

Studies examining the effect of caloric intake have had difficulties in design and in controlling for confounders: caloric intake is hard to measure accurately; it correlates with other nutrient intake,

especially protein; it links with prepreganancy weight; plus there are the potential confounders of race, height, age and socio-economic status. Hence the best studies quantifying the impact caloric intake has tend to be intervention studies where a randomly assigned group of pregnant women are given caloric supplementation and compared with controls who were not given the supplements.

Kramer examined the available literature on this in 1987 and found differences in under-nourished and well-nourished women (Kramer 1987). For the former there was a 99.7 g increase in birthweight per 100 kcal/day supplement. For the latter, the birthweight increase was only 34.6 g, i.e. one-third that of undernourished women. This of course fits with the data above regarding maternal weight gain. It is the position of the American Dietetic Association that most pregnant women need between 2,200 and 2,900 kcal/day "but prepregnancy body mass index, rate of weight gain, maternal age, and appetite must be considered when tailoring this recommendation to the individual."

62.5 Protein

Proteins are essential for growth: their constituent pieces, amino acids, are often termed "the building blocks of life". A recent study by Cuco et al. of 77 healthy women in Italy found protein intake was proportionately related to neonatal birthweight, once adjusted for energy intake, maternal age, prepregnancy BMI, parity, physical activity and smoking. It was reported a 1 g increase in daily protein intake results in 7.8–11.4 g increase in birthweight (Cuco et al. 2006). Although interesting, the number of participants in this study is relatively small. Most studies involving more women; however, have had difficulties with the confounders mentioned above and have used supplementation as a means to measure the effect of protein.

Kramer and Kakuma have recently (re-)examined the subject for the Cochrane Database and found that energy and protein supplements lead to a significant increase in birthweight, but not in height or head circumference (Kramer and Kakuma 2006). High-protein supplements did not result in any change to measured neonatal anthropometry, and though there was a non-significantly decreased risk of stillbirth, there was a similarly non-significant increased risk of neonatal death. Finally isocaloric protein supplements (providing less than 25% of energy intake, and replacing an equivalent amount in the diet) may increase mean birthweight, but may also increase the risk of small-for-gestational-age babies. The data on this are too few, however, to draw definitive conclusions. The authors felt that the increase in birthweight with energy and protein supplements was probably due to the increased energy intake, and that women given high-protein supplements ate less as a result.

Overall, despite protein being important for foetal growth, it would appear that the normal dietary fluctuance between women only accomplishes an increase in the neonatal arthropometric measure of birthweight through the extra energy that the consumption of protein brings.

62.6 Micronutrients

Micronutrients are vitamins and minerals required in small amounts for the normal growth and functioning of the body. There is a paucity of studies for many micronutrients in pregnancy; however, and the current trend of examining multiple micronutrient supplements makes teasing out the valuable from the less useful micronutrients somewhat difficult.

Vitamin A is one such micronutrient that may be a determinant of foetal growth. A study by Wang et al. has found that maternal serum levels of vitamin A are proportionately linked to birth outcomes,

such that a 1 umol/L increase in maternal serum vitamin A (note that absolute levels <0.7 umol/L were considered deficient) was associated with a 250 g increase in birthweight. A 1% increase in serum levels also correlated with a 0.8 cm increase in birth length. A relationship was noted with head circumference but it did not reach significance levels. There was no such relationship for *vitamins C and E*. It was postulated that the positive relationship may be due to the protective anti-oxidative effects of vitamin A, and this may make it especially important in smokers given the toxic oxidative effect of cigarette smoke. However, in these results Wang et al. only adjusted for age and parity. Given the importance of socio-economic factors and their likely relationship to vitamin A intake, however, these results should be interpreted with caution, especially given that previous studies have found no such link (Muslimatun et al. 2002).

Vitamin B9, or folic acid, has well known effects on nervous system development. Evidence has been accruing that it does influence birthweight, and in 2009 Timmermans et al. concluded from their analysis of 6,352 women in the Generation R study in Holland that folic acid supplementation (0.4–0.5 mg) was associated with 68 g higher birthweight (Timmermans et al. 2009). Folate is an important constituent of nucleic acid, a integral part of DNA, and is hence essential during the cell division that directs the growth of the unborn baby.

Vitamin B12 may be associated with birthweight. Past studies, in India and the UK, could find no association, but a more recent Indian study did report a link in a sample of 185 women (Muthayya et al. 2006). The authors felt the lack of a relationship demonstrated previously was due to the women being B12 replete in the case of the UK, and the spread of B12 being too narrow in the previous Indian study, to detect any effect. Vitamin B12 is important in regenerating folate within the body and hence a deficiency, if not compensated for by an increased intake of folate, is liable to have the same deleterious effects that a deficiency of folate will cause.

Vitamin D has been shown to be important in determining bone growth in the unborn baby. Mahon et al. writing in 2009 used high-resolution 3D ultrasound to measure foetal femur length and distal metaphyseal cross-sectional area, together with the ratio of femoral metaphyseal cross sectional area to femur length ("femoral splaying index"). They found: "Lower maternal 25-hydroxyvitamin vitamin D concentration was not related to foetal femur length, but was associated with greater femoral metaphyseal cross-sectional area and a higher femoral splaying index at 19 weeks' gestation" (Mahon et al. 2009). Another recent study, by Scholl and Chen, found "after control for energy, other nutrients, and other potential confounding variables, total intake of Vitamin D was associated with increased infant birthweight; gravidae below the current adequate intake (<5 microg/day or 200 IU) had infants with significantly lower birthweights ($p < 0.05$) (Scholl and Chen 2009). Interestingly a study into *calcium* supplementation in those deficient of calcium did not show any differences between fetuses whose mothers received calcium supplementation during pregnancy and those who received placebo. Vitamin D regulates calcium and phosphate in the blood enabling normal metabolism of bones. It is also an important immune regulator.

Zinc is another micronutrient of controversial importance; with regards pregnancy it is perhaps the most studied of the micronutrients. A review study in 2009 by Hess and King, at the University of California, found three studies, one by Goldenberg and Neggers, concluding supplemental zinc significantly increased birthweight. These studies were performed in those in whom zinc deficiency was likely. Eleven other studies failed to find a relationship but none of these stratified the effects of supplemental zinc on birthweight by maternal weight or zinc status. They concluded thus: "Most studies found no significant impact of maternal zinc supplementation on infant birthweight, but a subset of studies conducted in underweight or zinc-deficient women suggests that there may be a positive effect of zinc supplementation in such women" (Hess and King 2009).

In summary, energy intake, vitamin D, iodine and zinc appear to have significant effects on the growth of the unborn baby. Copper and vitamins A, B9 and B12 may have an impact, but there is

little evidence that normal variations in vitamin B6 and protein intakes at this stage cause changes in neonatal anthropometry. Current work on supplementation suggests that multiple micronutrient supplementation is the most efficacious ways of nutritionally maximising foetal growth in the developed world.

62.6.1 Parity and Interpregnancy Interval

Studies put the odds ratio of having a small for gestational age baby at between 1.3 and 2.1 for nulliparous versus multiparous women. Interpregnancy interval is the amount of time between the end of one pregnancy and the commencement of the next. Interestingly both short and long intervals are associated with low birthweight infants. However, there is still considerable debate as to whether the links are due to confounding effects or true biological pathways. A recent meta-analysis by Conde-Agudelo and colleagues in JAMA on this subject included 67 studies and 11 million births. They found that interpregnancy intervals shorter than 18 months and longer than 59 months are significantly associated with small for gestation age infants (in addition to prematurity). As a result they call on "reproductive clinicians" to advise women to delay subsequent pregnancies for "two to five years" (Conde-Agudelo et al. 2006). Possible biological theories for the link between short interval and low birthweight include the maternal nutrition depletion hypothesis, where a short pregnancy interval does not allow the restoration of maternal stores depleted by pregnancy. Confounders include poorer socioeconomic status, lack of engagement with health services and unplanned pregnancies in those with short intervals. The link between long interval and birthweight may be secondary to the gradual physiological decline in a woman's reproductive capabilities over time, so that a woman many years from her last pregnancy will be in a similar position to a primigravid woman. Confounding this however is the possibility that subfecundity, known to cause unfavourable birth outcomes in itself, is the reason for delayed subsequent pregnancies.

62.6.2 Socioeconomic Status

In the context of pregnancy, socioeconomic status (SES) is a composite measure of maternal or paternal occupation, family income and maternal or paternal education. That it has an effect on neonatal anthropometry is beyond doubt and with an abundance of literature supporting the notion that a considerable proportion of both intra-societal and inter-societal difference in birth outcomes may be secondary to the SES differences. A major limitation of the SES measure is that it has a rather nebulous definition, changing from report to report, not as easily quantifiable as smoking or maternal height.

62.6.3 Pathology

62.6.3.1 Hypertension

The terminology surrounding hypertension in pregnancy can be confusing. In essence there are four permutations, all of which are associated with small-for-gestation age infants in addition to

the potentially catastrophic outcomes for both mother and child. Chronic hypertension is defined as a blood pressure measurement of 140/90 mmHg or more on two occasions before 20 weeks of gestation or persisting beyond 12 weeks postpartum. It is associated with an odds ratio of growth restriction of 4.9 (Gilbert et al. 2007). Gestational hypertension, which has replaced the term pregnancy-induced hypertension, describes women who develop hypertension without proteinuria after 20 weeks of gestation. It is associated with worse outcomes than chronic hypertension, with a three-fold increased risk of small-for-gestational-age babies (Buchbinder et al. 2002). Pre-eclamsia is a multi-organ disease characterised by hypertension and proteinuria after 20 weeks' gestation. Eclampsia is the development of seizures as a result of cerebral oedema secondary to pre-eclampsia. They are associated with more severe forms of foetal compromise. The aetiology of pre-eclampsia is not clear, but abnormal placental implantation and immunological intolerance between fetoplacental and maternal tissue resulting in placental and foetal hypoxia are both candidates.

62.6.3.2 Malaria

Malaria is endemic in large parts of Africa. It is a parasite transferred from its vector, the female anopheles mosquito, to its human host where it infects red blood and liver cells. Pregnant women are more likely to contract malaria, and suffer with it more severely than others. This is related to the transiently impaired immunity associated with pregnancy. Malaria infection is associated with low birthweight babies, mainly due to its effect on disturbing intrauterine growth. It limits growth by sequestering in maternal red blood cells in the intervillous space in the placenta and causing the red blood cell to adhere to specific placental receptors. These receptors – chondroitin sulphate A is an example – transport oxygen and nutrients across the placenta, and hence their disruption limits resources available to the growing baby. It also causes maternal anaemia.

62.6.3.3 Anaemia

Studies of healthy women in developed countries usually fail to show a link between anaemia and birth outcomes. Some even show that mild anaemia is associated with high birthweight. Studies in developing countries, however, tend to show the opposite. Anaemia is a "normal" state for pregnant women: during pregnancy a mother's red cell manufacture increases, but her circulating fluid volume increases more. The result is a "haemodilutional" anaemia. A genuine anaemia of less than 110 g/L (iron-deficient in origin or for other reasons) in addition to this may interfere with oxygen delivery to the unborn baby.

62.6.3.4 Diabetes

Maternal diabetes predisposes to large babies, or macrosomia. In fact, there is a linear association between infant size and maternal blood glucose (from 9 mmol/L upwards) in blood taken two hours after a glucose tolerance test. Reasons are given in the diet section.

62.6.4 Toxins

62.6.4.1 Smoking

Animal studies in 1940 by Essenberg, Scwind and Patras had suggested that smoke exposure in pregnant rats and rabbits leads to lower birthweight babies in comparison with controls (Essenberg and Patras 1940). Winea Simpson published a report linking cigarette use to prematurity, defined at that time as birthweight less than 2,500 g (Simpson 1957). Concluding smokers had twice the risk of having premature babies as non-smokers, she precipitated a "tidal wave of research" in the area. More recent studies have of course confirmed this link and estimated that there are 32,000–61,000 excess low birthweight babies born each year as a direct consequence of maternal smoking (DiFranza and Lew 1995). Paternal smoking may also be related to such changes. Exposure to environmental tobacco smoke leads to a mean 79 g reduction in birthweight, with a dose dependent relationship apparent in the literature.

In utero exposure to tobacco affects the growing foetus, especially during the latter stages of pregnancy, through its effect on foetal oxygenation, skeletal growth plates and growth promoting factors. Although the exact process remains unclear there are several mechanisms that seem likely. The inhibition of growth may be secondary to restricted placental circulation. We now feel that decreased foetal oxygenation rather than nutrition is the exact mechanism. Nicotine in tobacco smoke is metabolised to cotinine, and cotinine has been shown in various animal models to decrease uterine blood flow, umbilical artery flow and foetal oxygenation and acid-base balance. In addition to the effect of nicotine, carbon monoxide is transferred across the placenta and reaches levels in the foetus 15% higher than in the mother. Here carbon monoxide irreversibly binds with haemoglobin to form carboxyhaemoglobin reducing significantly the amount of free haemoglobin available to carry oxygen. The theory that foetal hypoxia is the cause for growth restriction is backed up by findings that cord plasma erythropoietin is significantly higher in smokers, and as EPO is released in response to low oxygen levels, it is likely women who smoke are chronically hypoxic. Nicotine also seems to act directly on growth plate chondrocytes to decrease matrix synthesis and suppress hypertrophic differentiation (via nicotinic acetylcholine receptor type alpha7) leading to delayed skeletal growth. Further studies have linked smoking with decreased maternal placental growth hormone and cord blood insulin-like growth factor 1, both of which are important hormonal regulators of foetal growth (Coutant et al. 2001).

62.6.4.2 Alcohol

The term foetal alcohol syndrome first appeared in the medical literature in a 1973. The first attempts to systematically characterise the problems associated with pregnancy alcohol use; however, came from France in the 1950s and 1960s. In 1984 Mills et al. concluded from their prospective study of 31,604 pregnancies that after adjustment for other risks, a reduction in mean birthweight was seen in drinkers compared with nondrinkers, ranging from 14 g in those drinking less than one drink each day to 165 g in those drinking three to five drinks each day. Consuming less than one drink daily had a minimal effect on intrauterine growth and birthweight.

FAS results from in-utero exposure to alcohol that has been consumed by the mother. The alcohol crosses the placenta and in the developing baby causes cell death via increasing natural apoptosis

and inducing cell necrosis. Alcohol (ethanol) is thought to be directly toxic itself; and acetaldehyde, one of its metabolites, and excess glutamate activity are two more of what is ultimately likely to be a myriad of factors that are implicated in the disease pathogenesis.

62.7 Conclusion

To conclude we return to the debate mentioned in the introduction regarding the various conflict theories surrounding the different evolutionary needs of mothers, fathers and unborn babies. It has been said that pregnancy involves a dialogue between the mother and her fetus, modulating foetal growth from its genetically determined path in relation to her state, environment and history. This was vital to human evolution, and remains important today in the determinations of pregnancy outcome and later health of the offspring.

62.8 Applications to other areas of health and disease

Evidence is accruing that growth early in life has a profound effect on that individual's risk of many chronic diseases in late adulthood. Many factors, including maternal pathology (hypertension, malaria, anaemia and diabetes) and maternal lifestyle (diet, physical activity, cigarette and alcohol consumption) are related to birthweight in the offspring.

Summary Points

- **Age** Extremes of maternal age are linked with smaller babies
- **Race** Controversially linked with neonatal anthropometry
- **Parental birth anthropometry** Maternal birthweight predicts offspring birthweight
- **Parental height** Maternal is more important than paternal height, though paternal height is more important that paternal weight in determining foetal size
- **Parental weight** Maternal prepregnancy weight and pregnancy weight gain are both significant determiners of neonatal size
- **Maternal activity** There is evidence to suggest excessive activity predisposes to smaller babies
- **Diet** Energy intake levels and some micronutrients are important, but protein intake and other micronutrients have accrued fewer positive data
- **Parity and interpregnancy interval** Higher parity is linked to bigger babies, both long and short interpregnancy intervals predispose to smaller babies
- **Socioeconomic status** This nebulous concept seems intransigently linked to birth outcomes
- **Maternal pathology** Hypertension, malaria and anaemia are all associated with smaller babies, but diabetes causes increased foetal growth
- **Exposure to toxins** Tobacco smoke exposure is the single biggest modifiable factor predisposing to intrauterine growth restriction, alcohol causes multiple anthropometric anomalies, and cocaine has also been linked with small babies

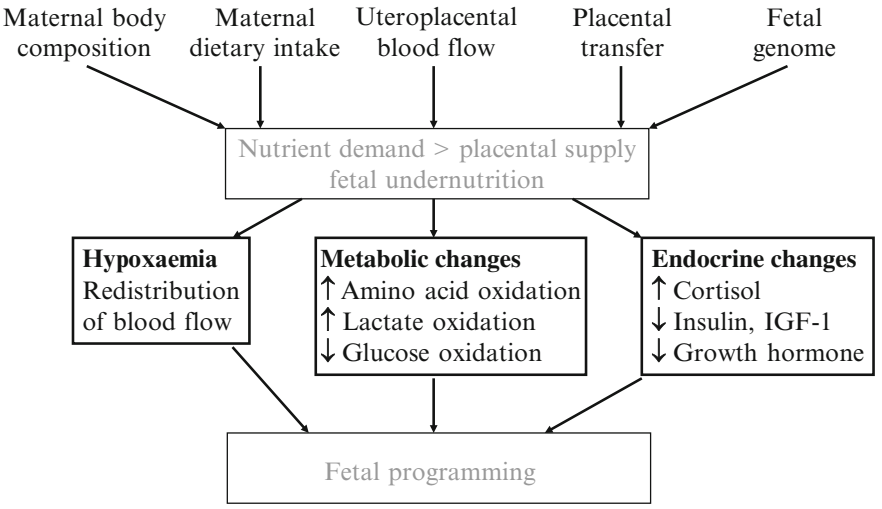

Fig. 62.1 This diagram summarises the way maternal undernutrition may affect foetal growth. Fetal adaptations to undernutrition: a framework

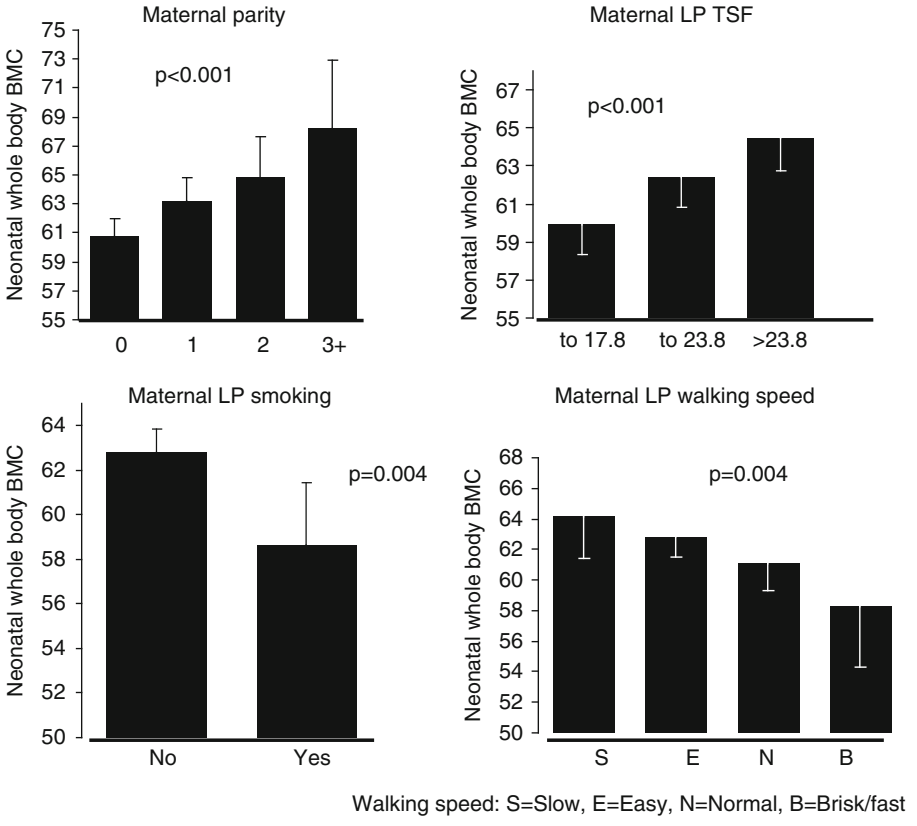

Fig. 62.2 Factors associated with higher bone mineral content in the offspring include higher maternal parity, larger maternal triceps skin fold thickness, abstinence from maternal smoking and slow maternal walking speed. Results are expressed as mean ± SEM, $n = 145$ (Data derived from Godfrey et al. (2001), with permission). Maternal determinants of neonatal whole body bone mineral content (g)

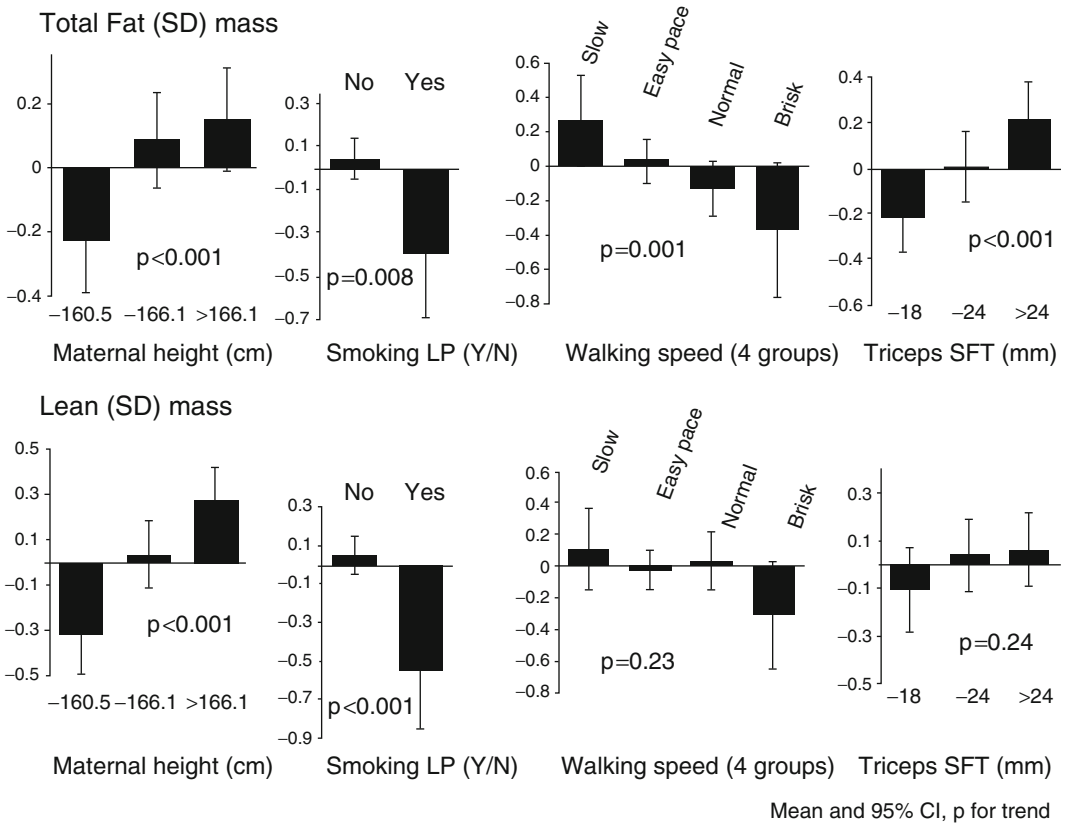

Fig. 62.3 Factors associated with greater fat and lean bone mass in the offspring include higher maternal parity, larger maternal triceps skin fold thickness, abstinence from maternal smoking and slow maternal walking speed. Results are expressed as mean ± SEM, $n = 448$ (Data derived from Harvey et al. (2007), with permission). Maternal determinants of neonatal content body composition

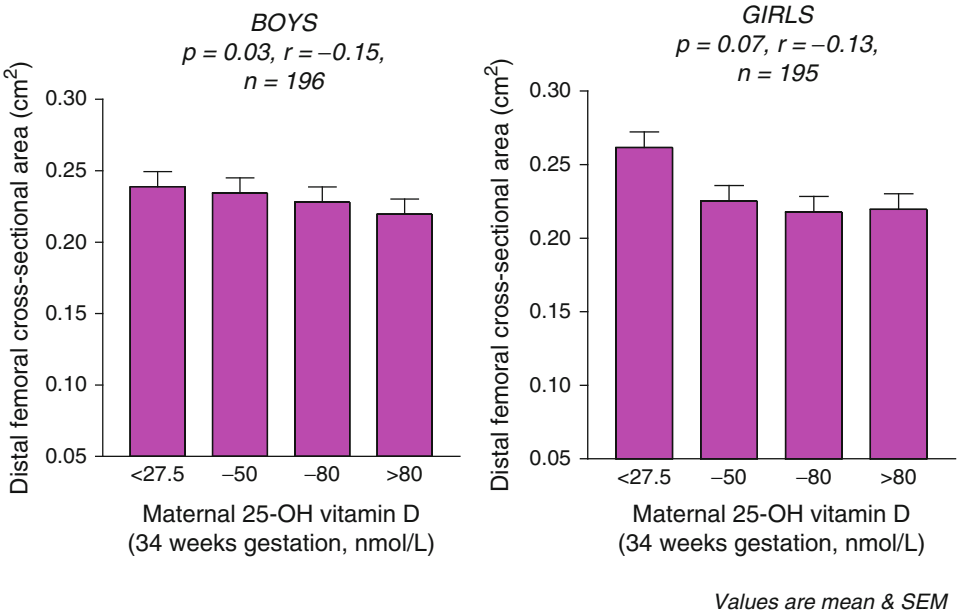

Fig. 62.4 Lower maternal 25(OH) vitamin D concentration at 34 weeks gestation is associated with greater distal femur cross-sectional area in the fetus. Results are expressed as mean ± SEM, $n = 424$ (Data derived from Mahon et al. (2009), with permission). Maternal vitamin D and 19 week distal fetal femur cross-sectional area

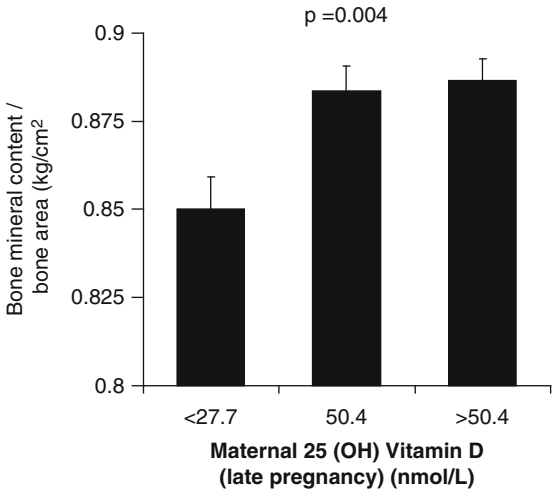

Fig. 62.5 Greater maternal 25(OH) vitamin D concentration in late pregnancy is associated with greater whole body BMC in the offspring at age 9 years. Results are expressed as mean ± SEM, $n = 198$ (Data derived from Javaid et al. (2006), with permission). Nine year whole body BMC by maternal 25(OH)D during late pregnancy and corrected cord blood calcium

Table 62.1 Key features of parity

- Parity may be defined as the state of having given birth to an infant or infants
- An absolute figure may be given to define the number of infants borne

Table 62.2 Key features: which parental factors are associated with neonatal anthropometry and how?

Factors associated with birthweight	Relationship
Age	Lower birthweight at extremes of age
Race	Controversial
Parental birth anthropometry	Larger parents have larger babies
Maternal weight gain in pregnancy	Generally positively associated
Maternal activity	Lower birthweight in very physically active mothers
Maternal diet	Nutrients important
Parity	Larger babies with higher parity
Interpregnancy interval	Lower birthweight if interval very large/small
Socioeconomic status	Controversial due to confounding
Maternal pathology	Many maternal illnesses associated with lower birthweight – diabetes associated with larger babies

This table summarises which parental features are related to anthropometry in the offspring, and describes the effect that feature has

Chapter 63
Use of Computerized Anthropometry and Morphometrics to Identify Fetal Alcohol Syndrome

Elizabeth S. Moore and Richard E. Ward

Abstract Direct craniofacial anthropometry has changed little in the century and a half since Reitzius used calipers to calculate the first "cranial index." It remains an inexpensive, readily learned technique for objectively measuring facial size and proportion. However, the development of new imaging technologies coupled with powerful computer programs for manipulating data and multivariate analysis for exploring data have opened new frontiers for the clinical application of anthropometry. Computerized anthropometry holds promise for improving our ability to define and recognize craniofacial disorders and for exploring the developmental forces behind variation in facial size and form. Such applications could have a great impact on the diagnosis, treatment, and prevention of fetal alcohol spectrum disorders (FASD), where simple, cost-effective methods for large-scale screening, diagnosis, and surveillance are needed. We review the various methods of indirect or computerized anthropometry that have been used to explore FASD. The vast majority of these studies have focused on creating an objective counterpart to the subjective "gestalt" that dysmorphologists have developed to recognize the phenotypic extreme of FASD known as fetal alcohol syndrome (FAS). Although several studies have demonstrated that computerized anthropometry can successfully recognize individuals previously diagnosed by clinicians as having FAS, no universally accepted "gold standard" has emerged from this work. In addition, only a few of these studies have addressed the potential of computerized anthropometry to recognize a wider range of individuals who have more subtle evidence of damage from gestational exposure to alcohol than is present in the extreme of FAS. However, the wide availability of commercial 3D imaging systems and the convergence of neural imaging studies that allow research to correlate alcohol-induced changes in brain structure to patterns of facial dysmorphology should allow for the collection and analysis of large samples of data, and in the near future may lead to improved recognition of both FAS and FASD individuals as well as greatly improve our understanding of the pathophysiology of alcohol on human development.

FASD	Fetal alcohol spectrum disorders

63.1 Introduction

The term fetal alcohol spectrum disorders (FASD) defines the adverse effects of alcohol on the developing fetus and represents a broad spectrum of structural anomalies and behavioral and neurocognitive disabilities (Barr and Streissguth 2001). The more restrictive diagnostic category of fetal alcohol syndrome (FAS) represents only those individuals at one end of the spectrum. Specifically, FAS is used to refer to individuals with intrauterine exposure to alcohol who exhibit growth deficiency and neurodevelopmental abnormalities, as well as a pattern of minor facial anomalies including short palpebral fissures, thin vermilion border of the upper lip, and smooth philtrum (Jones and Smith 1973; Bertrand et al. 2005) (see Fig. 63.1). In ideal situations, when a well-trained, experienced dysmorphologist is present and reliable maternal alcohol exposure information is available, the diagnosis of FAS can be made readily. However, most of the clinical features of prenatal alcohol exposure are not discrete abnormalities; they fall along a spectrum from mild to severe (Aase 1994; Stratton et al. 1996) and may be subject to ethnic differences in the expression of the phenotype (Douglas and Viljoen 2006; Moore et al. 2007; Mutsvangwa and Douglas 2007). Therefore, the diagnosis of even this well known pattern of abnormalities may be difficult. Further, the primary diagnostic features of prenatal alcohol exposure are fairly common, non-specific abnormalities and occasionally many of the features are expressed in individuals not prenatally exposed to alcohol. The diagnosis is also complicated by the fact that each of the features may be affected by multiple environmental and genetic influences unrelated to alcohol exposure. In addition, many individuals exposed prenatally to alcohol do not manifest the facial gestalt that is associated with FAS. For these reasons the clinical diagnosis of individuals with intrauterine damage due to alcohol exposure remains a challenge.

Given the primacy of the facial anomalies (Astley and Clarren 1995), much effort has gone into attempts to refine the degree to which these can be used to improve the diagnosis of FAS and identify other FASD. The goal of this chapter is to review efforts made to date to quantify the facial phenotype associated with FASD through the use of craniofacial anthropometry, specifically computerized craniofacial anthropometry and morphometric analysis. Computerized facial anthropometry and morphometric analysis refers to those techniques that derive measurements, shape assessment, or pattern recognition indirectly from captured images of the face. Although this definition could technically include radiographic images of the head and face (cephalometrics or computerized tomography), we refer here only to those techniques that focus on the surface features of the head and face.

Today, the clinically oriented anthropologist (or the anthropometrically oriented clinician) has an array of options for assessing the human head and face, including direct and indirect anthropometry (see Table 63.1). Indirect methods include two-dimensional (2D) photogrammetry (Clarren et al. 1987; Sokol et al. 1991; Astley et al. 1992, 2002; Farkas 1994; Astley and Clarren 1996, 2001; Hurwitz et al. 1999; Astley 2003; Huang et al. 2005) and three-dimensional (3D) computerized methods such as stereophotogrammetry (e.g., Burke et al. 1983; Burke and Hughes-Lawson 1989; Ras et al. 1996; Shaner et al. 2000; Meintjes et al. 2002; Douglas et al. 2003a, b; Douglas 2004; Douglas and Viljoen 2006; Grobbelaar and Douglas 2007; Mutsvangwa and Douglas 2007;

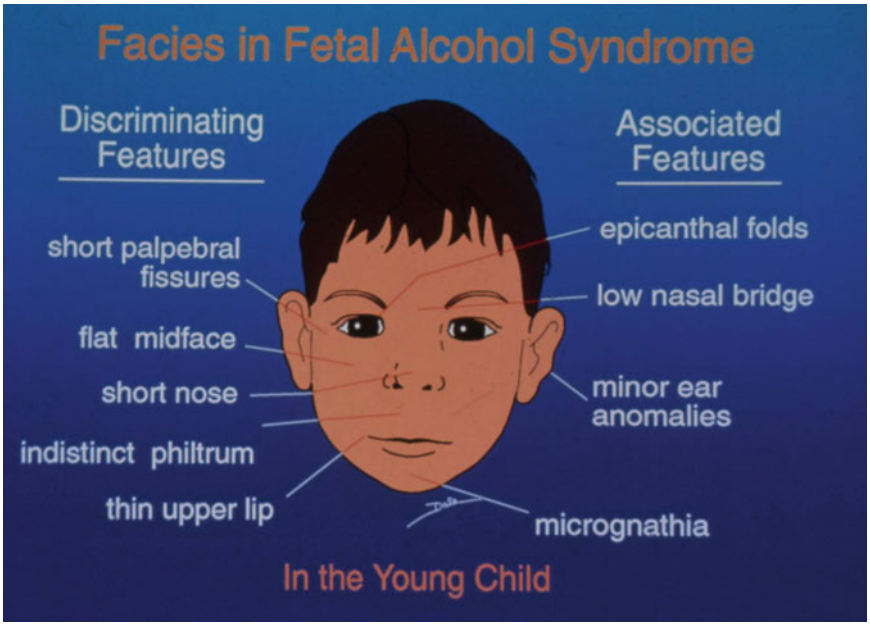

Fig. 63.1 Facial features associated with fetal alcohol syndrome (FAS). The diagram of the face shows both the discriminating and associated features of FAS (Reprinted from Streissguth and Little 1994, with permission)

Mutsvangwa et al. 2009), laser scanning (e.g., Arridge et al. 1985; Moss et al. 1989, 1991; Aung et al. 1995; Bush and Antonyshyn 1996; Aung 1999; Duffy et al. 2000; Da Silveira et al. 2003; Kau et al. 2004, 2005, 2006; Buckley et al. 2005; Hennessy et al. 2006; Moore et al. 2007; Fang et al. 2008), 3D photogrammetry (Hammond et al. 2003, 2004, 2005, 2008; White et al., 2004; Cox-Brinkman et al., 2007; Hammond, 2007), range camera (Strömland et al. 1998, 1999), and infrared photogrammetry (e.g., Ferrario et al. 1996, 1997, 1998a).

From an anthropometric and clinical perspective, indirect (computerized) anthropometry offers many advantages over conventional anthropometry. Computerized anthropometry is less time consuming for the patient and examiner, does not require extensive training, and allows the quantification of angles, surface area features, and volumes plus linear distances. In addition, these techniques provide permanent data that can be used to measure new facial features as knowledge of the craniofacial complex changes (Ferrario et al. 1998b; Hurwitz et al. 1999; Ferrario et al. 2005; Weinberg et al. 2006). These benefits are especially important when working with children and multiple observers, or when attempting to characterize a syndrome or disorder across different ages and ethnically diverse populations. The main weaknesses of computerized anthropometry are the cost of the instrumentation, the lack of reference standards for most populations, and the fact that some technologies are neither portable nor suited for use in the field.

The challenge of choosing the approach most appropriate for a given set of research objectives or of evaluating the results from particular studies requires an understanding of the strengths and weaknesses of each of these forms of computerized anthropometry versus the traditional direct measurement standard. Therefore we will first describe the strengths and weaknesses of the forms of computerized anthropometry that have been used in FASD research, then review their application to the study of FAS/FASD.

Table 63.1 Summary of methods used to capture anthropometric data

Type of anthropometric data capture	Advantages	Disadvantages	Applicability to understanding FAS/FASD	Cost
Direct anthropometry Utilizes calipers, tapes, and rulers to obtain linear, circumferential, and angular measurements directly from the head and face	Inexpensive portable equipment; "gold standard" for measurement accuracy; no limitation presented by hair or other poorly reflective surfaces; no limitation due to poor subject positioning; some population specific normative data available	Time consuming; some technical skill required; no permanent image created; difficult to use on young children; limited applicability for geometric or shape analysis	Widely used in clinical assessment, particularly for obtaining eye, head, and philtrum measurements	$
2D photogrammetry Measurements taken directly from standard or digital photographs	Rapid image capture; equipment cheap and portable; little technical expertise required; useful for young children; creates a permanent record for later analysis; can be easily shared; some geometric or shape analysis possible	Sensitive to subject positioning and lighting conditions; parallax effect can affect accuracy; measurements limited to two dimensions	Useful for assessment of subjective clinical features; measurements possible in two dimensions; collection of key measurements such as head circumference not possible	$
Stereophotogrammetry Measurements are "estimated" from calculations drawn from two or more simultaneously obtained photographs taken from different angles	Rapid image capture; equipment relatively cheap; limited technical expertise required; useful for young children; permanent record; useful for geometric shape analysis	Sensitive to subject positioning, expression, and lighting in original photographs; generally no 3D image produced; no commercially available systems; less portable; circumferential measurements not possible	Useful for large scale data collection; can be used for geometric shape analysis	$$
Computerized 3D Photogrammetry Utilizes full spectrum light, laser, or other energy to create a 3D model of the head and face on which a 2D digital image of the surface of the face is projected.	Rapid image capture; useful for young children; creates a permanent record; 3D data readily manipulated or "morphed" for advanced analysis; readily used for geometric and pattern recognition analysis; widely available commercial systems	The most expensive system; less portable; sensitive to subject facial expression and poorly reflective surfaces such as hair; circumferential measurements not possible	Useful for large scale data collection; reasonable comparability across 3D imaging system; easily manipulated for geometric and other "higher order" analysis	$$$

This table lists the different types of methods used to collect craniofacial anthropometric data, including direct anthropometry, 2D photogrammetry, stereophotogrammetry, and computerized 3D photogrammetry (2D: two-dimensional, 3D: three-dimensional)

63.2 Photogrammetry

Two-dimensional photogrammetry is the process of measuring objects from photographs; it has been used to aid in clinical anthropometry and direct observation (anthroposcopy) for over 50 years (Allanson 1997). The advantages of photogrammetry over direct anthropometry are that photographs can be obtained quickly and they provide a permanent record of the patient that can be retrieved and re-evaluated. In addition, there is no concern about subject movement during the measuring session. Unfortunately, there are also some disadvantages, including that fewer facial measurements may be taken from a photograph than by direct methods, that the quality of the photograph may be adversely affected by lighting and projection distortion (parallax), and that errors may occur in head positioning and in defining bony landmarks. In addition, a measure of scale is required for most data to be compared between subjects (Allanson 1997; Astley 2003; Hammond 2007).

Stereophotogrammetry derives measurements in three dimensions from photographs. This approach was first used clinically to quantify the human face in 1944 by Thalmaan Degen (Burke et al. 1983). Stereophotogrammetry makes it possible to measure soft tissue changes by *estimating* the 3D coordinates of points of an object. This is accomplished by comparing pre-marked points (on the photograph or individual) and then using triangulation from the camera to the common points in different perspectives to estimate distance between the camera and points and between combinations of points on the images. Several clinical studies using stereophotogrammetry have appeared over the last 2 decades (Burke et al. 1983; Burke and Hughes-Lawson 1989; Shaner et al. 2000; Meintjes et al. 2002; Douglas and Viljoen 2006; Mutsvangwa and Douglas 2007; Mutsvangwa et al. 2009). These methods combine the advantages of indirect anthropometry from photographs while avoiding most of the limitations. A major disadvantage of 3D photogrammetry is the lack of a commercially available system of image capture and analysis. This has resulted in the creation of "local" systems, thereby making comparison across studies difficult. In addition, image manipulation is more difficult in this methodology than in those that capture 3D data directly from the subject.

63.3 Computerized 3D Photogrammetry

A variety of indirect means of capturing 3D data from subjects are available. These systems differ from photogrammetric approaches in that the latter estimates 3D data from 2D photographs taken from different angles while the former constructs 3D data directly from light or other energy reflected from the surface of the "imaged" subject. Many of these systems combine photogrammetry data with dense range data from scanners. With these imaging systems 3D surface morphology is captured by recording the x, y, and z coordinates of hundreds of thousands of digital data points on a selected surface (Moss et al. 1989; Aung 1999). This usually requires a light (or alternate energy) source that is directed toward the subject; the reflected light is captured in the form of an individual point location in the x, y, z coordinates. The thousands of digital data points are connected by a triangulation network to render a surface texture (Aung 1999). The image can then be viewed using various computer software programs. A range of data can be collected from the images, including linear distances and the quantification of angles, surface areas, and volumes; in addition, the x, y, and z coordinate data can be extracted for a wide variety of statistical shape analyses (Weinberg et al. 2006).

Three-dimensional photogrammetry systems share the advantages of 2D photographs (speed of capture, permanency, and retrievability) and stereophotogrammetry (allowing for an expanded range of distance, geometric, and angle measurements). However, these systems have the distinct advantage of providing a true 3D model of the subject, which can be manipulated and adjusted ("morphed") to

reflect age-related or treatment-based projection of future appearance. In addition, several widely used commercial systems of both light- and laser-based image capture and analysis are available, thereby facilitating replication across studies. However, these systems remain the most expensive approach to indirect anthropometry.

Laser scanners offer a non-invasive technique that necessitates only a brief period of cooperation from study subjects. The 3D images are obtained by laser triangulation from an optical source projected onto the subject. The light pattern projected on the face is captured and converted into computer-generated images constructed around the projected "cloud" of points in the *x*, *y*, and *z* dimensions. Several studies have reported on the validity and high accuracy of the different laser scanning systems and the evaluated precision and reliability of data generated from the scans (Moss et al. 1988, 1989; Aung et al. 1995; Bush and Antonyshyn 1996; Coward et al. 1997; Kusnoto and Evans 2002; Kau et al. 2004, 2005; Ramieri et al. 2006). The Minolta-Vivid laser scanner is the most widely used, commercially available 3D scanner. It uses an eye-safe class I laser, and comprises a single unit that contains the laser projector as well as optical and digital cameras (the latter is used to capture a surface image that can later be wrapped around the cluster of *x*, *y*, and *z* spatial points). The main disadvantages of this technology include a relatively slow capture speed (compared to 3D light-based cameras), which can result in blurring due to movement of the subject, and sensitivity to non-reflective surfaces (such as hair), which are not well imaged.

Light-based 3D image capture operates in a manner similar to the laser method, except that full spectrum light patterns are projected onto the subject. Some systems project a structured light pattern (e.g., the Genex system) while others use a random light pattern (e.g., the 3dMD system). In addition, some have used a series of light patterns and a video camera to capture the data (the range camera method) (Strömland et al. 1998, 1999). Image capture systems that use light techniques have several advantages over the laser-based system used to capture 3D images. First, the acquisition time is extremely rapid, only 1.5 ms. This is similar to flash photography and eliminates blurred or distorted images from subject movement, which is common in young children (Hammond et al. 2004; Weinberg et al. 2006). In addition, the light-based system has less restrictive lighting conditions, allowing greater flexibility for the site of data acquisition. Several studies have evaluated the precision and error associated with the different 3D photogrammetry systems and found that data collected from these images are highly repeatable and precise (Weinberg et al. 2004, 2006; Aldridge et al. 2005; Gwilliam et al. 2006; Plooij et al. 2009).

63.4 Computerized Anthropometry in FASD

Direct anthropometry, specifically the measurement of eye distances (inner canthal, outer canthal, interpupillary, and palpebral fissure), philtrum length, and head circumference, is still used to assist in the diagnosis of FAS and screening for FASD. Several researchers have concentrated on assessing and measuring craniofacial traits on the actual subjects (Coles et al. 1985; Ernhart et al. 1987; Rostand et al. 1990; Autti-Rämö et al. 1992; Astley and Clarren 1995; Moore et al. 2001, 2002). One study (Astley and Clarren 1995) sought to objectify the FAS facial phenotype using craniofacial anthropometric measurements and a Likert scale on a group of racially mixed children. In addition, several computerized anthropometric methods have been utilized to study the facial features associated with prenatal alcohol exposure (see Table 63.2).

2D Photogrammetry: Digitized photographs have been used in the assessment of the facial phenotype in FAS. In general, their findings support earlier clinical findings of short palpebral fissures, a long midface relative to the length of the nose, a flattened midface in profile, and a somewhat small

Table 63.2 Summary of FAS/FASD studies that utilized computerized craniofacial anthropometry and/or morphometrics

Type of image capture	Authors	Publication date	Type of measurement	Results
2D Photogrammetry				
	Clarren et al. (Clarren et al. 1987)	1987	Shape analysis	They confirmed the FAS facial phenotype in children with heavy prenatal alcohol exposure: short palpebral fissures, relatively long and flat midface, and a retrusive mandible
	Sokol et al. (Sokol et al. 1991)	1991	Anthropometric facial measurements	FAS features were quantified and FAS neonates could be discriminated from non-exposed neonates using measurements obtained from the images. Important features were small nose, long philtrum, then vermilion, scooped bridge of nose, and short palpebral fissures
	Astley et al. (Astley et al. 1992)	1992	Shape analysis	Facial features compatible with FAS are not associated with marijuana exposure. Children with higher alcohol exposure had shorter noses relative to midface height, were retrognathic, and had shorter midface length. Results suggested ethnic differences in the expression of the FAS phenotype
	Astley and Clarren (Astley and Clarren 1996)	1996	Anthropometric facial measurements with other clinical features	FAS diagnosis can be done accurately using objective facial measurements of palpebral fissure length/inner canthal distance ratio, philtrum smoothness, and thinness of the vermilion
	Huang et al. (Huang et al. 2005)	2005	Automated facial recognition (AFR)	Using 2D digital photographs, AFR could moderately differentiate FAS faces from control faces
3D Image				
Range camera	Strömland et al. (Strömland et al. 1999)	1999	Anthropometric facial measurements	Children with FAS consistently had shorter palpebral fissures compared to non-alcohol-exposed children
Stereophotogrammetry	Mutsvangwa and Douglas (Mutsvangwa and Douglas 2007)	2007	Shape analysis	Confirmed FAS facial gestalt with some differences that may be due to ethnic variation
Laser	Moore et al. (Moore et al. 2007)	2007	Anthropometric facial measurements	FAS subjects can be discriminated, eye measurements are important, and ethnic differences are likely
Laser	Fang et al. (Fang et al. 2008)	2008	AFR	AFR techniques automatically detected and differentiated the FAS face from controls

This table lists the key computerized anthropometric studies that have been used to study FAS and/or FASD

mandible (Vitez et al. 1984; Clarren et al. 1987; Vitez 1987; Astley et al. 1992; Astley and Clarren 1996). These researchers concluded that photogrammetry may allow more accurate delineation of the facial phenotype of FAS, which would improve the subjective clinical diagnosis (Clarren et al. 1987; Vitez 1987).

Clarren et al. were the first to report the use of computerized anthropometry coupled with digitized photographs and shape analysis to assess the FAS face. Standard full face and lateral facial photographs were obtained on twenty-one 7-year-old children who had known heavy prenatal alcohol exposure. However, only two of the children had been previously diagnosed with FAS. An additional 21 photographs of 7-year-old children with negligible prenatal alcohol exposure were collected for control purposes. As in stereophotogrammetry, the investigators used a common set of premarked points but then employed geometric analysis (mean triangles) to compare the alcohol-exposed group with the control group. Their results demonstrated that significant differences in form existed between the two groups and that the differences conformed well with the descriptive features identified as characteristic by clinicians (Clarren et al. 1987).

Sokol et al. used measurements from digitized photographs of 97 neonates. To define neonatal facial features of FAS, three reference landmarks were chosen both in the frontal and lateral views (when available) and used to define seven salient frontal and lateral landmarks. The photographs were imaged onto a computer and appropriate reference landmarks were located and calibrated; then the measurement landmarks were digitized for analysis. The authors concluded that FAS-defining features could be quantified in the neonate from photographs as standardized x, y, z coordinates and that FAS could be reliably detected in the neonate with computer assistance (Sokol et al. 1991). Once again, this study appeared to confirm that areas of importance coincided with those previously described by clinicians: small nose with a long philtrum, short palpebral fissures, concave nasal bridge, and thin vermilion.

Following the earlier protocol developed by Clarren et al. (1987), Astley et al. conducted a computerized morphometric assessment of photographs using landmark analysis on marijuana-exposed and unexposed children that were group matched by alcohol exposure. A set of 23 facial landmarks were located and marked on photographs of each child. Landmarks were entered into a database using a computer digitizing table. Analysis of facial shape using geometric analysis was conducted and they found differences in facial traits depending on the type of first-trimester teratogen exposure. Individuals exposed to alcohol exhibited the unique facial features associated with FAS, while those exposed to cocaine and marijuana did not. Astley and coworkers suggested their results reinforce the sensitivity of their diagnostic approach in identifying individuals with FAS (Astley et al. 1992).

Astley and Clarren combined the use of anthropometric measurements of photographs with multivariate analysis to develop an FAS screening, diagnostic, and surveillance tool. Using stepwise discriminant analysis of three facial features (reduced palpebral fissure length/inner canthal distance ratio, smooth philtrum, and thin upper lip), they were able to differentiate individuals with and without FAS with 100% accuracy. The sensitivity and specificity were unaffected by age, sex, and race (Astley and Clarren 1996). The facial features used in this study were taken from an earlier study completed by the same researchers in which the measurements were taken on subjects and not on photographs (Astley and Clarren 1995). Astley and Clarren's work ultimately led to the development of the widely adopted 4-Digit Diagnostic Code (Astley and Clarren 2000) and the *FAS Facial Photographic Analysis Software* (Astley 2003), described in the Discussion section below.

Stereophotogrammetry: Mutsvangwa and Douglas used stereophotogrammetry to compare facial landmark data of FAS and normal subjects (see Fig. 63.2). In looking at only landmarks representing palpebral fissure length, upper lip thinness, and philtrum smoothness, they did not find any significant difference in shape between the two groups. However, when landmarks affected by mid-face hypoplasia were added, they found significant differences in shape between the two groups, broadly

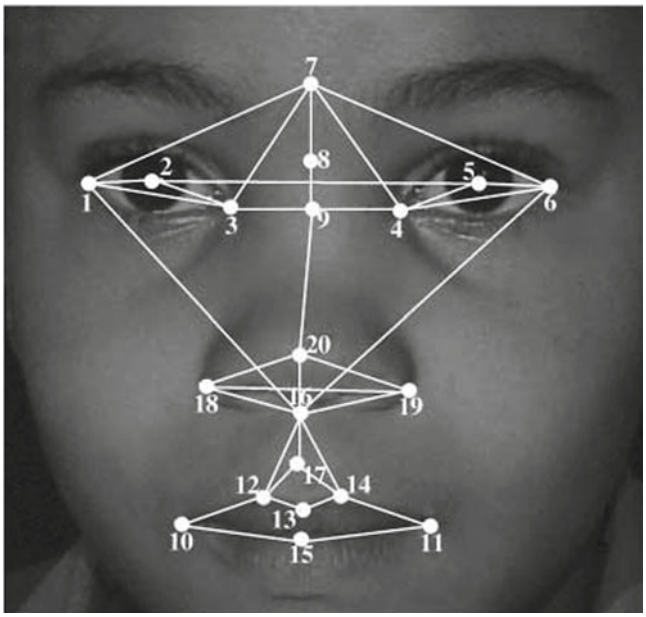

Fig. 63.2 Photographs and landmarks obtained using photogrammetry tools. The landmarks are: (*1*) left outer canthion; (*2*) left pupil centre; (*3*) left inner canthus; (*4*) right inner canthus; (*5*) right pupil centre; (*6*) right outer canthus; (*7*) glabella; (*8*) nasion; (*9*) sellion; (*10*) left cheilion; (*11*) right cheilion; (*12*) left crista philtre; (*13*) labiale superius; (*14*) right crista philtre; (*15*) stomion; (*16*) subnasale; (*17*) midpoint of philtrum furrow; (*18*) left alare; (*19*) right alare; (*20*) pronasale. The photograph shows the landmarks obtained using photogrammetry tools by Mutsvangwa and Douglas in their 2007 study. The landmarks are: (*1*) left outer canthion; (*2*) left pupil centre; (*3*) left inner canthus; (*4*) right inner canthus; (*5*) right pupil centre; (*6*) right outer canthus; (*7*) glabella; (*8*) nasion; (*9*) sellion; (*10*) left cheilion; (*11*) right cheilion; (*12*) left crista philtre; (*13*) labiale superius; (*14*) right crista philtre; (*15*) stomion; (*16*) subnasale; (*17*) midpoint of philtrum furrow; (*18*) left alare; (*19*) right alare; (*20*) pronasale. (Reprinted from Mutsvangwa and Douglas 2007, with permission)

confirming the FAS gestalt reported in the literature. In their study population, thinness of the upper lip was not a significant discriminator of FAS. They suggest that the disagreement in characteristic FAS facial shape between their results and that reported in the literature may be due to ethnic variation (Mutsvangwa and Douglas 2007).

Laser scanning: Moore et al. used a 3D laser scanner (Minolta Vivid 700 Series Non-Contact 3D) to assess linear measurements across four ethnic populations (North American whites, African Americans, Finnish whites, and "Cape Coloureds" from South Africa) (see Table 63.3 and Fig. 63.3). Measurements that reflected reduced size of the eye orbit were the most consistent feature discriminating FAS and controls across each study population. However, each population had a unique, though often overlapping, set of facial measurements that discriminated the two groups, suggesting important ethnic differences in the presentation of FAS. It is possible that these differences were accentuated by the wide age distribution between the study populations (Moore et al. 2007).

Light-based 3D image capture: In spite of its potential and the availability of commercial systems, few studies to date have employed this technology to study FAS/FASD. Strömland et al. used a range camera system to compare nine children with FAS to study controls. All children with FAS had shorter palpebral fissures, and in six of them the outer canthal distance was shorter than that in the reference group (Strömland et al. 1999). Ongoing work by the Collaborative Initiative on Fetal Alcohol Spectrum Disorders (CIFASD) is utilizing the 3dMD system to assess the FAS/FASD face in as many as 600 subjects from six different study sites.

Table 63.3 Craniofacial measurements and landmarks. Numbers keyed to Fig. 63.3

Type	Number	Measurement	Abbreviation
Width	1	Minimal frontal width	ft-ft
	2	Bizygomatic width	zy-zy
	3	Bitragal width	t-t
	4	Bigonial width	go-go
	5	Inner Canthal width	en-en
	6	Outer Canthal width	ex-ex
	7	Palpebral fissure length	en-ex
Depth	8	Upper facial depth	n-t
	9	Midfacial depth	sn-t
	10	Lower facial depth	gn-t
Length	11	Nasal length	n-sn
	12	Nasal bridge length	n-prn
	13	Philtrum length	sn-ls
	14	Lower facial height	sn-gn
	15	Total facial height	n-gn
	16	Ear length	sa-sba

This table lists the anthropometric measurements used by Moore et al. (2007) in their 3D laser scanner study that compared facial measurements of children with FAS across four different ethnic groups

Automatic facial recognition: Though not an image capture technique, automated facial recognition (AFR) uses machine training and higher order surface features to analyze 3D data generated from laser- or light-based systems. Automated facial recognition is utilized in several different application domains, such as forensics, biometrics, telecommunications, HDTV, and medicine, and it has shown promise for identifying individuals with FAS. It has many advantages over other techniques, including the fact that analysis is not dependent on linear measurements or geometric structures. The approach requires little expertise on the part of the observer, and it may more easily handle differences due to age, ethnicity, and gender compared to other forms of analysis (Huang et al. 2005). Huang et al. used AFR methods on 2D digital photographs of 31 FAS and 32 non-FAS facial images. The performance of the classifier for FAS prediction used 25 "components" and resulted in 70.0% correct classification of individuals previously identified by a trained dysmorphologist as having FAS (Huang et al. 2005). Fang et al. also used AFR techniques to demonstrate that computer algorithms can be used to automatically detect facial features that can discriminate FAS and control faces in 3D images (Fang et al. 2008). Thus, pattern recognition analysis may eventually lead to computerized diagnosis of individuals with FAS.

63.5 Discussion

It is remarkable that in spite of the multiple technologies applied and three decades in pursuit of a quantitative phenotype for the effects of intrauterine alcohol exposure, no "gold standard" has emerged. In fact, almost all previous research has done no better than an 80–90% correct classification of individuals already known to have FAS (by clinical diagnosis) compared to unaffected controls. It could be argued that prior studies have been limited in performance by the lack of a consistent standard for determining prenatal alcohol exposure. It could also be argued that progress has been slowed by the lack of agreement on critical diagnostic criteria for FAS and FASD. This has led to difficulties in

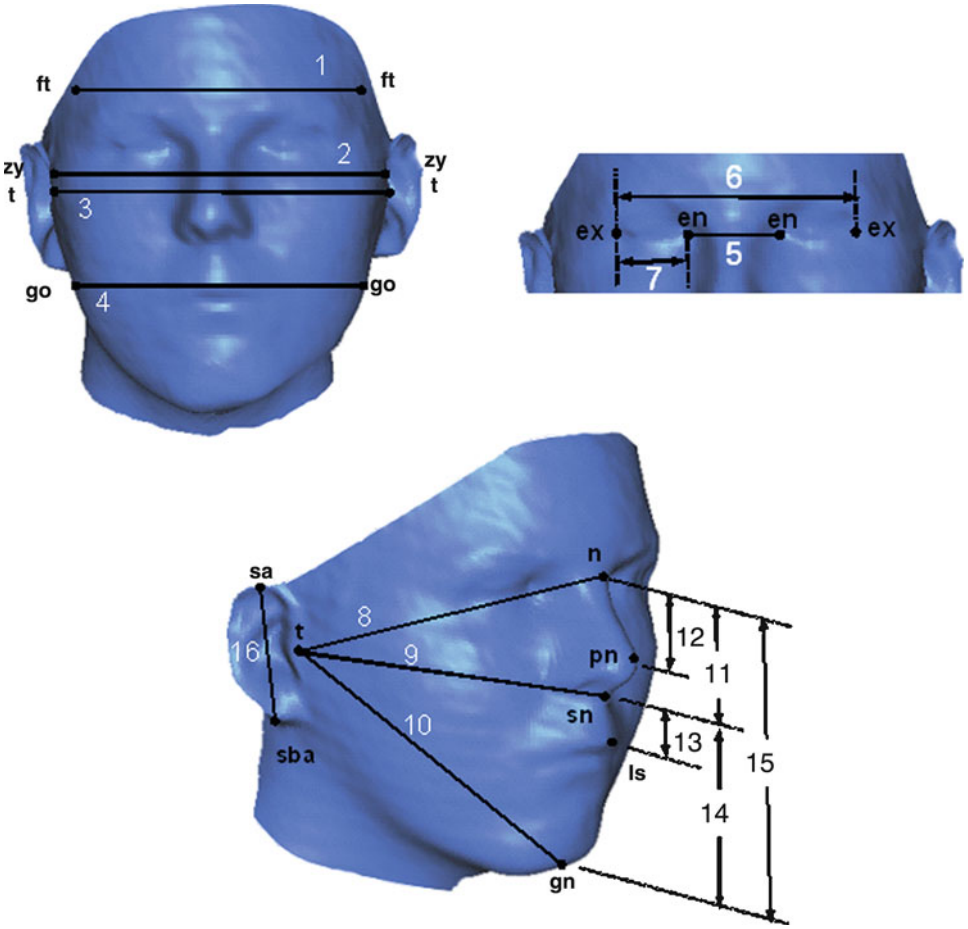

Fig. 63.3 Anthropometric measurements obtained using a 3D laser scanner (Minolta Vivid 910fw; KonicaMinolta Sensing Americas, Inc., Boulder, CO). Measurement names are listed in Table 63.3. Anthropometric measurements obtained by Moore and colleagues using a 3D laser scanner (Minolta Vivid 910fw; KonicaMinolta Sensing Americas, Inc., Boulder, CO). Measurement names are listed in Table 63.3. (Figure 63.3 and Table 63.3 are reprinted from Moore et al. 2007. With permission)

comparing results across studies and in consistently defining the target groups. More to the point, with one or two notable exceptions, none of these technologies has proven useful in (or been applied to) improving our ability to identify individuals who do not have clinically recognized facial gestalt associated with FAS. Thus, the sometimes bewildering array of studies and results reflect in part a lack of convergence of the research goals and objectives of the studies. However, we can assess the effectiveness of existing and previously used technologies in relation to three questions. The first would be, "Does it improve our ability to recognize individuals who fit the clinical diagnosis of FAS?" The second question would be, "To what degree can computerized anthropometry be used to expand the diagnostic phenotype for FASD?" The third question is, "To what degree can computerized anthropometry be used to improve our understanding of the pathophysiology of intrauterine alcohol exposure?"

Improving the phenotypic definition of the FAS face: Traditionally FAS is diagnosed using the gestalt method. The gestalt method, when used by an experienced, well-trained professional, can be highly accurate and reproducible (Clarren et al. 1987). However, its validity wanes when it is conducted by

untrained or inexperienced clinicians in the diagnoses of a condition like FAS that represents just part of the full spectrum (Astley and Clarren 1996). Astley and Clarren used anthropometry (and computerized anthropometry) in conjunction with other clinical tools to improve the accuracy and reliability of FAS diagnosis and to advance the identification of the full continuum of FASD (Astley et al. 1992; Astley and Clarren 1995, 1996, 2001; Astley 2003). They created the 4-Digit Diagnostic Code to provide a common standard for the diagnosis of FAS, one that correlates with structural, neurological, and functional measures of brain damage that are associated with prenatal alcohol exposure (Astley and Clarren 2000; Astley 2006). Their research has demonstrated a strong correlation between their 4-Digit Diagnostic Code classification and neuropsychological outcomes and brain structure anomalies (Astley et al. 2009a, b, c, d).

The 4-Digit Diagnostic Code was created to improve diagnostic accuracy. The four digits in the code reflect the magnitude of expression of the four key diagnostic features of FAS: (1) growth deficiency; (2) the FAS facial phenotype; (3) central nervous system damage/dysfunction; and (4) gestational alcohol exposure. The magnitude of expression of each feature is ranked independently on a four-point Likert scale with 1 representing complete absence of the FAS feature and 4 "classic" presence of the FAS feature. The 4-Digit Diagnostic Code is used for diagnosis, screening, and surveillance in several locations throughout the world. Computerized anthropometry is used to assess the magnitude of expression of two of the three facial features associated with the FAS facial phenotype. Three facial variables are assessed: palpebral fissure, upper lip, and philtrum. Palpebral fissure lengths are measured in standard deviations from the norm. These are adjusted for age, and when possible race, using published palpebral length standards. The upper lip and philtrum are measured on five-point photographic Likert scales using lip and philtrum guides (available for Caucasians and African Americans) (Astley and Clarren 1996, 2000; Astley 2006).

The *FAS Facial Photographic Analysis Software* developed by Astley and Kinzel measures the magnitude of expression of the key features of FAS by analyzing an imported digital photograph. According to Astley, the computerized image analysis program is very effective in measuring and ranking the magnitude of expression of the FAS facial phenotype (Astley 2003). The program requires standardized facial photographs (frontal, three-quarter view, and lateral) to be taken. In addition, an internal measure of scale is place on the patient's forehead. Digital photographs are scanned or downloaded into the software program. As in their direct assessment, three facial features (palpebral fissure length, upper lip thinness, and philtrum smoothness) are used in the analysis. The standards and guides used in the program are the same as used in the 4-Digit Diagnostic Code. Right and left palpebral fissure lengths and inner canthal distance are measured with a distance measurement tool. The user clicks the mouse pointer on the landmarks (endocanthion and exocanthion) and the program computes the distance between the landmarks. The program adjusts for the foreshortening of the length due the use of a 2D image. The phenotypic expressions of philtrum smoothness and upper lip thinness are recorded on a five-point Likert scale. The user selects the lip and philtrum (ranked 1–5) that best matches the patient's lip. Upper lip thinness is also recorded on a continuous scale with an objective measure of shape called circularity (or perimeter^2/area). Using the "circularity tool," the user outlines the upper lip and the program calculates the circularity and assigns a rank of 1–5. Once all three facial features have been evaluated, the software program assigns an A-B-C score to each feature based on the measurement or rank assigned. It then combines these results to assign an overall score (1–4) for the severity of the facial phenotype. Based on the 4-Digit Diagnostic Code, a rank of 4 represents a severe level of expression of the FAS facial phenotype and a rank of 1 is the absence of the expression of the facial phenotype (Astley 2003).

The 4-Digit Diagnostic Code creates homogeneous categories that are useful for clinical and research purposes; however, difficulties remain with the applicability of this tool due to the subjectivity in assessing the three cardinal facial features of FAS. Jones et al. noted that even after extensive

training, pediatricians were inconsistent in identifying a thin upper lip and smooth philtrum. Thus, despite the use of the Astley-Clarren lip-philtrum guides as a visual aid, only fair agreement was achieved in their assessment of small palpebral fissures (Jones et al. 2006). Cranston and colleagues evaluated consistency among the different methods used to measure palpebral fissure length (ruler, calipers, and Astley's photometric technique). Despite receiving training on the photometric method, the measurer obtained concordance between the ruler and photometric measures on only 42% of the subjects. The concordance was even lower between caliper measurements and those obtained with the ruler (24%) and photometric technique (18%) (Cranston et al. 2009).

Expanding the recognition of the FASD face: Moore et al. demonstrated that direct anthropometry could be used to identify individuals who lacked the full expression of clinical traits necessary to be classified as FAS, but who had known intrauterine alcohol exposure and at least one other clinical manifestation of the syndrome (Moore et al. 2001, 2002). These "partial FAS" individuals in fact were correctly discriminated (classified) from both the full FAS and the control population with an accuracy rate of 88%, a sensitivity of 86% (three FAS classified as PFAS), and a specificity of 94% (two members of the control group classified as PFAS) with just five variables (Moore et al. 2002). Moreover, Moore et al. demonstrated a distinct pattern of facial measurements in the partial FAS group that correlated strongly with that seen in the full-blown FAS cases, though it was less extreme (Moore et al. 2001, 2002). This finding supports viewing FASD as a continuum, though one that can be effectively identified through a wider range than is currently practiced.

Given the success of direct anthropometry in discriminating beyond the standard FAS phenotype, it is reasonable to expect the computerized anthropometric approaches and associated advanced analytical techniques to have similar or greater success in expanding our ability to identify a wider range of individuals with FASD. However, it is critical that such studies incorporate a design that is not dependent on the a priori definition of clinical FAS. Thus, a more efficient design would be one that grouped alcohol-exposed and non-alcohol-exposed samples matched for age, sex, and ethnicity. Results from such designs would not be tied to previously recognized "gestalt" features but rather would reflect the ability to detect the range of size and shape differences as a consequence of the effects of intrauterine alcohol exposure.

There is a clear need to develop an approach that combines the objective assessment of facial size and form made possible by computerized anthropometry with a clearly defined and widely accepted classification of the various clinical manifestations of FASD, as outlined by Astley and colleagues (Astley and Clarren 2000, 2001; Astley 2006; Astley et al. 2009a, b, d). In addition, the application of any variety of geometric shape analysis, such as that practiced by Hammond and colleagues (Hammond et al. 2003, 2004, 2005, 2008; Hammond 2007) and Klingenberg and colleagues (Klingenberg 2002; Klingenberg et al. 2002, 2004; Klingenberg and Monteiro 2005) could help move the anthropometric description of FAS/FASD beyond linear or proportional measures.

Improving the understanding of the pathophysiology of gestational alcohol exposure: Ultimately, computerized anthropometry analysis may have a larger impact on improving our understanding of the pathophysiology of alcohol exposure as neural imaging, craniofacial imaging, and data from animal models converge. Correlations between the magnitude of expression of the FAS facial phenotype and brain structure and function have been reported in both MRI and neuropsychological and behavioral studies (Astley and Clarren 1996, 2000, 2001; Astley et al. 2002, 2009a, b, d). As Astley and colleagues (Astley et al. 1999; Astley and Clarren 2001) point out, these results support the often cited reflection that "the face predicts the brain" (DeMyer et al. 1964); specifically, midline facial anomalies correlate with underlying developmental problems in the brain. These results are consistent with mice studies that found a similar parallel between in utero alcohol exposure, disruptions in the face, and structural deficits in the brain. Thus, studies consistently demonstrate that subtle midline facial

anomalies, such as those seen in FASD, appear to be pathognomonic of underlying structural brain deficiencies and malformations (Astley et al. 1999, 2009b; Astley and Clarren 2001).

63.6 Conclusion

The convergence of sophisticated imaging technologies (both facial and neural) coupled with higher level analytical approaches, including geometric and pattern recognition analysis, should lead to improvements in our ability to recognize and diagnose cases of FAS as well as a larger range of individuals with more subtle expressions of FASD. Simultaneously these applications should create new insight into the underlying pathophysiology of gestational exposure to alcohol. Of course, this added insight will only have meaning if it leads to a reduction in the occurrence and prevalence of this serious and ultimately preventable public health problem.

63.7 Applications to Other Areas of Health and Disease

Clearly, computerized anthropometry has wide applicability for the study of an array of craniofacial syndromes. In addition, these techniques have applicability in plastic and reconstructive surgery as well as in forensic science, such as predicting how a missing child's face would change with age. Perhaps most importantly, advances in computerized anthropometry and morphometrics may lead to advances in telemedicine, wherein computerized facial analysis can be applied to images obtained from isolated or remote locations and shared with physicians and other specialists who can use the remotely obtained data to assist in diagnosis, treatment planning, and outcome assessment.

63.8 Practical Methods and Techniques

Computerized anthropometry allows for the remote collection of data and it has been argued that it requires little expertise. This may be true for the original image processing, but for most of the methodologies outlined in this chapter, subsequent treatment of the data requires knowledge of human anatomy and of the craniofacial landmarks used in traditional anthropometric analysis. Future applications that involve automated analysis and categorization of facial patterns (facial recognition techniques) may obviate the need for anthropometric expertise. On the other hand, applications of these methodologies to exploring the link between facial form and the effects of alcohol on development will always require a deep understanding of craniofacial anatomy, growth, and development.

Summary Points

- Craniofacial anthropometry has a long association with clinical applications in the recognition, diagnosis, treatment, and understanding of craniofacial disorders.
- Craniofacial anthropometry is perceived as time consuming, difficult to use with young children, and necessitating a level of skill and experience that make it difficult to use in large-scale studies.
- Computerized craniofacial anthropometry offers a variety of options that overcome some of the

problems evident with direct anthropometry.
- Computerized anthropometry includes both 2D and 3D options.
- Computerized anthropometry offers the advantage of creating a permanent record of the face for continued analysis.
- Computerized anthropometry creates data that is easily utilized in geometric and other forms of morphometric analysis beyond size and proportion.
- 2D and 3D computerized anthropometry have been applied to the study of fetal alcohol spectrum disorders (FASD).
- Several studies have demonstrated that computerized craniofacial anthropometry can accurately identify individuals with previously diagnosed FAS, one end of the FASD continuum.

Key Points

Potentially improves the phenotypic definition of the FAS face
Expands the recognition of FASD
May improve the understanding of the pathophysiology of gestational alcohol exposure

- 3D studies offer the best hope of establishing objective criteria for identifying individuals within a wide range of FASD expressions.
- Computerized craniofacial anthropometry, coupled with information from other domains, such as neural imaging, should help generate improved understanding of the causes of the FASD phenotype.

Chapter 64
Correlating Maternal and Infant Anthropometric Variables and Micronutrients at Birth in the Pakistani Population

Shahzad K. Akram and Christine Carlsson-Skwirut

Children can be ensured a healthy start in life if women start pregnancy healthy and well nourished, and go through pregnancy and childbirth safely.

UNICEF/WHO, December 2004

Abstract Foetal growth restriction is a large scale global problem affecting millions of pregnancies annually. It is dependent on both environmental and genetic factors. The consequences of babies being born small for their gestational ages or with low birth weights are substantial with increase in both immediate mortality and morbidity among neonates and their mothers, as well as increased morbidity in later childhood and adult life. Environmental constraints are, in large part, preventable and are further sub-classified into physical and nutritional factors. Maternal size and poor nutritional states increase both morbidity and mortality risks. These problems are most prevalent in sub-Saharan Africa and south-central Asia, where poverty is rampant and diets are deficient in key nutrients. We looked at the correlation of maternal anthropometry and micronutrients with birth weight in the Pakistani population, where the prevalence of growth restriction and LBW is 17%. Correlations were seen between both maternal physical and micronutrient measurements and birth weight. This suggests the potential use of maternal anthropometrical measurements as an initial measure to identify pregnancies at a high risk of growth restriction. Furthermore, multi-micronutrient supplementation may also prove to be beneficial to both short- and long-term outcomes of maternal and foetal growth, and health.

64.1 Introduction: Causes and Measures of Maternal and Neonatal Health and Disease

Adequate nutrition is quintessential for normal growth, development and function, both pre-natally and following delivery, through to later life. Poor nutrition in the mother can lead to deficiencies in pregnancy, with profoundly devastating effects on both the child and the mother. Anaemia at the time of delivery, for example, is correlated with an increased risk of maternal mortality. Thus, we see that maternal and child nutrition exhibit a truly complex and sensitive relationship. This is more readily seen in under-nutrition in lower-income countries, particularly in sub-Saharan Africa and south-central Asia. The consequences of under-nutrition are vast and devastating, contributing to an estimated 3.5 million deaths per annum globally (Black et al. 2008). Furthermore, certain metabolic disorders in the mother may significantly affect birth size and weight. The most prevalent metabolic disorder is that of diabetes mellitus, which, in the gestational period, results in abnormal glucose metabolism in the placenta and foetus. This gestational diabetes mellitus (GDM) contributes to infant birth weights significantly greater than those of the normal population percentiles. The fine balances of foetal growth and birth weight are therefore crucial for both short- and long-term health outcomes in the child, with a tip of this balance in either direction contributing to increased morbidity and mortality in newborns and infants.

For the purposes of this chapter we chose to focus on a particular population group, that of rural Pakistan. This population represents the majority lower socio-economic class prevalent in south-central Asia, namely Pakistan, India, Sri Lanka and Bangladesh. In these countries, an estimated 70% of inhabitants live in poorer rural settings (WHO 2009). In terms of the population, this amounts to an astounding figure of approximately one billion people. It is in these settings that the greatest poverty and thus the vast problems associated with maternal and child under-nutrition exist. The topographical representation of Pakistan can be seen in Fig. 64.1, along with key population facts (Table 64.1).

Though the exact prevalence of low birth weight (LBW) is unknown, it is estimated between 10% and 25%, depending on the region. This can be seen more clearly in Table 64.2, where six independent studies have calculated the incidences of LBW in different cities across Pakistan (n = 2625, mean incidence 17%). These figures represent the documented cases of growth restriction and LBW and must therefore be seen as such, as the actual incidences may in fact be much higher. Infant and maternal morbidity and mortality statistics, given as population health figures, for the Pakistani population are represented in Table 64.3. The national figures are compared with regional averages, as shown in the World Health Statistics report, 2009 (WHO 2009). In the table, one can see that the percentage of 5 year olds who are underweight is a substantial 31.3%. This leads to increased morbidity with a corresponding increase in mortality rate in this population group, as can be seen in the table (92 per 1,000 live births).

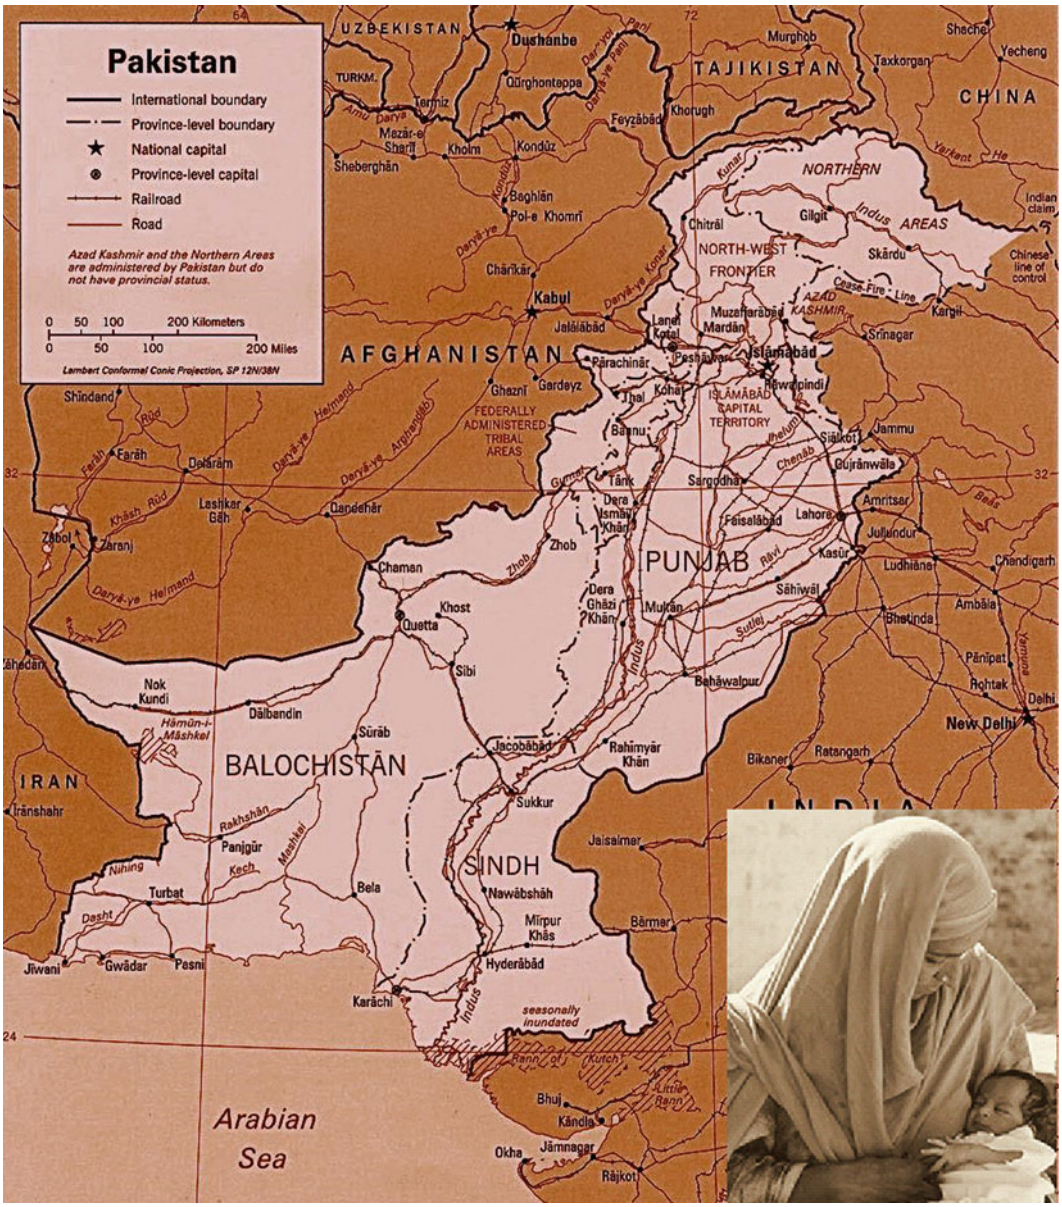

Fig. 64.1 Topographical map of Pakistan. A topographical map of Pakistan, showing bordering countries. The bottom right corner depicts a mother and child in the rural setting, as the majority of the population is based in rural areas

64.2 Maternal Anthropometry and Growth Outcomes

We began by briefly discussing the highly complex relationship between maternal and infant parameters, where maternal size not only factors in, but, directly correlates to foetal size. In simpler terms, the size of the mother is believed to affect the birth size of the infant. Physically, this can be described more appropriately as "Maternal Constraint". The physical size of the mother, along with her physiological state, "constrains" gestational growth, based on environmental factors. These physical constraints can

Table 64.1 Key facts of Pakistan

1. The total rural and urban population of Pakistan is estimated to be *147,100,000* (based on the most recent population census, 2006).
2. The rural population is estimated to be *95,000,000*.
3. The urban population is estimated to be *52,100,000*.
4. The total numbers of live births per year are estimated to be *3,800,000*.
5. The number of live births per year in rural areas is estimated to be *2,600,000*.
6. The number of live births per year in urban areas is estimated to be *1,200,000*.
7. The prevalence of growth restriction is an estimated 17% per annum, which amounts to *646,000* babies being born small for their gestational ages (SGA) per annum with the majority in rural areas.

This table lists key population statistics, including total population, number of live births and the estimated numbers of babies born small for their gestational ages (SGA), per annum. The statistics further describe the differences between rural and urban populations, as the greatest prevalence of SGA is in rural areas. All statistics are based on the Government of Pakistan population statistics (FBS 2006)

Table 64.2 Literature review on the incidence of low birth weight (LBW) babies in the Pakistani population

Author	Population included in study (*n*)	Incidence of LBW (%)
1. Janjua 2009	540	18.5
2. Akram 2008	89	13.4
3. Badshah 2008	1,039	9.9
4. Jalil 2008	695	16
5. UNDP 2005	N/A	19
6. Shamim 1999	262	25
	Total: 2625	***Mean: 17***

This table lists the incidence of low birth weight (LBW) in the Pakistani population. The mean incidence of LBW was seen to be 17% (6 studies, $n = 2625$) (Akram et al. 2008; Shamim et al. 1999; Janjua et al. 2009; Jalil et al. 2008; UNDP 2005; Badshah et al. 2008)

Table 64.3 Morbidity and mortality rates in Pakistan and South-East Asia

Morbidity/mortality parameter	Population statistics (Pakistan)	Regional averages (South-East Asia)
Neonatal mortality rate (per 1,000 live births)[a]	53	38
Infant mortality rate (per 1,000 live births)[b]	73	60
Children under 5 years underweight for age (%)	31.3	N/A[c]
Under 5 mortality rate (per 1,000 live births)	90	82
Maternal mortality ratio (per 100,000 live births)	320	420

The table summarises the morbidity and mortality statistics as a measure of population health for the Pakistani population, comparing the Pakistani population with regional averages (South-East Asia)
[a]Neonatal mortality rate = probability of dying between birth and the first 30 days of life
[b]Infant mortality rate = probability of dying between birth and 1 year of age
[c]N/A = not available) (WHO 2009)

only be taken in to consideration once other metabolic and genetic causes of disease have been excluded (Price and Coe 2000). These trends of growth restriction follow an inter-generational pattern, whereby daughters born with a LBW to small mothers are likely to be small themselves and thus perpetuate this cycle of growth restriction from generation to generation (Ounsted et al. 1988). This is clearly seen in the Pakistani population, where average maternal and subsequent birth- weights are significantly lower than those of higher-income countries.

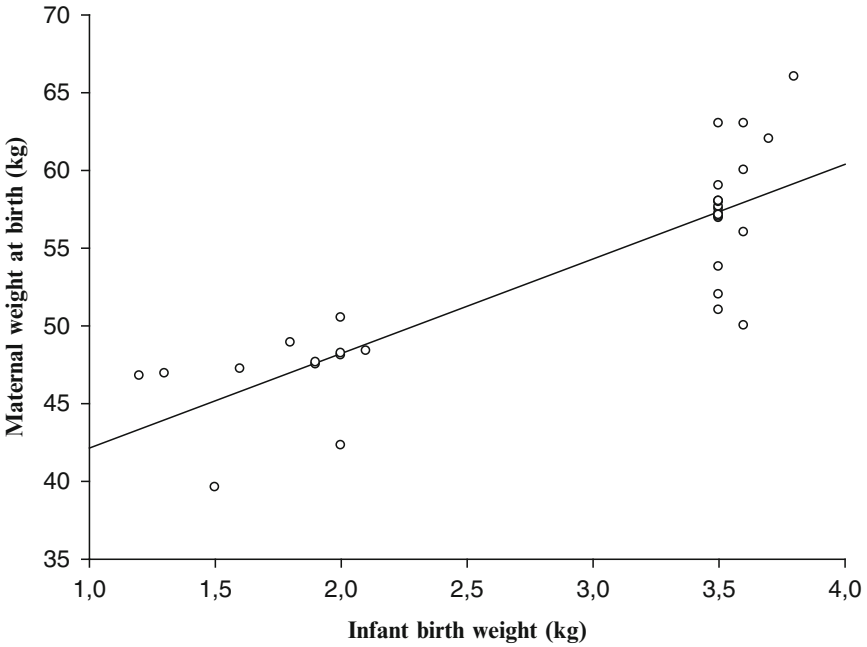

Fig. 64.2 Correlation of maternal and infant weight at birth. A correlation of infant birth weight (kg) and maternal weight at birth (kg) in the Pakistani population. The positive correlation emphasises the significance of maternal size influencing birth weight outcomes (Akram et al. 2008)

In keeping with the idea of maternal constraint, physical measurements of the mother should therefore correspond to foetal growth and birth weight outcomes. Akram et al., have shown these correlations in their study in rural Karachi, Pakistan (Akram et al. 2008). Figure 64.2 shows the positive correlation of maternal weight at birth and birth weight in the Pakistani population. Additional anthropometric measurements taken include maternal height, upper mid-arm circumference and mid-triceps skin fold thickness. These measurements represent body-fat composition and thus the nutritional status of the mother. Figure 64.3 depicts the use of callipers to measure the mid-triceps skin fold thickness.

64.3 Infant Anthropometry as a Reflection of Growth

Foetal growth is largely dependent on the foetal genome and the foetal environment. Abnormalities in either of these two variables may lead to foetal growth restriction (FGR). More specifically, genetic abnormalities, or environmental/nutritional changes, can alter the normal cycles of growth, thereby leading to inadequate growth. Prenatal, this growth restriction is better known as "intrauterine growth restriction" (IUGR), subsequently leading to children being born small for their gestational ages (SGA). FGR, or IUGR, is further classified as "symmetrical" and "asymmetrical", depending on the causes and onset of insult to the foetus resulting in poor growth outcomes. Nutritional deprivation in the early gestational period has been seen to symmetrically restrict foetal growth, as all developing cells are equally affected. In comparison, nutritional deficiencies seen in the latter half of gestation account for a more asymmetrical growth restriction, whereby the

Fig. 64.3 Callipers measuring skin-fold thickness. The use of skin fold callipers to measure the mid-triceps skin fold thickness as a measurement of body fat. Skin fold thickness is a key anthropometric variable.

basic organs have already developed. This results in shunting of the available nutrition away from the rest of the body to maintain nutrient supply to the brain, resulting in asymmetrically large heads in babies born with LBW. Though there are little data on the Pakistani population, the majority of growth restricted babies are seen to be symmetrical, implying that their nutritional deficiency is a chronic problem. This goes hand in hand with maternal constraint, where small mothers are more likely to give birth to babies with LBW. This is most likely the result of poor underlying maternal nutrition restricting foetal growth in an attempt to "save" the pregnancy (Gluckman and Hanson 2004).

64.4 Micronutrients and Their Correlations with Maternal and Foetal Anthropometry

Looking beyond the problems associated with anthropometry and metabolic disorders, nutritional and dietary intake of the mother also significantly contributes to pregnancy and foetal outcomes. Micronutrients, simply vitamins and minerals, are crucial for growth and development at both the cellular and systemic levels. Deficiencies of key micronutrients may lead to maternal anaemia, hypertension, diabetes, complications of labour and even death (Ramakrishnan 2002). Micronutrients,

An overview of key vitamins and minerals and their recommended daily allowances (RDAs) for women in the pregnancy age group (15–40 years), along with their correlation with maternal and infant anthropometry. The RDAs are based on North American recommendations (USDA 2009). All measures are given in SI units

therefore, play a significant role in pregnancy outcomes and maternal health. Recommended daily allowances (RDA) of all the vitamins and minerals during pregnancy can be seen in Table 64.4. Additionally, correlations with maternal and new born anthropometry can also be seen in the table, along with supporting references. The RDAs for all micronutrients, based on North American statistics, are higher during pregnancy (USDA 2009).

64.5 Fat-Soluble Vitamins

64.5.1 Vitamin A

Vitamin A deficiency is an extremely common form of micronutrient malnutrition. An estimated 5.6% of pregnant women worldwide are affected, and 20% of all maternal mortality is attributed to its deficiency. The most common clinical manifestations, however, are that of decreased immunity and poor vision, leading to blindness due to corneal scarring. Not much data are available on the affects of its supplementation during pregnancy in the Pakistani population. The RDA is 4,000 international units (IU), though in deficiency prone areas, WHO and UNICEF have recommended two supplemental injections of 200,000–400,000 IU. Though there is no direct correlation with maternal or foetal anthropometry in the Pakistani population, positive correlation trends have been seen in other parts of the world (Table 64.4). Furthermore, it is well known that adequate supplementation decreases maternal and infant mortality rates.

64.5.2 Vitamin D

Vitamin D is essential for the normal physiological balance of calcium and phosphate, both in blood and in skeletal tissue, as well as maintaining general cellular function, muscle contractions and nerve conduction. Unfortunately no data are available on vitamin D supplementation or correlations with maternal or infant size in the Pakistani population. Scholl et al., have shown that serum levels do in fact correlate with maternal body mass index (BMI) and infant birth weight, as can be seen in Table 64.4 (Scholl and Chen 2009).

64.5.3 Vitamin E

This vitamin plays a key role as an "anti-oxidant", helping the body dispose of potentially harmful free-radicals. If left unhindered, free-radicals are believed to adversely affect reproductive cells, as well as to potentiate erroneous cell reproduction. Deficiencies of this vitamin have, therefore, been shown to increase rates of infertility and frequent miscarriages, as well as an increased incidence of premature deliveries. However, not much data are available on the correlations with maternal or foetal anthropometry. Though deficiencies are suspected in the Pakistani population, there are no available data.

64.5.4 Vitamin K

Vitamin K is fundamental for the regulation of certain proteins, collectively known as vitamin K proteins. So far, the only known role of this vitamin in health is in the maintenance of normal coagulation. There is no evidence of its correlation with maternal or foetal anthropometry.

64.6 Water-Soluble Vitamins

64.6.1 Vitamin B-Complex

This family of vitamins, known as the B-complex, consists of several clinically significant vitamins, namely, B1, B2, B3, B5, B6, B12, folate and biotin. These are discussed in brief as follows:

Thiamin (vitamin B1), riboflavin (vitamin B2) and niacin (vitamin B3) are all essential cofactors for glucose and energy metabolism. As one can imagine, deficiencies present as marked metabolic effects in the mother, and, more significantly, may lead to impaired foetal growth. Thus, levels of these vitamins indirectly correlate to foetal anthropometry and birth weight outcomes.

Pantothenate (vitamin B5) is structurally part of the carrier protein co-enzyme A, which is an essential part of glucose metabolism. More specifically, co-enzyme A is integral in the tricarboxcylic acid (TCA) cycle. Deficiencies of this vitamin thereby also lead to impaired glucose metabolism and the corresponding growth restriction. Though there are no available data on the Pakistani population, Baker et al., have shown a significant positive correlation of levels with infant birth weight (Baker et al. 1977).

Pyridoxine (vitamin B6) deficiency has not been shown to alter pregnancy outcomes, nor correlate to maternal and infant anthropometry. Its principal function is that of amino acid metabolism. Interestingly, excesses of this vitamin may, in turn, be harmful to both the mother and foetus.

Folic acid and cobalamin (vitamin B12) are essential for normal cell reproduction, neural cell function and for the production of erythrocytes, amongst other functions. There have been no isolated trials on vitamin B12 supplementation, or correlations with maternal anthropometry. Deficiencies are, however, believed to cause growth stunting. Folate deficiencies, on the other hand, have clearly been shown to increase the risk of IUGR, thereby resulting in babies being born with lower birth weights (Tamura and Picciano 2006). Unfortunately, no data on the correlations of folate levels and anthropometry are available in the Pakistani population.

Biotin is essential for the production of fatty acids, fat metabolism and cell growth. There is little evidence for the role of supplementation of this vitamin in pregnancy and no evidence of correlations with maternal anthropometry or birth weight.

64.6.2 Vitamin C

This water-soluble vitamin plays a key role in the maintenance of collagen structure in the intracellular matrices. Deficiency of vitamin C results in poor wound healing and "scurvy". Mot much data are available, suggesting the possible beneficial effects of supplementation of this vitamin in pregnancy in decreasing the incidence of babies being born SGA.

64.7 Minerals

Details of key minerals can be seen in Table 64.4. Clinically, the most significant of these deficiencies are calcium, iodine, iron and zinc. These shall be discussed in more detail. There is limited evidence to conclude correlations with anthropometry and the minerals, copper, chromium, magnesium, manganese, molybdenum, phosphorus and selenium.

64.7.1 Calcium

Calcium plays an important role in bone metabolism, muscle contraction and neuronal cell signalling, where calcium-gated channels are present in certain synapses. Additionally, it is present in teeth, soft tissues and other processes of metabolism. An estimated 1–2% of adult weight consists of calcium. Low levels have been associated with osteoporosis and, in severe cases, muscle and nerve dysfunction. Though there are no data on its correlation with maternal and foetal anthropometry in Pakistan, Atallah et al., have correlated low calcium levels with LBW (Atallah et al. 2002).

64.7.2 Iodine

This mineral is important in the normal functioning of the thyroid gland and thyroid hormones. Deficiencies in pregnancy have been seen to positively correlate with LBW, though there is little evidence on correlations with maternal anthropometry.

64.7.3 Iron

Clinically, the most common micronutrient deficiency globally is that of iron. Iron deficiency anaemia increases the risks of maternal mortality, particularly towards the latter part of pregnancy. Furthermore, serum levels of iron have been correlated with foetal size and birth weight outcomes, suggesting the importance of supplementation during pregnancy (Scholl and Hediger 1994).

64.7.4 Zinc

Zinc is quintessential for normal DNA binding and function and thus for nuclear reproduction and cellular growth and development. Deficiencies have been well correlated with IUGR and birth weight. Similar trends have been seen in the Pakistani population, where serum zinc levels correlate positively to both maternal and new born anthropometry (Akram et al. 2008).

64.8 Other Trace Elements

The trace elements are key functional components in normal cell and tissue functioning. There are no data available on the correlation of these minerals with anthropometry in the Pakistani population. However, recent studies on copper and magnesium have shown strong positive correlation with both IUGR and babies being born small for their gestational ages. Furthermore, selenium levels inversely correlate with IUGR and birth weight, indicating the potential toxicity of this trace mineral in pregnancy. The roles of chromium, manganese, molybdenum and phosphorus are still unclear in pregnancy and birth weight outcomes.

64.9 Applications to Other Areas of Health and Disease

Based on current trials there is insufficient evidence to suggest, or negate, a multiple micronutrient supplementation programme, particularly in the Pakistani population, though a reduction of the number of "low birth weight" babies has been seen with multiple micronutrient supplementation in other countries. This may potentially help reduce the vicious cycle of under-nutrition. One would thus expect to see a reduction in the corresponding associated health problems of poor nutrition, thereby decreasing the health burden on already burdened low-income countries. Furthermore, timely nutritional supplementation has been shown to aid in positive maternal outcomes in pregnancy, with decreased incidences of preterm labour and pregnancy complications. As stated in a WHO report on LBW, "*children can be ensured a healthy start in life if women start pregnancy healthy and well nourished, and go through pregnancy and childbirth safely*" (WHO 2004).

64.10 Practical Methods and Techniques

Measurements of maternal and new born anthropometry include height, weight, BMI, mid-triceps/mid-calf skin fold thickness, mid-arm/mid-calf circumference, as well as abdominal wall thickness and head circumferences in new born infants (Table 64.5). With the correct instruments and training

Table 64.5 Key maternal and infant factors contributing to growth outcomes

Maternal factors	Infant factors
• Maternal size correlates with infant size (Maternal Constraint).	• Genetic and environmental factors affect birth weight outcomes.
• Adequate nutrition is important throughout pregnancy.	• Foetal and infant nutrition are important for adequate growth.
• Maternal glucose metabolism is an important regulator of birth weight outcomes.	• Thyroid hormone levels are essential for both growth stature and neurological development.
• Correct thyroid hormone levels are essential for normal foetal growth and development.	

This table emphasises the key maternal and infant factors contributing to foetal and infant growth outcomes and development

of personnel, these measurements can be made fairly accurately in even the most remote of rural settings. Simple training of health care workers in rural Pakistan may be a relatively cheap and effective way of identifying currently affected pregnancies and those at higher risks of developing growth restriction. The implications are potentially tremendous, as high risk pregnancies can be identified in a timely manner and referred to specialist facilities for further assessment and appropriate management. The current data, however, are rather limited, suggesting the need for further trials.

Summary Points

- Maternal anthropometry positively correlates with infant birth weight and anthropometry, emphasising the importance of maternal constraint. Maternal anthropometry can therefore be used to screen for pregnancies at a higher risk of developing growth restriction.
- The mean incidence of LBW in the Pakistani population is 17% (10–25%), based on several population-based studies.
- Foetal growth is dependent on both genetic and environmental factors. Environmental factors are based on both maternal size (maternal constraint) and nutritional state. Genetic factors include genetic malformations and disorders.
- Adequate maternal and foetal nutrition is paramount to normal growth and development. This can be more clearly seen with the vitamins A, C, D, E, B1, B2, B3, B5, B12, folate and pantothenate, as these vitamins positively correlate with birth weight outcomes.
- Adequate mineral consumption is also essential for normal growth. The minerals and trace elements calcium, copper, iodine, iron, magnesium and zinc, are of particular importance, as these have been shown to positively correlate with birth weight outcomes.
- Excessive consumption of certain nutrients may cause toxicity. Higher levels of the mineral selenium have been seen to negatively correlate with birth weight.
- Clinical measures of maternal anthropometry, namely BMI, limb circumference and skin-fold thickness, may be used to identify for growth restricted pregnancies. Timely identification of higher risk pregnancies can thus allow for the appropriate referral to specialised centres for further diagnosis and intervention.

Chapter 65
Neonatal Anthropometry: A Tool to Evaluate the Nutritional Status and Predict Early and Late Risks

Luis Pereira-da-Silva

Abstract Neonatal anthropometry is an inexpensive, noninvasive and convenient tool for bedside evaluation, especially in sick and fragile neonates. Anthropometry can be used in neonates as a tool for several purposes: diagnosis of foetal malnutrition and prediction of early postnatal complications; postnatal assessment of growth, body composition and nutritional status; prediction of long-term complications including metabolic syndrome; assessment of dysmorphology; and estimation of body surface. However, in this age group anthropometry has been notorious for its inaccuracy and the main concern is to make validated indices available.

Direct measurements, such as body weight, length and body circumferences are the most commonly used measurements for nutritional assessment in clinical practice and in field studies. Body weight is the most reliable anthropometric measurement and therefore is often used alone in the assessment of the nutritional status, despite not reflecting body composition.

Derived indices from direct measurements have been proposed to improve the accuracy of anthropometry. Equations based on body weight and length, mid-arm circumference/head circumference ratio, and upper-arm cross-sectional areas are among the most used derived indices to assess nutritional status and body proportionality, even though these indices require further validation for the estimation of body composition in neonates.

Abbreviations

AA	Arm area
AFA	Arm fat area
AGA	Appropriate-for-gestational age
AMA	Arm muscle area
BS	Biceps skinfold
BSF	Body surface
BW	Birth weight
CHL	Crown-heel length
CI	Cephalic index

TS	Tricipital skinfold
VLBW	Very low birth weight
WAA	Water arm area
W/L	Weight-for-length ratio

65.1 Introduction

In newborn infants, anthropometry has the advantages of being easy to perform and convenient for bedside measurements. Unfortunately, in this age group, anthropometry has been notorious for its inaccuracy in untrained hands and for its inter-observer variation (De Bruin et al. 1995; Prins 1995).

Direct measurements, such as body weight, length, and body circumferences are the most commonly used measurements for nutritional assessment in clinical practice and field studies (Pereira-da-Silva et al. 2007).

Some indices and equations derived from direct measurements have been proposed and used in newborn infants for improving the accuracy of the anthropometry (De Bruin et al. 1995; Prins 1995).

Most of the measurements are widely regarded as being too inaccurate to be recommended in everyday practice. Although such assumptions are superficially correct, it is possible to train health care professionals to perform accurate measurements. Furthermore, accurate sequential measurements are possible and provide more information than single measurements alone (Prins 1995; Pereira-da-Silva et al. 2007).

65.2 Neonatal Anthropometry as a Tool

65.2.1 Diagnosis of Foetal Malnutrition and Prediction of Early Postnatal Complications

Newborn infants with intrauterine growth restriction (IUGR) are usually small-for gestational-age (SGA), defined as body weight < 3rd centile (Olsen et al., 2010).

Most IUGR infants are the consequence of uteroplacental insufficiency occurring in the third trimester, affecting mainly the weight, so that the neonate appears wasted, presenting as an

asymmetric SGA. An early and prolonged insult during gestation causes chronic under-nutrition with impairment in both skeletal and soft tissue growth, resulting in a stunted neonate with reduction of both weight and length, a symmetrical SGA (Beattie 1994).

While the definition of SGA is based exclusively on the birth weight (BW), the classification of asymmetric or symmetric SGA is based on the ponderal index (PI) which includes the length (Patterson and Pouliot 1987).

SGA and IUGR are not synonyms. Some SGA infants are constitutional and not undernourished. Conversely, some appropriate-for-gestational age (AGA) infants are undernourished but cannot be defined as IUGR based on BW criteria (Beattie and Johnson 1994). In this case, mid-arm circumference/head circumference index (MAC/HC) or reduced skinfold thickness may identify foetal growth restriction regardless of BW (Owen 1997; Pereira-da-Silva et al. 2007). Reduced weight-for-length (W/L) ratio (Yau and Chang 1993) and individualized BW ratio (Wilcox et al. 1993) are other complimentary measurements capable of identifying IUGR.

Identifying IUGR at birth facilitates the anticipation of therapeutic measures for early metabolic and other complications, like poor gut function, hypothermia, hypoglycemia, hypocalcemia and polycythemia (Beattie and Johnson 1994). Asymmetrical IUGR neonates are more prone to these complications (Patterson and Pouliot 1987) and preterm infants with IUGR additionally are at higher risk of respiratory distress syndrome, sepsis, and necrotizing enterocolitis, as compared with AGA neonates of equivalent gestational age (Pereira-da-Silva et al. 2007).

At the other extreme, macrosomic and large-for-gestational age (LGA) neonates have a higher risk of vaginal birth trauma. When excessive growth is due to endocrine-metabolic disturbances, as in infants of diabetic mothers, increased risk of hypoglycemia, hypocalcemia, polycythemia and hyperbilirubinemia is present (Pereira-da-Silva et al. 2007). Nevertheless, most cases of macrosomic and LGA neonates are constitutional (Beattie and Johnson 1994).

65.2.2 Postnatal Assessment of Growth, Body Composition and Nutritional Status

In preterm infants, the changes in body compartments are greatly influenced by hydro-electrolytic management and energy-protein support. In these patients, direct and derived anthropometric measurements may estimate body composition, assess quality of growth and guide nutritional management. The fat compartment is more variable and sensitive to changes in nutritional status. Fat-free mass reflects the skeletal and body growth, assessed by crown-heel length (CHL) and length of body segments (Gibson et al. 2003).

A recent investigation using magnetic resonance imaging has shown that preterm infants born within 32 weeks have decreased subcutaneous adipose tissue and increased intra-abdominal adipose tissue. Their accelerated weight gain is accompanied by increased total and subcutaneous adiposity, while severity of illness is the principal determinant of increased intra-abdominal adiposity (Uthaya et al. 2005).

Skinfold measurements, MAC and derived measurements like muscle and fat upper-arm areas may estimate body fat and fat-free compartments. However, anthropometric techniques have limitations in estimating body composition in neonates and small infants; therefore, routine nutritional assessment in this age group is still mainly based on the body weight (De Bruin et al. 1995; Prins 1995).

65.2.3 Prediction of Long-Term Complications, Including Metabolic Syndrome

Neonatal morphometry may predict long-term complications.

Low BW, SGA and particularly asymmetrical SGA are predictors of high blood pressure, central obesity, dyslipidemia, diabetes type 2 and coronary heart disease in adulthood (Jaquet et al. 2005; Uhing and Das 2009). This is explained by multifactorial mechanisms which relate foetal undernutrition to insulin resistance and metabolic syndrome later in life (Jaquet et al. 2005).

Cognitive and neurodevelopment deficits have been associated with symmetrical SGA (Pereira-da-Silva et al. 2007).

In the other extreme, foetal macrosomia and LGA neonates, especially those related to maternal diabetes are associated with future obesity and metabolic syndrome (Pereira-da-Silva et al. 2007).

Morphometry at birth associated with the anthropometric outcome may predict late complications more accurately than the isolated morphometry at birth. For instance, greater postnatal catch-up growth in infants with IUGR predisposes to high blood pressure and metabolic syndrome (Jaquet et al. 2005; Uhing and Das 2009).

65.2.4 Dysmorphology Assessment

Anthropomorphic measurements provide more accurate assessment in infants with dysmorphic features. Appropriate techniques and standards are recommended for several anthropomorphic measurements (Fletcher 1998). This kind of assessment is facilitated by specialized computer programs (Zankl 2004).

For evaluating disproportionate growth disorders, measurements of trunk and limbs should be obtained, as well as arm span, crown-rump length, crown-rump length/crown-rump length (CHL) ratio, upper and lower limb lengths, hands and feet lengths, thoracic index, and inter-nipple distance (Dangerfield and Taylor 1983; Fletcher 1998).

For measuring the arm span, the arms should be extended at right angles to the body with open hands; the tip of each middle finger should be marked and the distance between the marks measured; the span should approximate the CHL, and a shorter span may indicate short upper limbs (Fletcher 1998).

For measuring the crown-rump length, the infant should be lying on the side with the hips flexed to 90° and the distance between the top of the head to the posterior distal part of the thighs should be taken (Fletcher 1998). The mean value of crown-rump length/CHL ratio varies from 0.653 at 27 weeks to 0.673 at 40 weeks, and an increased value may indicate short lower limbs (Fletcher 1998).

Perineal measurements such as anal placement, penile length, and testicular volume may be useful in particular conditions (Fletcher 1998).

For accurate assessment of craniofacial dysmorphisms some measurements should be taken: head length (maximal dimension of the sagital axis); head width (maximal biparietal diameter); ear width, protrusion and rotation measurements; in relation to the eyes, the outer and inner canthal distances, inter-pupillary distance, palpebral fissure length, and slant of the palpebral fissure; in relation to nose and mouth, the nasal length and width, length of colunella, philtrum length, and mouth width (Fletcher 1998). Cephalic index (CI) should be determined: CI = head width ×100/head length; the CI is 76–80.9 in a normal head, <75.9 in dolicocephaly and >81 in brachycephaly (Fletcher 1998). Standards for 15 angular and 11 linear craniofacial parameters measured on lateral head radiograph in term and preterm neonates, have been recently published (Paulsson and Bondemark 2009). Key points of CI see Table 65.1.

Table 65.1 Key points of cephalic index (CI)

1. CI is useful to define more precisely disproportionally long or narrow heads (dolicocephaly) and disproportionately wide heads (brachycephaly), present in some syndromal abnormalities.
2. For the head length measure the maximal dimension of the sagital axis and for the head width measure the maximal biparietal diameter. Then, calculate the CI = head width × 100/head length.
3. Normal head CI = 76–80.9; dolicocephaly CI < 75.9; and brachycephaly CI > 81

65.2.5 Estimate of Body Surface (BSF)

The BSF estimate is necessary for calculating the doses of some drugs, glomerular filtration rate and fluid balance in burns cases (Current 1998). BSF may be estimated by direct visualization of normograms based on weight and CHL (Meban 1983). In alternative, a simplified equation has been proposed for proportionate neonates: BSF = (weight + 4)/30, in which BS is expressed in m^2 and weight in kg (Current 1998).

65.3 Standards

To determine if an infant's measurements fall within normal ranges, an appropriate standard should be used. When comparing with population-based standards, the population should have similar backgrounds and potential, including gender, race, gestational age, genetic potential, altitude and type of feeding (Fletcher 1998). For example, measures of adiposity, such as skinfolds, are usually greater in female infants (Rodriguez et al. 2004). The growth pattern in infants with specific syndromes and conditions should be interpreted with specific charts, if available, as for Down's syndrome, Silver-Russell syndrome, cleft lip or palate and symptomatic congenital heart disease (Pereira-da-Silva et al. 2007). Specific intrauterine growth charts for twin infants are also available (Ananth et al. 1998). To evaluate intrauterine growth, the pregnancy should be accurately dated. The growth pattern of healthy breastfed infants differs to a significant extent from the NCHS/WHO international reference which is based on predominantly formula-fed infants. The new international growth references developed by the WHO multicentre growth reference study (www.who.int/childgrowth/en) describe how infants should grow rather than describing how infants grow. These growth references were constructed based on scientifically robust tools and an international sample of healthy breastfed infants living in health-promoting conditions.

Another issue concerns the consensus as to the limits for definition of normality. Depending on the epidemiologic power of the studies that produced the standards, their limits may be <10th and >90th centile, <5th and >95th centile, <3rd and >97th centile, <2.5th and >97.5th, or 2SD around the mean (Fletcher 1998). In fact, these are pure statistical definitions of normality, which should be confirmed by clinical risk assessments of the main adverse outcomes for each standard.

65.4 Direct Measurements

65.4.1 Weight

Since measurement of body weight is simple and reliable, it has been the most used isolated parameter for monitoring growth and nutritional status in neonates in clinical practice (Johnson et al. 1997; Gibson et al. 2003). It is has been reported that body weight is an independent predictor of body

Table 65.2 Classification of infants according to the birth weight (BW) and BW related with gestational age

- Normosomic: BW ≥ 2,500 g and ≤ 4,000 g
- Microsomic or LBW: BW < 2,500 g
- VLBW: BW < 1,500 g
- ELBW: BW < 1,000 g
- Macrosomic: BW > 4,000 g
- AGA: BW ≥10th and ≤90th centile, or ≥5th and ≤95th centile, or ≥3rd and ≤97th centile, ≥2.5th and ≤97.5th centile, or ≥–2SD and ≤+2SD of the mean, according to the standards used
- SGA: BW <10th centile, or <5th centile, or <3rd centile, or <–2SD below the mean, according to the standards used
- LGA: BW >90th centile, or >95th centile, or >97th centile, >97.5th centile, or >+2SD above the mean, according to the standards used
- Asymmetrical IUGR: PI <2.5th centile
- Symmetrical IUGR: PI >97.5th centile
- IUGR: commonly SGA. A small proportion of SGA infants are constitutional, and a small proportion of AGA infants suffered IUGR who should be diagnosed based on other anthropometric indices

AGA appropriate-for-gestational age; *ELBW* extremely low birth weight; *IUGR* intrauterine growth restriction; *LBW* low birth weight; *LGA* large-for-gestational age; *PI* ponderal index; *SGA* small-for-gestational age; *VLBW* very low birth weight

composition in preterm and term infants (Koo et al. 2000). However, it does not give any information on body compartments and quality of growth. For instance, in preterm infants the weight gain may result from positive balance of water and sodium rather than accumulation of fat or muscle mass (Prins 1995).

Based on the BW, neonates are classified as macrosomic if >4,000 g, microsomic or LBW if <2,500 g, very low birth weight (VLBW) if <1,500 g, and extremely low birth weight (ELBW) if <1,000 g. Classification of infants based on gestational age and birth weight see Table 65.2.

Technique and instrumentation: Patients are weighed naked, ideally to the nearest gram.

The digital electronic weighing scales have excellent precision and reproducibility and reduce dramatically the observer bias and reading errors as compared with beam-scales (Prins 1995; Gibson et al. 2003). With the aim of minimizing the handling of sick and fragile preterm infants, recent incubators are fitted with weighing scales, but their precision has not been validated. The weighing procedure is difficult because drips and inserted tubes should not touch the mattress, and errors may also be caused by the infant's movements (Prins 1995).

Standards: Appropriate charts and standards relate body weight with infant's age.

- Intrauterine growth is assessed by curves relating BW with gestational age. The old Lubchenco's curves (1966) (Fig. 65.1) have been widely used for many years (Fenton 2003), but their current use in preterm infants is fraught with several methodological problems that include the small sample of extremely preterm infants, errors in estimating gestational age and combined-gender curves (Rubin 2009). Contemporary charts should be preferred, such as the large gender-specific, racially diverse, population-based surveys of BW for various gestational ages published by Olsen et al. (2010); these provide 3rd and 97th percentiles cutoffs for defining SGA and LGA births and plausible mean and standard deviations as well (Tables 65.3 and 65.4); validated smoothed percentile curves are also available (3rd–97th) (Fig. 65.1). SGA and LGA classifications using Lubchenco's standards (1966) differ significantly from the Olsen's standards (2010). Specific BW standards stratified by placental chorionicity are available for monochorionic (Fig. 65.2) and dichorionic (Fig. 65.3) twins (Ananth et al. 1998).
- Ehrenkranz's postnatal growth chart (Ehrenkranz et al. 1999) has a longitudinal growth grid for 100-g BW intervals from 500 to 1,500 g (Fig. 65.4). This chart has the advantage of being based

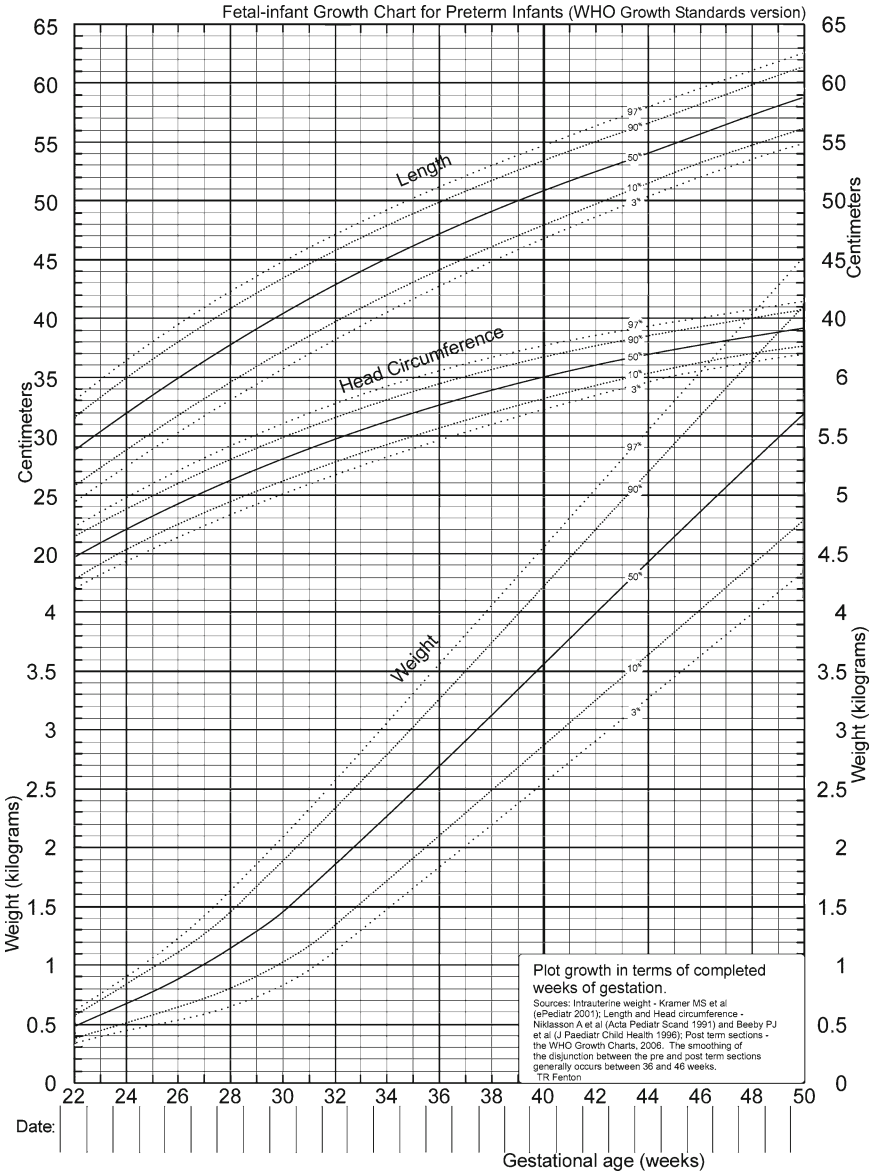

Fig. 65.5 Fenton's growth chart for very low birth weight (VLBW) infants up to 50 postnatal weeks Chart for monitoring weight, length and head circumference of VLBW (updated with recent data and a new format: Fenton 2003, courtesy of © BioMed Central).The Fenton's chart is useful for monitoring the growth of preterm infants from birth up to 50 postnatal weeks, including after discharge. Available at http://members.shaw.ca/growthchart/

on a large multicentric prospective cohort of VLBW infants. Reflecting imperfect and disparate nutritional practices, in fact it represents "things as they are" on current nutritional practices and not a guide for "ideal growth" (Rubin 2009). Using the Ehrenkranz's weight chart it is possible to monitor the weight up to circa 100 postnatal days (about 14 postnatal weeks). Furthermore, specific charts for SGA and AGA and for major morbidities are provided.

- Fenton's chart 2003 (updated in 2008) (Fig. 65.5) allows monitoring the growth of preterm infants up to 50 postnatal weeks. Fenton has updated the Babson and Benda's chart (1976) with

a meta-analysis of several recent data sets. In spite of the more recent update in 2008, this chart is not based solely on longitudinal data, it may not represent the actual growth of preterm infants, and its validity is limited by the heterogeneity of data sources.

- A more accurate assessment of growth in VLBW infants may be provided by the weight growth velocity i.e., measuring the body weight gain in g^{-1} kg^{-1} day (Olsen et al. 2002). Standards for neonatal growth velocity are available (Olsen et al. 2002), but as rule of thumb approximately 16 g^{-1} kg^{-1} day is the average weight gain for the entire period from 23 to 37 weeks' gestation (Uhing and Das 2009).

65.4.2 Crown-Heel Length

Length is considered a rough indicator of lean mass, reflecting the skeletal growth (Koo et al. 2000; Gibson et al. 2003). Since linear growth continues after birth despite acute loss of body weight, linear measurements may better reflect actual growth than body weight (Prins 1995).

Monitoring of linear growth has been neglected in preterm infants. This is probably due to the difficulty in obtaining accurate measurements of CHL in neonates (Prins 1995). Some factors influence the accuracy and reliability of crown-heel measurement in this age group (Johnson et al. 1997; Shinwell and Shlomo 2003). A major factor is the reluctance of the observer to extend the lower limbs forcefully, especially in full-term infants who are more comfortable in flexion (Fletcher 1998). Shinwell and Shlomo (2003) found that the CHL significantly increases over the first 2 days after birth, probably due to a gradual decrease of the intrauterine state of flexion. The accuracy of measured CHL is of utmost importance when CHL is included squared or cubed in indices, since a small error in CHL measurement causes an exponential distortion in the final results of the equations (Prins 1995).

Technique and instrumentation: Recumbent CHL is measured with the infant in supine position. Two participants should collaborate in the measurement, and the mother may be one of them. One participant positions the infant's head crown against the headboard of the length board according to the Frankfort plane: the eyes facing upwards and the lower margin of the orbit in the same vertical line as the upper margin of the auditory meatus. The second participant extends the lower limbs completely by gently pressing the infant's knees down, holds the feet vertically, at a right angle to the length board, move the footboard up against the heels firmly and registers the length (Prins 1995; Fletcher 1998). An alternative method with similar accuracy but causing significantly less discomfort has been proposed. It consists of measuring with only one lower limb extended. Using this method, trunk and limb axes should be parallel and the line between the ileac crests at a right angle with the trunk axis (Pereira-da-Silva et al. 2006).

Tape measurements are less expensive and easy to use but of doubtful reliability. More reliable measurements are obtained using recumbent infant boards to the nearest 1 mm, such as the neonatometer (Prins 1995). The prematurometer has been designed for measuring preterm infants inside the incubators (Gibson et al. 2003).

Standards: For assessment of intrauterine linear growth, contemporary Olsen et al. charts (2010) are available. These are large gender-specific, racially diverse, population-based surveys of birth length for various gestational ages (Tables 65.5 and 65.6); validated smoothed percentile curves are also available (3rd–97th) (Fig. 65.6). In spite of being old combined-gender curves and including small numbers of extremely preterm infants, the Lubchenco's chart (1966) has the advantage of permitting the assessment at birth of both length and PI which includes the length.

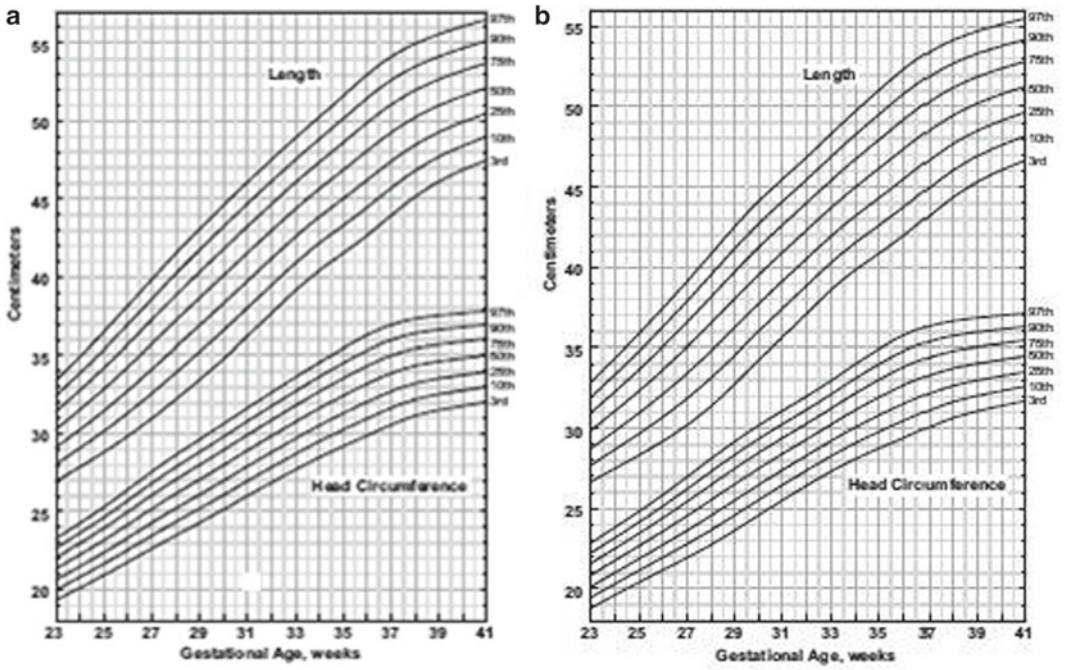

Fig. 65.6 Olsen's intrauterine gender-specific curves for birth length and head circumference. Intrauterine growth length curves for males (**a**) and females (**b**) as estimated from live birth at gestational ages from 23 to 41 weeks (Olsen IE et al. 2010. With permission by © American Academy of Pediatrics)

For monitoring the postnatal linear growth of premature infants, the Ehrenkranz's longitudinal growth grid (1999) provides the average weekly length versus postnatal age in weeks, stratified by 100-g BW interval (Fig. 65.7). Fenton's chart 2003 (updated in 2008), based on longitudinal data and meta-analysis of several recent data sets, provides the average weekly length versus postnatal age in weeks up to 50 postnatal weeks (Fig. 65.5). As a rule of thumb the linear growth rate in preterm infants should average 0.9 cm/week (Uhing and Das 2009). For key points of CHL see Table 65.7.

65.4.3 Length and Diameter of Body Segments

Assuming that the growth of body segments is proportionate to CHL, an alternative approach to quantifying linear growth is the measurement of short distances. This determines minimal daily variations in growth, especially in tiny and sick neonates who do not tolerate manipulations well (Prins 1995). Lengths and breadths are interpreted as skeletal dimensions because they are made between bony landmarks. The most used body segment measurements are the knee-heel length, foot length, and elbow-wrist length (Prins 1995).

Technique and instrumentation: Total upper limb length is measured between the acromion and the tip of the middle finger; the upper arm length: from the acromion along the posterior lateral aspect of the arm to the distal medial border of the olecraneon; the forearm: with the forearm pronated, from the most prominent point of the olecraneon to the distal process of the radius along the lateral surface of the forearm; the hand length: from the distal crease at the wrist to the tip of the middle finger; the

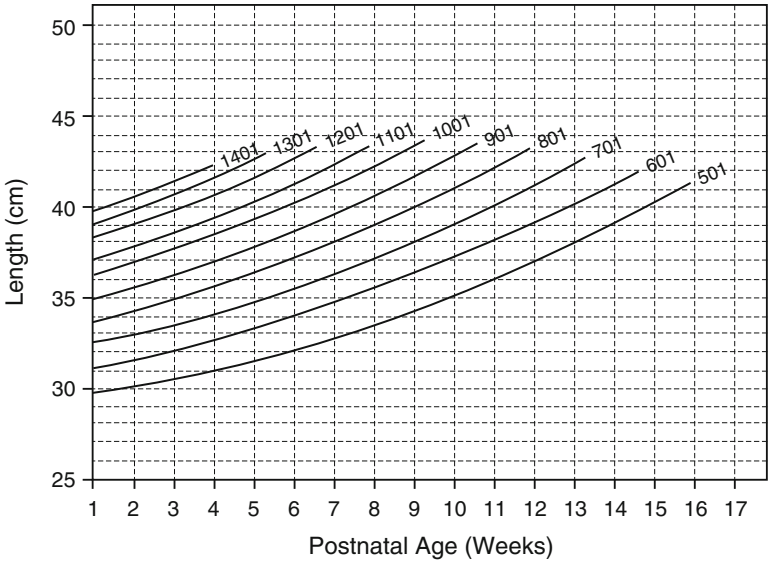

Fig. 65.7 Ehrenkranz's postnatal length grid for very low BW infants Postnatal longitudinal length grid for 100-g BW intervals, for VLBW infants (adapted from: Ehrenkranz et al. 1999. With permission by © *American Academy of Pediatrics*). Linear growth should regularly be measured in preterm infants to assess the skeletal growth. VLBW: very low birth weight. Available at http://pediatrics.aappublications.org/cgi/content/full/104/2/280

Table 65.7 Key points of crown-heel length

1. CHL measurement at birth is especially important for diagnosing stunted-born infants.
2. Forceful extension of lower limbs necessary for accurate CHL measurement causes discomfort, especially in full-term infants. Measurements with only one lower limb extended may be preferable, provided trunk and limb axes are parallel and the line between the ileac crests at a right angle with the trunk axis.
3. To define accurately symmetrical intrauterine growth restricted neonates, standards including both CHL and PI standards at birth are necessary.
4. Postnatal CHL measurements reflect the skeletal growth and should be included in the routine nutritional assessment.
5. Linear growth rate in preterm infants should average 0.9 cm/week

total lower limb length: from the greater trochanter of the femur to the lateral malleolus of the ankle along the lateral aspect of the leg; the foot length: from the posterior prominence of the heel to the tip of the longest toe (Fletcher 1998).

Measurements are more accurately performed if the chosen sites are marked (washable marker) before the measurements.

Tape measurements are easier and simple. The effects of soft tissues can be reduced and made less variable using recommended calipers which apply firm pressure (Fletcher 1998).

The knenometer is a hand-held device, resembling a pair of calipers, for a more reliable measurement of the knee-heel length. The measuring system, suitable for use inside an incubator, is based on a magnetic encoder which automatically records the knee-heel length when the pressure applied on the heel reaches a preset pressure. The measurements should be taken with the knee at 90° and the foot at a right angle. A less expensive electronic model has been described (Engstrom et al. 2003), and a simple perspex gauge has been proposed with satisfactory accuracy in skilled hands (Prins 1995).

Metal foot gauge allows a more accurate measurement of the foot length (Dangerfield and Taylor 1983).

Standards: There are neonatal references for several body segments, including: lengths of upper and lower limbs, arm, forearm, hand, foot, and bi-acromial and bi-iliac diameters. Some of these references are gender-specific and presented as mean and standard deviations (Dangerfield and Taylor 1983).

65.4.4 Body Circumferences

Most of the body circumferences are difficult to interpret, since they include the skin, subcutaneous tissue, muscle, bone, blood vessels and nerves. Trunk circumference and especially the abdomen circumference additionally include organs and deep fat tissue (Pereira-da-Silva et al. 2007).

65.4.4.1 Head Circumference

The increase in HC (synonym of occipito-frontal circumference) reflects brain growth, even though HC gives only an approximation of skull volume as a linear dimension and not a volumetric one (Prins 1995). The occipito-frontal circumference is one of the most reliable measurements in neonates (Johnson et al. 1997). When interpreting HC measurements, some factors should be taken into account. In the presence of head molding or scalp oedema, HC should be measured 48–72 h after birth, after their reduction or resolution (Prins 1995; Fletcher 1998). HC above or below the reference limits may represent a variant of normal, being constitutional or familial; therefore, the parents' HC should also be measured (Fletcher 1998).

In the neonatal period HC measurement is important for detection of cerebral pathology and as a guide to the need for an ultrasound scan. A macrocephaly may indicate hydrocephaly. Small HC at birth is associated with suboptimal cognitive and neurodevelopment outcome, especially in SGA infants (Pereira-da-Silva et al. 2007).

Technique and instrumentation: For measuring HC, the tape encircles the most prominent parts of the forehead and occiput, i.e., supraorbital ridge and occipital protuberance. The largest occipito-frontal circumference of three consecutive measurements is considered (Sasanow et al. 1986; Prins 1995). A flexible non-stretchable tape with precision to the nearest 1 mm is recommended. Disposable paper tapes may be more reliable and preferable to plastic or cloth tapes (Prins 1995).

Standards: Intrauterine head growth may be assessed using the contemporary Olsen et al. charts (2010). These are large gender-specific, racially diverse, population-based surveys of birth head circumference for various gestational ages (Tables 65.8 and 65.9); validated smoothed percentile curves are also available (3rd–97th) (Fig. 65.6).

For monitoring the postnatal head growth of premature infants, the Ehrenkranz's longitudinal grid (1999) provides the average weekly HC versus postnatal age in weeks for infants stratified by 100-g BW interval (Fig. 65.8). Fenton's chart 2003 (updated in 2008), based on longitudinal data and meta-analysis of several recent data sets, provides the average weekly HC versus postnatal age in weeks up to 50 postnatal weeks (Fig. 65.5). As a rule of thumb the HC growth rate in preterm infants should average 1 cm/week (Uhing and Das 2009).

65.4.4.2 Mid-Arm Circumference

The mid-arm circumference (MAC) reflects the combined arm muscle and fat. Since MAC is relatively unaffected by fluid shifts, it may be used in assessing loss or gain of muscle plus fat.

Table 65.8 Male birth head circumference (cm) charts in relation to gestational age (GA), expressed in centiles, means and standard deviations (Adapted from Olsen et al. 2010, Copyright © American Academy of Pediatrics, 2010) HC at birth should be measured, reflecting the intrauterine brain growth

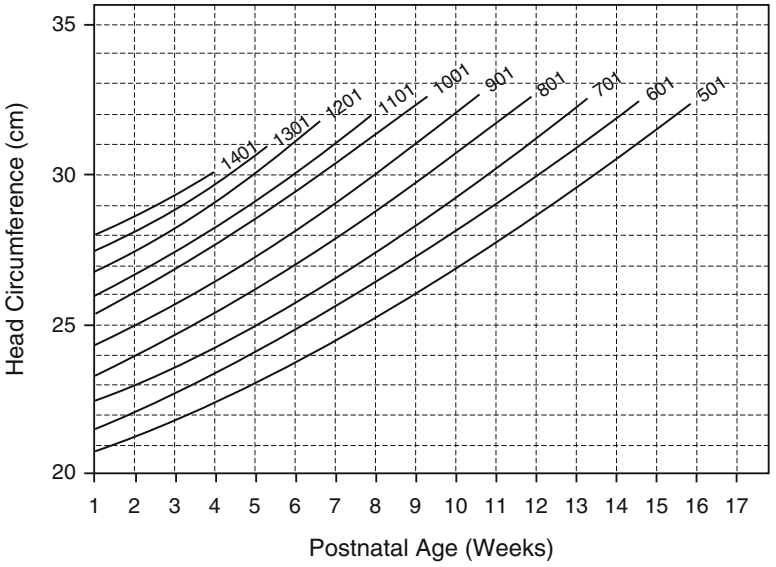

Fig. 65.8 Ehrenkranz's postnatal head circumference grid for VLBW infants. Postnatal longitudinal head circumference grid for 100-g BW intervals, in VLBW infants (Adapted from Ehrenkranz et al. 1999. With permission by © *American Academy of Pediatrics*). Head circumference should be regularly measured in preterm infants to estimate the brain growth. Available at http://pediatrics.aappublications.org/cgi/content/full/104/2/280

In conjunction with changes in weight, the quality of growth in preterm infants may be more accurately determined (Sasanow et al. 1986).

Low inter-examiner and intra-examiner reliability has been reported for MAC measurements in neonates (Johnson et al. 1997).

When compared to dual X-ray absorptiometry (DEXA) measurements, MAC reasonably correlates with lean and fat mass soon after birth (Koo et al. 2004). The discriminatory ability in detecting disturbances in body composition increases in derived anthromopetric measures including MAC, such as MAC/HC ratio and the mid-arm muscle area (Koo et al. 2004).

Technique and instrumentation: A flexible non-extendible tape is appropriate for MAC measurement. Measurements are taken with the arm extended in a horizontal position, at mid distance between the tip of acromion and the olecraneon process, where a typical crease may help indicating the site in preterm infants (Sasanow et al. 1986). In very premature infants, a poor reliability in MAC measurements has been reported (Prins 1985), which may result from compression of the skin when attempting to adjust the tape perfectly around the arm with very loose tissues, or by small spaces left between the wrinkled skins when avoiding compression (Prins 1985; Pereira-da-Silva et al. 2009). For tiny infants measurements may be easier using a flexible tape with approximately 1 cm width (Fig. 65.9).

Standards: For intrauterine nutritional assessment, the Sasanow's (1986) combined-gender MAC references are available for infants soon after birth, from 25 to 42 weeks of gestational age (Table 65.10), although a small number of ELBW infants has been included.

For monitoring the postnatal nutritional status of preterm infants, the Ehrenkranz's longitudinal grid (1999) may be used, which provides the average weekly MAC versus postnatal age in weeks for infants stratified by 100-g BW interval (Fig. 65.10).

Fig. 65.9 Measurement of mid-arm circumference. Mid-arm circumference (MAC) measurement. MAC reflects the combined arm muscle and fat. Measurements should be taken with the arm extended, at mid distance between the tip of acromion and the olecraneon process. A flexible tape with approximately 1cm width may be easier to use for tiny infants

Table 65.10 References for mid-arm circumference (MAC) and for mid-arm circumference/ head circumference ratio (MAC/HC) from 25 to 42 weeks of gestational age (GA) (Adapted from Sasanow et al. 1986, © Elsevier). Low MAC/HC at birth indicates foetal malnutrition and is especially useful in diagnosing malnourished AGA neonates not identified by the criterion exclusively based on birth weight, and has predictive value of early symptomatic metabolic abnormalities

65.4.4.3 Other Circumferences

Mid-thigh circumference (like MAC) is frequently used in developing countries to assess nutritional status of infants, when scales are not available (Prins 1995). Mid-thigh circumference is measured in supine position, in at mid distance between the proximal border of the patella and the anterior superior iliac spine, with the lower limb gently extended (Fletcher 1998). The average values in full-term neonates are 15.59 cm in Blacks and 15.48 cm in Caucasians (Pereira-da-Silva et al. 2007).

Neonatal references for other body circumferences like chest circumference and abdominal circumference have been published (Dangerfield and Taylor 1983), but these measurements, as mid-thigh circumference, have not been validated as indicators of body composition in this age group (Pereira-da-Silva et al. 2007).

65.4.5 Skinfolds

Skinfold thickness measurement is an inexpensive method for neonatal nutritional assessment, convenient for bedside measurements. The routine use of this method in neonates is limited due to a low reliability when the skill and practice of the observer is insufficient (Prins 1995).

When skinfold thickness is measured to estimate total body fat (TBF) it is assumed that thickness of subcutaneous fat reflects a constant proportion of TBF, and that the sites used for the measurements reflect the average thickness of the subcutaneous fat layer (Prins 1995). The most commonly used sites for measurements are the tricipital skinfold (TS) and the subscapular skinfold (SBS) (Prins 1995). Other sites used are the biceps (BS) and the suprailiac (SPS).

Fig. 65.11 Measurement of triceps skinfold. Triceps skinfold (TS) measurement. TS is the most commonly used skinfold to estimate peripheral subcutaneous fat. TS is measured on the posterior surface of the arm with the elbow extended, at the mid distance between the acromion and olecraneon

Although not yet validated, an equation has been proposed to estimate the central to total skinfold ratio (CTS) in neonates: CTS = (SPS + SBS)/(TS + BS + SPS + SBS) (Rodriguez et al. 2004).

Skinfolds as indicators of fat mass have been validated in neonates as compared with gold standard methods. The predictive value of regional and whole body anthropometry, for whole body composition, was validated by DEXA measurements. Good correlation was found between the skinfold measurements and fat mass (Schmelzle and Fusch 2002; Koo et al. 2004). In contrast, others found poor correlation between skinfold measurements and both total and regional body fat assessed by magnetic resonance imaging (Olhager and Forsum 2006; Pereira-da-Silva et al. 2009). This discrepancy may be explained by several factors, the most important being the influence of hydration on the skinfold compressibility (Olhager and Forsum 2006) and fact that skinfold measurements do not reflect non-subcutaneous fat, especially in preterm infants (Uthaya et al. 2005). Furthermore, low reproducibility and high inter-observer coefficient of variation have been reported for skinfold measurements in term and preterm infants (De Bruin et al. 1995).

Technique and instrumentation: The procedure for measurement consists of lifting a skinfold with the index or middle finger and thumb, while pulling away the subcutaneous tissue from the underlying muscle fascia. In the first minute after the application of the caliper there is a steady decrease followed by a relative stabilization of the registered thickness. Some authors suggest that reading may be taken 15 s after the application of the caliper (Schmelzle and Fusch 2002), but more reliable measurement is reached with 60 s readings, especially in preterm infants in whom the presence of edema may give a spuriously high estimate of subcutaneous fat (Prins 1995). The decrease of skinfold measurement from 15 to 60 s is called dynamic skinfold thickness measurement which correlates with the extracellular water (Thornton et al. 1982).

The TS is measured on the posterior surface of the arm with the elbow extended and the arm held by the side of the body, at the mid distance between the acromion and olecraneon (Fig. 65.11). The BS is measured on the anterior surface of the arm at the same level of TS measurement. The SBS is measured at the lower angle of the scapula with the arm relaxed (Fig. 65.12). The SPS is measured immediately above the iliac crest, along the axis of the anterior mamilary line with the infant lying supine (Prins 1995; Schmelzle and Fusch 2002).

Fig. 65.12 Measurement of subscapular skinfold (SBS). Subscapular skinfold (SBS) measurement. SBS is the most commonly used skinfold to estimate central subcutaneous fat. The SBS is measured at the lower angle of the scapula

Table 65.11 Triceps (TS), biceps (BS), subscapular (SBS) and suprailiac (SPS) skinfold thickness in male neonates, in relation to gestational age (GA) (Adapted from Rodriguez et al. 2004. With permission of © Springer Verlag, 2004)

	TS (mm)		BS (mm)		SBS (mm)		SPS (mm)	
GA (weeks)	Mean	SD	Mean	SD	Mean	SD	Mean	SD
32–33	2.59	0.58	2.31	0.63	2.49	0.56	1.73	0.52
34	3.07	0.70	2.42	0.69	2.89	0.80	2.20	0.67
35	3.25	0.61	2.61	0.62	3.03	0.64	2.30	0.63
36	3.44	0.84	2.77	0.79	3.25	0.78	2.53	0.75
37	4.05	0.98	3.46	0.91	3.77	1.01	3.15	0.85
38	4.03	0.85	3.47	0.83	3.69	0.80	3.17	0.76
39	4.21	0.84	3.61	0.89	3.92	0.90	3.32	0.76
40	4.23	0.83	3.63	0.83	3.95	0.85	3.35	0.74
41	4.26	0.88	3.68	0.77	3.94	0.79	3.43	0.78

Skinfolds are estimators of fat mass. TS and BS estimate peripheral subcutaneous fat and SBS and SPS estimate central subcutaneous fat. TS and SBS are the most commonly used sites for measurements. Skinfolds usually are thinner in male neonates

Appropriate calipers should be used, exerting a constant pressure of 10 g/mm^2 of contact surface area whatever the overture of the jaws of the calipers; the most commonly used are the Holtain (Holtain Ltd, Croswell, Crymych, UK) and the Harpenden (CMS Instruments, London, UK), respectively with resolutions of 0.1 and 0.2 mm (Prins 1995).

Standards: Gender-specific references for TS, BS, SBS, SPS and CTS at birth have been published for neonates from 32 to 41 weeks of gestational age. Female neonates not only had greater ST measurements but also larger CTS values (Tables 65.11–65.13) (Rodriguez et al. 2004).

Formulae and standards for dynamic skinfold thickness measurements in neonates were proposed to estimate the extracellular water content (Thornton et al. 1982).

Table 65.12 Triceps (TS), biceps (BS), subscapular (SBS) and suprailiac (SPS) skinfold thickness in female neonates, in relation to gestational age (GA) (Adapted from Rodriguez et al. 2004, with permission of © Springer Verlag, 2004)

	TS (mm)		BS (mm)		SBS (mm)		SPS (mm)	
GA (weeks)	Mean	SD	Mean	SD	Mean	SD	Mean	SD
32–33	2.72	0.62	2.32	0.63	2.81	0.76	2.04	0.72
34	3.17	0.72	2.53	0.78	3.17	0.94	2.34	0.87

41	48.13 ± 3.19	49.06 ± 3.52

A central accumulation of fat may be estimated by an increased CTS, calculated by the equation CTS = (SPS + SBS)/(TS + BS + SPS + SBS)

BS biceps skinfold; *CTS* central to total skinfold ratio; *SBS* subscapular skinfold; *SPS* suprailiac skinfold; *TS* tricipital skinfold

65.5 Derived Measurements

The derived anthropometric measurements are based on formulae which use direct measurements, assuming that the association of various direct measurements may predict body composition better than each value on its own (De Bruin et al. 1995).

65.5.1 Weight and Length Based Equations

Birth weight-for-length ratios allow the assessment of body proportionality. Assuming that length is affected to a relatively lesser extent than weight except in severe cases, these indices are used to predict symptomatic metabolic abnormalities in neonates with abnormal intrauterine growth due to under- and over-nutrition (Koo et al. 2004; Olsen et al. 2009).

65.5.1.1 Ponderal Index (PI)

[Weight (in g)/Length^3 (in cm)] × 100. Rohrer's PI is an index of thinness at birth, and is the appropriate criterion for defining SGA or IUGR of symmetrical or asymmetrical type (Tamim et al. 2004). The old Lubchenco's chart (1966) (Fig. 65.1) is one of the rare large population-based charts including a grid for PI at birth, and it is still used when this tool is needed (Olsen et al. 2009). It includes 0.1-PI intervals from circa 1.8 to 3.1 and from 26 to 42 weeks of gestation; it has the disadvantages of being combined-gender. More recently, gender-specific reference values for PI at birth from 32 to 42 weeks of gestation, including smoothed percentile curves (2.5th to 97.5th), estimated from 100,716 children, have been published (Lehingue et al. 1998) (Table 65.14). As a general rule of thumb, the SGA infant is classified as asymmetric if PI is <2 or <2.3 in preterm and term infants, respectively (Beattie and Johnson 1994; Pereira-da-Silva et al. 2007). Asymmetrical SGA at birth is a predictor of adverse early metabolic outcome and increased risk of mortality (Patterson and Pouliot 1987; Wilcox et al. 1993). From birth to discharge, the percentage of preterm infants with low PI seems to decrease, in spite of an increase in the percentage of those with weight deficit (Olsen et al. 2009).

65.5.1.2 Body Mass Index (BMI)

[Weight (in Kg)/Length^2 (in m)] × 100. BMI is synonym of both adiposity index and Quetelet's index. BMI has been proposed as an index of adiposity during the neonatal period, but it seems to be a weak measure of intrauterine malnutrition and a poor predictor of postnatal short-term outcome (Pereira-da-Silva et al. 2007). Gender-specific reference values for BMI at birth from 32 to 42 weeks of gestation, including smoothed percentile curves (2.5th to 97.5th), estimated from 100,716 children, have been published (Lehingue et al. 1998) (Table 65.15).

65.5.1.3 Weight-for-Length (W/L) Ratio

[Weight (in g)/Length (in cm)]. W/L ratio at birth, rather than PI or BMI, is reported as a good predictor of subcutaneous fat (Yau and Chang 1993; Rodriguez et al. 2004), and a complimentary tool in predicting early postnatal metabolic abnormalities (Owen 1997).

65.5.1.4 Benn Index

[Weight (in g)/Length^n (in cm)]. In the Benn index, the relative weight is calculated as the ratio of actual to predicted weight, where the length power n varies with gestation and is estimated by log–log regression. It is not a practical and simple mathematical formula, and like other weight-for-length indices it may not be appropriate for estimating intrauterine malnutrition, as different gestations require different indices (Pereira-da-Silva et al. 2007).

65.5.1.5 Individualized Birth Weight Ratio

This ratio is derived from the actual BW divided by predicted BW expressed as a percentage, for each individual infant (Wilcox et al. 1993). This is a good method for differentiating constitutional SGA and LGA from abnormal intrauterine growth (Pereira-da-Silva et al. 2007). This ratio is considered a more accurate, even though not a practical method for characterizing BW (Fletcher 1998).

65.5.2 Mid-Arm Circumference/Head Circumference Ratio

Assuming that in acute protein-energy malnutrition the brain is relatively spared compared to muscle and fat wasting, MAC/HC at birth has been proposed to identify intrauterine malnutrition and standards have been published (Sasanow et al. 1986) (Table 65.10). MAC/HC is especially useful in diagnosing malnourished AGA neonates who would be not identified as IUGR by the criterion exclusively based on BW (Patterson and Pouliot 1987). It has independent predictive value of body composition in infants with abnormal intrauterine growth (Koo et al. 2004), and a predictive value of symptomatic metabolic abnormalities as well (Patterson and Pouliot 1987).

65.5.3 Upper-Arm Cross-Sectional Areas

Equations have been proposed to calculate the upper-arm cross-sectional areas derived from MAC and TS: arm area (AA), arm muscle area (AMA) and arm fat area (AFA). Calculation of these areas is based on theoretical assumptions: the mid-arm is cylindrical, the subcutaneous fat is a concentric ring evenly distributed around a circular core of muscle, the fat thickness is half the TS, and the muscle includes the humeral diameter (Jellifee and Jellifee 1969). Using the Jellifee and Jellifee method (1969): $AA = MAC^2/4\pi$; $AMA = (MAC - \pi TS)/4\pi$; $AFA = AA - AMA$.

Based on dynamic skinfold measurement specific equations have been proposed (Thornton et al. 1982) to estimate the extracellular water content in neonates by calculating the water arm area (WAA), assuming that the 15 s (TS_{15}) reading reflects subcutaneous water *plus* fat, and the 60 s (TS_{60}) reading reflects only the fat, therefore WAA: $AMA_{15} = (MAC - \pi\ TS_{15})^2/4\pi$; $AFA_{60} = AA - (MAC - \pi\ TS_{60})^2/4\pi$; $WAA = AA - (AMA_{15} - AFA_{60})$.

Hypothesizing that Jellifee and Jellifee method (1969) might underestimate adiposity, Rolland-Cachera et al. (1997) proposed different equations for calculating the upper-arm cross-sectional areas, assuming that the AMA constitutes a circle surrounded by a rim (fat), the unrolled rim is a rectangle, and the outer circumference of the rim is equal to the inner circumference: $AFA = MAC \times TS/2$; $AMA = AA - AFA$.

Based on the Jellifee and Jellifee method (1969), standards for upper-arm cross-sectional areas have been published for neonates (Sann et al. 1988), and their validation for estimating body composition only recently has been published. Upper-arm muscle and fat areas are among the derived anthropometry that better predict whole-body composition, in comparison with with DEXA measurements (Koo et al. 2004). To be consistent with these results, the upper-arm anthropometry should also be a reliable predictor of regional body composition at the level where the anthropometric measurements were taken. However, a poor correlation was found between upper-arm anthropometry and both upper-arm ultrasound measurements in full-term infants (Pereira-da-Silva et al. 1999) and upper-arm magnetic resonance imaging measurements in preterm infants (Pereira-da-Silva et al. 2009). The discrepancy between the results may be explained by an oversimplification in the geometrical assumptions for calculation of upper-arm cross-sectional areas, and by the low reliability of MAC (Johnson et al. 1997) and of TS (De Bruin et al. 1995) measurements on which the equations are based. Therefore, upper-arm cross-sectional areas values in neonates should be interpreted with caution.

65.5.4 Formulae Derived from Multiple Measurements

Dauncey's formula, associating skinfolds measured in two sites (TS and SBS) and further nine anthropometric measurements, has been proposed to estimate TBF in neonates and older children. This method assumes that the body is a sum of a sphere (head) and several hollow cylinders of fat (trunk and limbs) (Pereira-da-Silva et al. 2007).

The Weststrate's method, based on equations including whole-body density and skinfolds measured in four sites, has been proposed to estimate the percentage of fat from the neonatal period up to 18 years (Pereira-da-Silva et al. 2007).

The Catalano's model includes the weight, CHL, HC and skinfolds, for predicting TBF in neonates with >2,000g (Pereira-da-Silva et al. 2007).

The reliability of the above-mentioned methods to predict body composition in neonates has been questioned, after being revalidated by total-body electrical conductivity and DEXA measurements (De Bruin et al. 1995; Schmelzle and Fusch 2002).

65.6 Applications to Other Areas of Health and Disease

Neonatal anthropometry may be a tool to predict long-term complications. Low BW and IUGR infants, especially if associated with rapid postnatal catch-up growth, are more susceptible to future insulin resistance and metabolic syndrome. Asymmetrical IUGR is especially prone to this outcome, while an increased risk of poor neurodevelopmental outcome is associated with symmetrical IUGR.

Summary Points

- **Morphometry at birth**: Identify small-for-gestational age infants, which may indicate intrauterine growth restriction (IUGR). For a more accurate diagnosis also check for reduced MAC/head circumference ratio, which can be used to diagnose foetal malnutrition regardless of BW. Use the PI to classify IUGR as asymmetric or symmetric. Identify macrosomic and large-for-gestational age infants as well. Anticipate therapeutic measures for the early complications expected in large-for-gestational age and IUGR infants.
- **Postnatal growth and nutrition**: In preterm infants measure body weight daily, since this is the most reliable measurement in neonates. Measure the crown-heel length (CHL) and length of body segments weekly to assess skeleton and body growth. For assessing the quality of growth, estimate body composition on the basis of weekly measurements of MAC, tricipital and SBS, and the cross-sectional muscle and fat areas. Interpret these measurements with caution, since they require further validation in neonates.
- **Long-term complications**: Identify low BW and IUGR infants (using the above-mentioned criteria), and avoid rapid postnatal catch-up growth which predisposes to future insulin resistance and metabolic syndrome. Using PI classify IUGR as asymmetric or symmetric type. Asymmetrical IUGR is especially prone to the referred outcome. Symmetrical IUGR is at increased risk of poor neurodevelopmental outcome.
- **Dysmorphies**: Measure arm span and crown-rump length/CHL ratio if a disproportional growth disorder is suspected. Use appropriate craniofacial measurements and standards for the diagnosis of craniofacial dysmorphies.
- **Body surface (BSF)**: When required, estimate BSF by direct visualization of normograms based on weight and CHL. As an alternative, use the simplified equation proposed for proportionate neonates: BSF = (weight + 4)/30, where BSF is in m^2 and weight in kg.

Chapter 66
Anthropometric Measurements in Sudanese Newborns: Value in Measuring Weight at Birth and Its Relationship with Maternal Characteristics

Eltahir M. Elshibly and Gerd Schmalisch

Abstract In developing countries, low birth weight (LBW) (<2,500 g) is the strongest determinant of infant morbidity and mortality. In this chapter we describe a method to measure birth weight (BW) using anthropometric measurements and investigate the effect of maternal age, anthropometry, education and socio-economic status on determining the risk for LBW and preterm birth.

Anthropometric measurements were performed in 1,000 singleton Sudanese newborns and their mothers. Maternal measurements (including weight, height and mid-upper-arm circumference) and 11 newborn anthropometric measurements were taken within 24 h of delivery. In addition, maternal age, education and socio-economic status were recorded. Correlation analysis and multivariate regression analysis with backward selection were used to investigate the value of newborn anthropometric measurements in measuring birth weight and the effect of maternal variables on gestational age and birth weight.

A simple formula utilizing chest (CC), mid thigh (MT) and head (HC) circumferences measured in cm was obtained to predict BW as follows: BW(g) = 97*CC + 74*MT + 85*HC – 4,000, with a standard error of 285 g. For birth weights <2,000 g the specificity of the formula was near 100% and the sensitivity was >80%. Applying a cut-off point of 2,500 g, all infants (100%) with birth weight <2,000 g were correctly identified.

Among maternal characteristics birth order was the strongest determinant of birth weight. Firstborn babies were nearly twice likely to be LBW than infants of multiparous mothers. All maternal anthropometric measurements and age were positively correlated ($p < 0.001$) with birth weight to a variable extent; however, maternal anthropometry explained less than 6% of the variability of the newborn anthropometry. The postpartum maternal lean body mass (LBM) was found to be the major associate of newborn size (birth weight, body lengths and body circumferences), while skin fold thicknesses were mainly associated with maternal age and maternal BMI. Maternal education was significantly associated with birth weight and body circumferences (except the abdominal) and the ponderal index increased significantly with increasing number of years of education. No association between social class and newborn anthropometry was obtained.

V.R. Preedy (ed.), *Handbook of Anthropometry: Physical Measures of Human Form in Health and Disease*, DOI 10.1007/978-1-4419-1788-1_66,

Our formula combining chest, mid thigh and head circumferences was found to predict birth weight. Birth order and the postpartum maternal LBM were found to be the most important maternal parameters which influence birth weight and the risk for LBW. The duration of maternal education, and not social class, was found to significantly affect the risk for LBW.

Abbreviations

BMI	Body Mass Index
BW	Birth Weight
CC	Chest Circumference
CI	Confidence Interval,
ELBW	Extremely Low Birth Weight
GA	Gestational Age
HC	Head Circumference
LBM	Lean Body Mass
LBW	Low Birth Weight
MANOVA	Multivariate Analysis of Variance
MH	Maternal Height
MT	Mid Thigh circumference
MUAC	Mid Upper Arm Circumference of the mother
MW	Maternal Weight
NGO	Non Governmental Organization
PI	Ponderal index
ROC	Receiver Operating Characteristic curve
SD	Standard Deviation
SL	Supine Length of the newborn
VLBW	Very Low Birth Weight
WHO	World Health Organization

66.1 Introduction

It is well recognized that infants weighing <2,500 g (LBW) contribute the lion's share to infant mortality and morbidity worldwide. Advances in modern obstetric and neonatal care (Grimmer et al. 2002) in industrialized countries greatly improved their outcome; however, the outcome of LBW infants is much less favorable in developing countries due to the lack of proper medical, perinatal and antenatal care and follow up (Simiyu 2005; Elshibly and Schmalisch 2008a).

According to a study by the World Health Organization (WHO) (WHO Report 1996) it is estimated that 98% of perinatal deaths worldwide occur in developing countries with Africa having the highest rate of almost 33%. Within Africa the highest rates occur in western, central and eastern parts with an average perinatal mortality around 80/1,000. The WHO report also showed that regions with the lowest coverage of trained birth attendants at delivery have the highest perinatal mortality rates.

In Africa the proportion of LBW infants is higher than in developed countries (Milabyo 2006; Mokhachane et al. 2006) and most deliveries occur at home in the absence of skilled personnel (Onayade et al. 2006). In Lesotho over 40% of women prefer to deliver at home under

the care of traditional midwives (Anonymus 1993). Scales to measure the birth weight in order to identify LBW babies are often not available. Consequently, only about half of the newborns are weighed at birth and for a smaller proportion of them gestational age is known (Blanc and Wardlaw 2005). Even when a community health worker or relative may be present to help, she or he cannot identify LBW babies and thus refer them to receive appropriate medical care. This situation calls for a method of identifying LBW babies that can be used where measuring scales are not available. Identifying LBW babies at home and referring them to a health facility will considerably improve their chances of survival and will lead to great reduction in infant mortality rates in Africa.

Beside biological factors like gestational age (GA), maternal weight and height (Voigt et al. 2004), life style factors such as tobacco, alcohol or caffeine consumption and dietary habits (Nordentoft et al. 1996) can affect birth weight. Socio-demographic and socio-economic factors are also known to affect birth weight. Wasunna and Mohammed (2002), for example, pointed out that maternal education and household income can influence birth weight considerably.

Despite the large body of literature there is no consensus as to which maternal characteristics are associated with newborn anthropometric measurements. The study of maternal-neonatal associations is of particular relevance and importance, especially in Africa where there are much higher percentages of women with low education, poverty and poor nutritional status who are therefore at increased risk of adverse reproductive outcomes including LBW and preterm birth. The identification of such women is therefore important in order to determine the level of care and priorities for referral to better equipped centers where reasonable obstetric and neonatal care can be provided.

Anthropometric measurements are non invasive, inexpensive, and rapid methods to assess nutritional status of newborns, detect growth abnormalities and monitor growth (Moyer-Mileur 2007). This is of special importance in developing countries where expensive measuring equipment is commonly not available. Personnel for measurements can be trained easily in using inelastic tapes which are readily available.

In this chapter we describe anthropometric measurements in a sample of mothers and infants from an inner urban area of Khartoum (Sudan) who delivered in the Soba University Hospital with an average of 4,000 births a year. We introduce a simple method of weighing infants where scales are not available and report the relationships between maternal age, anthropometry, education and socio-economic status and the features of the newborns.

66.2 Anthropometric Measurements in Mothers and Their Newborns

66.2.1 Techniques Used in the Assessment of Maternal and Newborn Anthropometry

As described recently (Elshibly and Schmalisch 2008b, 2009) anthropometric measurements were taken from 1,000 mothers and their newborns in the Soba University Hospital in Khartoum, Sudan. The mothers were recruited from a large inner urban area of Khartoum with wide differences in socio-economic status. The three social classes (low, middle, high) were determined by the area of residence.

In this study only healthy mothers with live born infants who were sure of the last date of their menstrual period were included. Mothers who were not sure of their dates or who had multiple pregnancy or diabetes mellitus or whose infants had anomalies were not included in the study.

The measurements were taken within 24 h of birth in the postnatal wards of the Soba University Hospital in Khartoum by one investigator (ELS) in order to avoid interobserver-variability. The newborn measurements included birth weight, head, chest, mid arm, mid thigh and abdominal circumferences. Furthermore, baby's supine (crown heel), crown rump and upper limb lengths were measured as well as triceps and sub scapular skin fold thicknesses. The ponderal index (PI) was calculated as follows:

$$\mathrm{PI} = 100 \cdot \frac{\mathrm{BW}}{\mathrm{SL}^3}$$

where BW is the birth weight in g and SL is the supine length in cm.

The maternal anthropometry included mother's weight, height and mid upper arm circumferences (MUAC). Using maternal weight and height the body mass index (BMI) was calculated as follows:

$$\mathrm{BMI} = \frac{\mathrm{MW}}{\mathrm{MH}^2}$$

where MW is the maternal weight in kg and MH is the maternal height in m. The lean body mass (LBM) was calculated as follows:

$$\mathrm{LBM} = 1.07 \cdot \mathrm{MW} - 148 \cdot \frac{\mathrm{MW}^2}{\mathrm{MH}^2}$$

where MW is the maternal weight in kg and MH is the maternal height in cm.

The baby's weight was measured by a scale (Atom Medical, Tokyo, Japan) to the nearest 10 g while the mother's weight was measured by a scale to the nearest 100 g. The mother's height was measured with a scale to the nearest millimeter. The baby's supine and crown rump lengths were measured by an infantometer (Atom Medical, Tokyo, Japan) to the nearest millimeter. Upper limb length was measured from the tip of the acromion process of the humerous bone to the most distal skin crease close to the hand. In order to minimize intra-observer variability all circumferences were measured by an inelastic tape to the nearest millimeter. The skin fold thicknesses were measured with a skin fold Caliper (Holtain, Dyfed, UK) to the nearest millimeter.

66.2.2 Education, Social Status and Anthropometric Measures of the Mothers

Of 1,000 mothers 71 (7.1%) had less than 3 years of education and 309 (30.9%) mothers had an education between 3 and 8 years. A considerable number of women had high school education (48.7%) and 13.3% had university education.

Most mothers (64.4%) belonged to a lower social class, 31.3% to the middle social class while only 4.3% were from a high social class. Between social classes and the education was a significant ($p < 0.001$) relationship, as shown in Fig. 66.1. Nevertheless of the 644 mothers from the lower social class, 354 (55%) had a high school education or more.

Six hundred and thirty (63%) mothers were multiparous with parity ranging between 2 and 14. The distribution of the parity of the mothers is shown in Fig. 66.2. Table 66.1 shows the descriptive statistics of the maternal anthropometric measurements. The maternal BMI shown in Table 66.1 is the postpartum BMI and not the commonly used BMI taken before pregnancy. This is because, in Africa it is seldom possible to obtain BMI before pregnancy as women commonly present to health facilities only when they are in the advanced stages of pregnancy.

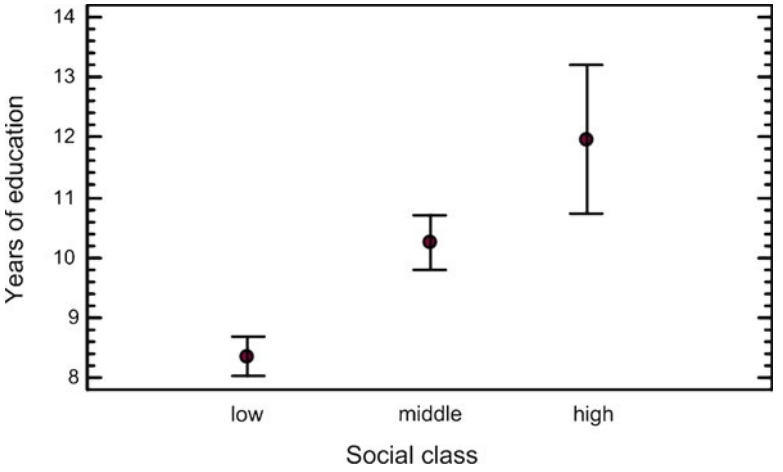

Fig. 66.1 Relationship between social class and years of education of the mothers. The figure shows a significant increase in the mean number (with 95% CI) of years of education with higher social class

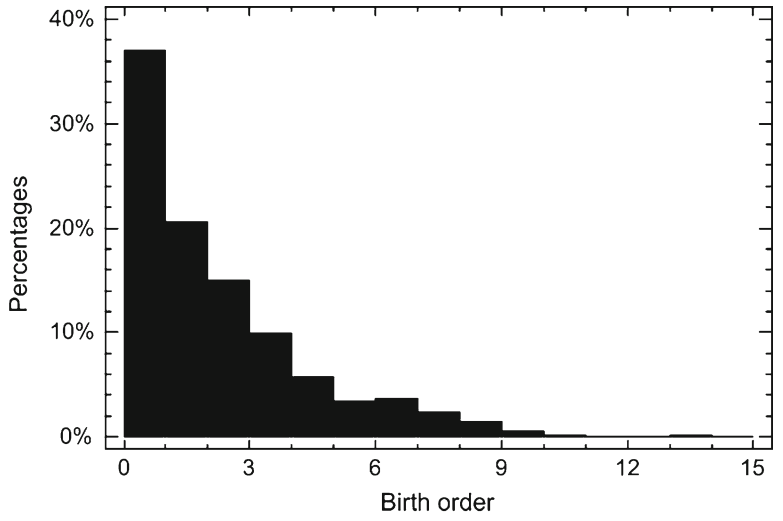

Fig. 66.2 Distribution of the birth order. The figure shows the relative frequency distribution of the birth order of the 1,000 investigated mothers

66.2.3 Anthropometric Measures of the Newborns

Of 1,000 singleton infants with complete anthropometric measurements, 514 were male (51.4%) and 486 were female (48.6%). Taking the mean, boys were 34.9 g heavier than girls; however, as shown in Table 66.2 there was no statistically significant difference between boys and girls in gestational age, birth weight, incidence of preterm birth, LBW, VLBW, ELBW and SGA. The descriptive statistics of the anthropometric measurements of all babies are shown in Table 66.3:

The relationship between anthropometric measurements and gestational age was investigated by a correlation analysis. As shown in Table 66.3, with the exception of PI there was a statistically

Table 66.1 Characteristics of the investigated mothers

	Mean (SD)	Range
Age (years)	27.0 (5.4)	16–52
Number of years of education	9.1 (4.3)	0–19
Birth order	2.8 (2.1)	1–14
Measured parameters		
Body weight (kg)	65.2 (13.0)	33.5–109.9
Body height (cm)	159.6 (6.2)	139.5–195.5
Mid arm circumference (cm)	26.9 (3.9)	17.0–40.9
Calculated parameters		
Body mass index (kg/m^2)	25.5 (4.8)	13.5–47.1
Lean body mass	44.2 (4.9)	27.6–57.5

This table describes the measured and calculated maternal anthropometric parameters

Table 66.2 Comparison between boys and girls

	Boys $N = 514$	Girls $N = 486$	P-value
Gestational age (weeks)	39.1 (1.75)	39.1 (1.09)	**0.993**
Preterm birth (<37 weeks)	28 (5.5%))	29 (6.0%)	**0.723**
Birth weight (g)	3148.7 (545.1)	3113.8 (532.4)	**0.306**
LBW (<2,500 g)	47 (9.1%)	36 (7.4%)	0.320
VLBW (<1,500 g)	5 (1.0%)	6 (1.2%)	0.768
ELBW (<1,000 g)	2 (0.4%)	2 (0.4%)	1.000
SGA (<10th percentile)	83 (16.1%)	80 (16.5%)	0.962

This table shows a comparison of anthropometric measurements between boys and girls. No statistically significant differences were observed because all *p*-values were >0.05

Table 66.3 Anthropometric measurements of the newborns

	Mean (SD)	Range	Correlation with gestational age (*R*-squared)
Gestational age (weeks))	39.1 (1.8)	28–42	
Measured parameters			
Birth weight (g)	3131.7 (538.9)	800–5,100	**11%*****
Supine length (cm)	49.3 (2.9)	28.0–60.2	**10.4%*****
Crown rump length (cm)	33.6 (2.2)	21.0–46.4	**11.2%*****
Limb length (cm)	15.0 (1.0)	10.3–21.2	**9.7%*****
Head circumference (cm)	34.4 (1.7)	25.0–40.0	**13.7%*****
Chest circumference (cm)	31.7 (2.4)	19.4–39.5	**13.3%*****
Abdominal circumference (cm)	28.2 (2.7)	15.3–37.5	**6.3%*****
Mid arm circumference (cm)	10.0 (1.1)	5.0–16.0	**9.4%**
Mid thigh circumference (cm)	15.0 (1.7)	6.5–21.5	**6.9%**
Triceps skin fold thickness (mm)	0.81 (0.21)	0.32–1.96	**1.4%****
Sub scapular skin fold thickness (mm)	0.83 (0.24)	0.18–3.4	**0.6%***
Calculated parameters			
Ponderal index (g/cm^3)	2.61 (0.45)	1.31–6.11	0.4%

This table describes mean, standard deviation (SD) and the range of the gestational age and the measured and calculated anthropometric parameters of the newborns. Their relationship with the gestational age was described by the square of the Pearson correlation coefficient in percentages. Statistically significant correlations are printed in bold: $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$

significant positive correlation with all investigated parameters. The highest correlations were seen for head circumference, chest circumference and crown rump length, whereas the influence of gestational age on skinfold thicknesses was distinctly lower.

66.3 Applications to Other Areas of Health and Disease: Weighing Newborns Without Using Scales

66.3.1 Prediction of Low Birth Weight by Anthropometric Measurements

Due to the high LBW rate and LBW mortality in Africa (WHO Report 1996) there is an urgent need to identify these babies and refer them to receive specialized medical care (Table 66.4). However, the measurement of birth weight in developing countries has always been a problem due to the unavailability of scales. Several aids have been suggested earlier. Mullany et al. (2006) suggested the use of a spring calibrated hand held scale to measure birth weight in order to overcome the difficulty and Mohanty et al. (2006) described the use of color-coded weighing machines, height rods and tapes for use by peripheral health workers and traditional birth attendants. Because these custom-made devices are not widely available, several studies were conducted to predict LBW using anthropometric parameters which can be easily measured.

The results of these studies are quite variable and there is no consensus as to which anthropometric parameter is the best predictor of LBW. A study in Turkey has shown that chest and mid arm circumferences were found as a good predictor (Arisoy and Sarman 1995), while in Nigeria (Ezeaka et al. 2003) occipitofrontal, midarm, and midthigh circumferences and length were found to be good predictors of both birth weight <2,500 and <2,000 g. Other studies (Gozal et al. 1991; Ramaiya et al. 1994) found midarm circumference to be useful for this purpose. Subscapular skin fold thickness was also found to be of value in this respect and together with mid arm circumference, they were found to be useful tools for determining the degree of maturity of a newborn, independent of birth weight (Excler et al. 1985). In a recent study in Nepal (Sreeramareddy et al. 2008) head and chest circumferences were the best anthropometric surrogates of LBW.

It is well recognized that all of these parameters are strongly correlated with the birth weight and a cut-off point may be of value to identify LBW infants – however, each parameter by itself is distinctly less accurate than measuring birth weight in g by a scale. Furthermore, predicting a category of birth weight using only one anthropometric measurement may be less accurate than using a number of measurements for that purpose. Therefore, we have developed a simple formula to determine birth weight using different anthropometric measurements.

Table 66.4 Key features of low birth weight

1. Low birth weight (LBW) is defined as birth weight <2,500 g
2. LBW is the strongest determinant of infant morbidity and mortality
3. In Africa the LBW rate is distinctly higher than in developed countries and contributes greatly to the high perinatal death rate
4. The identification of LBW infants is important in order to arrange for specialized medical care
5. However, in Africa the identification of LBW is often not possible due to unavailability of scales
6. An alternative could be the measurement of body circumferences in order to identify LBW newborns.
7. In addition to life style factors maternal characteristics such as parity, height, lean body mass index and education affect the LBW rate

This table lists the key facts of low birth weights and the problems of their identification in developing countries

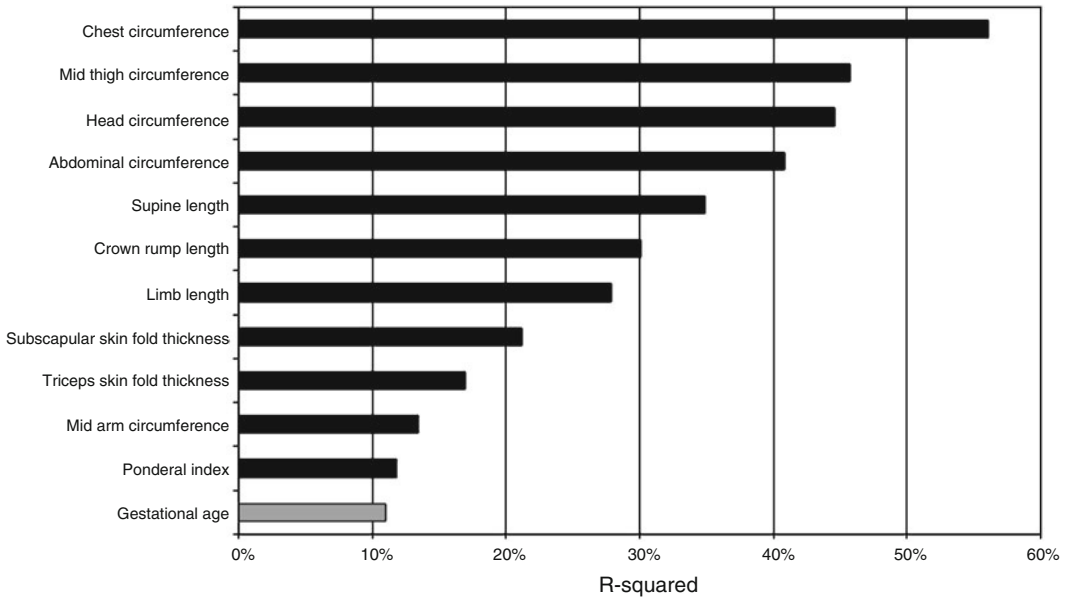

Fig. 66.3 Correlation of birth weight with anthropometric measures. The figure shows correlation of birth weight, measured as Pearson correlation coefficient (*R*-squared), with anthropometric parameters of the newborn (*black*) in comparison with correlation of birth weight with gestational age (*grey*). The anthropometric parameters are ordered according to decreasing *R*-squared

66.3.2 Prediction of Birth Weight Using a Regression Model

To investigate the relationship between birth weight and anthropometric measures, a correlation analysis was performed. As shown in Fig. 66.3, the birth weight is considerably better correlated with anthropometric measures than with gestational age. The highest coefficients of correlation (*R*-squared > 45%) were found between birth weight and chest, mid thigh and head circumferences. However, newborn anthropometric parameters were strongly correlated with each other (e.g. chest circumference and mid thigh circumference with *R*-squared =53%) which may hamper the interpretation of the correlations matrix shown in Fig. 66.3. For this reason a multivariate regression analysis considering all newborn characteristics together with a backward selection was performed to identify the most important correlation as shown previously (Elshibly and Schmalisch 2008a).

The backward selection showed that the three variables that predict birth weight best were chest, mid thigh and head circumferences. The resulting regression model was as follows:

$$\text{Birth weight}\,(\text{g}) = 96.8 * \text{CC} + 74.4 * \text{MT} + 84.5 * \text{HC} - 3{,}960$$

where CC is the chest circumference (cm), MT is the mid thigh circumference (cm) and HC is the head circumference (cm). The standard error of the mean was 285.2 g and *R*-squared was 71% and hence higher than any one parameter shown in Fig. 66.3. The scatter plot of the predicted and measured values of birth weights is shown in Fig. 66.4. The calculated regression line is nearly identical with the line of identity. For practical usage the formula was simplified by rounding off the figures, so that it can be used by health workers in the field as follows.

$$\text{Birth weight}\,(\text{g}) = 97 * \text{CC} + 74 * \text{MT} + 85 * \text{HC} - 4{,}000$$

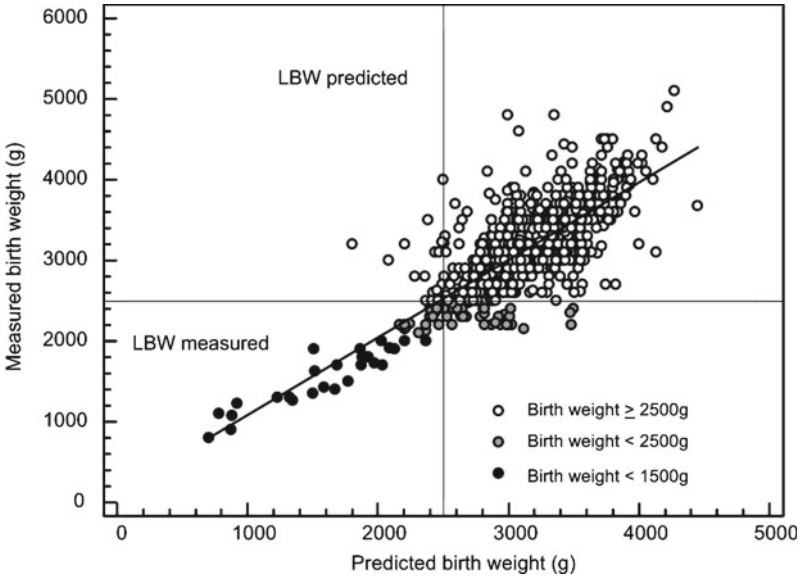

Fig. 66.4 Predicted and measured birth weight. This scatter plot shows the predicted and measured birth weight values of all newborns with the regression line. All infants <2,000 g (*bold dots*) are correctly identified when using a cut off value of 2,500 g

The mean difference in the estimated birth weight between the two equations is 22.5 g (0.7%) and is practically negligible.

This simplified formula may be a powerful tool to asses the BW and allow the health worker in the field to identify LBW infants and consequently determine the immediate management, including initiating breastfeeding, keeping the baby warm and isolated and adopting behaviors that minimize the risk of infection till transport is available to the nearest equipped health facility.

The weight can be calculated with a small pocket or cell phone calculator or manually. These measurements are recommended to be taken by a health professional like a midwife or a nurse who should have special training in taking these measurements. The health worker in remote areas may also obtain additional clinician support per telecommunication.

As far as birth weight measurement is concerned nothing can parallel measurement by a standard scale performed by a trained health professional, but our formula represents a reasonable and practical alternative method to be used in the developing world where scales to measure birth weight are not always available.

66.3.3 Sensitivity and Specificity of the Regression Model

To assess the predictive value of a regression model several statistical measures can be used (see Table 66.5). Sensitivity and specificity of the regression model were calculated by reclassification of the data. Youden's index (= Sensitivity/100 + Specificity/100 – 1) which estimates the probability of correct BW classification was then calculated (Youden 1950). Youden's index ranges between 0 which denotes no diagnostic value and 1 which denotes maximum accuracy.

As shown in Table 66.6, for birth weights <2,000 g specificity is near 100% and the sensitivity is >80%. For this birth weight category the regression model shows the highest Youden's index and thus

Table 66.5 Key features of specificity and sensitivity of regression models

1. Linear regression models can be used to predict birth weight by using one or more anthropometric parameters
2. By defining a cut-off value for birth weight allows every newborn to be assigned into one of the two weight classes (e.g. low birth weight and normal birth weight)
3. Sensitivity and specificity are statistical measures for assessing the correct prediction of weight classes by the regression model
4. Sensitivity represents the proportion of truly predicted low birth weight infants
5. Specificity represents the proportion of truly predicted normal infants.
6. The sensitivity and specificity are dependent on the cut-off value. In general, the higher the sensitivity, the lower the specificity, and vice versa.
7. This relationship can be represented graphically using a receiver operating characteristic (ROC), or simply ROC curve. This curve is a graphical plot of the sensitivity vs. (1 – specificity) for each cut-off point.
8. Youden's index is defined as sensitivity + specificity – 1. This is one way to attempt summarizing the performance of a predictive model. The higher the Youden's index the higher is the predictive value of a model.

This table lists the commonly used statistical measures to describe the accuracy of a predictive model

Table 66.6 Specificity and sensitivity of the predicted birth weight

	Birth weight <1,500 g	Birth weight <2,000 g	Birth weight <2,500 g
Specificity	99.8%	100%	98.3%
Sensitivity	81.8%	87.5%	66.7%
Youden's index	0.82	0.88	0.65

This table shows the specificity and sensitivity of the developed regression model to predict several weight classes. For birth weight <2,000 g the Youden's index has the highest values which means that for this weight category we have the highest number of correct predictions

the highest accuracy in the correct classification of birth weights. For birth weights about 2,500 g the sensitivity is lower; however, as shown in Fig. 66.4 if we use a cut-off point of 2,500 g, all infants (100%) with a birth weight <2,000 g are correctly identified. This means that newborns with the highest risk, e.g., very low birth weight infants (VLBW) with birth weight <1,500 g or extremely low birth weight infants (ELBW) with birth weight <1,000 g can be reliably identified.

66.4 Relationship Between Maternal Factors and Newborn Anthropometric Measures

66.4.1 Effect of Parity on Birth Weight

The association between maternal characteristics and newborn size at birth has been widely studied. Beside antenatal care and woman's health status, birth order was found to be one of the major factors affecting birth weight (Celik and Younis 2007), and several studies have shown that birth weight increases with increase in birth order (Maruoka et al. 1998; Peters et al. 1983; Seidman et al. 1988).

As shown in Table 66.7 an increasing birth order was associated with increasing maternal age, bodyweight and mid arm circumference but not with maternal height. There was no statistically significant association between birth order and social class but the number of years of education of mothers with three and more births was significantly lower when compared to mothers with one or two births.

Table 66.7 Effect of birth order on maternal and newborn characteristics

	First birth ($N = 370$)	Second birth ($N = 206$)	≥ Third birth ($N = 424$)	p-value
Maternal characteristics				
Maternal age	23.8 (4.6)	26.0 (4.4)	30.0 (4.8)	***p < 0.001***
Body weight (kg)	62.8 (12.6)	63.9 (13.1)	67.4 (13.0)	***p < 0.001***
Body Height (cm)	159.3 (6.4)	159.8(6.2)	159.9 (6.6)	$p = 0.401$
Mid arm circumference (cm)	26.2 (3.9)	26.8 (4.0)	27.6 (3.7)	***p = 0.002***
Years of education	9.94 (4.1)	9.92 (3.8)	7.98 (4.4)	***p < 0.001***
Newborn characteristics				
Gestational age (weeks)	39.1 (1.8)	39.1 (1.7)	39.0 (1.8)	$p = 0.573$
Birth weight (g)	3021.6 (527.2)	3156.9 (497.1)	3215.7 (553.0)	***p < 0.001***
LBW-rate (%)	12.2%	5.3%	6.4%	***p = 0.003***

This table shows that birth order was strongly associated with maternal characteristics except body height (statistically significant p-values are printed in bold). Birth order did not affect the length of gestation; however, it was the strongest determinant of birth weight and LBW rate

Table 66.8 Effect of social class on gestational age and newborn anthropometry

	High social class ($N = 43$)	Middle social class ($N = 313$)	Low social class ($N = 644$)	p-value
Gestational age (weeks)	39.1 (1.2)	39.1 (1.9)	39.0 (1.7)	$p = 0.777$
Birth weight (g)	3208.1 (590.7)	3164.9 (541.9)	3110.5 (533.5)	$p = 0.218$
Supine length (cm)	49.4 (2.8)	49.6 (2.8)	49.2 (3.0)	$p = 0.232$
Head circumference (cm)	34.4 (1.4)	34.3 (1.7)	34.4 (1.7)	$p = 0.944$

This table shows that the social class had no statistically significant effect on the length of gestation, birth weight supine length and head circumference.

Table 66.9 Effect of the number of years of education on newborn anthropometry

	0–8 years ($N = 380$)	9–12 years ($N = 487$)	>12 years ($N = 133$)	p-value
Gestational age (weeks)	39.1 (1.9)	39.0 (1.8)	39.2 (1.3)	$p = 0.505$
Birth weight (g)	3078.2 (552.0)	3139.3 (520.1)	3257.1 (550.8)	***p = 0.004***
Supine length (cm)	49.1 (2.9)	49.4 (2.9)	49.7 (2.8)	***p = 0.066***
Head circumference (cm)	34.2 (1.7)	34.4 (1.6)	34.8 (1.7)	***p = 0.006***

This table shows that birth weight and head circumference increase with increasing number of years of education, (statistically significant p-values are printed in bold)

In our study population birth order was the strongest determinant of birth weight (Elshibly and Schmalisch 2008b). With increasing birth order (parity) birth weight increased significantly ($p < 0.0001$) as shown in Table 66.7. However, increasing birth order did not seem to affect gestational age at all. The LBW rate of first-born babies of 12.2% was nearly twice that of infants of multiparous mothers.

66.4.2 Effect of Education and Social Status on Birth Weight

Despite the wide variation in the social status of the investigated mothers we did not see any effect of social class on newborn anthropometry (Table 66.8), while the number of years of education had a statistically significant effect on birth weight and head circumference but not on gestational age, as shown in Table 66.9. The fact that the duration of maternal education and not maternal social class

Table 66.10 Correlation between maternal and newborn characteristics

	Mothers					
Newborn	Age	Weight	Height	MUAC	BMI	LBM
Gestational age	–	–	1.02%$^{++}$	–	–	0.73%$^{++}$
Birth weight	1.16%$^{+++}$	2,74%$^{+++}$	2.22%$^{+++}$	2.92%$^{+++}$	1.26%$^{+++}$	4.31%$^{++}$
Supine length	–	1.16%$^{++}$	3.49%$^{+++}$	1.42%$^{++}$	–	3.49%$^{+++}$

Limb length	–	0.58%$^{+}$	3.80%$^{+++}$	–	–	2.25%$^{+++}$
Head circumference	–	0.78%$^{++}$	1.47%$^{+++}$	1.15%$^{++}$	–	1.80%$^{+++}$
Chest circumference	–	1.97%$^{+++}$	2.71%$^{+++}$	1.41%$^{+++}$	0.63%$^{+}$	3.89%$^{+++}$
Abdominal circumference	–	1.35%$^{+++}$	0.98%$^{++}$	1.05%$^{++}$	0.66%$^{+}$	2.23%$^{+++}$
Mid arm circumference	0.80%$^{++}$	3.98%$^{+++}$	2.63%$^{+++}$	4.82%$^{+++}$	2.14%$^{+++}$	5.60%$^{+++}$
Mid thigh circumference	0.53%$^{+}$	2.48%$^{+++}$	2.44%$^{+++}$	2.88%$^{+++}$	1.09%$^{+++}$	4.29%$^{+++}$
Triceps skin fold thickness	2.74%$^{+++}$	2.84%$^{+++}$	0.47%$^{+}$	5.01%$^{+++}$	2.50%$^{+++}$	2.56%$^{+++}$
Sub scapular skin fold thickness	1.41%$^{+++}$	2.55%$^{+++}$	–	3.75%$^{+++}$	2.79%$^{+++}$	1.72%$^{++}$
Ponderal index	–	–	–	–	0.50%$^{+}$	–

This table describes the correlation matrix of characteristics of mothers and newborns
– no statistically significant correlation, $^{+}p < 0.05$, $^{++}p < 0.01$, $^{+++}p < 0.001$

was found to significantly affect newborn anthropometry agrees well with the literature. Karim and Mascie-Taylor (1997) found that birth weight increases with higher maternal education while Raum et al. (2001) and Voigt et al. (2004) showed in Germany that better educated mothers give birth to heavier babies and income plays a minor role.

However, as shown in Fig. 66.1 social class and education were not independent ($p < 0.001$). To overcome this difficulty, a multivariate analysis of variance (MANOVA) considering the interaction of both items and using maternal characteristics (including birth order, age, weight, height, MUAC, BMI, LBM) as covariates was recently performed (Elshibly and Schmalisch 2009). The MANOVA confirmed the results of the univariate analysis and showed that there was no statistically significant effect of social class on birth weight. However, a significant effect of maternal education was obtained on birth weight ($p = 0.004$), head ($p = 0.007$), chest ($p = 0.022$), mid arm ($p < 0.001$), and mid thigh ($p = 0.015$) circumferences as well as on ponderal index ($p = 0.008$). All measurements increased with increasing number of years of education.

The increasing ponderal index (which describes the relationship between body weight and length) with increasing number of years of education indicates that the nutritional status at birth is improved with increasing number of years of education. Thus, if better education in the mother leads to better weight, height and head circumference measurements in their newborns, female education should receive the highest priority in policy making, especially in developing countries where there is a high percentage of less educated mothers.

66.4.3 Correlation Between Maternal and Newborn Anthropometric Measurements

As the mother provides the environment in which the infant grows, maternal characteristics are expected to be associated with newborn anthropometry. The correlation matrix of all maternal anthropometric measurements with those of their newborns is shown in Table 66.10. There was a wide variation in the correlation between maternal characteristics including (age, weight, height, MUAC, BMI, and LBM) and newborn anthropometric measurements. The strongest correlations

were seen for LBM with mid arm circumference (*R*-squared = 5.6%) and for maternal MUAC with triceps skin fold thickness (5.01%). Maternal characteristics showed only a weak association with gestational age and PI.

However, the interpretation of the correlation matrix is impaired by the fact that most maternal anthropometric parameters were strongly associated with each other (namely, maternal weight and BMI with $r = 0.921$, maternal weight and MUAC with $r = 0.812$, maternal height and LBM with $r = 0.685$). Therefore, in a recently described (Elshibly and Schmalisch 2009) multivariate regression analysis all maternal characteristics were considered and a backward selection was used to identify the most important associations between maternal and newborn anthropometry. The strongest effect of maternal characteristics on newborn anthropometry (*R*-squared = 5.6%) was seen on mid arm circumference, supine length and birth weight of the newborn. Maternal LBM showed the strongest association with newborn anthropometric profile except for the skin fold thicknesses which were mainly associated with maternal age and BMI. This agrees well with the results of Kulkarni et al. (2006) who found postpartum LBM to be the most important determinant of birth weight and consequently highlighted the importance of increasing lean body mass in young women.

It seems that maternal fat stores measured by maternal age and BMI are more associated with skin fold thicknesses while the fat free maternal mass is more associated with the size of the newborn. As maternal age advances, maternal BMI and weight increase significantly ($p<0.001$) and it may be that older more obese mothers give birth to infants with increased fat stores. Support to this assumption is provided in the Austrian study (Kirchengast and Hartmann 2003) which showed that offspring of younger mothers were lighter than offspring of older ones.

Summary Points

- Africa has the highest perinatal mortality rates accounting for almost 33% of perinatal deaths worldwide, most deaths are due to LBW.
- The identification of LBW infants is therefore important in order to institute immediate care and arrange for urgent referral.
- In Africa most deliveries occur at home in the absence of skilled personnel and scales to measure birth weight.
- In order to help health workers we developed a simple formula to estimate birth weight.
- This formula utilizes three newborn body circumferences (chest, mid thigh and head) which can readily be obtained by using an inelastic tape measure.
- The birth weight can then be calculated with a small pocket or cell phone calculator or manually.
- LBW infants can then receive immediate management and can urgently be transported to an equipped health facility.
- Maternal age and anthropometry were significantly associated with newborn anthropometric measures; however, maternal anthropometry explained less than 6% of the variability in newborn anthropometry.
- The postpartum maternal LBM was found to be the major associate of newborn size (birth weight, body lengths and body circumferences).
- Birth order and postpartum maternal LBM were the most important parameters that influenced birth weight and the risk for LBW.
- Skin fold thicknesses were mainly associated with maternal age and maternal BMI.
- The duration of maternal education and not maternal social class was found to significantly affect newborn anthropometry.

- The influence of maternal education is also shown by the increase in the ponderal index with increasing years of education.
- The high impact of education calls for better education for females, especially in developing countries.
- Improving female education should receive very high priority in United Nations, government and Non-Governmental Organisation (NGOs) projects.

Chapter 67
Total Body Water in Newborns

Maria Dalva Barbosa Baker Méio and Maria Elizabeth Lopes Moreira

Abstract In this chapter, the modifications that occur in water distribution from the fetus to the newborn, focusing on the neonatal period, are reviewed. This is a critical period in life as the newborn infant has to adapt itself to a new environment. The main water compartments, intra- and extracellular, undergo changes throughout infancy, with an increase in intracellular space and a decrease in extracellular space as the child grows. The mechanisms of water dynamics behind these modifications are discussed. The flow of water through the cell membranes occurs through the cells (i.e., transcellular) or between the cells (i.e., paracellular). Water crosses the cell membranes through the lipid bilayer or through membrane pores (aquaporins). In paracellular flow, the flux occurs through wide spaces between the cells. Water molecules can also cross the membrane through diffusion in response to osmotic or hydrostatic pressure differences. Motionally distinct water fractions have been described: free bulky water and bound water, where bound water can be tightly bound or loosely bound water. Water can be liberated according to the need of the organism from the bound water fraction irrespective of its location, in the intra- or extracellular compartments.

Healthy newborn infants lose approximately 5–10% of their body weight during the first week of life. This loss in birth weight is attributed to fluctuation of total body water. After birth, the extracellular water compartment undergoes a contraction, followed by natriuresis, diuresis, and weight loss; the infant is oliguric during the first 24–48 h of life. Gestational age is a strong determinant of water loss in newborn, mainly preterm, infants. Insensible water loss through the skin plays a major role in water depletion, as newborns possess a greater surface area, and it has been shown that preterm infants have greater transepidermal water loss than term infants, and this is more pronounced in appropriate-for-gestational-age infants compared to small-for-gestational-age infants. Small-for-gestational-age newborn infants have been shown to possess greater total body water than is appropriate for gestational age infants.

The knowledge of water distribution in neonates and the differences between the two major groups of newborns (appropriate and small-for-gestational-age infants) is fundamental for administering fluids for those infants in the intensive care units without challenging their homeostasis.

67.1 Total Body Water in Newborns

The human body is a complex organism that changes as the body develops, matures, and ages. The impressive changes in water distribution from the fetus to the newborn and thereafter from infancy to adulthood are now known. Although knowledge of the main body compartments and body composition has increased, some aspects of the flow of water between these spaces remain poorly understood. Research is being conducted to understand how changes in body composition are associated with renal functioning, insensible water losses, the distribution of water in the different organs, and the physiology of water flow.

The neonatal period is critical to development; it is during this period that the most striking changes in human body composition occur since the newborn has to adapt itself to a new environment while it is growing and developing. In premature babies, these physiological events occur in a body in which the organs are not yet fully developed. Technology has improved the survival of very tiny newborns, some of which have suffered a severe intrauterine growth restriction. In this chapter, data on water distribution, mechanisms of water flow, and differences in water distribution between appropriate and small-for-gestational-age newborns will be reviewed.

67.2 Body Water Compartments

Body water is distributed in two compartments: intracellular and extracellular spaces (interstitial and vascular spaces). Both compartments lose water as the fetus grows, and the extracellular compartment corresponds to approximately 40% of the newborn body at birth. Proportions of 46.3% (males) and 47.0% (females) of body weight for extracellular water and of 27.6% (males) and 26.2% (females) of body water have been reported for intracellular water (Butte et al. 2000). The decrease in water content during gestation is not uniform, and a decrease in extracellular water and an increase in intracellular water toward the end of gestation have been described (Friis-Hansen 1983). The modifications in the proportions of extracellular to intracellular water that occur in the human body from intrauterine life to adulthood as a consequence of the modifications in the content of body fat, proteins, and minerals are shown in Fig. 67.1 (Friis-Hansen 1983).

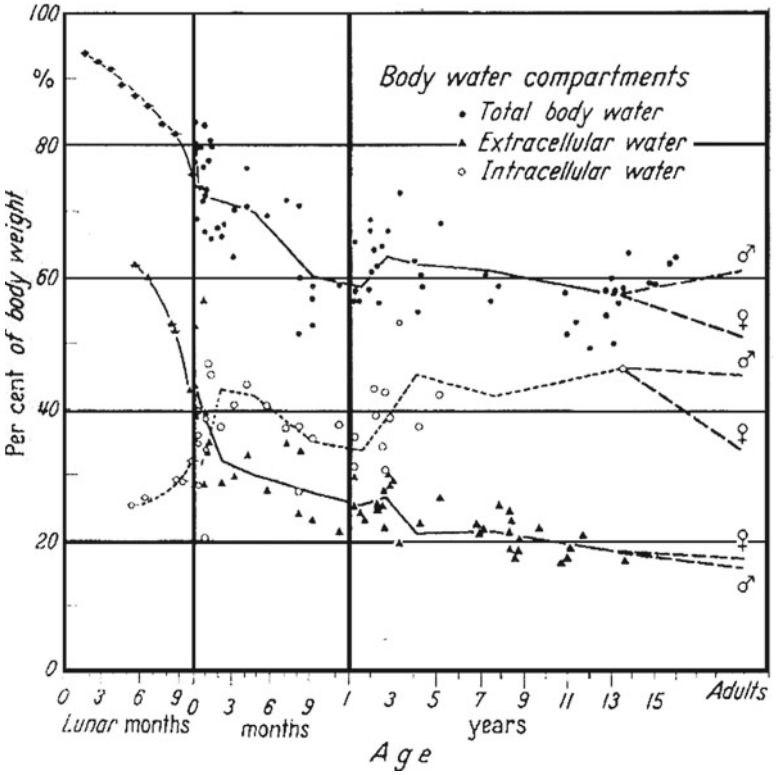

Fig. 67.1 Modifications in the proportions of extracellular to intracellular water in human body from intrauterine life to adulthood. Modifications in body water compartments from early fetal life to adult life: ●, total body water; ▲, extracellular water; ○, intracellular water (From Friis-Hansen (1983), reprinted by permission of the publisher)

During intrauterine life, the growing embryo and fetus possess a predominance of water in their bodies, ranging from 80% to 85% between 26 and 31 weeks of gestation to approximately 75% of body weight at full term (Yssing and Friis-Hansen 1965; Friis-Hansen 1983). This alteration in water content of the fetus corresponds to the great velocity of growth and cell division during intrauterine life; as the cells increase in number and become bigger, the intracellular substance diminishes and the proportion of body water decreases. The acquirement of solid mass, mainly protein, fat, and minerals, as the fetal body is being built accounts for this impressive modification in body composition during intrauterine life until the end of gestation. Although there is a reduction in growth velocity after birth, it is still very fast and up to 2 years of age there are important changes in body composition due to the acquisition of solid mass (Fomon and Nelson 2002).

Newborn infants have a high proportion of water, which diminishes as they get older. The reduction in the proportion of total body water is rapid during the first 130 days of life, and extracellular water decreases more rapidly than total body water during the same period. Furthermore, both total body water and extracellular water are greater in males compared to females (Fomon and Nelson 2002). Body composition in children up to 2 years of age has been analyzed, and the proportions of body water found were 73.9% of body weight for males and 73.2% of body weight for females in neonatal period (Butte et al. 2000). Although not striking, differences in the values reported by the different authors exist (Yssing and Friis-Hansen 1965; Butte et al. 2000; Fomon and Nelson 2002; Olhager and Forsum 2003; Ferreira and Souza 2004; Ellis et al. 2007) and are presented in Table 67.1. These differences are probably due to the measurement techniques used, as well as small

Table 67.1 Body composition: proportions of total body water in full-term newborn infants or preterm newborn infants

Author (year)	Gestational age and age at analyze (*n*)	TBW[a]	ECW[a]	ICW[a]	Technique
Yssing and Friis-Hansen (1965)	Full term	76.6 (boys) 74.3 (girls)	39.6 (boys) 39.3 (girls)	36.0 (boys) 31.8 (girls)	Not given
Butte et al. (2000)	Full term at 0.5 m (age) (76)	73.9 ± 6.8 (boys) 73.2 ± 5.2 (girls)	46.3 ± (6.8) 47.0 ± (6.3)	27.6 ± 2.4 26.2 ± 2.7	Deuterium dilution
Fomon and Nelson (2002)	Birth	69.6 (boys) 68.6 (girls)	42.5 42.0	27.0 26.7	Deuterium dilution (data from 1982)
Olhager and Forsum (2003)	30–33 w at term age (8) Full term (9)	67.4 ± 2.5 (64.0 – 71.3) 68.1 ± 4.1 (57.9 – 72.2)			Doubly labeled water
Ferreira and Souza (2004)	Full term 24 h (age) (30)	68 ± 4	39 ± 6	29 ± 6	Bioelectrical impedance
Ellis et al. (2007)	Full term 1.7–23 w (age) (49)	81.7 ± 1.7 (77.6 – 85.8)			Deuterium dilution

[a]% of body weight

differences in the ages of the children at the time of measurement. Regardless, both Butte et al. (2000) and Fomon and Nelson (2002) found slightly greater values for boys compared to girls (Butte et al. 2000; Fomon and Nelson 2002).

67.3 Mechanisms of Water Flow

During gestation, water volume is divided between the fetus, the placenta, and the amniotic fluid. Modifications of the proportion of water from the fetus to the term baby are equal to the alterations in the volume and composition of the amniotic fluid. These dynamic changes depend on fetal urine production, which starts as early as 7–8 weeks of gestation, with fetal glomerular filtration rates increasing during the last trimester of gestation; on fluid actively secreted by the fetal lungs; on fetal swallowing, which begins as embryogenesis is complete, and is functional by the end of gestation; and on intramembranous flux across the amnion between the fetus and the amniotic cavity (Beall et al. 2008).

The flux of water is regulated in part by biological membranes either transcellularly (i.e., through the cells) or paracellularly. The composition of the fluid that crosses the membranes is dependent on the type of flow. There are two routes for the transcellular flow: through the lipid bilayer (low) or through the pores or channels (aquaporins) of the membranes. The aquaporins allow the passage of free water and some small molecules. In paracellular flow, the flux occurs through wide spaces between the cells and both water and solutes cross the membranes, although large molecules are excluded.

Water molecules can also cross the membrane without net water flow via diffusion in response to osmotic or hydrostatic pressure differences (Beall et al. 2008). Osmotic differences are determined by the solute concentration on both sides of the membranes, which are dependent on renal function

and the active transport of solutes and ions (mainly sodium) across the membrane. Hydrostatic pressure differences are related to cardiac output and hormones, such as adrenergic hormones from the adrenal and renin–angiotensin systems.

67.3.1 Aquaporins

Aquaporins are cell membrane proteins that function as water channels. Their function is dependent on their location in the cell membrane. Their position on opposite sites of the cell membrane is important for the regulation of water transfer across the cell. Some aquaporins permit the transfer of other molecules, such as glycerol, urea, and other small molecules, and are called aquaglyceroporins (Beall et al. 2008). In the kidney, these are located in the collecting ducts. The binding of arginine-vasopressin (AVP) to the vasopressin receptor (V2) activates the adenylyl cyclase, increasing intracellular cAMP and thereby phosphorylating the aquaporin 2 (AQP2) localized in intracellular vesicles of the epithelial duct cell. The phosphorylated AQP2 reaches the apical plasma membrane of the collecting duct cell, forming channels in the membrane. Water flows through the channels inside the cell and exits the cell through aquaporins 3 (AQP3) and 4 (AQP4) localized in the basolateral membrane of the cell. AQP3 is the main channel in the cortical collecting duct and AQP4 is located primarily in the medullary collecting duct. However, in newborn infants, the capacity of the immature kidneys to respond to this physiologic pathway is low, and water absorption, and thus urinary concentration capacity, is limited during the first weeks after birth (Bonilla-Felix 2004; Sulyok and Nyúl 2005).

Water transport via AQPs occurs in both directions and is related to osmotic gradients created by the energy-dependent Na–K pump. Although there are other mechanisms for water transport, such as passive diffusion across the membrane lipid bilayer, cellular membrane co-transporters, and paracellular junctions, the AQPs allow a more specific regulation of water movement (Zelenina et al. 2005).

67.3.2 Physical Water Compartments

The distribution of water between the two major water compartments in the human body is related to the concept that the mobility of tissue water is important to understand the body fluid redistribution that occurs in the newborn infant more than the compartmentalization per se. Motionally distinct water fractions have been described: free bulky water and bound water, where bound water can be tightly bound or loosely bound water. Water can be liberated according to the need of the organism from the bound water fraction in the intra- or extracellular compartments, irrespective of its location (Sulyok 2006).

The term *physical water compartments* indicates a physical state of tissue water, with water molecules interactions between dipole water molecules and tissue biopolymers, including proteins and glycosaminoglycans, forming polarized water layers. Multiple layers of polarized water are arranged in parallel with alternating positive and negative sites, which enhance the degree of polarization and motional restriction, increasing the stability of the multilayer (Sulyok 2006). Bioexponential analysis revealed that the bound water fraction in proportion to total tissue water corresponds to 42–47% in the skin, 50–57% in the muscle, and 34–40% in the liver, and that this pattern of distribution does not vary with age or fluid intake. Moreover, in response to complete fluid deprivation, the reduction of the bound water fraction accelerates (Sulyok 2006). This is an interesting concept to understand the mechanisms of water flow control.

Table 67.2 Key facts about stimulus for secretion of arginine-vasopressin

- Changes in plasma osmolality.
- Changes in blood pressure.
- Arginine-vasopressin is secreted under stress conditions.
- The response of the immature neonatal kidney to arginine-vasopressin is limited.

This table lists the principal mechanisms for stimulation of arginine-vasopressin hormone, emphasizing the limitation in neonatal period

67.3.3 Arginine-Vasopressin

Arginine-vasopressin (AVP) is the principal antidiuretic hormone that regulates free water excretion by the kidneys. It is synthesized in the neurohypophysis and stored in nerve terminals of neurons originating primarily from the supraoptic and paraventricular nuclei of the hypothalamus. The two principal stimuli responsible for the secretion of AVP are changes in plasma osmolality and changes in blood pressure. Osmoreceptors located near the supraoptic nuclei detect changes in plasma osmolality and trigger or inhibit the release of AVP as needed. Whether the sensitivity of the osmoreceptors is fully mature at birth has not been established. Hemodynamic alterations are detected by baroreceptors localized in cells of the cardiac atria, carotid sinus, and aorta, and stimulate AVP secretion for blood pressure control (Zaffanello et al. 2008).

The ability to concentrate urine in children at birth is not well documented; it develops progressively during the first 18 months of life, at which point it reaches full maturity. The immature neonatal kidney is incapable of responding adequately to AVP. In newborn infants, many factors contribute to the inadequacy of neonatal kidney responses to control water reabsorption: transducer pathways for AVP are limited by PGE-2-mediated inhibition of cAMP synthesis; water movement across collecting ducts is limited by the low medullary tonicity; low protein intake results in low urea production and there is decreased salt reabsorption, both contributing to the low medullary osmolarity; and the physical length of the loop of Henle in the developing kidney is short, increasing progressively with renal growth after birth (Zaffanello et al. 2008).

Arginine-vasopressin is secreted under stress conditions. It has been demonstrated that preterm newborn infants with respiratory distress syndrome (RDS) requiring mechanical ventilation possess high levels of urine and plasma AVP (Ronconi et al. 1995). The renal osmotic response, as shown by urinary osmolality, to endogenous AVP in preterm infants becomes blunted with advancing age after birth (Table 67.2) (Kovács et al. 1986).

67.3.4 Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP), part of the family of natriuretics peptides, is produced chiefly in the heart and stored in the secretory granules of the atrial and ventricular myocites. Its liberation into the circulation is triggered by increased cardiac wall stretch and increased blood pressure. ANP acts primarily on the cardiovascular and renal systems through receptors localized in target tissues, and is a potent natriuretic, diuretic, and vasodilator hormone. The interaction and modulation of ANP actions by other hormones, such as arginine-vasopressin, glucocorticoids, and catecholamines, creates a dynamic equilibrium among different hormonal pathways and contributes to the preservation of total body water and blood pressure control (Zaffanello et al. 2008).

After birth, with the increase in pulmonary blood flow as a consequence of lung expansion and the elevation of systemic vascular resistance, substantial and very rapid changes in the circulation of the newborn infant occur in order for it to adapt itself to the new environment. Pulmonary circulation

Table 67.3 Key facts about atrial natriuretic peptide

• ANP is a potent natriuretic, diuretic, and vasodilator hormone.
• ANP is produced in the heart and it is stored in the secretory granules of atrial and ventricular myocites.
• ANP liberation is triggered by increased cardiac wall stretch and increased blood pressure.
• ANP acts in conjunction with other hormones contributing for the preservation of total body water.

This table lists the main physiological functions of atrial natriuretic peptide
ANP atrial natriuretic peptide

Table 67.4 Key facts about total body water in newborns

• As the human body changes from intrauterine life to adulthood, an increase in intracellular water and a decrease in extracellular water occur as a consequence of the modifications in the content of body fat, proteins, and minerals.
• The flux of water is regulated by biological membranes, aquaporins, and hormones such as arginine-vasopressin and atrial natriuretic peptide.
• Motionally distinct water fractions have been described: free bulky water and bound water. Water can be liberated according to the need of the organism from the bound water fraction irrespective of its location, in the intra- or extracellular compartments.
• Healthy newborn infants lose approximately 5–10% of their body weight during the first week of life as a consequence of water loss mainly from the skin and kidneys.
• Transepidermal water loss is inversely related to gestational age during the first 4 weeks of life.
• Small-for-gestational-age newborn infants possess greater total body water than appropriate-for-gestational-age newborn infants.
• Transepidermal water loss is higher in appropriate-for-gestational-age newborn infants than in small-for-gestational-age newborn infants during the first days of life.

This table lists the main facts of body water distribution and body water turnover during the neonatal period

and pressure changes occur, and the cardiac cavities increase in size and pressure, which stretches the atrial wall and thus releases ANP. Although the ANP concentration is similar in umbilical venous cord blood and peripheral venous blood on the day of delivery in full-term newborn infants, it increases after birth and reaches a peak level around the second day of life, and then diminishes and maintains a plateau after 1 week of life (Mir et al. 2003).

Preterm newborn infants with respiratory distress syndrome have high ANP plasma levels before the onset of respiratory recovery, and more severe lung disease is correlated with a later onset of diuresis (Ronconi et al. 1995). The ANP concentration gradually diminishes during the post-diuretic phase, returning to pre-diuretic levels after 1 week of age (Kojima et al. 1987). ANP is an important hormone in newborn infants for the control of water volume and blood pressure (Table 67.3)

67.3.5 Hyaluronan

Hyaluronan, with its polyanionic nature and gel-like properties, is implicated in the control of water mobility in lungs; as the major macromolecular compound involved in water balance, it is also found in the kidneys (Sedin et al. 2000; Sulyok 2005). Hyaluronan or hyaluronic acid is one of the glycosaminoglycans, which are unbranched polysaccharide chains composed of repeating disaccharide units. It is produced on the cytoplasmic side of the plasma membrane and transported across the plasma membrane to the extracellular space. Hyaluronan has been shown to be abundant in the interstitium of the renal inner medulla (Dwyer et al. 2000). It has been also shown to be present in the renal medullary interstitium, and its content in the papilla increases during water diuresis and modestly diminishes during water deprivation, thereby demonstrating a role for hyaluronan in water control (Hansell et al. 2000).

In the renal outer medulla, the concentration process results from the high medullary interstitial osmolality, which provides a driving force for osmotic water flow across the collecting ducts. However, controversies remain regarding the mechanism responsible for the concentration process in the renal inner medulla. A theory has been proposed in which the inner medulla, consisting of a hyaluronan matrix, functions as a mechanico-osmotic transducer produced by the renal pelvic wall contractions (Knepper et al. 2003). The renal inner medulla is surrounded by the renal pelvocalyceal wall, which undergoes intermittent contractions, compressing the renal medullary parenchyma and thus altering the flow rates in tubule and vascular structures of the inner medulla. Knepper et al. (2003) hypothesized that these peristaltic contractions would compress the hyaluronan matrix, producing osmotic changes in the renal inner medulla and hydrostatic pressures that would draw water out of the descending limb (Knepper et al. 2003). This hypothesis still needs to be tested. It has been argued that this mechanism would be unlikely to occur in the perinatal period because of the characteristics of the structure and functioning of the kidney in newborn infants. Another explanation has been postulated in which the incapacity to concentrate urine in the immature kidney results not only from the decreased cortico-papillary osmotic gradient and the diminished renal tubular response to arginine-vasopressin, but also due to the elevated hyaluronan encountered in the neonatal renal papilla (Sulyok and Nyúl 2005). Another argument against the mechano-osmotic theory has been proposed recently, suggesting that extravasated plasma albumin exerts a role in the process of concentrating urine in the renal inner medulla (Pinter and Shohet 2006). The mechanisms responsible for the concentration of urine in renal inner medulla remain unknown, necessitating further research.

67.4 Postnatal Adaptations of Body Water

Healthy newborn infants lose approximately 5–10% of their body weight during the first week of life. This loss in birth weight is attributed to the fluctuation of total body water. After birth, the extracellular water compartment contracts, followed by natriuresis, diuresis, and weight loss; the infant is oliguric during the first 24–48 h of life. Modifications in body composition in extreme preterm, appropriate-for- gestational-age, newborn infants during the first days of life have been studied (Bauer et al. 1991). It was found that weight loss was not accompanied by a reduction in body solids; instead, there was a significant decrease in total body water with a reduction in extracellular water related to a decrease in interstitial volume, while the plasma volume and intracellular volume remained unchanged. After regaining birth weight, these babies did not show any significant increases in body solids or total body water, but interstitial volume returned to birth values and there was no evidence of catabolism. These alterations in the dynamics of body fluid compartments were related to high extrarenal water loss on the first day of life, followed by marked diuresis on subsequent days. These data confirm the assumption that water loss occurs after birth, with a contraction of extracellular volume (Bauer et al. 1991).

Full-term infants possess significantly more total body water than do preterm infants when they achieve term age, but when the proportion of water for body weight was compared, the values were found to be similar and not significantly different (Olhager and Forsum 2003). The adipose tissue volume was higher for term than for preterm babies, but this difference was also not significant. When the proportion of total adipose tissue volume for body weight was compared, non-significantly higher levels were found for preterm babies, and a non-significantly smaller volume of subcutaneous total adipose tissue was demonstrated (Olhager and Forsum 2003). Furthermore, loss of body water after birth occurs to the same extent in healthy preterm neonates as in babies with respiratory distress syndrome and is unrelated to the volume of fluid administered (Tang et al. 1997).

67.4.1 Initial Weight Loss

Initial weight loss in newborn infants is a consequence of water loss, mainly from the skin and kidneys. Post-natal weight loss is a good estimate of extracellular volume depletion, and maximum weight loss in extremely low birth weight infants is correlated with maternal hypertension, fluid intake, urinary output, total days on oxygen, and gestational age (Verma et al. 2009). Post-natal weight loss is related to maturation; a multivariate analysis revealed that gestational age is a strong determinant of maximum weight loss in these babies (Verma et al. 2009). Transepidermal water loss is inversely related to gestational age during the first 4 weeks of life and is higher in preterm than in term babies, gradually decreasing after birth. Insensible water loss through the skin plays a major role in water depletion, as newborns have a greater surface area. It was also shown that insensible water loss through the skin is more pronounced in preterm babies than in term babies and, during the first days of life, its volume exceeds that of urine output (Hammarlund et al. 1983). Therefore, it has been hypothesized that the skin may serve as an important route of water depletion and extracellular volume decreases after birth in very preterm newborn infants. This epidermal water loss is a consequence of the lack of keratin in the skin of preterm babies, which poses an epidermal barrier; in extremely low birth weight newborn infants, the skin keratinizes after the first week of life, between weeks 2 and 3, explaining the vulnerability of these babies to water depletion (Sridhar and Baumgart 2006).

The loss of weight during the first days after birth in preterm newborn infants is a consequence of loss of water. The body composition of very low birth weight preterm babies (appropriate-for-gestational-age) has been studied, and the weight loss that occurs during the first 5 days of life was found to be due to the loss of water and diminished extracellular water. Furthermore and importantly, urine output significantly increased from day 1 to day 5 without significant changes in creatinine clearance, fractional excretion of sodium, and urine osmolality (Bauer and Versmold 1989).

In spite of the loss of water after birth as a consequence of the adaptation to extrauterine life, the efficiency of the control of water distribution in the body of the newborn is remarkable. Measurements of total body water in nine preterm newborn infants revealed that despite a wide variation in the water supply during postnatal days 3, 10, and 17, the percentage of body water remains constant, as shown in Fig. 67.2 (Micheli et al. 1994).

67.5 Differences in Water Distribution Between Appropriate- and Small-for-Gestational-Age Newborns

Appropriate- and small-for-gestational-age newborn infants differ in relation to transepidermal water loss. In both groups, an important water loss from the skin occurs during the first 4 weeks of life, primarily within the first 2 weeks. However, this loss of water is more intense in the appropriate-for-gestational-age (AGA) group compared to the small-for-gestational-age (SGA) group, as can be seen in Figs. 67.3 and 67.4. On the first day of life, the transepidermal water loss in AGA infants is higher than in SGA infants of corresponding gestational age, although in preterm infants born after 31–36 weeks of gestation the difference in transepidermal water loss between AGA and SGA is very small after the first 3 days of life (Hammarlund et al. 1983).

In SGA preterm newborn infants one to 2 weeks after birth, the insensible water loss is higher than in AGA of corresponding post-conceptional age, as shown in Fig. 67.4, possibly indicating that the metabolic rate and/or the activity of the SGA preterm babies increases after birth, influencing water loss (Hammarlund et al. 1983). In fact, the total energy expenditure resulting from the oxidative

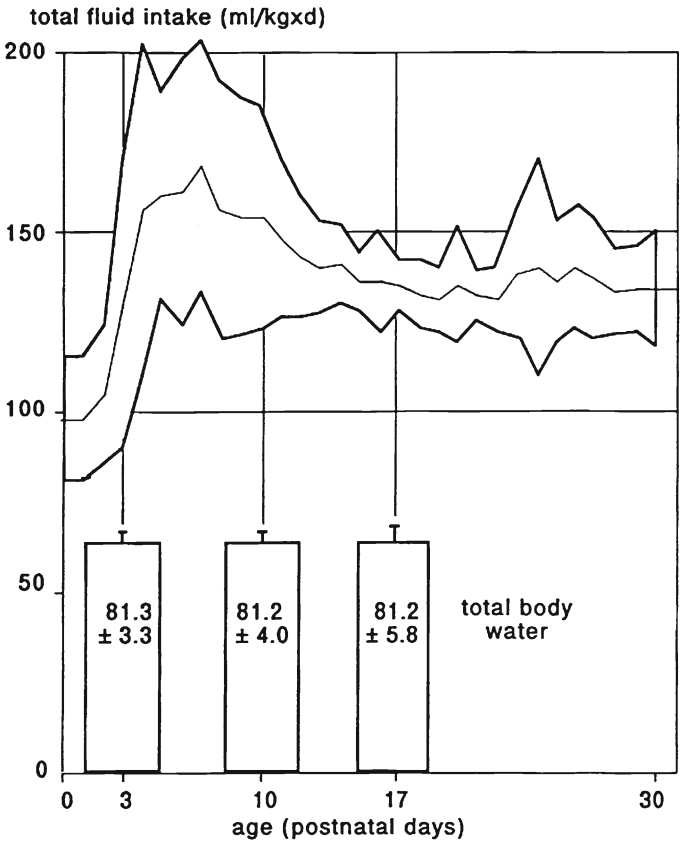

Fig. 67.2 Efficiency of the control of body water distribution in newborn infants. The upper part shows the mean (range) value of total fluid intake in nine healthy premature infants. It is striking how efficiently the concentration of water in the body is regulated; no change in the percentage of total body water over a very wide range of fluid intakes (From Micheli et al. (1994), reprinted by permission of the publisher)

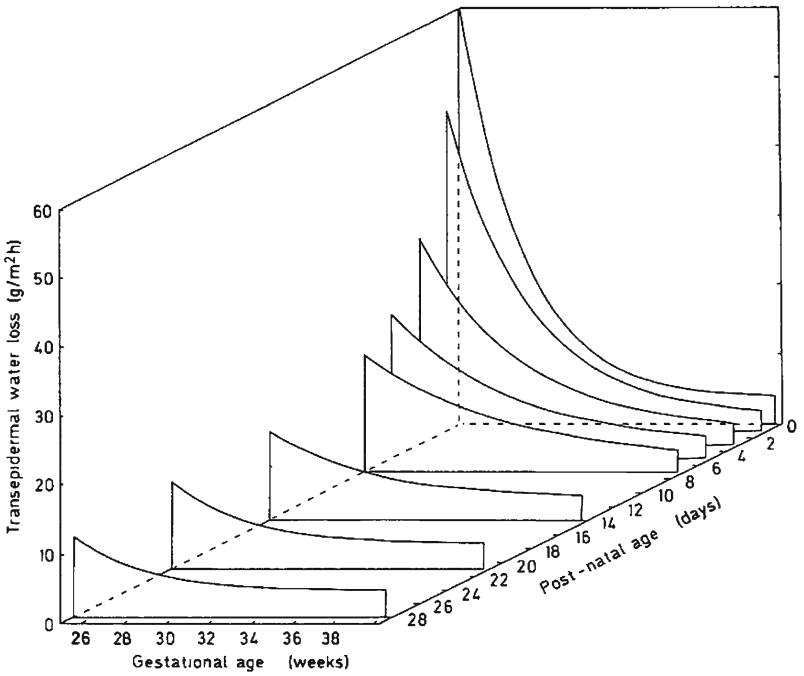

Fig. 67.3 Transepidermal water loss in appropriate-for-gestation-age newborn infants during neonatal period. The regression of transepidermal water loss (g/m^{2}h) on gestational age at birth at different post-natal ages in appropriate-for-gestational-age infants. This figure shows the differences in transepidermal water loss from birth to 28 days of life in relation to the gestational age at birth (From Hammarlund et al. (1983), reprinted by permission of the publisher)

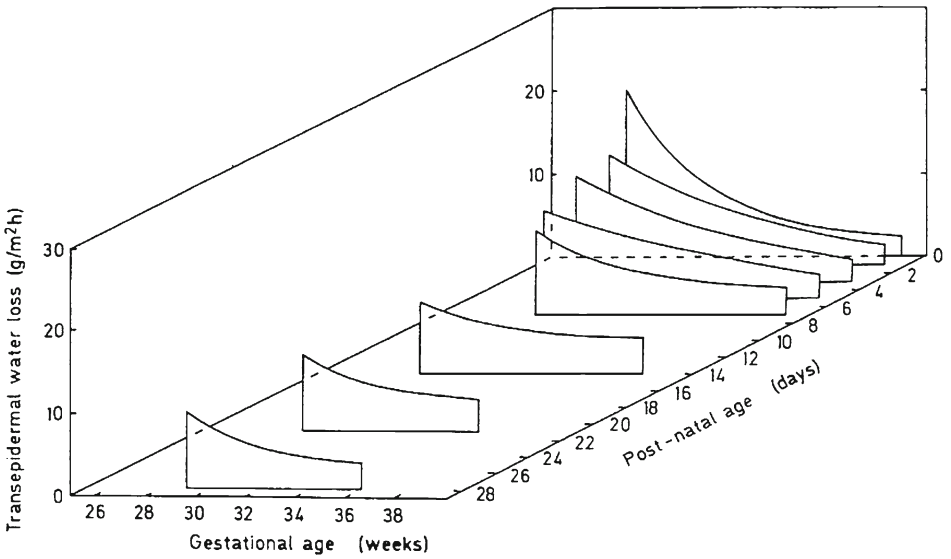

Fig. 67.4 Transepidermal water loss in small-for-gestation-age newborn infants during neonatal period. The regression of transepidermal water loss (g/m²h) on gestational age at birth at different post-natal ages in small-for-gestational-age infants. This figure shows the differences in transepidermal water loss from birth to 28 days of life in relation to the gestational age at birth (From Hammarlund et al. (1983), reprinted by permission of the publisher)

metabolism of carbohydrates, fat, and protein is greater in preterm infants at term age than in term babies, and it has been hypothesized that preterm infants are more active than their counterparts; this study did not compare SGA and AGA (Olhager and Forsum 2003). Neonatal body water turnover is greater in SGA babies; the loss of water via the urine is faster and greater in this group of babies compared to preterm and term AGA newborn infants (MacLennan et al. 1983).

SGA newborn infants possess greater total body water than their AGA counterparts (MacLennan et al. 1983; Hartnoll et al. 2000; Méio et al. 2008). The concern with the distribution of body water and nutritional gain among AGA and SGA infants after birth is important when dealing with these two groups of infants in the neonatal period. The provision of adequate nutritional support in the neonatal period is fundamental for the survival and outcome of newborn infants, as evidence points to long-term consequences of malnutrition, both during intrauterine life, in intrauterine growth restriction, and after birth, in post-natal growth failure (Finken et al. 2006). The distribution of water in the body is well known to be related to the nutritional status of the newborn infants.

In addition to possessing a greater proportion of water after birth, SGA preterm infants maintain this difference toward term age in relation to their AGA correspondents; term SGA also have more water than term AGA infants. Although SGA preterm newborn infants catch up in growth after birth, this increase in growth is not sufficient for them to outgrow their growth deficiency. Comparison of two groups of AGA and SGA babies, matched according to gender and gestational age, revealed that total body water in SGA preterm infants is greater than in AGA preterm infants both at 7 days of age and at term age. Although a decrease was detected in total body water and the weight *Z*-score from birth to term age (Fig. 67.5), and an increase was observed in measures that reflect gain in body mass, such as the triceps skinfold and Rohrer ponderal index (Fig. 67.6), in both groups, the change from birth to term age was quite similar in both AGA and SGA, as the differences between the groups were not significant (Méio et al. 2008). It appears that two components comprise the modifications in total body water between the groups: a greater water loss in AGA infants and an insufficient increase in solid mass in both groups, with a comparable growth velocity in both groups after birth.

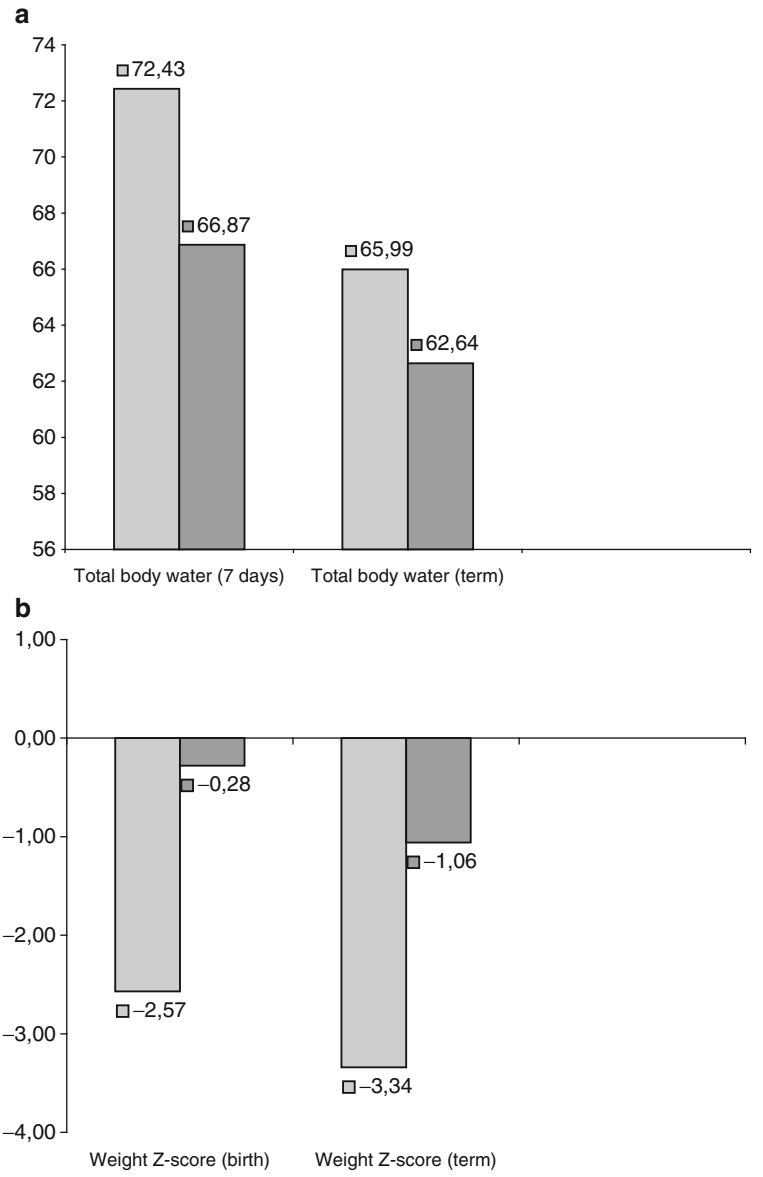

Fig. 67.5 Differences in total body water and weight *Z*-score between appropriate-for-gestational-age and small-for-gestational-age newborn infants. Comparison of the proportion of total body water (7 days of life and term age) and weight *Z*-score (birth and term age) in small-for-gestational-age and appropriate-for-gestational-age newborn infants matched by gender and gestational age, showing the decrease toward term age. (**a**) Total body water; (**b**) weight *Z*-score. First column (*light gray*) – small-for-gestational-age newborns, second column (*dark gray*) – appropriate-for-gestational-age newborns

In conclusion, knowledge regarding the water distribution in neonates and the differences between the two major groups of newborns (appropriate- and small-for-gestational-age infants) is fundamental for the appropriate administration of fluids to infants in intensive care units without challenging their homeostasis.

67.6 Applications to Other Areas of Health and Disease

In clinical practice, the management of fluid administration in critically ill newborn infants is critical. Assessments of body water, electrolyte concentrations, blood pressure, and renal function are important tools for controlling homeostasis in the neonatal period. In addition, knowledge of the mechanisms

Comparison of the proportion of ponderal index (birth and term age) and triceps skinfold (7 days of life and term age) in small-for-gestational-age and appropriate-for-gestational-age newborn infants matched by gender and gestational age showing the increase toward term age. (**a**) Triceps skinfold; (**b**) ponderal index. First column (*light gray*) – small-for-gestational-age newborns, second column (*dark gray*) – appropriate-for-gestational-age newborns

of water loss after birth, chiefly in preterm newborn infants, is of great importance in caring for these babies. The goal of fluid and electrolyte equilibrium is not to maintain body water status after birth, but to allow the physiological changes to occur appropriately. Inappropriate fluid management has important clinical implications in the incidence and severity of diseases, such as respiratory distress syndrome, patent ductus arteriosus, and bronchopulmonary dysplasia.

New equipment to measure body composition that can be used at the bedside can facilitate decisions that must be made during the first weeks after birth. Moreover, an understanding of the changes that occur during this period, mainly in preterm newborn infants, is crucial for the clinician.

Knowledge of the distribution of water between the body compartments, the mechanisms responsible for the regulation of water flow, and neonate kidney functioning in newborn infants and later throughout childhood is fundamental to understand the mechanisms of drug distribution and turnover. In clinical practice, pharmacological dosages of medicine are estimated based on body weight, total body water, or surface area. Knowledge of the body composition is an important issue for the pharmaceutical industry, as new drugs targeted at children are being developed and manufactured.

Summary Points

- From intrauterine life to adulthood, the content and distribution of body water changes as a result of growth. The two main compartments, extracellular and intracellular, exhibit dynamic changes, with a decrease in extracellular volume and an increase in the intracellular volume, as the child grows.
- The changes in the distribution of water in the human body, chiefly in the neonatal period, are characterized by a decrease in total body water. The initial water loss in newborn infants is reflected by the well-recognized weight loss during the first days of life. Moreover, this water loss is more evident in preterm than in term infants.
- Transepidermal water loss and insensible water loss are important mechanisms related to the initial water loss, chiefly in preterm infants. Moreover, this loss is more accentuated in appropriate-for-gestational-age than in small-for-gestational-age infants. Knowledge of how this water loss occurs is crucial for the management of small preterm newborn infants in intensive care units.
- The water balance in the neonate body results from the integration of hormones pathways and the target organs, mainly the cardiovascular system and the kidneys. Hormones such as arginine-vasopressin and atrial natriuretic peptide are important in the control of water and electrolytes homeostasis and in blood pressure control. Biological cell membranes are also involved in regulating water flux.
- Differences in appropriate- and small-for-gestational-age newborn infants are currently being studied, and the repercussions of intrauterine growth restriction in adulthood, with ongoing evidence of its role in adult metabolic disease, highlight the importance of a better understanding of the dynamic changes that occur during this period of life.
- Small-for-gestational-age newborn infants possess a greater proportion of body water than appropriate-for-gestational-age newborn infants. Although they demonstrate a catch-up growth after birth, they maintain the difference in the proportion of body water when compared with appropriate-for-gestational-age infants.

Part XII
Anthropometry of Infants and Children

Chapter 68
Failure to Thrive in Infancy: Anthropometric Definitions

Else Marie Olsen and Charlotte M. Wright

Abstract The term Failure to Thrive (FTT) has been widely used during the last century to describe poor growth in early childhood. The condition has traditionally been classified on the basis of the presence or absence of somatic illness, with most cases being of non-organic or mixed origin. In early literature definitions of FTT included emotional and behavioural symptoms, which strongly linked the condition to maternal deprivation and psychosocial adversity. However, a consensus in 1985 concluded that the primary identification of FTT must be based solely on anthropometric parameters. Albeit, there is no consensus about a specific anthropometric definition, and a broad range of different anthropometric indicators and cut-off points have been used to identify FTT. Most criteria have been based on weight measures, equalling FTT with slow weight gain, and FTT have thus for example been defined as weight falling below the 3rd percentile, downward crossing of weight over two or more main percentile lines, and weight gain below the 5th percentile conditioned on birth weight taking into account the normal phenomenon of regression towards the mean. The concurrence between different criteria of FTT, however, is low, and different criteria are likely to identify different child populations with different risks of adverse outcome. Thus, during the last decade it has been suggested that this rather vague term should be abolished in favour of more valid anthropometrical descriptions based on explicit measures of growth or nutritional status.

68.1 Introduction

The concept of FTT has been recognised for more than a century, and was first described in 1899 by Holt as a condition of malnutrition in infants with weight faltering and wasting in connection to weaning (Kessler and Dawson 1999). Since the mid-nineteenth century the term 'failure to thrive' has been widely used to describe various kinds of inadequate growth in childhood, with or without obvious organic disease. Early studies also included a variety of emotional and behavioural symptoms within the 'diagnosis' of FTT (Kessler and Dawson 1999). However, a consensus in 1985 concluded that the primary identification of FTT needs to be based solely on anthropometric parameters (Drotar 1985). However, no consensus exists concerning a specific anthropometric definition of FTT, and the term has been used to cover a broad range of different anthropometric indicators not necessarily identifying the same populations of children at risk (Wilcox et al. 1989; Olsen 2006). This has hampered comparisons between studies and research results and the utility of the term concerning prevention and treatment.

Within the last couple of decades, there has been a growing recognition that the concept of FTT is unclear, and several clinicians and researchers have suggested that the term should be abolished, in favour of, for example 'pediatric undernutrition', or a more specific use of the different growth parameters (Kessler and Dawson 1999).

In this chapter we describe different conceptions of FTT used during the last century with special focus on the use of different anthropometric definitions and its consequences concerning the identification of children at risk.

68.2 Approaching the Concept of FTT

Neither the WHO International Classification of Diseases, ICD-10, nor the American Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) includes FTT as a specific diagnosis, and no anthropometric definition is mentioned in either. In the ICD-10 FTT is included within the diagnostic entity "Other lack of expected normal physiological development", with the diagnostic code 'R628', also including 'Infantilism not otherwise specified', 'lack of growth', and 'physical retardation', are placed in the main section 'General symptoms and signs'. Thus, although the term FTT has often been used as a specific diagnostic entity or syndrome, it is in fact a symptom with multifactural causality. In both the DSM-IV and the ICD-10, FTT is included in the description of reactive attachment disorder, while the ICD-10 also includes it in the description of feeding/eating disorders of childhood. It has thus long been recognised that a common characteristic in FTT is relative undernutrition (Kessler and Dawson 1999; Wright 2000), which relates FTT to the concept of malnutrition in general, and especially to 'protein-energy malnutrition' (PEM/Kwashiorkor), with the ICD-10 code E45. The term PEM, however, has primarily been used to describe nutritional deprivation among children in developing countries, while the term FTT has mainly comprised children in more

affluent societies. FTT and malnutrition/PEM are thus described in different literatures, and also, somewhat different anthropometric criteria have been used to define both.

Early childhood is characterised by rapid growth, including rapid changes in weight and height,[1] and deviations of growth parameters from the normal pattern may be the first or most prominent symptom of disease in a small child. At the individual level, FTT is thus an important indicator of physical and/or psychosocial problems in infancy, while at the population level it may constitute a significant problem involving a large number of children. Its prevalence, however, varies greatly with the definition used and the population investigated. In early clinical studies from the US, 1–5% of hospitalised children and 10–30% of children seen in out-patient clinics were reported to have FTT (Kessler and Dawson 1999). Likewise, in a Danish registry-study from 2002, done by one of the authors (EMO), 4% of 0–2-year-old hospitalised children were diagnosed with FTT, using the ICD-10 diagnosis R628. Population studies, defining FTT as conditional weight gain below the 5th percentile (see Sect. 68.5 anthropometric parameters for an explanation of this) or as weight dropping below the 3rd percentile on a weight-for-age chart have, not surprisingly, identified 3–5% (Skuse et al. 1994; Wilensky et al. 1996; Wright and Birks 2000; Blair et al. 2004; Olsen et al. 2007b), while population studies using downward crossing of two or more major weight-for-age percentiles have identified around 20% of an infant population as failing to thrive (Edwards et al. 1990; Olsen et al. 2007b). Thus, the anthropometric criteria used for defining FTT obviously influence the prevalence found and, as we shall see, also the characteristics of the children identified.

68.3 Applications to Other Areas of Health and Disease

Traditionally, FTT has been seen as either organic, or non-organic, based on the presence or absence of serious or persistent somatic illness (Kessler and Dawson 1999). Almost any kind of disease in the major organs can cause weight loss, or impede growth and weight gain in a child, but organic disease in fact primarily explains only a minority of cases (Sills 1978). Thus, in population-based studies, it has been a consistent finding that less than 10% of children identified with FTT seem to have a pure organic origin, while approximately 15% have a mixed causation. In the remaining majority of children, no organic disease is found (Wright et al. 1997; Drewett et al. 1999). Until the mid-1980s, FTT was almost entirely described in institutionalised or psychosocially disadvantaged children, and especially 'non-organic FTT' (NOFTT) was considered as being primarily caused by the absence of the mother or psychosocial deprivation (Kessler and Dawson 1999). Also, psychosocial dwarfism, a condition with retarded height growth and depressed growth hormones – primarily seen in toddlers – was sometimes used interchangeably with NOFTT. In addition to anthropometrical indices, criteria involving behavioural characteristics of the child, or the quality of the mother–child-relationship were thus proposed in early clinical studies, which strongly linked the condition to emotional deprivation. Later population studies, however, found no evidence of such an association in general (Kessler and Dawson 1999). Instead, FTT, defined solely by anthropometrical criteria (and the absence of an obvious somatic explanation), has been found to be associated with early neurodevelopmental problems, including oral motor dysfunction and early feeding problems. It has thus been recognised that a clear distinction between organic FTT and NOFTT can rarely be made, and it has been recommended that FTT should be regarded as a continuum of multifactural causality (Drotar 1985; Kessler and Dawson 1999).

[1] In children under the age of approximately 2 years, height is in principal the supine height, that is length, and height and length are used interchangeable in this chapter.

68.4 What Is the Ideal Definition of FTT?

First of all, if this is a measure of poor growth or 'thriving' the definition should identify children with exceptionally slow growth or weight gain, as opposed to children who are constitutionally small. What is ideally required therefore is a definition based on two or more anthropometrical measurements over time. Secondly, it should identify children whose slow growth relates to undernutrition and/or disease processes, and places them at a greater risk of adverse outcome. Testing the validity of the different definitions that have been used is particularly handicapped by the absence of any gold standard measure of undernutrition or abnormal growth. In practice, therefore, the only measure that can usually be applied is the proportion of normal children who fall below any particular threshold. However, a further test can be the extent to which different definitions identify children with other anthropometric criteria that suggest poor (or good) growth in combination with results from longitudinal population studies indicating reasonable anthropometrical thresholds concerning long-term risk.

68.5 Anthropometrical Parameters Used in Previous Research

Many different anthropometrical parameters and cut-off values have been used in connection with FTT, and the most frequently used anthropometrical criteria during the last couple of decades are listed in Tables 68.1 and 68.2. Table 68.3 shows some classic criteria of moderate and severe malnutrition, sometimes used interchangeably with FTT (Wright et al. 1994).

68.5.1 Attained Measures

The criteria for FTT have mainly been based on static criteria which are in turn based on the attained low size: such as single measurements of weight and/or height, usually using weight-for-age or height-for-age. In contrast, fewer have used weight-for-height or body mass index (BMI), which equates to the anthropometric classifications of malnutrition in children. The classic definition of protein-energy malnutrition (PEM) by Gomez is thus based on low weight-for-age, while WHO has long recommended height-for-age and weight-for-height as the primary indicators of nutritional status in children. When low length or height has been used as the only anthropometric parameter in connection with FTT, this has predominantly been done to identify older children with chronic FTT; this condition now resembles 'Stunting' as in chronic undernutrition. Failure to thrive in infancy may be regarded an acute or semi-acute condition resembling 'Wasting', which involves some degree of thinness as a result of loss of body tissues and poor weight gain prior to the reduced gain in height seen in chronic undernutrition or stunting. However, although the WHO still recommend low weight-for-height as the primary anthropometrical parameter of acute undernutrition (wasting), neither weight-for-height nor BMI has been used much to diagnose FTT in affluent countries (WHO 1995).

Most early studies of FTT used criteria based on attained measures of low weight or, sometimes, low length with a cut-off around the 3rd or 5th percentile, but a cut-off as high as the 10th percentile has been used in some cases. Others have based the definition on Standard Deviations (SD) and used cut-offs as low as minus 2 SD, corresponding to an attained value just above the 2nd percentile (2.28th) (Drotar 1985; Wilcox et al. 1989; Olsen 2006).

Although both weight and height measures have been used separately as the defining parameter of FTT in infancy, the term has primarily been used to clinically describe poor height or

Table 68.1 Static criteria of failure to thrive most commonly used during the last two decades

Attained growth parameter	Cut-off value	Additional requires
Weight-for-age	<3rd percentile <5th percentile <10th percentile <-2 SD-scores[a]	*Some require the criterion to be fulfiled for several months or persistently.*
Height-for-age	<3rd percentile <5th percentile ≤20th percentile <-2 SD-scores[a]	
Height as percentage of the median height-for-age	≤90%	
Weight-for-height	<3rd percentile <5th percentile ≤10th percentile <-1 SD-scores[a] <-2 SD-scores[a]	*Some require the criterion to be fulfiled for several months or persistently. And some corrects for gestational age.*
Discrepancy between height (*H*) and weight (*W*)	*H* > *W* with more than 2 SD	

Many different growth parameters and a broad range of cut-off points have been used as defining criterion of failure to thrive. This table shows examples of commonly used criteria based on attained measurements
[a]SD = standard deviation using a standard growth reference (for example the WHO/NCHS/CDC references)

Table 68.2 Dynamic criteria of FTT used during the last two decades

Attained growth parameter	Cut-off value	Additional requires
Downward crossing of weight-for-age	≥1 major percentile lines ≥2 major percentile lines ≥2 SD	
Conditional weight gain:	Identifying the slowest gaining 5% of children after adjusting for regression to the mean conditioned on a previous weight, often birthweight.	
Fall in weight-for-age From either:		
• Normal/appropriate/ >2,500 g at birth,	<3rd percentile	*Some require the criterion to be fulfiled for several months or persistently.*
• Above the cut-off value at birth	<5th percentile	
• From an earlier established curve	<10th percentile	
Persistent decline/lack of weight gain	No specification	
Documented weight loss		
Fall in height-for-age or weight-for-height	<10th percentile	
Growth failure		*Some require the presence of psychosocial/ cognitive problems*

Failure to thrive is currently most often described as weight faltering, but still, many different criteria are being used. This table shows some examples, with the most commonly used in bold

weight gain. The use of such static criteria may be convenient or necessary when follow up measures are not available, but static criteria based solely on a low weight or height will inevitably over-include constitutionally small, but otherwise normally growing children, while initially under-including larger children with slow postnatal weight gain who have not yet crossed the given low percentile cut-off.

Table 68.3 Classical criteria of Malnutrition sometimes used interchangeable with FTT

Type of malnutrition	Definition	Algorithm	Cut-off		
			Mild	Moderate	Severe
Gomez	Weight as percentage of median weight-for-age	$\frac{\text{Actual } W \cdot 100}{\text{Median } W \text{ for age}}$	75–90%	60–74%	<60%
Waterlow (Wasting)	Weight as percentage of median weight-for-height	$\frac{\text{Actual } W \cdot 100}{\text{Median } W \text{ for the actual height}}$	80–90%	70–80%	<70%
McLaren and Read	Ratio between weight and height as percentage of the ratio between the median weight and median height for age	$\frac{\text{Actual } W / H \cdot 100}{\text{Median } W \text{ for age/Median H for age}}$	85–90%	75–84%	<75%
Waterlow (Stunting)	Height as percentage of median height-for-age	$\frac{\text{Actual } H \cdot 100}{\text{Median } H \text{ for age}}$	90–95%	85–89%	<85%

This table shows some traditional definitions of malnutrition (FTT), widely used in developing countries, using an international standard growth curve; for example the NCHS/CDC/WHO curves
W = weight, H = height

68.5.2 Dynamic Measures

Dynamic measures of growth and weight gain are thus greatly to be preferred in principle, and more recent studies have attempted to using change-based (dynamic) measures (Wilcox et al. 1989; Olsen 2006).

Early population-based studies often used semi-dynamic criteria by excluding children with birthweights at or below the cut-off value (usually the 3rd percentile), resulting in identifying children with a fall from a birthweight above the cut-off value. The required birthweight differed, however, from a weight just above the 3rd till above the 25th percentile, leading again to the identification of presumably very different risk populations (Skuse et al. 1994; Wilensky et al. 1996; Drewett et al. 2001), but this impedes the monitoring of children with lower birthweights and will still under-include larger children. An attempt to solve this uses a definition of dropping through two or more major percentile lines/spaces (e.g. crossing both the 25th and 10th centile) on an ordinary weight chart. This definition seems reasonable and is widely used in both clinical practice and research, especially in the US. However, this criterion also hampers the identification of FTT in constitutionally small children because the conventional chart 'runs out' of major percentile lines to cross. Furthermore, criteria based on a simple fall on an ordinary growth chart do not allow for the phenomenon of regression towards the mean, where large children tend to cross downwards towards the mean, while small children, on average, tend to move upwards. This therefore has the effect of over-identifying over-large children regressing downwards. A further complication is that the spacing of centiles varies in some countries (notably the US) from 0.4 to 0.7 SD.

Within the last couple of decades, the use of conditional weight gain has emerged, identifying the slowest weight gaining children after allowing for the expected regression to the mean (Wright et al. 1994; Cole 1995; Olsen 2006). This is predominantly a research-based method as most conditional methods require the use of SD scores (also called Z scores). SD scores adjust for both age and gender and on average children will maintain the same SD score over time. Thus a fall in weight centile can be detected by observing a negative change in SD score and the effect of baseline SD score can be allowed for by using the method of residuals.

$$\text{Conditional change} = \text{late SDS} - \text{early SDS} * R$$

where *R* is the regression coefficient of early on late SD scores for the whole (or a reference) population. The normal range of conditional change can be predicted theoretically on the basis of *R* and this has been shown to be valid empirically (Wright et al. 1994; Cole 1995). Most commonly, weight faltering would be defined as the lower 5% or 1% threshold for conditional weight gain.

68.6 How Do Different Criteria of FTT Concur?

The basic problem concerning definitions of FTT is that the many different criteria in use can be expected, on theoretical grounds, to identify different populations of children exhibiting different risk of adverse outcomes and we cannot assess which is the best as there is no gold standard method of diagnosing FTT. However, if failure really is a condition characterised by undernutrition, you might expect that the different definitions would nonetheless to substantially overlap.

Only a few studies have compared different definitions of FTT in affluent child populations. The early studies were performed in selected clinical cohorts of referred children (Wright 1994; Raynor and Rudolf 2000). Thus, Wright and colleagues compared the degree of malnutrition according to the three criteria of Gomez, Waterlow, and McLaren and Read (see Table 68.3) in a group of 258 children under the age of 48 months (average age 17.8) referred to an infant/toddler growth clinic for evaluation of FTT. Only children with weight less than the 5th percentile or deceleration of weight crossing two major percentile-lines (defined as 95th, 90th, 75th, 50th, 25th, 10th, and 5th) were included. In addition, Raynor and Rudolf also included BMI and the Thrive index method with slow weight gain conditioned on birthweight, and compared these five criteria in a group of 83 children between 4 and 30 months of age referred to a FTT clinic with weight below the 3rd percentile or deceleration in weight gain over two percentile channels. In the latter study, children were only included in the absence of organic disease. Both studies found large differences regarding the prevalence of FTT and degree of undernutrition as identified by the different criteria. However, these two studies are prone to major selection bias since children were all identified for referral on the basis of a growth abnormality of some kind.

To our knowledge ours is the only population study to compare different definitions within a whole unselected population (Olsen et al. 2007b). In this study, seven commonly used anthropometric criteria of FTT/PEM were applied to an affluent birth cohort of Danish infants born in the year 2000, and the prevalence and concurrence were investigated in two age periods: 2–6 months and 6–11 months of age. In Table 68.4 the crude prevalence of the seven different criteria when applied to this cohort are shown. As can be seen, the prevalence greatly varied among criteria. As many as, 27% of this non-selected infant population met one or more criteria in at least one of the two age groups, and 10% met at least one criteria at both ages. Thus, according to the criteria of Gomez and Waterlow less than 2% of the children were failing to thrive in one or both of the age periods, and next to none at both ages, while more than 20% crossed two or more percentile lines from birth till at least one of the two age periods. If conditional weight gain is a reflection of undernutrition you would expect a substantial overlap with low BMI (wasting) and to some extent with low height (stunting), but in fact the concordance between them is poor, and arguably no more than chance; although many thin children were also among those with the slowest conditional weight gain and vice versa, most children with slow conditional weight gain were not wasted, and most wasted children did not have slow weight gain. Also, wasting was on the whole associated with tall stature rather than low stature.

Table 68.4 The prevalence of moderate failure to thrive when applying seven different anthropometric definitions to a normal infant population from an affluent society

	Anthropometric criterion of failure to thrive						
Age at which failure to thrive is identified	Weight fallen ≥ 2 major percentile lines from birth	Weight gain conditioned on birth weight ≤ 5%	BMI < 5th percentile	Weight < 5th percentile	Length < 5th percentile	Weight < 75% of median weight for age (Gomez)	Weight < 80% of median weight for length (Waterlow)
Age 2–6 months	14.7	5.0	4.8	3.7	3.3	1.8	1.3
Age 6–11 months	20.6	5.0	4.3	4.7	3.3	0.6	0.5
At least one of the two age groups	22.2	7.3	6.5	5.8	5.0	1.8	1.3
Both age groups	11.4	1.8	1.5	2.0	1.2	0.3	0.0

This table gives the crude prevalence of seven commonly used anthropometric criteria when applied to the Copenhagen Child Cohort 2000 (CCC 2000), in percentage of children screened by each specific criterion. The CCC 2000 consists of 6,090 children born during the year 2000 in Denmark and follow prospectively (references 22 + 11).

68.7 The Use of Growth Curves When Identifying FTT

Usually the identification of FTT has been based on age- and sex-specific percentile charts for weight or height, so valid diagnosis depends on valid growth charts. In the mid-1990s, the adequacy of older growth references was questioned, including the American NCHS reference, used since 1978 by WHO as the international standard (De Onis et al. 1997). The concerns included low frequency of measurements during the first year of life, outdated curve-smoothing techniques, and evidence of secular changes in the body size. Also, evidence of a different growth pattern in breastfed children had been found. New updated growth references from affluent societies have been published in recent years, including the UK 1990 reference (Freeman et al. 1995), the new American CDC charts based on national surveys (Kuczmarski et al. 2000), and a European growth reference (Euro Growth) based on the data from 11 European countries (Haschke et al. 2000). Also, new age-specific BMI charts covering childhood have been published recently making this method more feasible (Cole et al. 2000; WHO 2006).

However, all of these updated growth charts are growth references, showing how children in a certain population grew at a particular time, whereas a growth standard would show the optimal growth pattern for all children. Since a standard defines how children should grow, deviations are evidence of abnormal growth, and does not provide as sound a basis for such value judgements. The new growth standard from WHO provides a worldwide international standard of child growth up to age 5, using data from 6 optimally nourished cohorts worldwide (WHO 2006). The WHO have shown that infants in all six centres showed very similar linear growth, thus justifying the construction of a single world standard. When this standard is applied to UK children it shows an excellent fit for length at all ages, as expected, but also shows UK infants to be considerably heavier by the age of a year, with only around 0.5% of infants below the 2nd percentile, and similarly lowered rates of centile falls (Wright et al. 2006). This therefore suggests that the lower thresholds in use, based on local reference data, may have been set too high up till now.

68.8 Does Failure to Thrive Matter in the Long Term?

Failure to thrive, on the whole, has been found to be associated with subsequent growth delay and cognitive deficiencies in later childhood (Kessler and Dawson 1999). Furthermore, FTT has long been regarded an indicator of physical and/or psychosocial problems in early childhood with expected adverse prognoses as a result of the primary cause. However, risk factors associated with FTT have been shown to vary according to the anthropometric definition used (Olsen et al. 2007a). Thus, being among the slowest weight gaining 5% of children (from birth till around 9 months) in an affluent infant population was associated with lower size at birth, birth complications, and abnormal overall development as assessed by public health nurses. When adding the criterion of thinness (BMI below the 5th percentile) to the above criterion, FTT was associated with being small for gestational age, being thinner at birth, having poor eye-contact around 9 months of age as perceived by the parents, and again with abnormal overall development. However, when defining FTT as downward crossing of weight with two or more main percentiles (from birth till around 9 months), it was found to be associated with larger size at birth, being fully breastfed the first four living months, higher maternal age and social status of parents and with parents living together, but not with abnormal development. This strongly indicates that the validity of different anthropometric definitions of FTT greatly varies concerning identification of infants truly at risk. The commonly used criterion of downward crossing of weight with two or more main percentiles thus clearly seems to be far too over-inclusive, including children at presumably lower risk.

Only testing criteria against subsequent outcomes can truly determine whether a growth pattern is pathological. In developing countries with high child mortality rates, attained weight-for-age has been found to be a good discriminator of long-term mortality, while slow weight gain indicates short-term mortality (Bairagi et al. 1985). However, child mortality is a rare outcome in affluent societies, though poor conditional weight gain has been found to be associated with "sudden infant death syndrome" (Blair et al. 2000). Alternatively, cognitive delay and behavioural difficulties are possible outcomes of FTT in affluent populations, and, in a meta-analysis, including controlled population-based studies, Corbett SS and Drewett RF found evidence of minor cognitive delays in the children with early FTT independently of the anthropometric criteria used (Corbett and Drewett 2004). Only three of the eight population studies, however, showed a significant difference, and of these one was performed in a population of preterm children, while the other two studies, as the only ones, included both weight and height in their criterion of FTT, with Dowdney et al. defining cases as children with both weight and height below the 10th percentile at 4 years when the height of the parents were allowed for, while Wilensky et al. defined FTT as weight-for-age below the 3rd percentile for at least 3 months within the first year of living combined with a weight-for-length at or below the 10th percentile.

68.9 Conclusions

We argue that FTT as a concept defies definition simply because it does not represent an identifiable syndrome. The concurrence between different criteria of FTT is low and no single measurement seems adequate on its own for identifying undernutrition or growth delay in the general child population. Rather than using this inevitably vague and often confusing term, clinicians and researchers should be encouraged to characterize their patients on the basis of explicit and well validated measures of growth or nutritional status. For example, a combination of slow weight gain and thinness could be a valid definition of weight faltering related to undernutrition in infancy.

Table 68.5 Key features of percentiles in ordinary growth charts

1. Growth charts constitute a visual description of the expected size of children at different ages in a given population.
2. At each age point an ordinary growth chart represents the percentage distribution of ranked growth measurements at that age in the given reference population and percentile lines join given percentiles for each age.
3. In paper versions of growth charts (used in everyday clinical work) only certain main-percentiles are shown.
4. In American charts the main-percentiles are usually the 5th, 10th, 25th, 50th, 75th, 90th, 95th, while most European charts include the 3rd and 97th percentile instead of the 5th and 95th.
5. Percentiles should be interpreted as follows: if a child has an attained weight at a given age corresponding to, for example, the 25th percentile then 25% of children in the given reference-population have a weight at or below that weight at that age.
6. In some cases standard deviation (SD) lines are used instead of percentiles and these can then be used to describe more extreme parts of the distributions (e.g. -3SD).
7. UK growth charts use selected main centiles all spaced 2/3SD apart (98th, 91st, 25th, 50th, etc.) and include as extreme centiles the 0.4th (-2.67 SD) to the 99.6th (+2.67 SD).
8. As most growth charts are based on cross-sectional data, percentiles do *not* describe the growth pattern (although they are often used that way), but only whether a given child is average (or extreme) at a given point in time.
9. In computerised growth programmes, data can be expressed as Standard Deviation Scores (*Z*-scores), making description of extreme percentiles and direct comparison between different measurements, gender and ages possible.

This table gives a short description of the interpretation and use of percentiles.

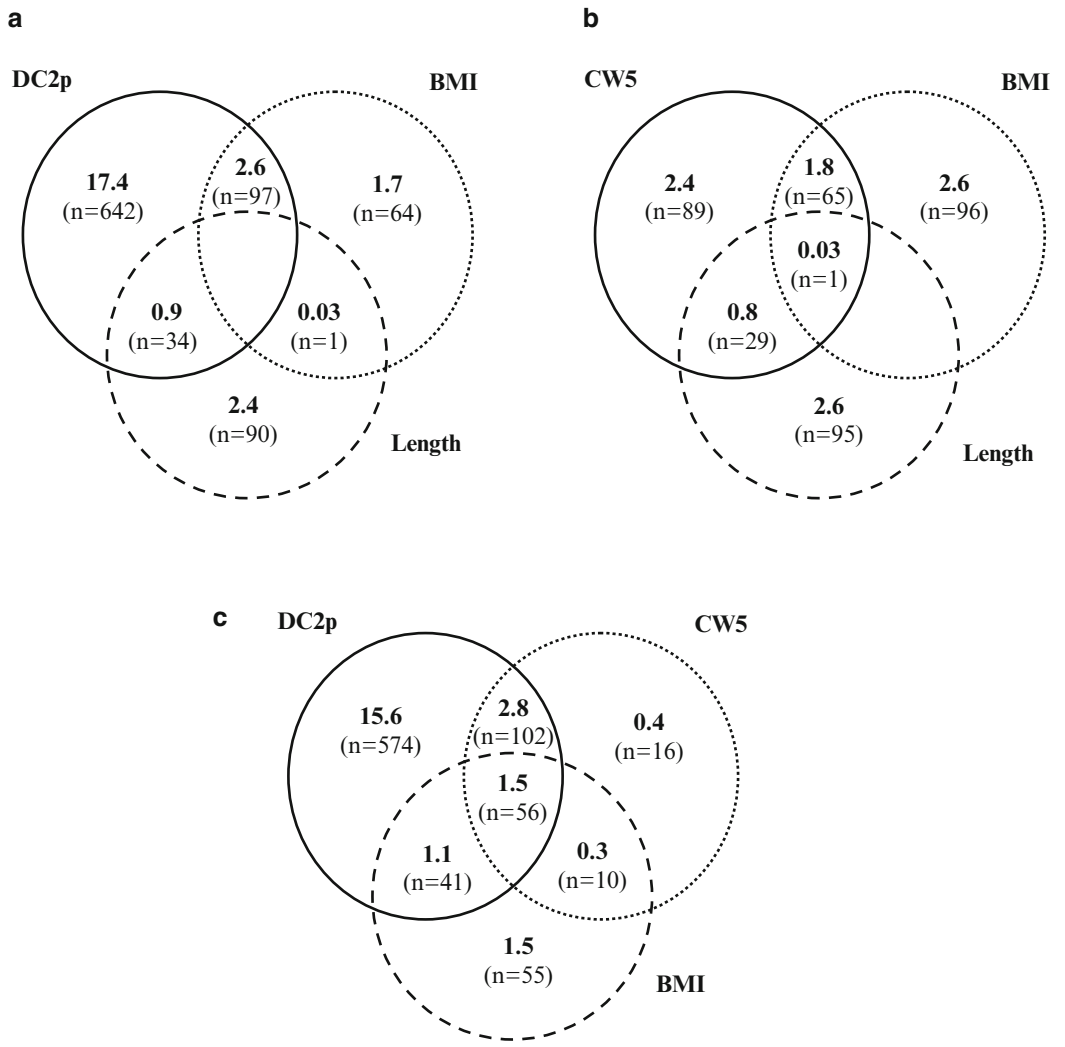

Fig. 68.1 (**a**–**c**) The concurrence between different anthropometrical criteria of weight faltering in a Danish population sample of 3,692 infants at the age of approximately 8 months (Olsen et al 2007b). (**a**) The figure shows the concurrence between 'weight downward crossing from birth ≥2 main percentile lines' (DC2p), 'BMI < 5th percentile', and 'Length < 5th percentile' in percentage of the total 3,692 children (*n*). Among the 3,692 children, 928 (25.1%) fulfiled one of these three criteria at the age of approximately 8 months. (**b**) The figure shows the concurrence between 'weight downward crossing from birth ≥2 main centile lines'(DC2p), 'weight gain < 5th percentile conditioned on birthweight'(CW5), and 'length < 5th percentile' in percentage of the total 3,692 children (*n*). Among the 3,692 children, 375 (10.2%) fulfiled one of these three criteria at the age of approximately 8 months. (**c**) The figure shows the concurrence between 'weight downward crossing from birth ≥ 2 main centile lines' (DC2p), 'weight gain < 5th percentile conditioned on birthweight' (CW5), and 'BMI < 5th percentile' in percentage of the total 3,692 children (*n*). Among the 3,692 children, 854 (23.1%) fulfiled one of these three criteria at the age of approximately 8 months

Summary Points

- Failure to thrive is a symptom, not a specific condition or syndrome.
- Various different anthropometric parameters and cut-off values have been used to define it, resulting in widely varying prevalences.
- Concordance between commonly used criteria is low

- The correlates of FTT are largely determined by the criteria used to define it, but undernutrition seems to be the commonest underlying cause.
- Definitions that involve a fall down the centile chart should always allow for the phenomenon of regression to the mean.
- The new WHO growth standards suggest that the lower threshold for weight and weight gain may have been set too high.
- It has been suggested that the term FTT is both pejorative and too vague to be clinically valid and should be replaced with more explicit descriptors such as 'weight faltering' or 'slow growth'.
- A combination of slow weight gain and thinness seems to be the most valid way of identifying weight faltering related to undernutrition.

Chapter 69
Estimation of Children's Weight in Medical Emergencies

Anne-Maree Kelly

Abstract In medical emergencies drug dosage, equipment sizing and electrical countershock dose are based on a child's weight. Severity of illness and urgency of treatment usually preclude formal measurement of weight on scales. Incorrect weight estimation could result in drug toxicity or sub-therapeutic treatment, both of which may carry serious adverse outcomes. Methods for estimating weight rely on age–length–weight relationships and include age-based formulae and length-based methods. An alternative is visual estimation of weight by a parent or clinician. Available evidence suggests that parental estimation is the most accurate [where the parent is prepared to give an estimate], followed by length-based methods such as the Broselow Tape with age-based formulae being least accurate. Among the age-based formulae, the Best Guess formulae appear to perform best. Challenges to the age- and length-based methods are significant inter-ethnic variation in the age–height–weight relationship, the trend towards increasing weight across the world and how to factor body habitus into estimation methods in a way which is easily applied.

Abbreviations

CI	Confidence interval
cm	Centimeter
ED	Emergency department
kg	Kilograms
RMSE	Root mean square error
SD	Standard deviation

69.1 Introduction

In emergency departments, it is often necessary to know a child's weight for assessment of clinical status, to enable accurate drug and intravenous fluid dose calculation, to aid selection of correctly sized equipment [such as endotracheal and nasogastric tubes] and to determine the strength of

electrical cardiac counter shock for paediatric resuscitation. Overestimation of weight could lead to drug overdosing and underestimation could result in sub-therapeutic treatment. Measuring a child's weight on a set of calibrated scales is the gold standard, but is not always possible due to the severity of illness and the urgency of treatment.

Without again going into the details of child growth, it is clear that age, height [length] and weight are inter-related. These relationships have formed the basis for methods devised to estimate children's weight in emergency situations. In the past, age-weight and length-weight charts derived from population data were used. In recent years, such charts have fallen out of use, being replaced by age-based formulae and length-based weight estimation methods. An alternative with some support is the use of weight estimation made by parents or clinicians. This chapter summarizes the basis and evidence for the more commonly used techniques, their limitations and feasibility in critical care practice.

69.2 Definitions and Statistical Considerations

For consistency and ease of understanding, agreement with actual weight will, wherever possible, be reported as an average difference, 95% limits of agreement and/or root mean square error [RMSE]. The 95% limits of agreement indicate the range within which 95% of the difference between measured and estimated would fall. Wide limits of agreement indicate poor agreement between methods, even when the average difference is small. This is based on the methodology for comparing test outcomes promoted by Bland and Altman (1986). RMSE combines an assessment of both average difference and spread of data. Where the above were not reported, standard deviation [SD] or mean percent difference is used. Where a negative difference is reported, this implies that the formula or method underestimated actual weight (Table 69.1).

69.3 Age-Based Formulae

Age-based weight estimation formulae are summarized in Table 69.2. Only some have been validated. This section will focus on formulae that have undergone validation and are in common use.

Table 69.1 Key features of estimation of children's weight in medical emergencies

1. With respect to age-based formulae, the most accurate are the Best Guess formulae, with the caveat that they have not been validated outside Australia.
2. The Broselow Tape is more accurate than age-based formulae and has the added advantage that drug doses and equipment sizes can be read directly off the tape.
3. Clinician estimation of children's weight has unacceptable error for use in clinical practice.
4. Where they are prepared to give an estimate of weight, parents are more accurate than other weight estimation methods.

This table lists the key facts relating to estimation of children's weight in medical emergencies including the relative accuracy of age-based formulae, length-based approaches and estimation by parent or clinician

Table 69.2 Summary of age-based formulae

Formula name	Ages of application (years)	Formula
Age-plus-four (also known as APLS)	1–10	Weight (kg) = 2 × [age in years + 4]
Argall	1–10	Weight (kg) = [age + 2] × 3
Best Guess Formulae	<12 months	Weight (kg) = [age in months + 9]/2
	1–5 years	Weight (kg) = [2 × age in years [rounded to the half]] + 10
	5–14 years	Weight (kg) = 4 × age in years.
Luscombe	1–10 years	Weight (kg) = [3 × age in years] + 7
Leffler	1–10 years	Weight (kg) = [2 × age in years] + 10
Theron	1–10 years	Weight (kg) = exp[0.175571 × age in years + 2.197099]
Shann	1–9 years	Weight (kg) = [2 × age in years] + 9

This table provides information regarding age of application and the formulae for calculation of more commonly used age-based weight estimation formulae

69.3.1 Age-Plus-Four Formula (Also Known as Advanced Paediatric Life Support Formula)

The age-plus-four formula, as it is called, has gained popularity through the Advanced Paediatric Life Support course and manual (Mackway-Jones 2001). The formula is expressed as weight (kg) = 2 × [age in years + 4] and applies to children aged 1–10 years.

In validation sets, mean differences between estimated and measured weight have been reported of –3.52 kg [95% CI –2.95–4.09] in a sample of UK children (Argall et al. 2003), –2.84 kg [95% CI –7.66 to +13.43 kg] in a sample of New Zealand and Pacific Island children (Theron et al. 2005), –4.2 kg [RMSE 7.5] in a sample of Australian children (Krieser et al. 2007) and 2.3 kg [95% CI 0–5.90 kg] in a sample of Indian children (Varghese et al. 2006). Thompson et al. (2007) report mean differences of –2.0 kg [SD 2.3 kg] in preschool children and –9.5 kg [SD 11.2 kg] in school aged children.

Sandell and Charman (2009) took a different approach to analysing agreement between this formula and measured weight, preferring to report the average ratio of estimated to observed weight. They found the age-plus-four formula had an average ratio of 0.88 (i.e. underestimated by an average of 12%), with 95% limits of agreement for the ratio of 0.54–1.22. Average difference was found to increase with increasing weight. Similar results were reported by Luscombe and Owens (2007) who reported a mean underestimate of weight by this formula of 18.8% [95% CI 18.42–19.21%].

When compared to other methods, the age-plus-four formula has been reported to perform less well than the best guess formulae (Krieser et al. 2007; Thompson et al. 2007), the Argall formula (Krieser et al. 2007), length-based methods (Sandell and Charman 2009), the Broselow Tape (Krieser et al. 2007; Theron et al. 2005; Varghese et al. 2006) and parental estimate (Krieser et al. 2007).

Importantly, Theron et al. (2005) elegantly demonstrated that ethnicity and related body size significantly impacts this formula. They report that the mean percent error difference [(actual weight – estimated weight × 100)/actual weight] varied from +11.13% in Pacific Island children to –5.12% for Asian/Indian children.

69.3.2 Argall Formula

This formula was derived by Argall et al (2003) from a 300-patient dataset that they collected to test the agreement between actual weight and estimated weight using the age-plus-four formula and the Broselow Tape. The formula they derived is weight (kg) = [age in years + 2] × 3. In their derivation set, they reported a mean difference between actual weight and estimated weight of –0.52 kg, but did not report 95% limits of agreement or range of differences by age.

Two validation studies have been reported. Nguyen et al. (2007) investigated it in a multiethnic sample of 410 children attending an Australian ED. They reported a mean difference between measured and estimated weight of –1.66 kg, with wide 95% limits of agreement (–12.3 to +8.9 kg). RMSE was 5.65. Overall, only 37% of Argall estimates were within 10% of measured weight. The formula underestimated weight in heavier children, especially those weighing more than 35 kg. It performed better in Asian children than in Caucasians (mean bias –0.86 vs. –1.66 kg, RMSE 4.66 vs. 5.71). In a sample of Indian children (Varghese et al. 2006), the Argall formula was found to overestimate weight. Mean difference was 2.38 kg [95% CI –0.80 to +8.70] for the <15 kg group and 7.0 kg [95% CI –0.21 to +14.32] for the >15 kg group. Black et al. (2002) report a mean percent difference from actual weight of –13.8%, with percent difference increasing with age.

When compared to other methods, the Argall formula has been reported to better estimate children's weight than the age-plus-four formula (Krieser et al. 2007). It has been reported to be less accurate than parental estimate, the Best Guess formulae and the Broselow Tape (Krieser et al. 2007; Varghese et al. 2006).

69.3.3 Best Guess Formulae

This set of three formulae, each for a different age group, was developed by Tinning and Acworth (2007) by applying regression analysis to data on 70,181 presentations of children to a tertiary ED in Brisbane, Australia. Two validation studies have been reported: one in the population from which the formulae were derived and the other in a different Australian ED with a multiethnic population.

Thompson et al. (2007), in a retrospective study of high acuity patients, found a mean difference between estimated and actual weight of –0.1 kg [SD = not reported] for infants, 0 kg [SD 2.3 kg] for preschool children and 0.6 kg [SD 9.6 kg] for school age children. The Best Guess formulae were considerably more accurate than the age-plus-four formula.

In a multiethnic sample from another hospital, Kelly et al. (2007) reported a mean difference for the preschool age group of 0.9 kg [95% CI –0.5 to 5.3 kg]. However, for 24% of the sample the estimated weight was more than 20% different from the measured weight. Almost all of these were overestimations of weight. For the school-age group, the average difference between estimated and measured weight was 0.4 kg, but with very wide 95% limits of agreement, –14.4 to +15.2 kg. In 36% of cases, estimated weight was more than 20% different from the measured weight, with approximately two-thirds of these being overestimations of weight. In ten children, the formula overestimated weight by more than 50%. Further analysis showed that overestimation occurred in the lower body mass index children in this multiethnic sample.

When the Best Guess formulae have been compared to other weight estimation methods, they have been reported to be more accurate than the Argall and age-plus-four formulae, have a similar accuracy to the Broselow Tape, and be less accurate than parental estimation (Krieser et al. 2007). It should be noted that the Best Guess formulae have not been tested outside Australia.

Table 69.3 Summary of agreement between age-based formulae and actual weight

Formula		No. studies	No. subjects	Weighted mean difference [estimated – actual weight, kg]	Range of mean differences (kg)
Age-plus-four		4	1,786	–2.79	–4.2 to +2.24 kg
Argall		2	577	–0.22	–1.7 to +3.43
Best	Infant	1	272	–0.1	*
Guess	Preschool	2	1,025	0.35	0 to 0.9
	School	2	957	0.56	0.4 to 0.6

This table summarizes agreement between age-based formulae and actual weight for formulae where this data is available

69.3.4 Weaknesses of Age-Based Formulae

While age-based formulae are, in the main, easy to calculate, the evidence suggests that ethnicity and body habitus pose serious challenges to them. Unless they have been satisfactorily validated in the population to which they are being applied, there is considerable risk of a clinically relevant difference between estimated and actual weight. This risk is less for younger children and increases with increasing weight. Additionally, as age–weight relationships may change with time, the accuracy of these formulae may diminish unless the formulae are re-validated at intervals.

69.3.5 Summary

The relative weighted performance of the age-based formulae is summarized in Table 69.3. Available evidence suggests that the most accurate are the Best Guess formulae, with the caveat that they have not been validated outside Australia.

69.4 Length–Weight Relationship-Based Methods

69.4.1 The Broselow Tape

While length–weight charts have been available for some decades, in the 1980s, James Broselow, a North Carolina-based emergency physician, extended this concept by developing a simple tool to improve weight estimation using height–weight data from the National Center for Health Statistics [USA]. Based on the 50th centile of weights for height, the Broselow Pediatric Emergency Tape® provides emergency personnel with standardized, precalculated medication doses, fluid resuscitation volumes and equipment sizes using color-coded zones based on similar height–weight correlations. The tape is used by laying it alongside the patient and reading the color zone that matches the child's height (Table 69.4). It is important to note that it can be used only for children between 46 and 145 cm in length and between 3 and 36 kg. It has undergone several revisions over the years, the last in 2007.

The predictive accuracy of the Broselow Tape has been tested in a number of studies. Reported mean differences between estimated and actual weight range from –2.4 to +0.3 kg, with a weighted mean difference of –1.07 kg (Table 69.5). Several studies have reported that agreement is better for

Table 69.4 Key features of the Broselow Tape

1. The tape can only be applied to children between 46 and 145 cm in length and between 3 and 36 kg.
2. It is used by laying it alongside the patient and reading the color zone that matches the child's height.
3. The length–weight relationships used to calculate the Broselow Pediatric Emergency Tape® are based on the 50th centile of weights for height of US children.
4. The tape classifies children, based on length, into color-coded weight zones.
5. Zones on the tape list precalculated medication doses, fluid resuscitation volumes and equipment sizes based on length–weight correlations.

This table lists the key features of the Broselow Tape

Table 69.5 Summary of agreement between estimated weight using Broselow Tape and actual weight

Authors	Year	Sample size	Mean difference between estimated and actual weight (kg)
Argall et al.	2003	300	–2.74
Hofer et al.	2002	904	–0.52
Jang et al.	2007	665	–1.54
Krieser et al.	2007	410	–1.80
Nieman et al.	2006	7,813	–1.01
Theron et al.	2005	909	–1.89
Varghese et al.	2006	500	0.03
Weighted mean difference			–1.10

This table summarizes agreement between estimated weight using Broselow Tape and actual weight along with a calculation of weighted mean difference

smaller children but that this method increasingly underestimates weight for older children, especially above 15–20 kg (Hofer et al. 2002; Jang et al. 2007; Krieser et al. 2007; Lubitz et al. 1988; Nieman et al. 2006; So et al. 2009; Varghese et al. 2006). Overall the Broselow Tape has been shown to predict weight within 10% in 60% of cases (Hofer et al. 2002; Lubitz et al. 1988; Nieman et al. 2006).

Where the Broselow Tape has been compared to other methods, it has been found to be more accurate than the age-plus-four and Argall formulae (Krieser et al. 2007; Varghese et al. 2006) and the Best Guess formulae (Krieser et al. 2007). It has been shown to be less accurate than parental estimate (Krieser et al. 2007).

The accuracy of Broselow Tape has been shown to be subject to interethnic variation. It underestimates weight in Pacific Island and New Zealand Maori children with a reported mean difference of –1.89 kg with wide limits of agreement (–8.87 to 5.11 kg) (Theron et al. 2005). On the contrary, it has been shown to overestimate weight for Indian children with the size of the overestimation increasing with increasing weight (Ramarajan et al. 2008).

69.4.1.1 Refinements and Adaptations

The approach taken by Broselow and colleagues has been successfully adapted for use in third world countries where the children have different height–weight relationship and the range of treatments is smaller (Molyneux et al. 1999). They report that a locally developed tape correctly estimated actual weight with less than 20% error in 79% of children. This compared favorably with clinician estimates that were only accurate to within 20% in 54% of cases.

Yamamoto et al. (2009) proposed a refinement of the Broselow method using the color-coded section on the tape combined with a body habitus icon to calculate drug doses. The suggested icons

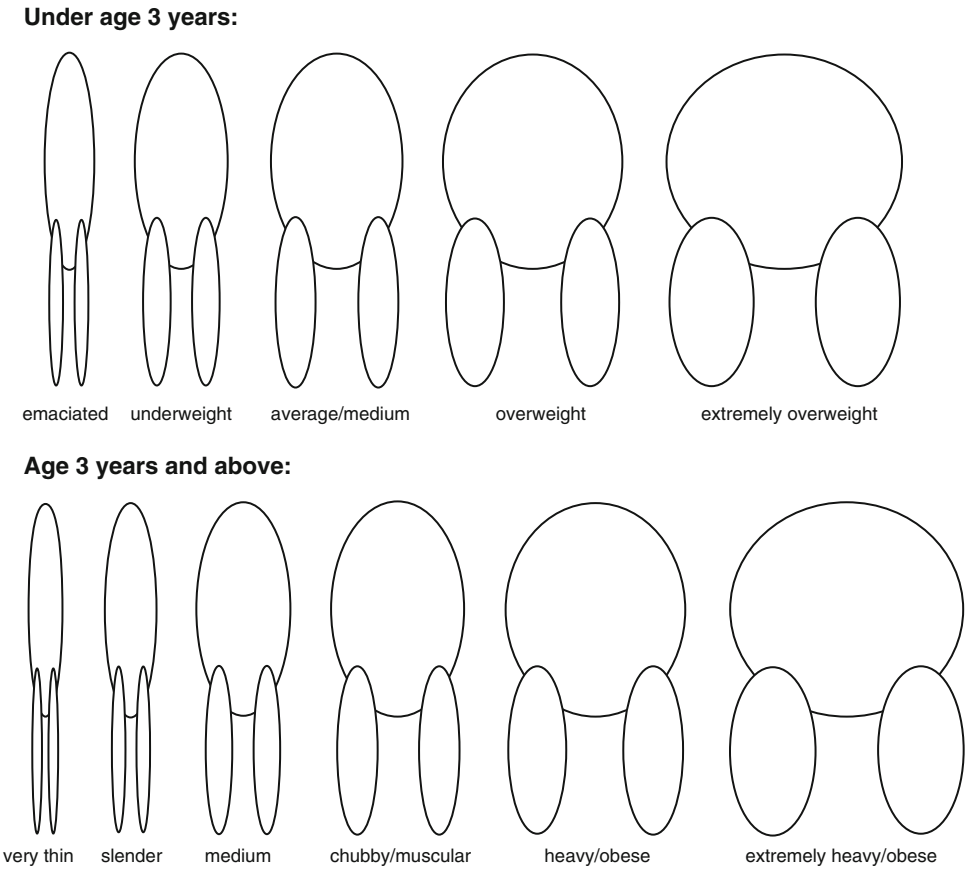

Fig. 69.1 Body habitus icons used by Yamamoto in refinement of Broselow Tape weight estimations. (Reproduced with permission from Yamamoto et al. 2009). This figure shows the body habitus icons used by Yamamoto in a refinement of Broselow Tape weight estimations

are shown in Fig. 69.1. Epinephrine doses estimated using the new method showed significantly smaller mean errors compared to estimations made using the Broselow Tape. No data comparing weight estimations given. The new method requires a subjective assessment of body habitus against charts and a computer program as calculations are quite complex and logarithmic. This will likely limit its application in emergency situations.

69.4.2 Devised Weight Estimation Method

This method, developed by Garland et al. (1986), is based on the height–weight curves and incorporates weight and body habitus to estimate children's weight. Children are subjectively classified as "slim", "average", and "heavy" and weights are estimated from the 5th, 50th and 95th percentiles on the height–weight curves. They reported that using this method 61% of estimated weights were within 10% of actual weights and 95% were within 25% of actual weights. In validation sets, mean percent error has been reported as –3.7% (Dubois et al. 2007) and 0.55% (Black et al. 2002). Error increased at weights above 20 kg (Dubois et al. 2007). A potential weakness of this method is

inter-rater variability in the assessment of body habitus. Both of the validation studies explored this and found good to excellent agreement, with accuracy dependent on experience (Black et al. 2002; Dubois et al. 2007).

69.5 Other Methods Based on Physical Features

Foot length is used in forensic science and archeology to estimate height and weight, but few studies have explored its use in estimation of children's weight, especially in medical emergencies. Bavdekar et al. (2006) collected data from 500 children aged up to 24 months and found good correlation between foot length and weight ($r^2 = 0.88$). They derived a formula for prediction of weight from foot length: Weight (g) = –5.15 + [1.35 × foot-length (cm)]. They tested its accuracy by calculating doses of emergency drugs based on actual weight and weight predicted from foot length and found that the calculated dose exceeded the dose based on actual weight by 2.4%. To date, this method has not been validated or compared for accuracy to other weight estimation methods.

69.6 Estimation by Parents or Clinicians

69.6.1 Parental Estimate

Data regarding accuracy of parental estimation of weight is mixed. Goldman et al. (1999) reported good accuracy of parental estimation with 51.5% of estimates within 5%, 73.4% within 10% and 87.5% within 20% of actual weight. They also found that mothers were in general more accurate than fathers. Harris et al. (1999) reported a mean percent difference between estimated weight and actual weight of –1.3% with there being more than 15% error in 16% of cases. Of concern, however, was the finding that the range of percent error was from –41% to +292%. Leffler and Hayes (1997) found parents to be accurate to within 10% of actual weight in 80% of cases and that parental estimation was more accurate than the age-based formula.

One of the larger studies of parental weight estimation is by Krieser et al. (2007). They found it to be quite accurate when parents were prepared to give an estimate (89% of cases). They report a mean difference of –0.6 kg [RMSE 3.1] and that parental estimate was more accurate than the Argall formula, age-plus-four and Best Guess formulae and the Broselow tape (Table 69.6). Parent estimate maintained its accuracy across the weight range; whereas, the Argall and age-plus-four formulae's performance dropped off sharply with increasing weight (particularly above 40 kg), as did that of the Broselow tape.

69.6.2 Clinician Estimate

It could be suggested that hospital staff see and treat lots of children, so they should be able to accurately estimate a child's weight based on that experience. Evidence, unfortunately, does not support this hypothesis. On the contrary, the data suggests that clinicians are poor at estimating weight and that methods to assist them in weight estimation are required.

Table 69.6 Comparison of weight estimation methods (Reproduced with permission from Krieser et al. 2007)

Method	Mean difference (kg)	RMSE[a]	% agreement within 10% of measured weight
Parent estimate	–0.6	3.1	78
Broselow tape	–1.8	4.4	61
Best Guess formulae	0.7	5.4	42
Argall formula	–1.7	5.7	37
Age-plus-four formula	–4.2	7.5	34

This table compares the accuracy of weight estimation methods including parental estimate, the Broselow Tape, the Best Guess formulae, the Argall formula and the age-plus-four formula
[a]Root mean square error

69.6.2.1 Doctors

Three studies have explored the accuracy of doctors at estimating children's weight. Uesugi et al. (2002) in a study of children undergoing surgery, found that on average 42% of weight estimations by clinical staff were outside an acceptable percent error range. The percent error in estimation was larger for infants and small children (particularly those weighing ≤20 kg) than for older children. Harris et al. (1999) found a mean percent difference from actual weight of –4.8% with more than 15% difference in 29% of cases. Grieg et al. (1997) reported an average difference between estimated and actual weight of 0.21 kg (SD 7.14 kg); however, the range of error was –100% to +300%, with wide individual variation between doctors in accuracy.

69.6.2.2 Nurses and Other Clinicians

Data regarding weight estimation by clinicians other than doctors is sparse. Molyneux et al. (1999) found that clinic staff were only accurate to within 20% of actual weight in 54% of cases. Similarly, Lubitz et al. (1988) found clinical staff to be accurate within 10% of actual weight in 47% of cases. Harris et al. (1999) reported a mean percent difference from actual weight of –7%; however, in 40% of cases there was more than 15% error. Regarding paramedics, Vilke et al. (2001) reported that while the majority of the estimations [82.5%] were within 50% error of the actual weight, 17.5% of cases had between 50% and 100% error.

69.6.3 Summary

Clinician estimate is not sufficiently accurate or consistent to be acceptable in safe clinical practice. Where they are prepared to give an estimate of weight, parents are more accurate than other weight estimation methods.

69.7 Challenges to Weight Estimation Methods

The weight estimation methods that rely on age–height–weight relationships are challenged by how they were developed, interethnic variation and the changing pattern of the age–height–weight relationship.

Most age-based formulae and the Broselow Tape were developed in first world countries with largely Caucasian populations. There has been little exploration of whether they are generalizable to

poorer countries and different ethnic backgrounds. Indeed, there is some data to suggest significant problems with age-based formulae weight estimations between ethnic groups (Theron et al. 2005; Ramarajan et al. 2008; Varghese et al. 2006). How these differences are quantified and adaptions made remain unanswered.

An additional challenge is posed by large for age, small for age and obese children. Two methods have attempted to factor body habitus into weight estimations with some success (Garland et al.1986; Yamamoto et al. 2009). These methods share the potential weakness of inter-rater variability in the assessment of body habitus. More research is needed to address this issue.

The data upon which both of the age and length [height]-based weight estimation methods are based is population data of age–height–weight relationships. This is by no means stable over time. Better nutrition will alter it in developing countries while the trend to childhood obesity may alter it in the first world. Regular re-validation/re-calibration may be necessary to ensure acceptable accuracy for clinical use.

69.8 Practical Considerations

In medical emergency and resuscitation situations, estimation of weight needs to be simple and accurate. Parental estimate fulfils these criteria, if the parent is not too distressed to give a considered answer. The Broselow Tape [or similar] is also easy to use with acceptable accuracy. It has the added advantage of providing drug doses and equipment sizes read directly off the tape. For drugs, this cuts out a calculation step that can be the source of error. Most of the age-based formulae only require simple calculation, but correctly remembering the formula or having it at hand when needed might be problematical. The methods that rely on computer calculations cannot be applied in facilities that do not have this infrastructure, including large parts of the developing world.

Summary Points

- With respect to age-based formulae, available evidence suggests that the most accurate are the Best Guess formulae, with the caveat that they have not been validated outside Australia.
- The Broselow Tape is more accurate than aged-based formulae and has the added advantage that drug doses and equipment sizes can be read directly off the tape.
- Clinician estimation of children's weight has unacceptable error for use in clinical practice.
- Where they are prepared to give an estimate of weight, parents are more accurate than other weight estimation methods.
- In order of descending accuracy, preferred methods for estimating children's weight in medical emergencies are parental estimation, The Broselow Tape [or similar] followed by age-based formulae.

Chapter 70
Anthropometry and HIV-Infected Children in Africa

Herculina Salome Kruger

Abstract The epicentre of the HIV/AIDS epidemic is in sub-Saharan Africa. There are few data on the growth and anthropometric indices of HIV-infected children in Africa. HIV-infected children are at risk for malnutrition and have unique nutritional needs due to the physiological demands of growth and the infection. Anthropometry is an affordable and noninvasive method of assessment of body composition and can be used to monitor changes in body composition and nutritional risk of HIV-infected children. Measurements in children should include serial measurements of height/length and weight, mid-upperarm circumference, waist circumference and skinfolds in children older than 1 y to reflect fat and lean body mass. These measurements are often the only option in African countries, because more sophisticated methods of body composition assessment are expensive and seldom available. HIV-infected children not receiving HAART had significantly smaller weight-for-age *z*-score (WAZ) and height/length-for-age *z*-score (HAZ) than control children. After HAART became more generally available around 2004, studies indicated significantly improved WAZ, but not HAZ, in children from the initiation of HAART to 6–24 months of treatment. Before HAART became available, more than 50% of infants died before attaining the age of 2 y in Uganda, whereas 8–9% of children died in equally resource-limited African countries within the first 12–24 months of receiving HAART. There are indications that HAART improves lean body mass in HIV-infected children, with a delayed effect on linear growth and a trend to an increase in fat mass. Such increase in lean body mass is remarkable, because maintenance and increases in lean body mass can be problematic in HIV-infected children. However, HAART has side effects, such as the lipodystrophy syndrome, characterized by peripheral fat wasting, central fat accumulation and metabolic changes. HIV-infected children in the USA and Europe have been shown to develop lipodystrophy syndrome. No published data of lipodystrophy in HIV-infected children receiving HAART in Africa are currently available, probably due to limited availability of HAART in Africa. It is difficult to use anthropometry to measure lipodystrophy in HIV-infected children due to the changes of normal growth and development that occur during childhood and adolescence. The challenge remains to improve height and reduce protein catabolism in HIV-infected children concomitant to a decrease in viral load to undetectable levels. Anthropometry can detect stunted growth, underweight and excessive fat deposition on the trunk. Appropriate interventions can prevent detrimental effects of both undernutrition and overweight in HIV-infected children in Africa.

70.1 Introduction

Human immunodeficiency virus (HIV) infection progressing to acquired immunodeficiency syndrome (AIDS) is one of the leading causes of death in Africa. The epicentre of the HIV/AIDS epidemic is in sub-Saharan Africa, with an estimated 2.3 million children under the age of 15 y living with HIV in South Africa in 2005 (Shisana et al. 2005). There are still few data on the growth and anthropometric indices of HIV-infected children in Africa. The effects of both HIV infection and antiretroviral (ARV) therapy on body composition had been studied in adults in various studies. The progressive, selective wasting of subcutaneous fat from the face and limbs of HIV-infected adult patients treated with highly active antiretroviral therapy (HAART) first emerged in the 1990s. Lipodystrophy is an abnormality in the metabolism or deposition of fats which is often seen in HIV-infected patients, especially in patients receiving ARV therapy (Viraben and Aquilina 1998). Data are becoming increasingly available about the effects of HIV infection and ARV drugs on body composition in children in Africa (Beau and Imboua-Coulibaly 1997; Berhane et al. 1997; Bobat et al. 2001; Reddi et al. 2007). HIV-infected children are at high risk of malnutrition and have unique nutritional needs due to the physiological demands of growth and development. Malnutrition in children results in growth retardation, increased susceptibility to infection and decreased functional capacity (Berhane et al. 1997; Bobat et al. 2001; Ellis and Molyneux 2007; Ferrand et al. 2007; Berger et al. 2008).

Anthropometry is an affordable and noninvasive method of assessment of body composition and can be used to monitor changes in body composition and nutritional risk of children with HIV infection. Measurements in children should include serial measurements of height (or length) and weight, with calculation of body mass index (BMI) and plotted on the World Health Organization (WHO) growth charts for children (WHO 2005). Mid-upperarm circumference (MUAC), skinfolds and mid-upperarm muscle area in children older than 1 y reflect fat and lean body mass stores. Lean body mass changes measured by anthropometry agree reasonably well with fat-free mass (FFM) changes measured by dual X-ray absorptiometry (DXA) in patients with HIV infection (Knox et al. 2003). Changes in waist circumference (WC) can be measured to detect visceral fat accumulation over time. WC percentiles have been published for children 5–17 y and can be used to monitor 'normal' and excessive increase in WC over time (Fernandez et al. 2004).

70.2 Growth in Healthy and HIV-Uninfected Children

Children have unique nutritional needs due to the physiological demand of growth and physical development. Undernutrition has been related to growth retardation, higher susceptibility to infections and decreased functional capacity (Knox et al. 2003). During adolescence body composition changes take place along with adipose tissue redistribution. Assessment of body fat abnormalities in children is complicated by the difference between abnormal body composition and normal physical development and growth. Serial measurements over time must take normal increases due to growth into account. Similarly, waist:hip ratio (WHR) may not be a useful tool for identification of abnormal truncal obesity in children, because unlike in adults, waist and hip circumferences change with age in children (Knox et al. 2003; Fernandez et al. 2004). In some studies WHR was measured and applied to detect abnormal fat distribution in children. If serial measurements of at least weight and height of HIV-infected children can be done, trends over time can be followed and growth failure can be identified early, so that appropriate interventions can be implemented (Knox et al. 2003).

Undernutrition in children is generally reported in terms of prevalence of stunting, underweight and wasting. Berger et al. (2008) compared these conventional indices with a composite index of anthropometrical failure in a group of HIV-infected and affected orphaned children in Kenya. Because the conventional indices are not mutually exclusive, the total prevalence of undernutrition could not be determined from these indices. When the composite index was used, it was possible to identify children with multiple anthropometric failures, who may have been at risk for poor health outcomes. One-third of the children in this study presented with some form of anthropometric failure. These children were at an increased risk for adverse health outcomes and were in need of nutrition assistance. Furthermore, 22 out of the 170 children (13%) had multiple anthropometric failures and were in urgent need for aggressive nutrition support. If only conventional indices were used to categorize the children, it would not have been possible to identify the 13% of children in urgent need for intervention (Berger et al. 2008). MUAC and mid-upperarm muscle circumference reflect lean body mass, whereas triceps and sub-scapular skinfold thickness in children older than 1 y reflect body fat stores (Miller et al. 2001). These measurements are often the only option in African countries, because more sophisticated methods of body composition assessment are expensive and seldom available (Knox et al. 2003).

70.3 Growth and Body Composition in Children with HIV and Aids

During acute infection HIV-infected children generally lose weight and even when they are not acutely ill, they do not gain weight at the same rate as uninfected children. Poor linear growth is also an indication of advanced AIDS (Verweel et al. 2002). HIV-infected children not receiving HAART had significantly smaller weights and heights than control children (Beau and Imboua-Coulibaly 1997; Berhane et al. 1997; Arpadi et al. 2000; Bobat et al. 2001; Berger et al. 2008; Arpadi et al. 2009). HIV RNA content was positively associated with growth failure in HIV-infected children in the USA and the Netherlands (Arpadi et al. 2000; Verweel et al. 2002).

Children with growth failure had lower energy intakes, but also lower total energy expenditure (EE) and resting EE than children with a normal rate of growth. When resting EE was adjusted for differences in FFM and age, there were no differences between the resting EE of children with and those without growth failure. Rate of growth and FFM, respectively, were inversely related to plasma HIV content (Arpadi et al. 2000). Studies suggest that tissue lost consists of a greater proportion of FFM than would be expected from undernutrition alone, probably due to increased protein catabolism (Beau and Imboua-Coulibaly 1997; Arpadi et al. 2000; Villamor et al. 2005). Factors such as poor oral intake, malabsorption and hypermetabolism may be involved in growth failure of HIV-infected children. It appears that viral replication and possibly inflammatory response could impair dietary intake, disturb normal metabolism and subsequently impede growth of the children. Loss of fat and FFM could both contribute to body weight loss, but studies of their relative contribution have yielded conflicting results (Arpadi et al. 2000). Observations from studies suggest that a preferential loss of FFM occurs early in the disease progression and that cachexia, rather than protein-energy malnutrition, is an important mechanism of weight loss (Moscicki et al. 2006). However, FFM as a percentage of body weight was not significantly different between groups of HIV-infected and non-infected children. These findings suggest that no preferential catabolism of FFM occurs in HIV-infected children. Improved lean body mass is likely to be associated with a reduction in morbidity and mortality (Berhane et al. 1997; Arpadi et al. 2000; Knox et al. 2003), whereas severity of growth failure, indicated by a low weight-for-age *z*-score (WAZ), height/length-for-age *z*-score (HAZ) and weight-for height/length *z*-score (WHZ) or BMI-for-age *z*-score (BMIZ) and loss of lean body mass as measured by low MUAC were associated with an increased risk of mortality (Berhane et al. 1997; Bobat et al. 2001; Villamor et al. 2005). Conservative treatment of HIV infection in children with nutritional support alone apparently helps to increase weight and fat mass, but does not necessarily improve linear growth or lean body mass (Verweel et al. 2002).

70.4 Studies of Growth and Body Composition in Children with HIV Infection in Africa

HIV infection in children in Africa is associated with general undernutrition (Eley et al. 2002; Ferrand et al. 2007). HIV-infected children not receiving HAART had significantly smaller WAZ and HAZ than control children in some studies in South Africa (Bobat et al. 2001) and Uganda, (Berhane et al. 1997) but the difference was not significant in a study in Cote d'Ivoire (Beau and Imboua-Coulibaly 1997). Stunting was not a discriminating factor for HIV infection in this study. The lack of difference may have been due to the endemic malnutrition in the study area (Beau and Imboua-Coulibaly 1997). In studies where children were followed from birth, these differences were already statistically significant at the age of 3 months (Bobat et al. 2001). After HAART became more generally available around

2004, studies indicated significantly improved WAZ and WHZ in children from the initiation of HAART to 6–24 months of treatment (Bolton-Moore et al. 2007; Jaspan et al. 2008; Kabue et al. 2008). In studies in Malawi and South Africa of children with mean age of 7.5 and 5.7 years, respectively, WAZ and WHZ, but not HAZ, improved significantly over 6 months after initiation of HAART (Reddi et al. 2007; Kabue et al. 2008). In this age group, reversal of stunting could not be achieved over the relatively short period of 6 months. Baseline WAZ above +1 was protective against stunting and the most severely undernourished children had a higher prevalence of stunting (Kabue et al. 2008). Before HAART became available, more than 50% of HIV-infected infants died before the age of 2 y in Uganda (Berhane et al. 1997), whereas 8–9% of children died in equally resource-limited African countries within the first 12–24 months of receiving HAART (Bolton-Moore et al. 2007; Ellis and Molyneux 2007; Jaspan et al. 2008). The results of studies describing anthropometric indices of HIV-infected children in Africa are summarized in Tables 70.1 and 70.2.

70.5 Antiretroviral Drugs and Anthropometric Indices

70.5.1 Antiretroviral Drugs and Improved Body Composition

ARV therapy is a combination of medications used to suppress viral replication and progression of HIV disease. A combination of three ARV drugs working synergistically is referred to as HAART. A list of ARV drugs prescribed for HIV-infected children is presented in Table 70.3 and typical ARV drug choices as prescribed in South Africa and other African countries are shown in Table 70.4 (Department of Health 2005; Jaspan et al. 2008). ARV treatment dramatically improved growth and body composition in HIV-infected children after starting treatment (Bolton-Moore et al. 2007; Ellis and Molyneux 2007; Kabue et al. 2008). HIV-infected children treated with HAART exhibit large decreases in plasma HIV RNA concentrations (viral load) and subsequent increases in the number and percentage of circulating CD4 T-lymphocytes. These changes have resulted in significant improvements in clinical outcomes and quality of life, dramatically decreasing the risk of serious opportunistic infections, progression to AIDS, and death. For many HIV disease has been transformed from an acutely life-threatening illness into a manageable chronic disease, allowing children once not expected to survive to live well into adulthood (Miller et al. 2001; Verweel et al. 2002; Reddi et al. 2007; Jaspan et al. 2008). Studies showed that the survival of peri-natally HIV-infected children improved as a result of the introduction of combined ARV therapies (Verweel et al. 2002; Bolton-Moore et al. 2007; Reddi et al. 2007).

Studies reported a positive influence on the growth of HIV-infected children treated with HAART. Height and weight in relation to age improved in children in whom a reduction of the viral load was achieved (Miller et al. 2001; Verweel et al. 2002; Bolton-Moore et al. 2007; Ellis and Molyneux 2007; Kabue et al. 2008). WAZ and WHZ, but not HAZ, improved significantly over 6 months after initiation of HAART in most studies. In contrast to the increase of the BMI in adults on HAART, BMI did not increase in all studies of children effectively treated with HAART (Miller 2001; Verweel et al. 2002; McComsey et al. 2003; Guillen et al. 2007). BMI increased more in children with an advanced stage of infection and who had a poor nutritional status at initiation of HAART (Verweel et al. 2002). Miller et al. (2001) found no significant increase in HAZ, triceps skinfold or mid-upper-arm muscle circumference percentile in HIV-infected children with a mean age of 6.8 y after 2 y of treatment with HAART, including PI. After controlling for age, sex, CD4 *z*-score and viral load, a significant increase in mid-upperarm muscle circumference percentile was found, as well as a

Table 70.1 Results of studies of HIV-infected children in Africa not receiving HAART

Author and country	Study participants	Aim/exposure and outcomes measures	Results
Beau and Imboua-Coulibaly (1997) Ivory Coast	66 children, >15 months, with marasmus, 45% HIV-infected	To assess whether stunting is a discriminating factor for HIV infection	HIV-infected children had lower mean WAZ, WHZ, BMIZ and HAZ than uninfected children, but differences were not significant
Berhane et al. (1997) Kenya	520 infants enrolled at birth from HIV-infected ($n = 84$) and uninfected mothers, followed over 25 months	To study the effect of HIV on somatic growth of infants and the relationship between nutritional status and mortality	Weight-for-age and length-for-age growth curves of HIV-infected infants were significantly lower than those of HIV-uninfected controls; 54% of HIV-infected infants died before attaining the age of 2 y
Bobat et al. (1998) South Africa	48 HIV-infected and 93 uninfected infants, followed for 12 months	To study the effect of HIV infection on somatic growth of infants and the relationship between nutritional status and mortality	HIV-infected infants had significantly lower mean WAZ and HAZ, but not lower WHZ than uninfected infants from 3 months of age; infants who died early had more severe stunting, underweight and wasting than those who survived
Villamor et al. (2004) Tanzania	687 children 6–60 months old, hospitalized with pneumonia, followed up 2 y	To estimate risk of mortality according to HIV status of the children	HIV infection was associated with an adjusted fourfold higher risk of mortality; stunting, wasting and low MUAC were significantly associated with risk of death
Eley et al. (2002) South Africa	60 HIV-infected children, median age 25 months	To document anthropometric and micronutrient disturbances	28% of children had WAZ <–2, 58% had a HAZ <–2; no association between micronutrient status and HAZ or WAZ
Ferrand et al. (2007) Zimbabwe	32 HIV-infected children, 8–19 y	To document anthropometric and clinical features	62% of children had HAZ <–2 and were immune-suppressed
Berger et al. (2008) Kenya	170 children younger than 5 y, orphaned or vulnerable children, impacted by HIV/AIDS	Comparison of conventional indices of undernutrition with a composite index	Conventional index: 31% stunting, 14% underweight, 6% wasting compared to a composite index estimating 38% anthropometric failure. Conventional indices underestimate undernutrition.

This table summarizes results of studies of HIV-infected children in Africa not receiving HAART, including country, aims or exposures and outcome measures

Table 70.2 Results of studies of HIV-infected children in Africa receiving HAART

Author and country	Study participants	Aim/exposure and outcomes measures	Results
Bolton-Moore et al. (2007) Zambia	Cohort of 2,938 HIV-infected children, median age of 81 months at initiation of HAART	To report early clinical and immunological outcomes of children receiving HAART	8.3% of children died, 56% of these within 90 days of initiating HAART; Low WAZ (median –3.5, IQR –4.5 to –2.2) was associated with mortality; mean WAZ increased from –2.2 (95%CI – 1.9, –1.7) to –1.6 (95%CI – 1.7, –1.6) at 6 months
Ellis and Molyneux (2007) Malawi	238 HIV-infected children, 7–212 months old	To assess changes in WAZ, WHZ and survival of the children after initiation of HAART	WAZ and WHZ improved significantly from baseline to 12 months on HAART, 8.4% of children died before 12 months on HAART
Reddi et al. (2007) South Africa	Cohort of 151 children, mean age 5.7 y at initiation of HAART	To report clinical and immunological outcomes of children receiving HAART over at least 8 months	8.6% of children died; median WAZ increased with +1 (p, 0.0001) and HAZ increased with +0.4 ($p = 0.28$) over 8 months
Jaspan et al. (2008) South Africa	Cohort of 391 HIV-infected children, median age of 26 months at initiation of HAART	To report clinical and immunological outcomes of children receiving HAART over 24 months	9% of children died; WAZ increased from median –2.5 (interquartile range –4, –1.2) to –0.1 (interquartile range –1.5, 0) over 24 months
Kabue et al. (2008) Uganda	Cohort of 749 children, mean age 7.5 y at initiation of HAART	To report clinical and immunological outcomes of children receiving HAART over at least 6 months	WAZ increased from mean 7.7th percentile to mean 13.3th percentile, WHZ improved from 7.9th to 13.8th percentile over 6 months, but HAZ remained unchanged at the 8.6th percentile; baseline WAZ >1 was protective against stunting

This table summarizes results of studies of HIV-infected children in Africa receiving HAART, including country, aims or exposures and outcome measures

Table 70.3 A list of ARV drugs prescribed for HIV-infected children

Drug class	Antiretroviral drug
Non-nucleoside reverse transcriptase inhibitors (nNRTI)	Efavirenz (EFV)
	Nevirapine (NVP)
Nucleoside reverse transcriptase inhibitors (NRTI)	Stavudine (D4T)
	Lamivudine (3TC)
	Zidovudine (AZT)
	Didanosine (ddI)
	Abacavir (ABC)
Protease inhibitors (PIs)	Nelfinavir (NFV)
	Indinavir (IDV)
	Lopinavir (LPV)
	Ritonavir (RTV)
	Lopinavir/Ritonavir (LPR/r)

This table lists ARV drugs prescribed for HIV-infected children according to drug class

Table 70.4 ARV drug choices for HIV-infected children in South Africa and other African countries

Regimen	6 months up to 3 years	Over 3 years and >10 kg
First-line	Stavudine (D4T)[a]	Stavudine (D4T)[a]
	Lamivudine (3TC)[a]	Lamivudine (3TC)[a]
	Lopinavir/Ritonavir[b] (LPR/r)	Efavirenz (EFV)
Second-line	Zidovudine (AZT)[a]	Zidovudine (AZT)[a]
	Didanosine (ddI)	Didanosine (ddI)
	Nevirapine (NVP) if age <3 years OR	Lopinavir/Ritonavir[b] (LPR/r)
	Efavirenz (EFV) if age > 3 years	

Department of Health, South Africa (2005)
This table lists ARV drugs prescribed for HIV-infected children in South Africa according to drug class
[a]Abacavir (ABC) may be prescribed if adverse events occur with other NRTIs
[b]If tolerance develops for Lopinavir/Ritonavir, nelfinavir may be prescribed

borderline increase in HAZ of 0.17 SD ($p = 0.1$). The authors concluded that PI therapy in HAART contributed to improved lean body mass in HIV-infected children, with a delayed effect on linear growth and a trend to an increase in fat mass, measured by triceps skinfold thickness. This is in line with experience from nutritional treatment of children with undernutrition from chronic disease, where improved linear growth followed the initial response of an increase in weight (Miller et al. 2001; Verweel et al. 2002). The increase in lean body mass in this study is remarkable, because maintenance and increases in lean body mass can be problematic in HIV-infected children (Arpadi et al. 2000; Villamor et al. 2005). Verweel et al. (2002) found a trend toward significant increases in HAZ and WAZ of HIV-infected children after 96 weeks of HAART. When the results of children who responded to HAART with a significantly reduced viral load to <500 copies/mL and improved CD4 T-cell *z*-score were analyzed separately, significant increases in HAZ and WAZ were found. There was a significant positive correlation between increases in WAZ and BMIZ, respectively, and CD4 T-cell *z*-score increase from baseline. The study showed that improved growth of HIV-infected children receiving HAART can be sustained for at least 96 weeks (Verweel et al. 2002)

70.5.2 Antiretroviral Drugs and Lipodystrophy

However, this therapy has numerous side effects, such as the lipodystrophy syndrome characterized by peripheral fat wasting, central fat accumulation and metabolic changes (Viraben and Aquilina 1998). Two types of lipodystrophy can be distinguished namely lipoatrophy, characterized by localized fat loss in limbs, face and buttocks, and lipohypertrophy characterized by central fat accumulation on the abdomen, breasts and the posterior neck ("buffalo hump"). This syndrome has been well described in adults (Viraben and Aquilina 1998), but HIV-infected children in the USA and Europe have also been shown to develop lipodystrophy syndrome (Amaya et al. 2002; McComsey and Leonard 2004; Hartman et al. 2006; Guillen et al. 2007). No published data of lipodystrophy in HIV-infected children receiving HAART in Africa are currently available, probably due to the short time since the initiation of HAART at pediatric clinics and limited availability of HAART in Africa (Bolton-Moore et al. 2007). It is difficult to measure lipodystrophy in HIV-infected children due to the changes of normal growth and development that occur during childhood and adolescence (McComsey et al. 2003).

Table 70.5 Reference values for hypercholesterolemia and hypertriglyceridemia according to the toxicity scales of the Pediatric AIDS Clinical Trials Group Protocol

Toxicity scale	Hypercholesterolemia		Hypertriglyceridemia	
Grade 0	0–4.4 mmol/L	0–170 mg/dL	0–1.5 mmol/L	0–135 mg/dL
Grade 1	4.41–12.9 mmol/L	171–499 mg/dL	1.51–8.46 mmol/L	136–749 mg/dL
Grade 2	12.95–19.4 mmol/L	500–749 mg/dL	8.5–13.5 mmol/L	750–1,199 mg/dL
Grade 3	>19.4 mmol/L	>750 mg/dL	>13.5 mmol/L	>1,200 mg/dL

Adapted from Amaya et al. (2002)

This table presents reference values for hypercholestrolemia and hypertriglyceridemia according to the toxicity scales of the Pediatric AIDS Clinical Trials Group Protocol

In the absence of a unifying definition for lipodystrophy, children are often assessed based on the individual features associated with lipodystrophy. In a study by Amaya et al. (2002) fat redistribution was defined as fat wasting of extremities, face or buttocks; fat accumulation on the abdomen or dorsocervical spine ("buffalo hump") and/or breast enlargement. Children were categorized into four groups depending on the number of lipodystrophy features observed: no clinical or laboratory abnormalities (Group A), hyperlipidemia alone (Group B), fat redistribution and hyperlipidemia (Group C) and fat redistribution, hyperlipidemia and peripheral insulin resistance (Group D). Hyperlipidemia was defined as the presence of either hypercholesterolemia or hypertriglyceridemia according to the toxicity grading scales of the Pediatric AIDS Clinical Trials Group Protocol as shown in Table 70.5 (Amaya et al. 2002). Hartman et al. (2006) rated lipoatrophy in HIV-infected children in the face, neck, arms, legs and buttocks, whereas lipohypertrophy was rated at the abdomen, breasts and dorsocervical spine as absent, mild (noticeable on close inspection), moderate or severe (readily noticeable). Cases with one or more moderate or severe features of lipodystrophy were classified as cases (Hartman et al. 2006). In persons with lipodystrophy regression equations to calculate percentage body fat based on anthropometry may not be appropriate. Anthropometry may, however, be useful to detect regional fat distribution changes (Knox et al. 2003). The torso:arm ratio (TAR) of skinfold thickness was calculated in a study of Dutch children as the ratio of (subscapular + supra-iliac) to (biceps + triceps) skinfolds and was used as a measure of relative abdominal obesity (Hartman et al. 2006). During acute illness when an increase of tissue fluids occurs, anthropometry may not accurately reflect skinfold thickness. Nutritional risk can be better defined if a marker for lean body mass or body cell mass is available (Knox et al. 2003).

In this study of forty children, 2–16 y old in the USA, seven children (18%) showed evidence of fat redistribution at a mean age of 11.7 ± 0.8 y. The characteristics of the three boys and four girls with fat redistribution were as follows: one had peripheral wasting alone, one had abdominal adiposity alone, one had breast enlargement alone, one had both abdominal and dorsocervical adiposity and the remaining three had both peripheral fat wasting and abdominal adiposity (Amaya et al. 2002). In a study in France children without lipohypertrophy had significantly smaller BMI and skinfold thickness, within the normal range, compared to children with lipohypertrophy. The children with lipohypertrophy also had BMI in the normal range, but greater skinfold thickness at central body sites. Their increased supra-iliac skinfold thickness in relation to peripheral skinfold thickness indicated an abnormal fat distribution for their age (Beregszaszi et al. 2003). A study of Dutch children did not detect any cases of lipohypertrophy or mixed lipodystrophy, but four out of 34 children had lipoatrophy. The children were between 3 months and 18 y of age and received a range of different HAART regimens. The children with lipoatrophy had significantly smaller arm and leg circumferences and thinner skinfolds than children without lipoatrophy, but significantly higher WHR and TAR, indicating relatively higher abdominal fat content (Hartman et al. 2006). In a study in Spain children with lipohypertrophy had a significantly higher BMI than those without lipohypertrophy (Guillen et al. 2007).

Of forty children in the USA study, 29 (73%) had hyperlipidemia at a mean age of 9.4±3.3 y. No organomegaly or ascites was present, but seven children with fat redistribution also had hypertriglyceridemia and hypercholesterolemia. Three children (8%) had laboratory evidence for peripheral insulin resistance. Nine children (23%) successfully completed a 3-day diet history. Eight of these nine children presented with hyperlipidemia, and one had no lipodystrophic features. Four hyperlipidemic patients had elevated dietary fat intake. The remaining four hyperlipidemic children and the single unaffected child had normal dietary fat intakes (Amaya et al. 2002). The sample size in this study was small, but indicates a fairly high prevalence of hyperlipidemia, not necessarily associated with high dietary fat intake.

Although no published data of lipodystrophy in HIV-infected children receiving HAART in Africa are currently available, children should be monitored for the development of lipodystrophy and appropriate interventions should be made.

70.5.3 Putative Factors for the Development of Lipodystrophy

Progressive peripheral subcutaneous fat wasting, truncal fat accumulation, dyslipidemia and insulin resistance in HIV-infected patients on antiretroviral therapy have been attributed to the long-term toxicity of ARVs, especially HIV protease inhibitors (PIs) (Viraben and Aquilina 1998) (Table 70.6). There was no apparent relationship between exposure to a specific antiretroviral agent and the development of lipodystrophic features in some studies (Amaya et al. 2002; Hartman et al. 2006), whereas PIs such as nelfinavir, indinavir and ritonavir as well as zidovudine, stavudine and didanosine have been implicated in other studies (Viraben and Aquilina, 1998; McComsey et al. 2003). The use of a combination of medication containing stavudine and didanosine (NRTI) for longer than 1 year was significantly more often seen in children with lipoatrophy (Hartman et al. 2006).

Fat wasting, however had been observed in patients who have never taken PIs in more recent studies, possibly implicating the effect of nucleoside analogue reverse transcriptase inhibitor (NRTI) therapy. PIs have a predominant influence and may act synergistically with NRTIs. NRTIs appear to predispose individuals to slowly progressive fat loss, which is markedly accelerated when a PI and

Table 70.6 Key features of HAART and lipodystrophy

Anti-retroviral (ARV) therapy is a combination of medications used to suppress viral replication and progression of HIV disease in HIV-infected persons.
HIV-infected persons will not receive treatment with one ARV drug only, but with a combination of three ARV drugs according to standard country-specific protocols.
A combination of three ARV drugs working synergistically is referred to as HAART.
HIV-infected children receiving HAART present with significantly better weight gain than controls not receiving HAART.
HAART may cause side-effects including nausea, vomiting, diarrhea, headache or skin rash
The lipodystrophy syndrome is characterized by fat wasting of the face, arms and legs, central fat accumulation on the trunk, increased blood cholesterol and increased triglycerides.
Two types of lipodystrophy can be distinguished namely lipoatrophy, characterized by fat loss on the limbs, face and buttocks, and lipohypertrophy characterized by central fat accumulation on the abdomen, breasts and the posterior neck (“buffalo hump”).

(Viraben and Aquilina 1998).

This table summarizes key features of HAART and lipodystrophy, including possible side-effects and benefits of HAART

ARV anti-retroviral, *HAART* highly active anti-retroviral therapy

NRTIs are combined. Stavudine leads to an earlier onset of clinically apparent fat wasting and higher serum lactate concentration compared with zidovudine. In the cohort study of Hartman et al. (2006), PI was not related to lipoatrophy (Hartman et al. 2006).

Other risk factors considered to be associated with the development of lipodystrophy in HIV-infected children include age, HIV-1 viral load, exposure to individual ARV medications, duration of ARV therapy and dosing of drug regimens. Patient age, viral load, duration of PI or NRTI therapy did, however, not appear to be associated with the development of lipodystrophy in children (Amaya et al. 2002; Beregszaszi et al. 2003). An important factor that showed a significant association with lipodystrophy was antiretroviral drug dosing. Young children who received pediatric dosing were less likely to develop lipodystrophy than older children with drug dosing based on adult recommendations (Amaya et al. 2002).

Changes in body composition progress with increased exposure to ARV therapy and the degree of peripheral fat loss and visceral fat accumulation were associated with the duration of treatment, but independent of the immunologic stage of the disease or immunologic response (Amaya et al. 2002; Beregszaszi et al. 2003). All children with lipodystrophy in the study of Hartman et al. (2006) were pubertal and had used stavudine and didanosine. Their mean duration of HAART was 70.5 months, compared to 51 months of the children without lipoatrophy (Hartman et al. 2006).

70.5.4 Use of Anthropometry to Detect Lipodystrophy

When considering the measurement of body composition, a precise measure of the regional body composition is essential to distinguish between true central obesity and pseudotruncal obesity. Early detection of lipodystrophy is difficult and there are no clear anthropometric cut-off points (Hartman et al. 2006). In clinical observation the abdomen may appear to be more extended with thinning of the limbs. Anthropometry can help to monitor changes in MUAC, WC and skinfold thickness over time in children receiving HAART, but cannot be regarded to give a precise characterization of these changes (Amaya et al. 2002; Knox et al. 2003). It was observed that the children with lipodystrophy had significantly smaller arm and leg circumference, and their skinfolds were thinner. They could also be distinguished from controls by a WHR *z*-score of +1 standard deviation or higher and a sum of skinfolds *z*-score of at least -1 standard deviation (Hartman et al. 2006).

The physical examination and anthropometric measurements that were performed in the study of Hartman et al. (2006), rated the fat redistribution in the arm, back and abdominal areas. The biceps and triceps skinfold thicknesses were measured at the upper arm midway between elbow and shoulder, the subscapular skinfold at the back, at the lower tip of the scapula and in the abdominal region above the iliac crest. The torso:arm ratio (TAR) of skinfolds was measured for an indication for relative abdominal obesity. Children with lipoatrophy had borderline, significantly lower median BMI *z* scores than controls, and median arm and leg circumference *z*-scores were also lower. Median triceps skinfold, suprailiac skinfold and the sum of skinfold *z*-scores were also lower, whereas median waist:hip ratio (WHR) *z*-score was significantly higher. Median TAR *z*-score was increased in children with lipoatrophy, but the difference was not statistically significant (Hartman et al. 2006).

Children with lipoatrophy had a normal waist circumference, but WHR was significantly higher compared with controls, showing that the abdominal circumference was relatively greater than hip circumference. These findings suggest a relatively greater intra-abdominal fat content. However, normal waist circumference implies that the abdomen seems extended through thinning of the limbs and the higher WHR represents pseudotruncal obesity, which is in concordance with a large study in adults (Hartman et al. 2006).

70.5.5 Treatment of Lipodystrophy in HIV-Infected Children

Longitudinal studies of the consequences of lipodystrophy in children are lacking, but the expected outcome would be premature cardiovascular disease. There are also no published data regarding the treatment of hyperlipidemia in HIV-infected children receiving HAART. Dietary changes and exercise are generally recommended as the first intervention in uninfected children with hyperlipidemia. Lipid-lowering drugs may interact with ARV drugs. The best strategy may be to switch from a PI to a PI-sparing regimen (McComsey et al. 2003). A study in 17 HIV-infected children showed that a switch from a PI to efavirenz was associated with significant lowering of fasting total cholesterol, low-density lipoprotein cholesterol, triglycerides and the total cholesterol:high-density lipoprotein cholesterol ratio after 24 and 48 weeks of efavirenz treatment. None of the children received lipid-lowering drugs. No indication of insulin resistance was found in the children, and neither fasting insulin nor C-peptide changed significantly over the duration of the study. No changes in body fat content, mid-thigh and mid-upperarm circumferences, triceps or thigh skinfolds, or waist:hip ratio was found over the 48 weeks of the study. Lean body mass, measured by BIA did, however, increase significantly. Throughout the study period virologic suppression was maintained (McComsey et al. 2003). Children should be monitored for early signs of lipodystrophy and appropriate interventions should be done. In most cases ARV drugs may be switched, but dietary changes may be recommended by a dietician in children with hyperlipidemia.

70.6 Applications to Other Areas of Health and Disease

Detection of undernutrition by using anthropometry is useful to identify children in need for nutrition support. Prevalence of undernutrition in a community or population provides the necessary information on which to base nutrition policy and programmes. Instead of conventional indices of undernutrition, it is recommended that a composite index of undernutrition should be applied to identify children with multiple anthropometric failure. These children are in need for urgent nutrition intervention and can be targeted for nutrition support. If anthropometric failure is found in >30% of a community or population, this may be an indication for blanket intervention (Berger et al. 2008). A study on infants born to HIV-infected mothers indicates that children with a WAZ <-1.5 were at an increased risk of death. The poor nutritional status of these infants may have represented the association between infection-induced cachexia, associated with poor food intake, malabsorption and mortality (Berhane et al. 1997; Arpadi et al. 2000; Bolton-Moore et al. 2007). Alternatively poor nutritional status may have accelerated the progression from HIV infection to AIDS and death. Early aggressive nutrition support for undernourished children may delay HIV progression to AIDS and death (Berhane et al. 1997; Bobat et al. 2001; Bolton-Moore et al. 2007).

The influences of changes in body composition (weight, height, growth, body fat, muscle mass or fat and muscle distribution) on the pharmacokinetic parameters of the antiretroviral drugs need to be explored. These changes in body composition can be monitored using anthropometric measurements and should be used to calculate appropriate pediatric dosages of HAART and other medications. Dosages are currently mainly calculated on the basis of body weight, but adjustment of dose for the proportion of lean mass to fat mass may be more appropriate.

Fat redistribution is associated with metabolic alterations in glucose homeostasis and lipid metabolism, even in HIV-uninfected persons. Insulin resistance occurred only in HIV-infected

lipodystrophic children, but dyslipidemia was also found in non-lypodystrophic children receiving ARVs (Beregszaszi et al. 2003). Children with lipodystrophy could be distinguished from controls by an increased C-peptide level, an indication of increased insulin resistance (Hartman et al. 2006). In children with C-peptide above the upper limit of normal, median *z* scores of the waist circumference were significantly increased when compared with children with normal C-peptide. Children with C-peptide above upper limit of normal had significantly increased median *z* scores of the BMI, arm and waist circumference in comparison with the controls that had normal C-peptide (Hartman et al. 2006).

Grade 1 hyperlipidemia, hyperglycemia, hyperinsulinemia and glucose intolerance were evaluated in a study of lipodystrophy by Amaya et al. (2002). There were no significant differences in the values between the children with lipoatrophy and the controls (Amaya et al. 2002). High-density lipoprotein cholesterol, free fatty acids, glucose and insulin were not above the upper limit of normal for patients or controls (Hartman et al. 2006). A study in France also found no glucose intolerance in HIV-infected children receiving HAART, but signs of insulin resistance in the children in this group with lipohypertrophy (Beregszaszi et al. 2003). These results underline the importance of monitoring of HIV-infected children receiving HAART for signs of lipodystrophy and early treatment.

70.7 Practical Guidelines

Anthropometry should be used to monitor growth and nutritional status of HIV-infected children, independent of whether they are receiving HAART or not. In resource-poor settings at least height, weight and MUAC should be measured. If children receive HAART, WC and/or WHR should also be measured in an attempt to detect lipodystrophy. Because children are growing, an increase in all parameters is expected. It is thus important to calculate *z*-scores or use percentiles on growth charts or tables to assess progress of children according to their age and gender (WHO 2005).

70.8 Conclusion

Significant differences in body composition were found between HIV-infected children and age-matched controls, although wasting was rare. Treatment with HAART had a positive effect on height and weight in children with HIV-infection. This effect is sustained for at least 2 y and is associated with the successful application of HAART. Contrary to the BMI increase in adults treated with HAART, BMI in children does not increase in all patients successfully treated with HAART, but only in those with a low BMI at initiation of HAART (Verweel et al. 2002). FFM decreased relatively to age in some children receiving HAART, while there is redistribution of fat mass and these changes resulted in the BMI remaining relatively constant. The challenge remains to improve height and weight and reduce protein catabolism in HIV-infected children concomitant to a decrease of viral load to undetectable levels (Arpadi et al. 2000). HIV-infected children have a longer life span with the use of HAART, but the effective and safe treatment of the adverse effects of ARV therapy is imperative. Nutritional assessment, including anthropometry can help to detect stunted growth, as well as excessive fat deposition on the trunk and appropriate interventions can prevent detrimental effects of both undernutrition and overweight.

Summary Points

- Measurements in HIV-infected children should include serial measurements of height/length and weight, mid-upperarm circumference, waist circumference and skinfolds in children older than 1 y to reflect fat and lean body mass.
- HIV-infected children not receiving HAART were significantly more underweight and stunted than control children.
- With HAART undernutrition improved significantly in children from baseline to 6–24 months of treatment and a smaller percentage of children died before the age of 2 y.
- HAART has side effects, such as the lipodystrophy syndrome, characterized by peripheral fat wasting, central fat accumulation and metabolic changes. No published data of lipodystrophy in HIV-infected children receiving HAART in Africa are currently available.
- Anthropometry can help to detect stunted growth, underweight and excessive fat deposition on the trunk, so that interventions can prevent detrimental effects of both undernutrition and overweight in HIV-infected children in Africa.

Chapter 71
Waist Circumference Measures and Application to Thai Children and Adolescents

Uruwan Yamborisut and Kallaya Kijboonchoo

Abstract The prevalence of childhood obesity has been increasing worldwide. Assessment of changing trends in nutritional and health status of the child population could be achieved using accurate and reliable body composition techniques. Waist circumference is a simple anthropometric measure that is useful for the detection of abdominal obesity which reflects the sum of subcutaneous and visceral adipose tissues in the trunk region. Research evidence shows that waist circumference is highly correlated with weight-for-height and body mass index. Waist circumference is also a good predictor of cardiovascular risk factors. Measurement of waist circumference can be performed at different sites of the trunk region and the measurement technique requires a standardized procedure. Reference data of percentile distributions of waist circumference among children and adolescents are now available in many countries, including Thailand. Waist circumference cut-off can be an advantageous tool for a large-scale screening of children who are at risk for overnutrition and for tracking child growth. Future studies need to address the universal waist circumference benchmark and the application of waist circumference as well as weight-to-height ratio for growth monitoring and public health intervention program towards promoting a healthy child population.

Abbreviations

AUC	Area under curve
BMI	Body mass index
CT	Computerized tomography
DBP	Diastolic blood pressure
FFM	Fat-free mass
HDL-C	High-density lipoprotein cholesterol
IAAT	Intra-abdominal adipose tissue
LDL-C	Low-density lipoprotein cholesterol
MRI	Magnetic Resonance Imaging

WHZ	Weight-for-height *Z* score

71.1 Introduction

The prevalence of childhood obesity has been strikingly increasing worldwide (Dehghan et al. 2005; Ogden et al. 2006). Overweight and obesity in children have significant impact on both physical and psychological health. Children who are obese tend to become obese adults and are at great risk of developing non-communicable chronic diseases. The increase in childhood obesity rate stimulates clinicians and nutritionists to search for reliable and appropriate anthropometric techniques to use for identifying children and adolescents who are at risk. Biological factors regarding child age, gender, and ethnic differences also influence changes in body composition during child growth. In general, girls accumulate body fat more than boys, and much more during pubertal development. With respect to fat-free mass (FFM), gender difference is negligible until the age of 14 years after which males will have more FFM than female adolescents (Ellis 1997; Malina 2005). Obese children tend to have greater total body fat (TBF) with excess fat on the trunk region than normal weight children. Assessment of intra-abdominal adipose tissue (IAAT) can be directly quantified with sophisticated imaging techniques, that is, computerized tomography (CT) and magnetic resonance imaging (MRI), and the amount of adipose tissue is measured as cross-sectional area or volume of fat mass. However, these are seldom used due to their high cost and radiation exposure in the CT technique, and they may not be appropriate for health screening in a large population. Among many reference methods, waist circumference (WC) has been proved to be an indirect anthropometric index to determine body fat distribution (Goran 1998a) and change in WC could predict risk for adverse health consequences. In this chapter, the authors will present WC measurements associated with fat distribution as well as measurement technique. The use of WC as a tool for childhood overweight and obesity screening in many countries including Thailand will also be highlighted.

71.2 Significance of Waist Circumference

Waist circumference (WC) is an anthropometric measure of fat distribution, particularly abdominal obesity, and is widely used. The inter-subject variation in WC reflects the variation in IAAT. The use of WC as an index of adiposity provides additional health information to weight-for-height or body mass index (BMI) since WC is tracked on the given abdominal fatness.

71.2.1 Factors Influencing Intra-Abdominal Adipose Tissue

71.2.1.1 Gender and Ethnic Differences in Fat Distribution

The anatomical distribution of adipose tissues shows different patterns of change with age and gender. Sexual dimorphism of fat distribution is clearly explicit during pubertal development. Generally, subcutaneous adipose tissue (SAT) deposition increases in the trunk in boys leading to the phenotype known as "android" and SAT deposition increases in the gluteal–femoral region in girls, the "gynoid" fat pattern. A study by Fox (Fox et al. 2000) in adolescents using the MRI technique indicated that IAAT and SAT areas are significantly increased in boys and girls by the second year of follow-up period. Boys had deposited greater IAAT and the IAAT/SAT ratio increased significantly, but this ratio decreased in girls. The influence of ethnicity on body fat distribution has been investigated in a few studies. Huang (Huang et al. 2001), based on a CT study, estimated that the rate of change of abdominal visceral adipose tissue (VAT) was greater in White than Black prepubertal children but no difference in SAT between ethnic groups was found. Change rates for VAT and SAT did not differ between boys and girls. He (He et al. 2002) showed that African–American and Caucasian prepubertal girls had greater arm, leg, and gynoid fat compared with boys whereas Asian girls and boys had greater trunk fat compared with African–American and Caucasian adolescents. A study in adolescents using skinfold measurement also found more trunk SAT deposition in Asian than White and Black children (Malina et al. 1995).

71.2.1.2 Total Body Fat Mass

Total body fat is an important determinant factor of IAAT. The difference in adiposity between obese and non-obese children is remarkably found in SAT (Fox et al. 1993) and the portion of the variance in IAAT is explained by total fat mass (Goran et al. 1998b).

71.2.1.3 Hormones

The change in hormone levels, particularly female sex hormones, during puberty is known to affect regional fat distribution (de Ridder et al. 1992) and at different Tanner stages, puberty was associated with greater fat mass which was more accumulated in the trunk region (Goulding et al. 1996).

71.2.2 The Relation of Waist Circumference to Fat Distribution and Metabolic Disorders

Increased abdominal adiposity in children and adolescents is associated with dyslipidemia, diabetes, insulin resistance, and high blood pressure whether the fat distribution is assessed with advanced techniques (Caprio et al. 1995; Gower et al. 1998; Huang et al. 2002) or assessed with WC (Savva et al. 2000; Maffeis et al. 2003; Lee et al. 2006; Kim and Park 2008). As mechanism underlying these metabolic disorders, it has been explained that IAAT is more sensitive to lipolysis than adipose tissue at other sites, thereby, releasing the increased free fatty acids into the portal circulation. Excess of circulating free fatty acids may induce an increase in hepatic triglycerides (TG) synthesis leading

to hyperinsulinemia and insulin resistance (Bjorntorp 1992). Attempts have shifted toward the use of simple anthropometric tools, for example, WC and/or trunk-to-extremity subcutaneous fat ratio, to describe fat distribution. In addition, enlarged WC has been proved to be a reliable anthropometric index for screening the metabolic syndrome in children and adolescents (Moreno et al. 2002).

71.3 The Relation of Waist Circumference to Other Anthropometric Indices

While WC has been proved to be a reliable index of abdominal adiposity, waist-to-hip ratio (WHR) has been shown to be a less sensitive proxy measure of central adiposity in prepubertal and adolescent children (Goran et al. 1998b; Taylor et al. 2000). One study found the WHR was not consistently associated with cardiovascular risk in prepubertal children (Gillum 2001). A few studies found a relationship between combined WC and BMI on health outcomes. Janssen (Janssen et al. 2005) found in children 5–18 years old that combined BMI and WC provided greater predictive value on cardiovascular risk than BMI or WC alone. Moreover, WC and BMI showed a relatively strong positive correlation (r = 0.68–0.73) (Neovius et al. 2005; Fredriks et al. 2005).

Another measure, the waist-to-height ratio (WHtR), has been recently shown to be positively associated with abdominal obesity and cardiovascular risk factors in children (Savva et al. 2000; Kahn et al. 2005; Yan et al. 2007). Freedman (Freedman et al. 2007) also indicated that WHtR rather than BMI provided a higher predictive value on serum cholesterol while BMI was slightly better in predicting children with high systolic blood pressure (SBP). In adults, the WHtR value of ≤ 0.5 is proposed as cut-off value for normal weight persons (Hsieh and Yoshinaga 1995). WHtR can be easily obtained by measurement of WC and height and then calculated by dividing WC by height. WHtR permits the same boundary values for gender and ethnicity in the adult population. However, the application of this ratio index and its relation to metabolic disorders should be investigated in children and adolescents.

71.4 Practical Guidelines for Waist Circumference Measurement

Accurate measurement of pediatric body composition is challenging. Waist circumference correlates well with body fat mass and is a good predictor of intra-abdominal fat. Waist circumference can be used alone or combined with body weight, height and subcutaneous skinfold to reflect child growth and over-nutrition problems. Owing to its simplicity, children can measure and evaluate WC themselves. However, such measurement still requires standardized procedures and well-trained staff to get accurate and reliable values.

The measurement technique involves several important practical points. The measuring tape should be flexible but inelastic and it is recommended to be about 0.7 cm wide. Measuring WC with tape that has a spring-retractable mechanism should be carefully done and the retraction spring tension on the tape should not affect the measurement. Prior to measurement, the subject should wear light clothing and stand erect with the abdomen relaxed with both arms at sides and the feet together. The positioning of the tape on the trunk region is important because this can affect the reliability. The plane of the tape around the trunk must be perpendicular to the long axis of the body and the tape is held around the body part but not compressing the subcutaneous tissue. Waist circumference should be taken at the end of normal expiration with measurement recorded to the nearest 0.1 cm (Callaway et al. 1988). Measurements should be performed in triplicate.

The locations of WC measurement have varied according to the anatomical site of body. Many investigators have documented the reference site of WC: midway between the lowest rib and the iliac crest is recommended by the Word Health Organization (World Health Organization 1998); the smallest circumference of the torso which is at the level of natural waist (Lohman et al. 1988), at the level of the umbilicus (Savva et al. 2001), and at the level immediately above the iliac crest (National Institute of Health 2000).

71.5 Waist Circumference of Children and Adolescents in Different Countries

In children and adolescents, body fat distribution can be described by WC, by WHtR and/or extremity-to-trunk skinfold ratio. Since the evidence shows that enlarged WC is positively associated with high risk for metabolic complications and morbidity, the use of WC as an anthropometric tool for identifying children at risk gains more attention in research and intervention applications. Waist circumference distribution and reference data have been widely studied in many countries (Table 71.1). The differences in location sites of measurement make it somewhat difficult to compare the results among countries and a single standardized location site should be considered as an important point to overcome this problem. Waist circumference can be easily determined by practitioners and/or children and adolescents themselves and it is an informative index in addition to BMI and weight-for-height measures. However, measurement of WC should be carefully done because child age, gender, and ethnicity as well as the abdominal site of measurement affect the variation of the WC values.

71.6 Risk Classification Based on Waist Circumference Cut-Off Value

Research on WC cut-offs for predicting adverse health consequence in children and adolescents is limited. Most studies had been carried out to determine the cut-off values of WC derived from maximization of sensitivity and specificity of the measure and the value corresponding to ≥75th percentile was found to be more associated with adverse fasting blood glucose, lipid profile, and elevated blood pressure (Table 71.2). The WC cut-off that should be adopted for different child age groups remains open for discussion and research. Even though gender and ethnic difference are considered as the determinant factors, the common site for measurement should be chosen in accordance with the selected procedure in order that the comparison among countries can be done. Development of a universal WC cut-off is the ideal goal and cross-validation of the results is needed for other children's populations.

71.7 Application of Waist Circumference Measurements to Thai Children and Adolescents

In Thailand, childhood obesity is becoming a major public health problem. Results from one national representative survey conducted in 8,655 children from 17 provinces, including Bangkok, found the prevalence of obesity in 2–5, 6–12, and 13–18 years children were 7.9%, 6.7%, and 8.6%, respectively (Mo-suwan et al. 2004). In 2006, the National Statistical Office conducted a nutrition survey in 9,404 children aged under 5 from 26 provinces of Thailand that also indicated the proportion of

Table 71.1 Study on waist Circumference in different countries

Region	Country	Study subjects	Age range	No. of subjects	Site of measurement	Reference
North America	Canada	1981 Canada Fitness Survey	11–18 years	3,064	Midway between the 10th rib and the iliac crest	Katzmarzyk (2004)
	USA	NHANES III (1988–1994)	2–18 years	9,713	Above the uppermost lateral border of right ileum	Fernandez et al. (2004)
	USA	NHANES 1999–2004	2–19 years	24,216	High point of iliac crest	Li et al. (2006)
	Mexico	School children from middle-income area of Mexico City	6–10 years	833	At the level of the greatest frontal extension of the abdomen between the bottom of the rib cage and the top of iliac crest	Gomez-Diaz et al. (2005)
	Cuba	Three municipal areas of the Havana City	4.5–20.5 years	7,285	Midway between the lower rib and iliac crest	Martinez et al. (1994)
South America	Brazil	School children from City of Santa Catarina, South Brazil	7–10 years	2,919	Midway between the 10th rib and the iliac crest	de Assis et al. (2007)
Europe	Italy	School children in a region of Central Italy	6–14 years	2,858	Not indicated	Zannolli and Morgese (1996)
	Spain	School children from Central part of Spain	6.0–14.9 years	1,728	Midway between the lowest rib and iliac crest	Moreno et al. (1999)
	UK	School children from geographical regions of Great Britain	5.0–16.9 years	8,355	Midway between the 10th rib and the iliac crest	McCarthy et al. (2001)
		Avon Longitudinal Study of Parents and Children (ALSPAC) 1995–1998	2–5 years	1,821	Midway between the 10th rib and the iliac crest	McCarthy et al. (2005)
Europe	Greece	Primary and secondary school children in 5 districts of Cyprus	6–17 years	2,472	At the level of umbilicus	Savva et al. (2001)
	Germany	Elementary schools in Nuremberg	3–11 years	3,531	Midway between the lowest rib and iliac crest	Schwandt et al. (2008)
	Netherlands	Fourth Dutch Growth Study	3 months–21 years	14,500	Midway between the lowest rib and the top of iliac crest	Fredriks et al. (2005)

Middle East	Iran	School children from 23 province; urban and rural areas	6–18 years	21,111	Midway between the lower border of rib cage and the iliac crest	Kelishadi et al. (2007)
	Turkey	Primary and secondary schools from 2 urban and 10 suburban areas of Kayseri	7–17 years	4,770	Midway between the lowest rib and the top of the iliac crest	Hatipoglu et al. (2008)
Asia	Japan	National survey	6–18 years	10,614	WC1 = at the level of maximal waist narrowing WC2 = at the level of the top of the iliac crest	Inokuchi et al. (2007)
	Hong Kong Chinese	Sampling primary and secondary school children from 18 districts	6–18 years	14,842	Midway between the lowest rib and the superior border of the iliac crest	Sung et al. (2008)
Australia	Australia	School children from Australian Health and Fitness Survey (AHFS)	7–15 years	8,439	At the level of umbilicus	Eisenmann (2005)

This table lists the research studies on waist circumference (WC) in various age groups of children and adolescents; it was found that the anatomical sites for WC measurements varied among countries

Note: Iliac crest is the prominent bony ridge at the top of the hip bone

Table 71.2 Studies on Waist Circumference Cut-offs in Children and Adolescents

Country	Age range (years)	No. of subjects	Ethnicity	Gender	Waist circumference cut-off (cm.)	Biomarker end points	Reference
USA	5–9	1,068	White-American		WC corresponding to 90th percentile	LDL-C, HDL-C, TG, plasma insulin	Freedman et al. (1999)
				Boys	59–77		
				Girls	57–73		
			Black-American	Boys	56–74		
				Girls	56–78		
	4–11	87	White and Black	Boys and Girls	WC corresponding to the highest L_{pos}	Fasting insulin, LDL-C, HDL-C, TG	Higgins et al. (2001)
					≥71		
	12–19	2581	Hispanic	Boys	84.3	Lipid profile, fasting glucose, insulin and high BP	Messiah et al. (2008)
				Girls	80.9		
			Non-Hispanic White	Boys	76.6		
				Girls	80.5		
			Non-Hispanic Black	Boys	82.0		
				Girls	78.4		
Mexico	6–10	833			WC corresponding to 85th percentile	BMI > 85th percentile	Gomez-Diaz et al. (2005)
				Boys	69.5		
				Girls	66.2		
Japan	9–15	124		Girls	77.0	TG, Alanine amin-otransferase, fasting insulin	Asayama et al. (2000)
	6–15	194		Boys	79.4	TG, Alanine amin-otransferase, fasting insulin	Asayama et al. (2005)
China	6–12	2,593	Hong Kong		WC corresponding to 85th percentile	Four of the six risk factors (SBP and/or DBP, TG, HDL-C, LDL-C, glucose, Insulin	Sung et al. (2007)
				Boys	58–76 cm		
				Girls	57–71 cm		

China	12–19	2,102	Hong Kong	Boys	WC corresponding to 76th percentile 12–15 years; 71.6–75.4 cm 16–19 years; 76.4–79.3 cm	Fasting glucose, LDL-C, HDL-C, TG, SBP or DBP	Ng et al. (2007)
				Girls	WC corresponding to 77th percentile 12–15 years; 67.8–69.6 cm 16–19 years; 69.7–69.8 cm		
China	7–18	4,224	Han		WC corresponding to 85th percentile	Based on study by Sung et al. (2007)	Yan et al. (2008)
				Boys	7–18 years; 62.9–84.2 cm.		
				Girls	7–18 years; 59.0–75.6 cm		
			Uygur	Boys	7–18 years; 57.7–77.2 cm.		
				Girls	7–18 years; 54.8–75.4 cm		

This table shows the results from some countries that demonstrated the association between WC cut-off points and the occurrence of cardiovascular risk factors in children and adolescents. The ethnicity of the population also influenced the variation of WC value

Note: *LDL-C* low-density lipoprotein cholesterol; *HDL-C* high-density lipoprotein cholesterol; *TG* triglycerides, alanine aminotransferase: one liver enzyme used for the diagnosis of liver function, *SBP* systolic blood pressure; *DBP* diastolic blood pressure; A percentile: a value on a scale that indicates the percent of a distribution that is equal to it or below it, for example; 85th percentile is the value (score) below which 85% of the observation may be found

obesity in young children at 13.7% (National Statistical Office 2006). These figures were derived from nutritional assessment using weight-for-height index. Since WC data of Thai children and adolescents are less available, therefore, the authors performed analysis using recent data from three cross-sectional studies.

71.7.1 Preschool Children

Saraburi is a province located in the central region of Thailand. The Saraburi project was aimed to explore the prevalence of obesity in preschool children and parental feeding practices. The study was conducted during July–September 2008. Subjects were children aged between 3 and 6 years and they were randomly enrolled from nine kindergartens. Anthropometric measurements in children were performed by the same researcher. Body weight, height, and WC were measured in children. Waist circumference measurement was done in each child by positioning horizontally an inelastic tape at midway between the lowest rib and the iliac crest. Table 71.3 shows the anthropometric characteristics of the preschool Thai children. There were increasing trends in body weight, height, waist, and hip circumference with age. The results of percentile distribution of WC and WHtR of children are also shown in Tables 71.4 and 71.5. Waist circumference values were relatively greater in boys than in girls and the values increased with age. The WHtR value of boys was also slightly greater than that of girls and the values increased with age (Yamborisut et al. unpublished data).

71.7.2 Prepubertal Children

The dual form malnutrition project was carried out between June 2003 and March 2004. The study was to explore risk factors associated with obesity and wasting in prepubertal children in Nakhon Pathom and Bangkok. Subjects were 107 obese and 51 normal weight children whose age ranged between 6 and 10 years. They were enrolled from primary schools located in six districts of Nakhon Pathom province and in four nearby districts of Bangkok. An obese child was categorized by weight-for-height Z score (WHZ) of >+2SD and a normal weight child by WHZ of between -1.5SD and +1.5SD of median, Thai Growth Reference (Department of Health 1999). Waist circumference was measured at midway between the lowest rib and the iliac crest. Twelve-hour fasting blood samples were also obtained from subjects for the determination of plasma glucose and serum lipids. Results demonstrated that among boys and girls, obese children tended to have more cardiovascular risk factors, that is, high blood level of TG and LDL-C and low HDL-C (Table 71.6). In this study, WC was found to be highly positive correlated with weight-for-height index in children (Fig. 71.1); therefore, it has been suggested that WC could be used as a proxy measure to identify health risk in children. The results also indicated that girls who had WC value of ≥75th percentile (≥78.2 cm) had significantly higher blood TG and lower HDL-C level than girls who had WC value of less than 75th percentile (Table 71.7).

71.7.3 Adolescents

The authors conducted one cross-sectional study to determine WC cut-off points that correlated with over-nutrition in Thai adolescents. This work was done as a part of a research study on the reliability

Table 71.3 Anthropometric characteristics of preschool Thai children (Yamborisut et al., unpublished data)

Age (months)	No. of subjects	Weight (kg)	Height (cm)	WHZ	BMI (kg/m^2)	Waist circumference (cm)	Hip circumference (cm)	WHR	WHTR

This table shows the average value (as mean ± standard deviation) of anthropometric parameters of preschool Thai children. Body weight, height, WC, and hip circumferences of children increase with age

Note: *WHZ* weight-for-height *Z*-score, can be calculated by observed value-median reference value/standard deviation of reference population; *BMI* body mass index, can be calculated from body weight and height (kg)/ht^2(m); *WHR* waist-to-hip ratio; WHtR waist-to-height ratio

Table 71.4 Percentile distribution of WC for preschool Thai children (Yamborisut et al. unpublished data)

Gender	Age (months)	No. of subjects	Percentiles						
			5th	10th	25th	50th	75th	90th	95th
Boys	36–47	7	46.8	46.8	46.8	49.4	50.9	60.4	60.4
	48–59	328	45.3	46.2	47.9	50.2	53.6	59.9	63.9
	60–71	382	46.1	47.2	48.8	50.7	55.3	65.5	71.0
	72–85	66	45.9	46.5	48.9	51.6	56.6	64.1	71.9
Girls	36–47	11	46.4	46.4	46.7	48.6	50.6	59.3	60.6
	48–59	305	44.4	45.3	46.9	49.2	51.9	57.7	61.4
	60–71	400	45.4	46.3	48.1	50.6	54.5	61.7	67.1
	72–85	81	46.2	47.1	48.2	51.0	54.2	59.2	68.4

This table shows the distribution of WC as percentile value by gender- and age-specific group of children. Waist circumference values increased with age and boys had greater WC than girls

Note: A percentile is a value on a scale that indicates the percent of a distribution that is equal to it or below it, for example; 85th percentile is the value (score) below which 85% of the observation may be found

Table 71.5 Percentile distribution of waist-to-height ratio (WHtR) for preschool Thai children (Yamborisut et al. unpublished data)

Gender	Age (months)	No. of subjects	Percentiles						
			5th	10th	25th	50th	75th	90th	95th
Boys	36–47	7	0.46	0.46	0.47	0.49	0.52	0.55	0.55
	48–59	328	0.43	0.44	0.46	0.48	0.50	0.54	0.58

Girls	36–47	11	0.44	0.45	0.48	0.49	0.50	0.60	0.61
	48–59	305	0.43	0.44	0.45	0.47	0.49	0.53	0.57
	60–71	400	0.42	0.43	0.44	0.46	0.49	0.53	0.57
	72–85	81	0.41	0.42	0.44	0.45	0.47	0.52	0.54

This table shows the distribution of waist-to-height ratio (WHtR) as percentile value by gender- and age-specific group of children. Children who had greater WHtR have high body weight and normal height or high body weight and/or short stature

Note: A percentile is a value on a scale that indicates the percent of a distribution that is equal to it or below it, for example; 85th percentile is the value (score) below which 85% of the observation may be found

and validity of nutrition tool development for the prediction of body fat and physical activity of Thai children and adolescents. Subjects were 509 adolescents, aged 10–18 years and they were enrolled from four primary schools and five secondary schools in Bangkok and Nakhon Pathom province. Anthropometric parameters of subjects are shown in Table 71.8. Waist circumference was measured at four different sites of the trunk region: WC1, midway between the lowest rib and the iliac crest; WC2, at the narrowest waist; WC3, at immediately above the iliac crest; and WC4, at the umbilicus level. Trunk fat and TBF were measured with whole-body dual energy X-ray absorptiometry. Results indicated that WCs measured at all four sites were correlated well with trunk fat mass in adolescent boys (R^2 = 0.81–0.85) and girls (R^2 = 0.80–0.86). Because WC measured at the umbilicus level (WC4) could be easily located and self-evaluated by practitioner themselves, further data analysis was done to determine the strength of association between WC4 and trunk fat mass. Figure 71.2 demonstrated the highly positive correlation between WC4 and trunk fat mass in adolescent boys and girls and it was shown that the variance of trunk fat mass explained by WC measured at the umbilicus level was 85% for boys and 83% for girls. By receiver operating characteristic (ROC)

Table 71.6 Anthropometric and biochemical parameters of prepubertal Thai children (Yamborisut et al. unpublished data)

	Boys		Girls	
Parameters	Obese	Normal weight	Obese	Normal weight
Number of subjects	66	23	41	28
Age (years)	8.1 ± 1.2	8.3 ± 0.9	8.3 ±1.1	8.1 ± 0.9
Body weight (kg)	45.0 ± 8.5*	24.0 ± 3.9	43.0 ± 7.3*	24.4 ± 3.8
Height (cm)	133.0 ± 7.3*	125.1 ± 6.8	132.1 ± 6.8*	125.2 ± 6.7
WHZ	3.6 ±1.2*	–0.35 ± 0.8	3.0 ± 0.8*	–0.11 ± 0.7
Body mass index (kg/m^2)	25.3 ± 3.1*	15.2 ± 1.4	24.5 ± 2.5*	15.5 ± 1.3
Waist circumference (cm)	81.1 ± 7.6*	54.1 ± 4.7	76.7 ± 5.9*	54.9 ± 4.2
WHtR	0.61 ± 0.05*	0.43 ± 0.03	0.58 ± 0.04*	0.44 ± 0.03
Fasting plasma glucose (mg/dL)	87.6 ± 5.4	85.2 ± 9.9	85.0 ± 7.2	81.8 ± 6.7
Total cholesterol (mg/dL)	209.2 ± 33.8*	192.4 ± 25.6	213.4 ± 32.5	201.7 ± 21.7
LDL-cholesterol (mg/dL)	140.5 ± 34.6*	126.5 ± 26.0	140.5 ± 31.9	132.8 ± 22.0
HDL-cholesterol (mg/dL)	48.4 ± 8.0	51.6 ± 8.6	48.2 ± 10.4*	52.8 ± 7.3
Triglycerides (mg/dL)	101.8 ± 50.9*	71.8 ± 18.7	123.8 ± 51.1*	80.4 ± 39.3

This table shows that within each gender, obese children had significantly greater body weight, height, weight-for-height Z-score, WC, and weight-to-height ratio than the normal weight children. Similarly, high blood levels of TG were found in obese boys and girls and significantly higher blood levels of total cholesterol and LDL-C were also found in the obese than normal weight boys. Results were expressed as mean ± standard deviation

Note: *WHZ* weight-for-height *Z* score was calculated by observed value-median reference value/standard deviation of reference population; *WHtR* waist-to-height ratio; *LDL-C* low-density lipoprotein cholesterol; *HDL-C* high-density lipoprotein cholesterol

*Significant mean differences between the obese and normal weight children, by Student's *t*-test at $p < 0.05$

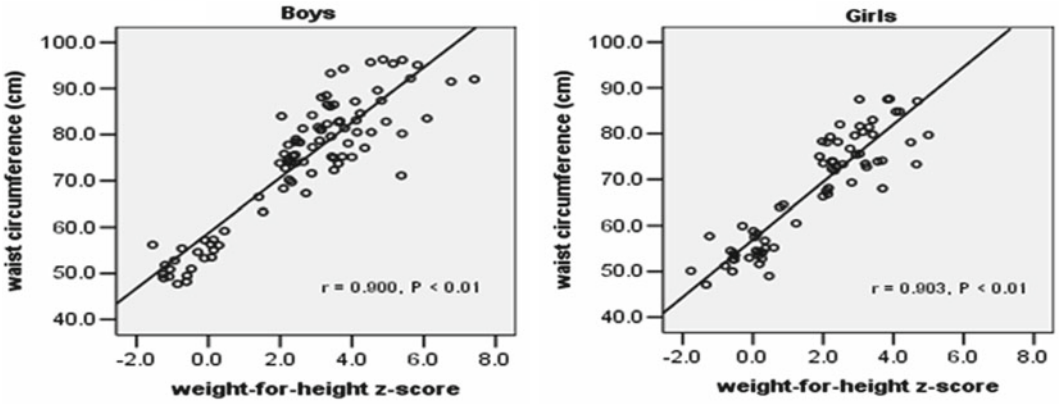

Fig. 71.1 Waist circumference index was found to be highly positively correlated with weight-for-height of children in both genders. Boys $n = 89$ and girls $n = 69$ (Yamborisut et al. unpublished data)

curve analysis, WC cut-offs that predicted the overweight adolescents were 73.5 cm for boys and 72.3 cm for girls (Table 71.9). The WC threshold to detect obesity was increased to 75.8 cm for boys and 74.6 cm for girls (Yamborisut et al. 2008). However, when considering the low positive predictive value (PPV) of WC in adolescent girls, 53.2% for overweight and 54.2% for obesity detection, these cut-off values might misclassify some girls as in fact they did not have high adiposity as expected. In such cases, other anthropometric indicators such as trunk skinfold and/or WHtR would be helpful to identify the problem. It is also suggested that further studies need to address the relationship between WC cut-offs and morbidity in adolescents.

Table 71.7 Cardiovascular risk factors in children according to WC at 75th percentile cut-off (Yamborisut et al. unpublished data)

	Waist circumference	
Cardiovascular risk factors	<75th percentile	≥75th percentile
Boys		
Number of subjects	67	22
Plasma fasting glucose (mg/dL)	87.2 ± 7.4	86.4 ± 5.2
Triglycerides (mg/dL)	91.4 ± 49.0	101.9 ± 38.3
Total cholesterol (mg/dL)	202.4 ± 30.8	212.2 ± 37.4
LDL-C (mg/dL)	134.9 ± 32.1	142.6 ± 35.8
HDL-C (mg/dL)	49.2 ± 8.4	49.2 ± 7.8
Girls		
Number of subjects	52	17
Plasma fasting glucose (mg/dL)	82.9 ± 6.9	86.3 ± 7.6
Triglycerides (mg/dL)	97.5 ± 47.1	132.8 ± 54.9*
Total cholesterol (mg/dL)	209.2± 26.5	206.8 ± 36.6
LDL-C (mg/dL)	138.2 ± 26.6	134.8 ± 33.9
HDL-C (mg/dL)	51.5 ± 9.9	45.5 ± 6.4*

This table indicates the girls who had WC at or higher than 75th percentile (≥78.2 cm) would have high blood levels of TG with low HDL-C level compared with girls who had WC less than 78.2 cm. Results were expressed as mean ± standard deviation

Note: *LDL-C* low-density lipoprotein cholesterol; *HDL-C* high-density lipoprotein cholesterol

*Significant mean difference between two groups by Student's *t*-test

Table 71.9 Proposed WC cut-offs for screening overweight and obese Thai adolescents (Adapted by permission, from Yamborisut et al. 2008, Copyright ©2008 Medical Association of Thailand, All right reserved)

	AUC[a] (95% CI)	WC Cut-off[b] (cm)	Sensitivity[c] (%)	Specificity[d] (%)	PPV[e] (%)	NPV[f] (%)
Boys						
Thai WHZ >+1.5 SD	0.971 (0.953–0.989)	73.5	96.8	85.7	70.9	98.6
Thai WHZ > +2.0 SD	0.968 (0.948–0.988)	75.8	96.3	86.4	67.5	98.8
Girls						
Thai WHZ > +1.5SD	0.969 (0.944–0.993)	72.3	96.1	80.5	53.2	80.4
Thai WHZ > +2.0 SD	0.983 (0.970–0.997)	74.6	95.1	85.7	54.2	98.8

Note: *WHZ* weight-for-height *Z*-score, was calculated by observed value-median reference value/standard deviation of reference population. *WC* waist circumference

[a]AUC: Area under the curve indicates the probability that an adolescent with over-nutrition has a higher value of the WC than an adolescent without over-nutrition; 95% confidence intervals are given within parentheses

[b]Cut-off producing equal values of sensitivity and specificity

[c]Sensitivity: true positive rate, the proportion of the overweight or obese adolescents who are correctly identified as "positive" by the test

[d]Specificity: the proportion of non-overweight or non-obese adolescents who were correctly identified as "negative" by the test

[e]Positive predictive value (PPV): The probability of adolescents become overweight or obese when the test results are positive

[f]Negative predictive value: The probability of adolescents are non-overweight or non-obese when the test results are negative

71.8 Application of Waist Circumference Measure for Public Health Intervention

Waist circumference is considered as a simple tool and reliable anthropometric index to identify children and adolescents who become at risk for overweight and obesity, particularly abdominal obesity. Research evidence shows that WC is positively correlated with weight-for-height index and BMI.

Table 71.10 Key features of WC

- Waist circumference is a simple anthropometric index that can be used as a proxy of abdominal obesity.
- Waist circumference is highly positive correlated with intra-abdominal adiposity and an increase in WC predicts the risk for diabetes, insulin resistance, dyslipidemia, and high blood pressure.
- Waist circumference measurement involves several important techniques: the measuring tape should be inelastic, the positioning of tape held on the trunk must be perpendicular to the long axis of the body, and measurement should be taken at the end of normal expiration.
- Waist circumference measurement can be performed at midway between the lowest rib and the iliac crest of hip bone, at the narrowest waist, at the umbilicus level or at the level immediately above the iliac crest.
- Waist circumference distribution has been studied in both developed and developing countries and WC values vary depending on ethnicity, gender, and pubertal development.
- Universal WC cut-offs are needed for general use in the detection of children and adolescents at risk for over-nutrition and cut-off points should be established against multiple health risk indicators

This table indicates that WC is an anthropometric index that reflects the accumulation of fat tissues in the abdominal cavity and the increase in WC is associated with increased risk for chronic diseases. Factors that influence change in WC are ethnicity, gender, and pubertal development. Techniques for WC measurement also require standardized procedures

Note: Dyslipidemia: a condition involving an abnormal concentration of blood lipids, for example, excess levels of total cholesterol, low-density lipoprotein cholesterol (bad cholesterol), and TG concentration and a low level of high-density lipoprotein cholesterol (good cholesterol). Both elevated levels of LDL-cholesterol and low levels of HDL-cholesterol can cause the clogging or hardening of blood vessels; insulin resistance: a condition in which the body does not respond to insulin properly, for example, the decreased ability of body cells to respond to the action of insulin in transporting glucose (sugar) from the blood stream into muscle cells and other tissues. Insulin resistance typically develops with obesity and can induce the onset of type 2 diabetes. Insulin resistance is also linked to high blood lipids and high blood pressure; iliac crest: the prominent bony ridge at the top of the hip bone

Children who have greater WC will be more susceptible to have multiple cardiovascular risk factors, such as hypertriglyceridemia, diabetes dyslipidemia and elevated blood pressure, leading to mortality in later life. The difference in WC cut-off points derived from studies in many countries are affected by ethnicity, child age, and pubertal development. The optimal WC cut-off derived from maximization of sensitivity and specificity can provide useful information related to health outcomes. However, an age-specific cut-off point is suggested because using single cut-off point to identify children at risk, particularly when interpretation is based on age range, may pose a problem such as a value may overestimate in young child and underestimate in the older child. The establishment of a WC and weight-to-height ratio reference would be advantageous for public policy as WC could be applied as a nutrition tool for tracking child growth and screening children who are at risk for over-nutrition. In addition, WC can be used as a self-monitoring index for the evaluation of intervention programs such as school nutrition and physical fitness program.

71.8 Summary

The majority of research evidence shows that abdominal obesity is associated with increased cardiovascular risk factors leading to morbidity and mortality. Among many anthropometric methods, WC is found to be well correlated with subcutaneous and visceral trunk fat and is highly correlated with weight-for-height and BMI. Age and sex-specific WC percentile distribution has been widely studied in many countries and WC cut-off points have been proposed by studies in some countries. Future research need to address the universal WC cut-off that could have far-reaching application for child monitoring, health screening, and public intervention programs.

Summary Points

- Waist circumference is a reliable anthropometric tool that correlates well with trunk fat and serves as an index to identify excess abdominal fat in children and adolescents.
- Enlarged WC could contribute to the risk for non-communicable chronic diseases such as diabetes, dyslipidemia, high blood pressure, and cardiovascular disease in later life.
- Measurement of WC can be easily performed using standardized procedures. The common site for measurement is at the midway between the lowest rib and the iliac crest of hip bone.
- Waist circumference reference data have been generated in many countries. Regarding Asian countries, percentile distribution of WC has been studied in prepubertal children and adolescents and that of preschoolers in one cross-sectional study in Thailand.
- In addition to weight-for-height index and BMI, WC should be adopted as an important nutritional index for child screening in intervention programs and for monitoring child growth. The optimal WC cut-offs points should be derived based on health outcomes.

Chapter 72
Secular Changes in Craniofacial Dimensions of Indigenous Children in Southern Mexico

Bertis B. Little and Robert M. Malina

Abstract Studies of adult European immigrants by Franz Boas early in the twentieth century indicated secular change in craniofacial dimensions, suggesting plasticity of the craniofacial skeleton. Subsequent analyses of the original Boas data and data for other populations have shown variation in the pattern of change in craniofacial dimensions and indices over time. Cranial length tends to increase while width tends to decrease, resulting in brachycephalization (increase in the cranial or cephalic index). A generalized trend toward brachycephalization and upper and lower facial narrowing has been noted across adult populations that were also experiencing a secular increase in height. Cranial height has also increased, resulting in a taller, narrower skull and cranial vault. Secular trends in craniofacial dimensions in a rural indigenous community in the Valley of Oaxaca in southern Mexico have followed the general population trends. Facial changes probably reflected environmental change associated with diet (softer, processed foods) while cranial vault changes were more likely associated with genetic variation. Although growth of the cranial vault is largely established prenatally, craniofacial remodeling extends throughout the growth period with major changes occurring in conjunction with rapid growth of neural tissues between birth and 5 years. Secular changes observed in indigenous children of school age (6–14 years) were extrapolated to young adulthood using a longitudinal component in the data set. Review of the limited literature suggests that environmental and genetic influences on craniofacial dimensions established early during growth are reflected in corresponding dimensions in young adulthood.

72.1 Introduction

Secular gains in height are well documented in children and adults and are generally interpreted as reflecting improvements in living conditions, specifically related to health, nutrition and associated economic circumstances (Malina 1979). However, some populations have experienced either no secular change or a secular decline in height indicating no change in or decline in living conditions, respectively. Positive secular changes are thus not universal and are reversible. The proximate causes of secular trends in height remain unresolved but are generally agreed to be multifactorial (Susanne and Bodzsar 1998; Susanne et al. 1988), but proportions of the secular increase attributable to genetic and environmental factors or their interactions are controversial. The worldwide epidemic of obesity has shifted attention to recent gains in weight-for-height. The secular increase in body weight in the presence of minimal or no change in height reflects environmental conditions related to energy balance i.e., increased intake in the presence of reduced expenditure (Malina and Little 2008).

Secular trends in craniofacial dimensions are more complex. The well-known early study of European immigrants by Boas (1912, 1940) has been cited for almost a century as evidence of cranial plasticity associated with environmental change (Sparks and Jantz 2002, 2003). Specifically, exposure to different environments during the growing years was postulated as the proximate cause of differences in the craniofacial complex between American-born and European-born children of immigrants (Gravlee et al. 2003).

Changes that occur over the relative short-term, i.e., two or three generations, are usually assumed to be environmental (Smith et al. 1986). Changes over longer intervals (i.e., brachycephalization) are assumed to involve genetic and environmental components (Ruff 2002; Schwidetzky and Rösing 1990). Brachycephalization has slowed over the past 145 years in European populations (Jantz and Jantz 2000). In Japanese populations, the trend toward brachycephalization may be reversing while a trend toward dolicocephalization may be emerging (Kouchi 2000; Zellner et al. 1998). Climate has been linked to long-term changes in the cranial vault (Beals 1979; Beals et al. 1983; Croninger 1981). More recently, it has been suggested that a large proportion of changes in skull shape on account of climate occurs in "extremely cold regions," and that "…if genetic drift is not explicitly accounted for, the effect of natural selection can be greatly overestimated" (Betti et al. 2010).

Secular changes in height of the cranial vault are associated with corresponding changes in body height (Jantz and Jantz 2000). Dimensions of the facial skeleton are also correlated with height and long bone length (Smith et al. 1986), so that increases in height and leg length are associated with narrower and taller faces (Mizoguchi 1992).

72.1.1 Literature Review of Secular Trend in Child Craniofacial Dimensions

The literature on secular trends on craniofacial dimensions in children is limited to only two studies. In one study from Croatia, craniofacial measures of schoolchildren were taken 13 years apart (Gazi-Coklica and Muretic 1991). In another investigation, Zapotec school-aged children from the Valley of Oaxaca, southern Mexico, were compared across a 30-year period (Little et al.2006b). A comparison of these two studies yielded conflicting findings. Over time the faces of Croatian children became broader and shorter, the skull longer, and cranial index decreased (debrachycephalization). In Zapotec children, change in the opposite direction occurred, with narrower faces, shorter skulls, and increased cranial indices (brachycephalization).

In southern Mexico, the living conditions in the community where the Zapotec children were reared improved over time, as indicated by childhood mortality figures that decreased significantly

over time. In parallel, growth in children's stature and weight increased over the same 30-year period. In contrast, living conditions in Croatia probably deteriorated over time. Economic conditions in the Eastern European Bloc were generally worsening during the final decade of communist rule, the period when the Croatian secular trend study was conducted. The Zapotec children had a pattern of change consistent with improvement in health and nutritional conditions (i.e., brachycephalization, gracilization of the face). In contrast, craniofacial changes over time in Croatian children reflect a worsening of health and nutritional conditions (debrachycephalization, robustness of the face). Thus, the two published studies of secular trend in craniofacial dimensions are congruent with one another given changes in living conditions. In order to further discuss craniofacial dimensions in children and their secular changes given the paucity of information, the investigation in Zapotec children is reviewed and augmented in this chapter.

This review of secular change in craniofacial dimensions concentrates on school children aged 6–13 years from a genetically isolated Amerindian population in the Valley of Oaxaca in southern Mexico between 1968 and 2000. The data for school children are complemented with a longitudinal component of individuals measured in 1968 as children and in 1978 as young adults. Using equations developed from the 1968–1978 longitudinal component, craniofacial dimensions of young adults in 2000 were predicted for children who were measured in 1978.

72.1.1.1 Review of Secular Trend of Craniofacial Dimensions Among Children

In this review of the extremely limited literature on the secular trend of craniofacial dimensions among children, the focus is a rural Zapotec-speaking community in the Valley of Oaxaca. Characteristics of the valley and community have been previously described (Malina et al. 2008a, b). The community is indigenous to the Valley and was listed by name in a census (Tribute Rolls) dating to 1536 (Iturribarria 1955). Their lifestyle is typical of traditional Middle America. Socially, the population is based on kinship and is largely endogamous. Economically, the community is characterized by small-scale farmers working relatively small plots of individually owned land which fits the subsistence model. Population size has increased over time, somewhat rapidly from 1960 (1,086) through 1970 (1,423) and 1980 (1,823) and then at a slower rate to 1990 (1,954) and 2000 (1,939). Population size, however, has historically been influenced by a high rate of out-migration, especially of males, starting about 1940. Migration and an increase in adults working outside of the community underlie the changing conditions in the community, perhaps a shift from the traditional lifestyle.

Families typically work small plots (<1 acre) of individually or communally owned land. About 90% of heads of households were full-time farmers in 1978, but the proportion had declined to about 30% by 2000. By inference, many are now part-time farmers; other occupational activities include vendors, artisans, construction workers, and industrial workers. Daily household chores, walking and leisure activities of youth 9–17 years of age in the community suggest a moderately active lifestyle for girls and moderately-to-vigorously active lifestyles for boys (Malina et al. 2008c). Household activities of boys are related to animal care and agriculture; those of girls are related to cleaning, washing and food preparation. With increased out-migration of adult males, youth are more often involved in family subsistence activities.

This review is focused on the genetic and environmental associations of secular change in craniofacial dimensions and indices of school children 6–13 years who were surveyed in 1968, 1978 and 2000. The projects were approved by the respective committees at the University of Texas at Austin and Michigan State University. Community authorities also granted permission for each survey. Parents granted permission for primary school children (grades 1–6). Self-assent was obtained from older individuals (10+ years).

Table 72.1 Population genetics of study community

	1978	2002	Comparative rank	References
Estimated gene flow	3.3%	4.7%	Very low	Little et al. (1989, 2008)
Selection for body size	0.0	–	Low average	Little et al. (1989)
Selection potential	110%	–	10% above average	Little and Malina (1989, 2006)
Genetic drift	25.4	–	Moderate-high	Little and Malina (1989)
Inbreeding	0.01	–	Moderate-high	Little and Malina (1989)

As previously published, the growth status of school children was the primary focus of three surveys: (1) 1968, 331 children: 166 boys and 165 girls (Malina et al. 1972); (2) 1978, 363 children: 175 boys and 188 girls (Malina et al. 1980); and (3) 2000 (late 1999 early 2000, for convenience 2000), 363 children: 179 boys and 184 girls (Peña Reyes et al. 2003a, b). The primary school population was largely 6–14 years in the earlier surveys but the number of 14-year-old children in 2000 was small. Hence, the analyses were limited to children 6–13 years of age. Height and sitting height were measured with a field anthropometer. Intra-observer technical errors of measurement for height were 0.33 and 0.32 cm in the 1978 and 2000 surveys, respectively, while those for sitting height were 0.48 and 0.40 in the two surveys, respectively. Inter-observer technical errors between anthropometrists in the 1968 and 1978 surveys were 0.23 cm for height and 0.35 cm for sitting height. Leg (subischial) length was estimated as standing height minus sitting height.

During the 1978 survey, an attempt was made to locate the sample of school youth surveyed in 1968. Of the 1968 sample, 184 (56%), 91 males and 93 females, were still resident in the community in 1978. These individuals comprise the longitudinal component of most of the investigation on craniofacial measures in this community.

Age of children was obtained from school records. For the follow-up sample, date of birth was obtained at the time of measurement and age was calculated. For those who could not recall their birth date, age as of last birth day was recorded and was indicated at mid-year.

Prior analyses indicated that the population was genetically isolated (i.e., gene flow was very low), perhaps experienced a greater potential for natural selection than was average for similar subsistence agrarian communities, and the probability for random inbreeding was moderately high (Table 72.1). Interestingly, social mating practices (non-random inbreeding) reduced observed inbreeding by 41% (Little and Malina 2005).

Four craniofacial dimensions were measured in each survey of school children and the follow-up sample in 1978: head length (glabella-opisthocranion), head breadth (euryon-euryon), bizygomatic breadth (zygion-zygion) and bigonial breadth (gonion-gonion). Intra-observer technical errors of measurement based on replicates in the 1978 and 2000 surveys, respectively, were as follows: head length, 0.15 and 0.12 cm; head breadth 0.11 and 0.10 cm; bizygomatic breadth, 0.11 and 0.12 cm; and bigonial breadth, 0.24 and 0.13 cm. Inter-observer technical errors between anthropometrists in the 1968 and 1978 surveys were 0.13 cm for head length, 0.08 cm for head breadth and bizygomatic breadth, and 0.17 cm for bigonial breadth. The cranial index (head breadth/head length × 100) and zygomandibular index (bigonial breadth/bizygomatic breadth × 100) were calculated (Little et al. 2006).

Heritability of craniofacial measures was high for the four dimensions: head length > head breadth > bizygomatic ~ bigonial (Table 72.2). Heritability of growth velocity based on a one-year longitudinal study from 1978 to 1979 was zero for bigonial and bizygomatic breadths but significantly greater than zero for head length (0.16) and breadth (0.48).

A secular trend in craniofacial dimensions of children 6–13 years across the three surveys was previously reported (Little et al. 2006a). The trend indicated a shorter skull, narrower mid-face,

smaller mandible, increased brachycephalization and a narrower face over time in males, and a shorter broader skull, narrower mid-face, smaller mandible and increased brachycephalization over time in females (Table 72.3).

72.2 Synthesis of Prior Studies

Secular changes in craniofacial dimensions and indices observed in children 6–13 years (Table 72.3) are ultimately reflected in adult status (Table 72.4). Prediction of 1978 dimensions from 1968 measurements in males had R^2 values of 0.40 for head length, 0.73 for head breadth, and 0.59 for the two facial measurements. Corresponding R^2 values for females were 0.85 for head length, 0.57 for head breadth, and 0.48 for the two facial dimensions. The predicted values for young adults in 2000 compare favorably with observed values for children in 2000. They also reflect the same trend for young adults as for children in 2000, but the magnitude of the difference is less. This suggests that the equations

for predicting young adult craniofacial dimensions in 2000 are sensitive to detecting the secular trend and permit a reasonable extrapolation of the magnitude of change. The cephalic index observed for young adults in 1978 was 82.8 for males and females, while the predicted index for young adults in 2000 was 83.3 for males and 83.4 for females, reflecting a trend toward brachycephalization. Similarly, the zygomandibular index observed in 1978 was 76.9 and 77.6 for males and females,

respectively, while the predicted index for young adults in 2000 was 76.0 for males and 77.2 for females, consistent with the trend toward a narrower face (Table 72.4).

Secular changes in linear dimensions (height and estimated leg length) and craniofacial indices are summarized in Table 72.5. Height and leg length did not increase between 1968 and 1978, but the cranial index did change over this interval. Both the linear dimensions and cranial index increased between 1978 and 2000. On the other hand, the zygomandibular index did not change among the three surveys spanning 32 years. Moreover, the relationship between long bones (leg length) and specific craniofacial dimensions was not different from the relationship with sitting height (trunk length) (Table 72.6). The relationship of leg length to birth year for the study sample showed that only the 2000 cohort of children experienced a marked secular increase in leg length (Fig. 72.1). Interestingly, the trends observed among Zapotec children are opposite of those reported among Croatian children. Croatian children tend toward debrachycephalization and more robust facial parameters. Speculating, it may be possible that the inconsistency of results between the Croatian and Zapotec children is related to increase or decrease in the standard of living for the majority of the population, and is associated with the variation within the two groups.

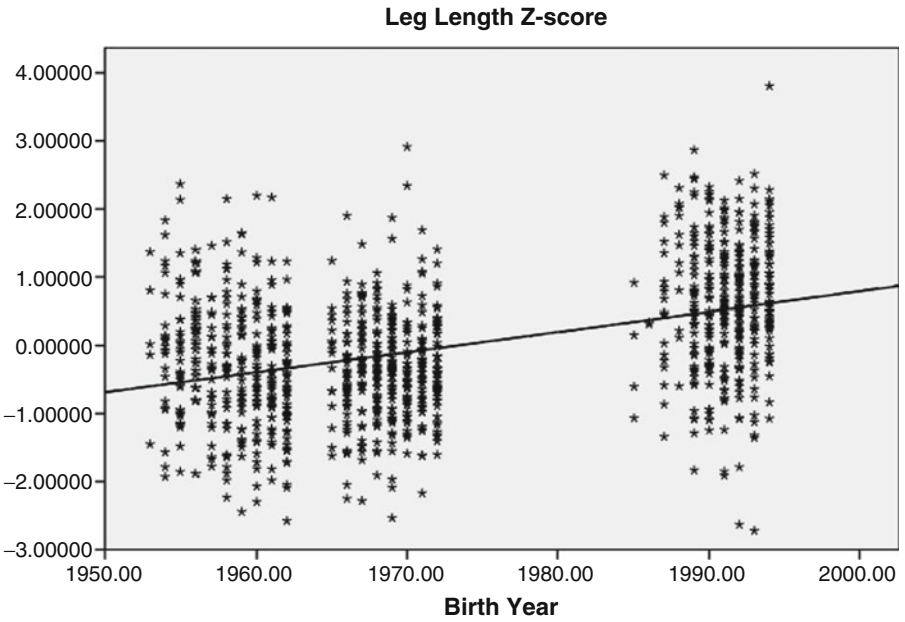

Fig. 72.1 Leg length z-scores by birth year for 1968, 1978, and 2000 cohorts. Note that leg length increase is apparent only in 2000 (n = 1037)

72.3 Discussion

An analysis of the longitudinal series of individuals observed in 1968 as children and in 1978 as young adults indicated an increase in absolute size of craniofacial dimensions (Table 72.4). The longitudinal series also indicated that trends in craniofacial dimensions and indices observed among adults were established during childhood prior to six years of age. Thus, observations for the indigenous population were consistent with prior postulates that secular trends in craniofacial dimensions are established early in child growth (Jantz and Jantz 2000). Although absolute differences established during childhood were absolutely larger in young adults, the trends were similar. Relative measures (indices) followed a similar trend.

It has been posited that changes in cranial vault dimensions must occur by early childhood because of the early development of the vault (Jantz and Jantz 2000). This is based upon logical deduction from adult data rather than actual analysis of data for children. A review of the craniofacial secular trend for indigenous children in Oaxaca who were observed as young adults included a longitudinal component that was analyzed to test the hypothesis that differences in cranial vault and facial dimensions originate in childhood. The differences observed in young adulthood were established in childhood. The data are, however, limited, since the age of the youngest subjects was 6 years. Thus, it is likely the differences observed at 6 years were established at younger ages.

In the present review, investigators suggest that prediction of young adult status has implications for the timing of the onset of differences in craniofacial dimensions. First, the observed trends indicate that differences in dimensions have their origins early in child growth, before the age of six which is the youngest group of children in studies reviewed. Secondly, the trends observed seem to be part of a continuum because the 1968–1978 equations give the impression that the trend they model is a reasonable estimate of young adults in 2000. Interestingly, the young adults in 2000 are similar to children in 2000. This indicates that the same trend (direction, magnitude) observed for

Table 72.7 Cephalic index in Zapotec adults between 1899 and 1978

Males		Females			
N	Mean	*N*	Mean	Year of survey	Source
100	81.0	25	82.0	1899	Starr (1902)

50	81.1 ± 3.4	–	–	1933	Leche (1936)
236	84.7	–	–	1941	Gomez-Robleda et al. (1949)
41	82.8 ± 3.1	46	82.8±3.4	1978	Unpublished data[a]

[a]Youth 10–15 years in 1968 who were seen in 1978 as young adults: males 23.2 ± 2.3 years and females 22.3 ± 1.9 years

1968–1978 is observed for 1978–2000, implying that the secular trend is a process which builds on size and shape changes not only across ages (ontogenetically) but across time (generations).

The first systematic and quantitative craniometric analysis was conducted by Boas in 1899 (Boas 1899) and in the early 1900s (Boas, 1912, 1940) on European immigrants in America. Boas concluded that the change in size and shape of human crania over time among immigrants was a response to changes in environmental conditions and genetic influences exerted during childhood. Craniofacial dimensions and indices differed between those whose childhood growth occurred in Europe compared to those who grew up in the United States; Boas attributed the differences to "cranial plasticity." Re-analysis of the Boas dataset with more sophisticated techniques led to a quite different conclusion and shifted focus from high environmental effects to a very high degree of genetic influence (Sparks and Jantz 2002). The interpretation of the re-analyses, however, is not universally accepted; others argue that the environment played a larger role than genetics (Gravlee et al. 2003). Sibling analyses reveal that for indigenous children, head length was under high genetic control (98%) and head breadth was under moderate genetic influence (> 75%), whereas facial measures (bizygomatic and bigonial) reflected a high environmental influence (> 50%) (Little et al. 1987, 1991).

Brachycephalization has been noted over time in a number of populations (Kobyliansky 1983; Mikic 1990; Susanne et al. 1988), but a counter trend, 'de-brachycephalization,' has also been observed (Kouchi 2000; Zellner et al. 1998). Brachycephaly means literally "short skull" (length/breadth). An unresolved issue is the contribution of environmental or genetic influences, or genetic-environmental interactions in the observed trends (Sparks and Jantz 2002; Gravlee et al. 2003). Advances in standards of living are associated with brachycephalization (Jantz and Jantz 2000; Gyenis et al. 2003; Mikic 1990). Some studies also suggest that gene flow (admixture) may be associated with brachycephalization, including increased cranial height (Billy 1975, 1979; Hulse 1957; Palsson and Schwidetzky 1973). Cranial plasticity posited by Boas (1912, 1940) suggested a major role for the effect the American environment on immigrants from Europe. By inference, the conditions in Europe from which the individuals migrated were relatively impoverished and were associated with a shorter, narrower skull (lower cranial index). Among Zapotec children, the secular trend was toward brachycephaly (Table 72.3, Little et al. 2006b), while in Croatian children the trend was in the opposite direction, toward debrachycephalization (Gazi-Coklica and Muretić 1991). The cranial index of Zapotec adults in the Valley of Oaxaca also showed a trend to increase from 1899 to 1978 (Table 72.7).

Changes in craniofacial dimensions are correlated with changes in stature in forensic skeletal collections; long bone length (leg length) is highly correlated with skull length and cranial height (Jantz and Jantz 2000). Among children in the Oaxaca study an interesting observation is that the cranial index increased between 1968 and 1978 (Table 72.3, Little et al. 2006) while height and leg length did not change (Fig. 72.1) in subsequent years, the cranial index continued to increase while height

and leg length increased between 1978 and 2000 (Table 72.5, Little et al. 2006b). This suggests that changes in cranial dimensions are possibly a leading indicator that future changes in leg length in the next interval (decade or so) are possible. In other words, secular changes in cranial dimensions may predict the onset of secular increase in the post-cranial skeleton. Previous investigators have noted that secular changes in cranial dimensions were larger than in the post-cranial skeleton (Jantz and Jantz 2000).

Of interest is that the zygomandibular index was unchanged across the three surveys. However, relationships between the four craniofacial dimensions and leg/trunk length were not as strong as expected from the literature (Table 72.6). The regression slopes were not different between estimated leg length or sitting height.

Increase in body size including height, particularly leg length, and body weight characterize the secular trend (Malina 1979). The longitudinal component of the data for an indigenous population demonstrated that changes in cranial dimensions observed in adults were established early in child growth. It was previously noted that secular trends in cranial and post-cranial skeletons follow a similar course in the secular trend (Jantz and Jantz 2000). The unexpected finding was that secular change in cranial dimensions may be a leading indicator for secular increase in leg length and height. However, it is important to consider that cranial vault morphology and secular trends are population-specific.

Cranial size and shape are established early in child growth, including prenatal growth. Secular changes are associated with improved health and nutritional conditions, and include: (1) brachycephaly, (2) narrower mid-face, (3) narrower cranial vault and (4) narrower lower face. Craniofacial anthropometry data in the Oaxaca studies of Zapotec schoolchildren did not include measures of cranial height or facial height, but published data associate the secular trend with increased cranial vault height and a taller face. Analysis of changes in craniofacial dimensions and leg length suggest craniofacial changes in an indigenous Amerindian population may be leading indicators for onset of the secular increase in the post-cranial skeleton (height) in the next interval (10–20 years).

72.4 Synthesis of Studies Reviewed

The secular trend in craniofacial dimensions of the two populations for which data have been reported yield opposite results. Among Croatian children the trend was toward a more robust face and debrachycephalization (Gazi-Coklica and Muretić 1991), perhaps related to environmental conditions under communism. Zapotec children's craniofacial dimensions tended toward a more gracile face and brachycephalization (Little et al. 2006). Among the Zapotec children transition to softer, smoother food over time was associated with facial gracilization and brachycephaly. Among the Zapotec children the trend was analyzed even further because observations of secular change in craniofacial dimensions in children (ages 6–13 years) in the Valley of Oaxaca, southern Mexico (Little et al. 2006b) were extended to an analysis of a longitudinal series of individuals observed in 1968 as children and in 1978 as young adults. Equations developed from the longitudinal component were applied to the year 2000 cohort to predict their values as young adults. The analysis showed a relatively stable absolute increase in size of the craniofacial dimensions. Hence, trends in craniofacial dimensions and indices observed among adults were established during early childhood. The proportional change in dimensions was consistent from early childhood to young adulthood, similar to prior postulations that secular trends in craniofacial measures are established early in child growth, as early as during fetal development. Possible clinical implications of the findings may be that

treatment of craniofacial growth anomalies among children (craniofacial syndromes, orthodontics, helmeting, etc.) may require consideration of possible secular trends in absolute and relative measures. Craniofacial anthropometrics have been used to evaluate hypothesized syndromes (Little et al. 1996). Clinically, it may be important to note the trend for consistent proportions with increase in absolute size from early childhood into adulthood in the case of secular trend. Ultimately, children will likely not resemble their parents to the extent that may be expected to in the absence of a secular trend.

Summary Points

- Secular change in body size (positive secular trend) – An increase in body size that is associated with improved health and nutritional conditions, but some authorities have suggested that gene flow confounds the direction relationship between the environment and the secular trend. Generally, it is agreed that the secular trend is multi-factorial in causation. The post-cranial skeleton secular trend is toward taller and heavier individuals, with much of the increase in stature due to increased leg length.
- Secular change in cranial skeleton – Secular changes in the cranial skeleton have tended toward a shorter, taller skull, also termed brachycephaly. These are trends that span hundreds or even thousands of years. However, in some modern populations, the trend toward brachycephalization has slowed (Northern Europe) or even halted (Japan).
- Secular change in facial skeleton – The secular change in the facial skeleton is a change from robust short and wide faces to a more gracile, taller, narrower face. Some authorities have argued that change in diet from hard, rough food sources (nuts, seeds, stone ground food, etc.) to softer, smoother food (processed grains and seeds, machine ground food, etc.) is mechanically related to facial changes over generations.
- Secular change in cranial index – The cranial index tends to increase over time and indicates the tendency toward brachycephaly. Franz Boas analyzed the cranial index among immigrants to the United States and those who were born in America.
- Inter-relationships of secular changes – Increases in stature are associated with craniofacial changes. Leg length is strongly correlated with increased skull height, increased cranial index and taller, narrower faces. Within the craniofacial skeleton, narrower, shorter and taller skulls are associated with taller, narrower faces, reflecting the secular trend for robust features to become gracile across time.

Key Points

Secular change in body size (positive secular trend)
Increased height
Increased leg length
Secular change in cranial skeleton
Narrower skull
Shorter skull
Taller skull

Secular change in facial skeleton
- Narrower face
- Taller face
- Narrower mandible
- Narrower mid-face

Secular change in indices
- Brachycephalization (higher cephalic index)
- Gracilization of face (lower facial indices such as zygomandibular)

Inter-relationships of secular changes
- Cranial changes associated with post-cranial skeleton
- Secular changes in cranial dimensions occur before post-cranial skeleton

Interpretations
- Secular increase in size associated with improved living conditions

Chapter 73
Anthropometric Indexes of Low-Income Brazilian Children

Sylvia do Carmo Castro Franceschini, Silvia Eloiza Priore, Fabiana de Cássia Carvalho Oliveira, Cláudia Aparecida Marlière de Lima, and Silvia Nascimento de Freitas

Abstract Brazil is a very large country, with more than eight million square kilometers, and comprises five different regions with distinctive social and economic characteristics. This gives rise to considerable inter-regional disparities in the analysis of child health status. In the last four decades, five surveys were conducted nationwide, and the first survey showed that protein–energy malnutrition was the most serious nutritional problem among Brazilian children. However, these rates have been declining sharply in all Brazilian regions as a result of an improvement in the social and economic conditions of families and in the sanitation coverage, and of wider offer of and access to health services, education, and food supplementation programs. More recent studies indicate that although there has been a reduction in height deficit in all Brazilian regions, it is still significant among Brazilian children and affects 7.0% of them. In addition to socioeconomic, biological, and quality-of-life determinants, the prevalence of low height can be partially attributed to the high frequencies of iron deficiency anemia and vitamin A deficiency among Brazilian children (20.9% and 17.4%, respectively), considering the importance of these micronutrients on linear growth and immune response. Child obesity affects 6.6% of Brazilian children and should be addressed immediately by the National Food and Nutrition Policy.

73.1 Introduction

73.1.1 Characterization of the Group

The child group includes newborns, infants, preschool and school children, that is, all individuals below10 years. This phase of life is characterized by intense growth and development, which is determined by genetic factors and by extrinsic factors such as eating habits; social, economic, and household (water supply and sewage) conditions; access to health services; and others. Fast growth and greater susceptibility to diseases are characteristics of this group, especially of children aged under 5, who are a major and primary target of the initiatives of the health system.

Brazil is a very large country, with more than eight million square kilometers, and comprises five different regions with distinctive social and economic characteristics. This gives rise to considerable inter-regional disparities in the analysis of child health status. The greatest social differences are found between the South region, where slightly more that three million people have a per capita family income below the poverty line, and the Northeast region where the population under this condition corresponds to approximately 22 million individuals (Brasil 2009a).

Approximately one-fourth of the Brazilian population has a per capita family income below the poverty line (Brasil 2009a). Thirty-nine per cent of children below 6 years live in families that are considered poor and this proportion is 61.5% in the Northeast (UNICEF 2004). Therefore, conditions affecting the child population are still related to nutritional deficiencies and diseases spread through inadequate sanitation systems.

Malnutrition, iron deficiency anemia, and vitamin A deficiency are the nutritional deficiencies that are the major causes of concern as regards public health, due to their high prevalence and deleterious effects on child health. The World Health Organization (WHO 2009) estimates that approximately 2,405,000 (13.3%) of Brazilian preschool children are affected by vitamin A deficiency, which is a moderate public health problem. Estimates for the number of anemic children in Brazil, in turn, point at 9,923,000 (55.0%), and this is considered a severe public health problem (WHO 2008).

73.2 Nutritional Profile

According to the United Nations Children's Fund (UNICEF 2007), 8% of Brazilian newborns are low-weight (weight below 2.5 kg at birth), a percentage that is similar to that of industrialized countries (7%), and lower than that of developing countries (15%).

In developing countries, the World Health Organization estimates that the prevalence of weight-to-age, weight-to-height, and height-to-age deficits are 20.2%, 10.0%, and 32.0%, respectively, and in South America, they are 4.1%, 0.6%, and 13.8%, respectively (Black et al. 2008).

In the last four decades, five surveys were conducted nationwide, and the first survey showed that protein–energy malnutrition prevailed as the most serious nutritional problem among Brazilian children. However, these rates have been declining sharply in all Brazilian regions as a result of an

improvement in the social and economic conditions of families and in the sanitation coverage, and of wider offer of and access to health services, education, and food supplementation programs (Monteiro et al. 1993). According to Monteiro et al. (2009), two-thirds of the reduction in the prevalence of malnutrition can be attributed to increase in maternal educational level (25.7%), greater purchasing power of families (21.7%), health-care expansion (11.6%), and improvement of basic sanitation (4.3%).

The survey of the nutritional status of Brazilian children at the national level started in the 1970s with the National Study on Family Expenses [*Estudo Nacional de Despesas Familiares*] (ENDEF), conducted in 1974–1975, by the Brazilian Institute of Geography and Statistics [*Instituto Brasileiro de Geografia e Estatística*] (IBGE). Children were assessed according to the weight-to-age ratio using the anthropometric reference recommended and used by the National Center for Health and Statistics (NCHS) at that time. The results indicated that 18.4% of children presented malnutrition (weight-to-age ratio below – 2 *Z*-score), in that the North and Northeast regions had the highest prevalence and the South region had the lowest (Monteiro et al. 1993).

In the following decade, national anthropometric data were obtained from the National Health and Nutrition Survey [*Pesquisa Nacional sobre Saúde e Nutrição*] (PNSN), conducted in 1989, by the National Institute of Food and Nutrition [*Instituto Nacional de Alimentação e Nutrição*] (INAN), with the cooperation of the Government Management Planning Institute [*Instituto de Planejamento de Gestão Governamental*] and the Brazilian Institute of Geography and Statistics. The age group assessed and the method used were the same of the survey described above. The comparison of the ENDEF and PNSN studies showed a drop of approximately 61% in the prevalence of malnutrition rates in children below 5 years for weight-to-age ratio (18.4% in 1975 and 7.1% in 1989). The North and Northeast regions had the highest prevalence and the South region had the lowest. However, the lowest decline in malnutrition rates was observed in the North and Northeast regions, whereas the highest decline was observed in the South region, which widened inter-regional inequality. The drop in malnutrition prevalence was substantial in all quartiles of per capita family income, but was sharper in the highest quartiles (Monteiro et al. 1993).

In 1996, the National Survey on Demographics and Health [*Pesquisa Nacional sobre Demografia e Saúde*] (PNDS) analyzed the nutritional status of children under 5, according to the weight-to-age, weight-to-height and height-to-age ratios, using the same anthropometric reference of the previous surveys. The survey showed that 5.7% had low weight for their age, 10.5% had low height for their age, and 2.3% had low weight for their height.

According to the study, 18.0% of children in the Northeast region had height deficit, whereas in the South region, 5.1% had it, evidencing that the wide gap between the regions of the country remained. The height deficit rate was 19.0% in children living in rural areas, and 7.8% in those living in urban areas. The prevalence of this deficit dropped as maternal educational level increased (PSNS 1997).

The publication of the data of the latest Family Budget Survey [*Pesquisa de Orçamentos Familiares*] (POF), conducted in 2002–2003 by the IBGE in partnership with the Ministry of Planning, Budget and Management, made known the nutritional status of Brazilian children below the age of 10 years. The anthropometric ratio assessed was weight-to-age and the reference used was the same as that used for other surveys, i.e., that of the NCHS. According to the data, the prevalence of low weight-to-age in children under 10 was 5.8%, and in those below 5 years the prevalence was 7.0%. Prevalence was similar in rural and urban areas, but the North region continued to present the highest rates: 11.4% for children below 5 years, and 8.5% for children between 5 and 9 years. It is important to highlight that the situation is especially worrisome in the rural North region where 15.0% of children were malnourished (Brasil 2006).

The most recent data on the nutritional status of Brazilian children come from the latest National Survey on Demographics and Health (PNDS), conducted in 2006 (Table 73.1). Just as the 1996 PNDS,

Table 73.1 Prevalence of protein–energy malnutrition and obesity among Brazilian children

Characteristics	H/A < -2 *Z*-score %	W/H < -2 *Z*-score %	W/H ≥ +2 *Z*-score %	W/A < -2 *Z*-score %

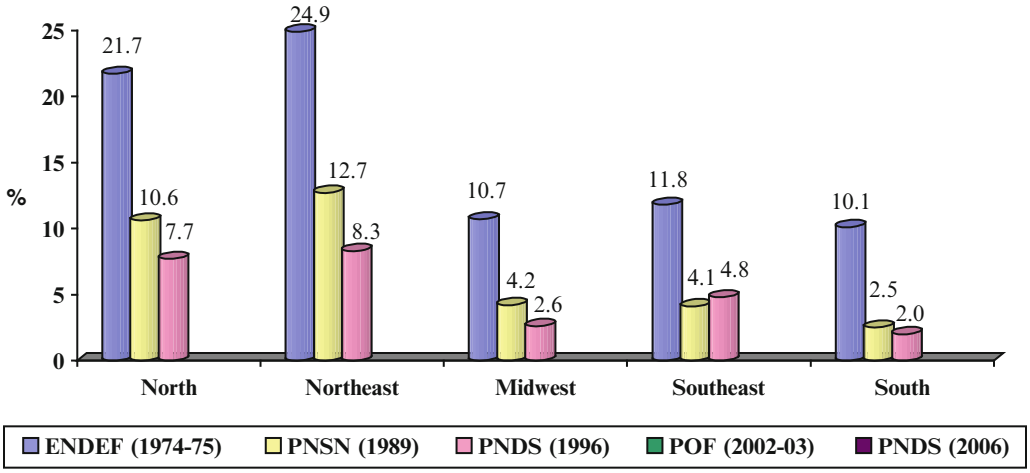

Fig. 73.1 Trend of the prevalence of weight-to-age deficit in children under 5 years of age for each Brazilian region. 1974–2006 (*Sources*: IBGE, National Study on Family Expenses (ENDEF) 1974–1975; National Institute of Food and Nutrition, National Health and Nutrition Survey (PSNS) 1989; *Sociedade Civil Bem-Estar Familiar no Brasil*, National Survey on Demographics and Health (PNDS) 1996 and 2006; IBGE, Department of Surveys, Coordination of Work and Income, Family Budget Survey (POF) 2002–2003)

this survey assessed children under 5 according to the weight-to-age, weight-to-height, and height-to-age ratios, but it used the 2006 international recommendation of the World Health Organization (WHO) as its anthropometric reference. The survey evidenced that the deficits in the weight-to-age, weight-to-height, and height-to-age ratios were 1.7%, 2.0%, and 7.0%, respectively (Brasil 2008).

Figure 73.1 shows the trend of malnutrition in Brazilian children below 5 years, in time, for each Brazilian region. The reduction in the prevalence of weight-to-age deficits in all regions especially in the North and Northeast regions is worthy of notice. These regions were heavily targeted by government initiatives.

73.3 Current Nutritional Status of Brazilian Children

Table 73.1 presents the current nutritional status of Brazilian children, according to the latest survey conducted in 2006, the National Survey on Demographics and Health [*Pesquisa Nacional sobre Demografia e Saúde*].

Table 73.1 shows that the primary nutritional problems currently affecting Brazilian children are height deficit and excess weight. The low prevalence of weight-to-age deficit and acute malnutrition, which is evidenced by the weight-to-height ratio, stands out.

Also worthy of notice is the high frequency of low height in the North region, and its higher prevalence among males compared to females.

The data presented in Table 73.2 come from recent *ad hoc* studies, and aim to demonstrate the prevalence of malnutrition in specific groups. Although there has been a drop in prevalence of malnutrition over the last four decades and in all Brazilian regions, prevalence is still very high in some specific groups, such as indigenous children and children living in shanty towns, where height deficit also stands out.

Height is an important indicator of quality of life, and reflects the cumulative nutritional status. Data from the National Health and Nutrition Survey (1989) indicated that the average growth of Brazilian children was beginning to decline compared to North American children who were used as anthropometric reference (NCHS) as of the fourth month of age, which indicated the importance of the environment in the expression of growth potential in childhood. Therefore, considering the high prevalence of height deficits in certain groups of Brazilian children, children living in the North of the country (Table 73.1), low-income and indigenous children (Table 73.2) should be prioritized in government initiatives designed to fight child malnutrition in the country.

Obesity has become a very worrisome nutritional problem even in developing countries like Brazil. This recent epidemics has been attributed to changes in children's eating habits, such as early weaning and increased consumption of sugar and fats from industrialized products, in addition to changes in life style, such as increased sedentarism.

The most recent data on overweight in childhood come from the 2006 PNDS (Table 73.1), which indicates an obesity prevalence of 6.6%, with the highest prevalence in the South region (8.8%).

Table 73.2 Data on the prevalence of malnutrition in indigenous children and low-income children

Age group	Population characteristics	Place of study	Prevalence (%)	Authors
<5 years	Indigenous children in the Amazon	Rondonia (North region) and Mato Grosso (Midwest region)	H/A: 45.5 W/A: 16.2 W/H: 1.2	Orellana et al. (2009)
<5 years	Kaingáng indigenous children	Mangueirinha Indigenous Land, Parana (South region)	H/A: 24.8 W/A: 9.2 W/H: 2.1	Kühl et al. (2009)
6 months to 6 years	Shanty-town residents	Municipio de Sao Paulo (Southeast Region)	H/A: 13.1 W/A: 15.5 W/H: 4.8	Santos et al. (2008)
6–30 months	Low-income families	Duque de Caxias, Rio de Janeiro (Southeast region)	H/A: 8.6 W/A: 2.8 W/H: 3.3	Barroso et al. (2008)

H/A height to age, *W/A* weight to age, *W/H* weight to height

The age group with the highest frequency of overweight was the group between 36 and 47 months and the prevalence was similar for females and males, 6.8% and 6.4%, respectively (Brasil 2008).

73.4 Specific Nutritional Deficiencies

73.4.1 Iron Deficiency Anemia

The data presented in Table 73.3 are from a compilation of studies published between 1997 and 2009, in Brazil, and aim to demonstrate the prevalence of anemia in Brazilian children in different Brazilian regions.

Until 2006, when the National Survey on Demographics and Health [*Pesquisa Nacional sobre Demografia e Saúde*] was conducted, there was no study in Brazil on the prevalence of anemia in Brazilian children with a nationwide representation. This survey assessed the levels of hemoglobin of 3,455 children aged below 5 years using the cyanmethemoglobin method in different regions of the country. Those with hemoglobin below 11 g/dL were considered anemic. The prevalence of anemia was 20.9%. The Northeast region had the highest prevalence (25.5%) and the North the lowest (10.4%). Although no statistical association has been observed between the economic classification and prevalence of anemia in children, there was a lower prevalence of anemia in higher-income children. The prevalence of anemia was higher in children living in urban areas and in those under 24 months of age (Brasil 2009b).

73.4.2 Vitamin A Deficiency

The compilation of the data of 23 *ad hoc* studies published on the prevalence of vitamin A deficiency in the country over the last 10 years, with a total sample of more than 6,500 children, showed a minimum prevalence of 7.0% and a maximum prevalence of 75.4% in these studies.

As in the case of iron deficiency anemia, the country lacked a nationwide survey on vitamin A deficiency in Brazilian children until 2006, when the National Survey on Demographics and Health was conducted. The survey studied 3,499 children below 5 years, and their serum retinol concentrations were determined using the dried droplet technique, with high-performance liquid chromatography (HPLC), and 0.70 μmol/L was considered as an indication of inappropriate nutritional status for vitamin A (low levels).

According to the study, 17.4% of children had inadequate levels of this micronutrient. The highest prevalence of vitamin A deficiency was found in the Northeast (19.0%) and Southeast (21.6%) regions of the country. Children living in urban areas and those with mothers aged over 35 years presented a higher prevalence of retinol deficiency as compared with their peers (Brasil 2009b).

Table 73.3 Prevalence of anemia in children aged 0–10 years in different Brazilian regions (1997–2009)

Region	Number of studies considered	Total number of children studied	Prevalence (%) (min – max)
North and Northeast	14	6,804	20.2 – 73.2
Midwest	04	1,084	11.9 – 60.9
Southeast	22	5,485	11.2 – 69.5
South	07	2,461	25.7 – 63.7

73.5 Conclusions

Anthropometric indicators of Brazilian children point to a reduction of protein–energy malnutrition over the last four decades, especially as regards the weight-to-age and weight-to-height ratios. However, despite these reductions, height deficit still affects 7.0% of Brazilian children, and the children of the northern region suffer more (15%). Indigenous and low-income children present a higher rate of malnutrition, especially low height. In addition to the classic determinants of child malnutrition, the significant prevalence of iron deficiency anemia (20.9%) and of low and marginal levels of vitamin A (17.4%) in Brazilian children stands out. These micronutrients play an important role in linear growth and these deficiencies have an impact on the immune system. Therefore, individuals with such deficiencies present higher morbidity due to infectious processes with a deleterious effect on their nutritional status. More recent studies indicate that child obesity has become a major nutritional problem in the country and requires immediate action under the National Policy on Food and Nutrition [*Política Nacional de Alimentação e Nutrição*.]

Summary Points

- **Characterization of the Group:** Child group includes newborns, infants, preschool and school children, that is, all individuals below 10 years. This phase of life is characterized by intense growth and development, which is determined by genetic factors and by extrinsic factors such as eating habits, social, economic, access to health services, and others.
- **Nutritional Profile:** In the last four decades, five surveys were conducted nationwide, and the first survey showed that protein–energy malnutrition prevailed in the Brazilian children and, nowadays, it is decreasing.
- **Current Nutritional Status of Brazilian Children:** The low prevalence of weight-to-age deficit and acute malnutrition, which is evidenced by the weight-to-height ratio, is worthy of notice. Also is high the frequency of low height in the North region, and presents higher prevalence among males than females.
- **Specific Nutritional Deficiencies:** The prevalence of anemia was higher in children living in urban areas those under 24 months of age. The highest prevalence of vitamin A deficiency were found in children living in urban areas, and those with mothers above 35 years of age presented a higher prevalence of retinol deficiency.
- **Conclusions:** More recent studies indicate that childhood obesity has become a major nutritional problem in the country and requires immediate action of Brazilian Government.

Key Points

Key features of protein-energy malnutrition in children

1. Protein–energy malnutrition is characterized by low-energy ingestion.
2. If children are classified with protein–energy malnutrition, they have low macronutrient and micronutrient ingestion.
3. Its distribution changes according to gender, whether urban or rural area, and the specific Brazilian region.

Table 73.1 lists the key factors of protein–energy malnutrition and obesity among Brazilian children. An anthropometric index was used to assess children with protein–energy malnutrition and obesity as recommended by WHO

Key features of prevalence of malnutrition in indigenous children and low-income children

1. Prevalence of malnutrition in indigenous children is higher in the northern region than southern region, but is high in both regions.
2. Children with low-income residents in shanty town (Sao Paulo) present higher prevalence of malnutrition than children with low-income families living in Rio de Janeiro.
3. All indexes (H/A, W/A, and W/H) are higher in the shanty-town than of children who live in low-income families.

Table 73.2 lists the key factors of malnutrition in indigenous children and those who live with low-income families in Sao Paulo and Rio de Janeiro cities, respectively

Key features of prevalence of anemia in children from 0 to 10 years in different Brazilian regions (1997–2009)

1. Prevalence of anemia is high in all Brazilian regions.
2. The prevalence of anemia is high – in the north and northeast, the less developed regions, and also in the southern region, the region that is more developed.
3. Anemia is present in all social classes in the Brazil.
4. Children are considered anemic when the hemoglobin level is below 11g/dl.

Table 73.3 lists the key factors of distribution of anemia in children from 0 to 10 years in several Brazilian regions (1997–2009)

Key features of the trend of malnutrition in Brazilian children under 5, in each Brazilian region

Figure 73.1 reveals the data on the nutritional status of Brazilian children come from the latest National Survey on Demographics and Health (PNDS), conducted in 2006 and lists the keys facts that reveal the reduction in the prevalence of weight-to-age deficits in all regions especially in the North and Northeast regions

Chapter 74
Adipokines and Anthropometry: Childhood and Adolescent Obesity or Adipocytokines and Anthropometry in Childhood and Adolescence

Panagiota Pervanidou, Makarios Eleftheriades, and Ioannis Papassotiriou

Abstract Adipose tissue is no longer considered an inert tissue simply devoted to energy storage, but it has emerged as an active organ in regulating a variety of physiological processes. Adipokines, such as leptin, adiponectin, resistin, adipsin, and visfatin, are proteins secreted by the adipocytes and released into the circulation, participating in the regulation of insulin sensitivity, food intake, inflammation, immunity, and vascular sclerosis. The prevalence of obesity is dramatically increasing worldwide in both children and adults and, along with the increase of obesity, is a parallel increase in the prevalence of comorbid disorders such as hyperlipidemia, arterial hypertension, insulin resistance, and diabetes type 2. In obesity, adipocytes enlarge and macrophages infiltrate adipose tissue, resulting in the large-scale release of several adipokines and in an imbalance between molecules and peptides secreted by the adipose tissue. The proinflammatory cytokines contribute to the "low-grade inflammatory state" of obese individuals, especially those with the Metabolic Syndrome (MetS), a clustering of metabolic abnormalities related to obesity, in both adults and children. Leptin and adiponectin are the two most studied adipokines in neonates, children, and adults and the majority of studies in obese individuals have shown hyperleptinemia and hypoadiponectinemia compared to normal-weight individuals. Furthermore, levels of circulating leptin are negatively associated with insulin sensitivity and conversely, adiponectin improves insulin sensitivity by stimulating glucose uptake and fatty acid oxidation in skeletal muscle. However, anthropometric changes during growth and puberty as well as changes in endocrine and metabolic parameters may contribute to the varied effects of adipokines on insulin sensitivity and the metabolic profile.

74.1 Introduction

An innovative concept in the past few years was that the adipose tissue is not simply a reservoir of energy, but also serves as an active secretory organ, releasing a variety of peptides, complement factors, and cytokines into the circulation (Trayhurn and Wood 2004). These "adipokines" participate through endocrine, paracrine, and autocrine mechanisms of action in a variety of physiological processes such as insulin sensitivity, food intake, inflammation, and vascular sclerosis (Trayhurn and Wood 2004; Trayhurn 2005). Since the discovery of the protein leptin, product of the *obese* (ob) gene, the adipose tissue was found to produce more than 50 molecules (Lago et al. 2007) including adiponectin, resistin, visfatin, and other factors.

There is now convincing evidence that obesity, the state of excessive fat mass in the organism, is related to elevated markers of inflammation and it is now considered as a proinflammatory state. In the presence of excessive fat mass, with enlarged adipocytes and macrophages inserted within them, the balance between these peptides and molecules is altered and more proinflammatory cytokines, such as TNF-α and IL-6, and fewer anti-inflammatory peptides, such as adiponectin (Wellen and Hotamisligil 2005) are secreted (Fig. 74.1). The proinflammatory adipokines seem to contribute to the "low-grade inflammatory state" of obese individuals, especially those with the Metabolic Syndrome (MetS), a clustering of metabolic abnormalities related to obesity, including insulin resistance, dyslipidemia, increased blood pressure, and type 2 diabetes (Trayhurn et al. 2006).

Fewer studies have examined the relations between obesity and adipokines in childhood and adolescence. Though the same principals apply in younger individuals, the effects of linear growth and puberty as well as the normal changes in anthropometric and metabolic parameters from childhood

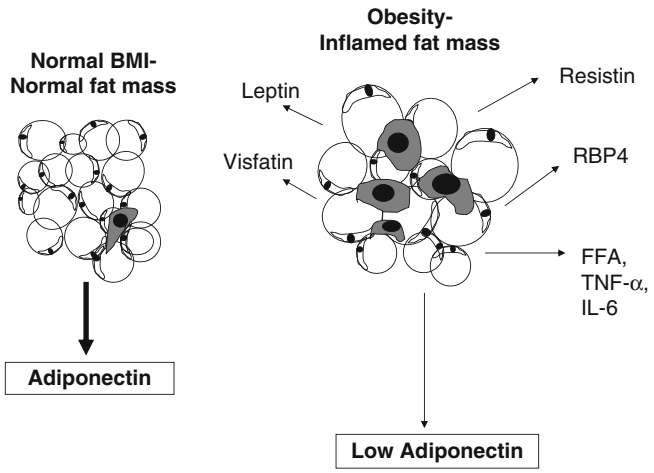

Fig. 74.1 The adipose tissue and secretion of adipokines in lean vs. obese individuals. The adipose tissue of lean individuals contains few macrophages and secretes relatively high levels of adiponectin and low levels of inflammatory cytokines. In obesity and insulin resistance, the adipose tissue contains many macrophages and secretes high levels of a variety of adipokines and low levels of adiponectin

to adulthood may differentiate the physiologic and pathophysiologic role of those molecules. The present chapter aims to review studies investigating the role of the adipokines in pediatric and adolescent obesity and in relation to the normal changes of growth and pubertal development.

74.2 Anthropometric Measures of Obesity in Childhood and Adolescence: Practical Methods and Techniques

Obesity is generally defined as the excessive accumulation of fat in the adipose tissue, to the extent that health may be impaired (WHO 2000). The ability to accurately estimate the level of adiposity, together with the simplicity of the measure, the easiness of use, the cost, and acceptability to the subject are important criteria for an effective measure of obesity (Power et al. 1997). Furthermore, the measure has to be well documented with published reference values. The two most popular methods in the clinical practice are the estimation of Body Mass Index (BMI) and the measurement of Waist Circumference (WC) and are outlined below; however, none of these methods meet all these standards.

74.2.1 Body Mass Index for Age

Body Mass index (BMI) is the ratio of the body weight in kilograms divided by the square of the height in meters. BMI is a good indicator of adiposity in adults and adequate evidence supports that an increased BMI is associated with an increased risk of morbidity and mortality in adults. Similar to adults, BMI seems to be a useful tool for identifying overweight and obese children. However, its value has been limited by the lack of standard reference values. Not all countries have developed reference growth charts, which includes BMI for age and gender percentiles. Most countries have chosen the 85th and 95th percentiles of BMI for age and gender to define overweight and obesity (Cole et al. 2000). However, this definition has limitations as it has not been proven that BMI for age is associated with ill health. Furthermore, regardless of the absolute amount of fat mass, children and adolescents are defined as overweight or as obese based on the median and BMI distribution of the

national reference curve they belong. This means that BMI percentiles are not comparable among different countries, or within the same country after several years, because the mean, the median, and the distribution of BMI are not the same.

BMI-z score (BMI of the individual-mean BMI of the population/Standard Deviation) measures the distance of a value from the mean in a specific population and it represents a more accurate practical measure of obesity in childhood and adolescence. The use of BMI-z score allows us to not only measure childhood obesity in a more accurate manner but also to follow-up patients more precisely, compared to percentiles. Furthermore, using the BMI-z score, the clinician is able to calculate fatness in the very obese children, those with a BMI over the 97th percentile. However, despite the advantages of this method, defining childhood obesity in BMI-z-scores is based on a specific national population chart and suffers from the same limitations as percentiles.

To overcome this limitation, a Workshop organized by the International Obesity Task Force (IOTF) in 1997 proposed a set of BMI percentile curves based on an international reference population and by defining cutoff points in relation to the percentiles that equate to the adult cutoff points, 25 for overweight and 30 for obesity. Based on this approach, Cole et al. developed the international cutoff points and data for this development were obtained from growth surveys in six different countries worldwide (Bellizzi and Dietz 1999; Cole et al. 2000).

74.2.2 Waist Circumference (WC)

Central (abdominal) obesity has been determined as a key factor in the etiology of diabetes type 2 and cardiovascular disease in adults. WC is a well-established anthropometric parameter of measuring intra-abdominal fat and has a clear association with the risk of metabolic disease in adults. Its value is less clarified in children; however, recent evidence has suggested that WC is associated with cardiovascular risk markers. Thus, the additional inclusion of WC measure to the BMI percentile has improved the prediction of obesity-related health risks in youth. Similar to BMI, WC values in childhood can only be used in relation to reference values from national WC percentile curves. The importance of WC as a pediatric anthropometric parameter of obesity has been highlighted in the relatively new consensus on pediatric Metabolic Syndrome by the International Diabetes Federation, where a WC ≥ 90th percentile has replaced the BMI ≥ 95th percentile (Zimmet et al. 2007).

74.3 Adiposity and the Metabolic Syndrome

The Metabolic Syndrome (MetS), a clustering of clinical and metabolic parameters, such as central obesity, dyslipidemia, impaired glucose tolerance, and arterial hypertension, is highly prevalent among overweight and obese adults, whereas studies in children are limited (Fig. 74.2). Insulin resistance seems to be the key pathophysiologic mechanism in the development of MetS. The MetS is associated with the subsequent development of diabetes type 2 and cardiovascular disease in adults: Adults with MetS are twice as likely to die from and three times as likely to develop cardiovascular complications compared to those without the syndrome. Furthermore, adults with MetS have a fivefold greater possibility of developing type 2 diabetes (Pervanidou et al. 2006). Although there are no studies directly connecting the MetS in childhood to the above-mentioned conditions, it is believed that the pediatric MetS leads to adult MetS and that young individuals presenting multiple risk factors related to obesity are at a great risk of developing disease in later life.

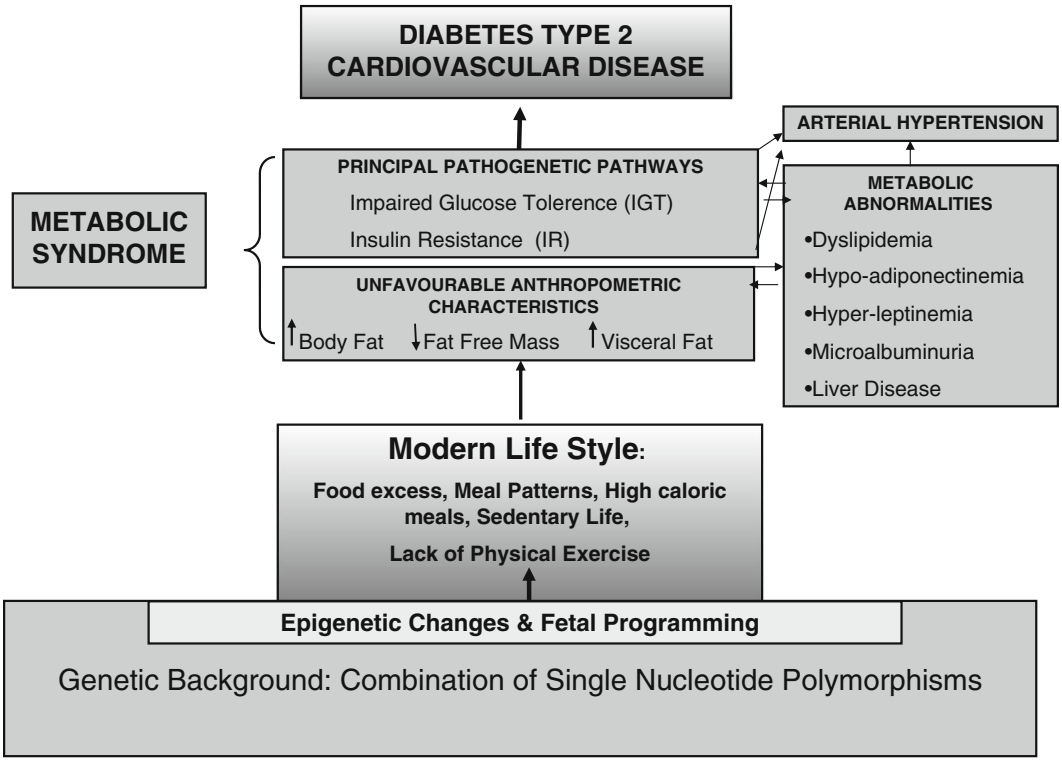

Fig. 74.2 Pathophysiologic mechanisms in the development of the Metabolic Syndrome. The interaction between the genetic background with epigenetic changes and the modern life style can lead to unfavorable anthropometric characteristics, such as obesity, increased visceral fat, and low fat-free mass, in children and adults. The Metabolic Syndrome, a clustering of obesity-related clinical and metabolic manifestations, is associated with insulin resistance and the development of diabetes type 2 and cardiovascular disease

Similar to adults, several definitions of MetS in children and adolescents aim at including as many individuals at risk as possible; however, no general consensus exists. The majority of pediatric studies on MetS use percentile charts for BMI or Waist Circumference, blood pressure, and lipid profile (HDL and triglycerides), while a standard cutoff is recommended for fasting glucose concentrations or glucose intolerance. At least three criteria are required to fulfill the definition of pediatric MetS. Recently, in 2007, a consensus on criteria for pediatric MetS was published by the International Diabetes Federation (Zimmet et al. 2007). This definition includes the measurement of waist circumference (WC) and requires a WC ≥ 90th percentile to define obesity. According to the IDF report, cutoff values for triglycerides, HDL, blood pressure, and glucose are expressed in absolute numbers instead of percentiles, depending on age and gender (Table 74.1).

Worldwide, the growing prevalence of diabetes type 2 in the youth, in parallel with the obesity epidemic, has highlighted the importance of MetS diagnosis in children and adolescents as a high-risk condition for developing disease in later life. The National Health and Nutrition Examination Study (NHANES) 1999–2000, using the ATP III definition modified for age, identified that the prevalence of the MetS among US adolescents increased from 4.2% in NHANES III (1988–1992) to 6.4% in NHANES (1999–2000). The prevalence of MetS was found high almost exclusively among obese adolescents (Cook et al. 2008).

However, pediatric definitions of the MetS use criteria extrapolated from the adult definitions and, in general, do not take into account the influences of growth and puberty. Thus, the MetS as an entity

Table 74.1 Key features of the pediatric metabolic syndrome (MetS)

1. The Metabolic Syndrome is a clustering of clinical and metabolic manifestations related to obesity. Insulin resistance is the key pathophysiologic pathway in the development of MetS, while an alteration in the secretion of several adipokines is also involved.
2. Though the prevalence of MetS is not high in the general population, it is highly prevalent among overweight and obese individuals. The MetS is associated with an increased risk for diabetes type 2 and cardiovascular disease.
3. A range of published pediatric definitions of the MetS suggests three or more of the following criteria: obesity, arterial hypertension, high triglycerides, low HDL, and increased fasting glucose/impaired glucose tolerance.
4. Central obesity is measured by Body Mass Index (BMI), or Waist Circumference (WC), age and gender specific. In pediatrics, a BMI ≥ 95th percentile, or a BMI-z score ≥2.0 in the national BMI charts is considered as a positive criterion for obesity. According to the IDF definition, a WC ≥ 90th percentile is also a measure of obesity.
5. Arterial hypertension is considered a systolic or diastolic blood pressure (BP) ≥ 90th or the 95th percentile for age, gender, and height. Based on the IDF definition, a fixed cutoff of systolic BP ≥130 or diastolic BP ≥ 85 mmHg is required to define hypertension, or treatment of previously diagnosed hypertension in adolescents older than 16.
6. Hypertriglyceridemia is a triglyceride level ≥ 90th or the 95th percentile for age and gender. The recent IDF definition recommends a cutoff of ≥150 mg/dl for triglycerides, or specific treatment for high triglycerides in adolescents older than 16.
7. HDL-Cholesterol ≤5th or the 10th percentile for age and gender, or, according to the IDF, an HDL <40 in both genders <16 years old and <40 in males and <50 in females or specific treatment for low HDL in adolescents older than 16 is a positive criterion for MetS
8. Impaired glucose tolerance is defined as a glucose level >140 mg/dl, but <200 in the oral glucose tolerance test. According to the IDF definition, a fasting glucose ≥100 mg/dl or the presence of known Type 2 Diabetes Mellitus is a positive criterion to define pediatric MetS.

This table lists the key features of the pediatric metabolic syndrome, including obesity, arterial hypertension, dyslipidemia, and increased fasting glucose/impaired glucose tolerance. Criteria for diverse pediatric MetS definitions described in this table are based on Zimmet et al. (2007)

is developing progressively and in accordance to age and pubertal changes, so that the full MetS cannot be easily diagnosed in childhood, especially when using cross-sectional assessments. Furthermore, the "normal" insulin resistance during puberty, in addition to changes in fat and fat-free mass observed during puberty, as well as changes in growth and sex steroids hormone secretion may play an important role in MetS stability.

74.4 Developmental Origins of the Metabolic Syndrome and the Adipocyte

Both human and animal studies have shown that being exposed to inappropriately low or high nutrition levels during crucial periods of fetal and postnatal development is associated with an increased risk for obesity, MetS, and diabetes type 2 in children and adults. The concept of fetal origins of obesity and the metabolic syndrome supports that exposure to excessive or deficient nutrition before birth alters the development of the adipocyte resulting in a permanent increase in the capacity to form new cells in the adipose tissue or to store lipids in existing adipocytes (lipogenesis) (Muhlhausler and Smith 2008).

Adipogenesis, the process of adipocyte development, occurs mainly during late fetal and early postnatal life, and it is highly sensitive to the nutritional environment at this time frame. It was also suggested that the number of adipocytes is relatively fixed in adulthood, with a very low turnover rate of adipose cells, supporting further the idea that fetal and early postnatal periods are crucial for the development of adipose tissue.

Experimental and human data have shown that infants suffered from fetal growth restriction, resulting most often from a compromised placental function, have lower adipose stores at birth. However, the postnatal exposure of the growth restricted infant to a nutrient-rich environment results in growth acceleration (catch up) and increased visceral adipose tissue accumulation.

Apart from fetal growth restriction, maternal obesity and/or maternal diabetes constitute major risk factors for childhood obesity and related disease. Based on animal data, it has been hypothesized that changes in gene expression within visceral adipocytes before birth influence the subsequent properties of subcutaneous adipose tissue that continues to develop. These "programmed" adipocytes may secrete factors that promote preadipocyte differentiation in other depots, resulting in further increase in adipocyte number (Muhlhausler and Smith 2008).

74.5 Obesity, Adipose Tissue and Inflammation

Obesity in adults and children is characterized by a state of chronic, low-grade systemic inflammation. Indeed, inflammatory markers, such as CRP and IL-6 are increased in obese individuals compared to controls, though not to the same extent observed in inflammatory diseases. This state of chronic inflammation in obesity has been successfully associated with a risk of developing diabetes type 2 and cardiovascular disease in later life. In the last few years, a large body of evidence has supported the role of the adipose tissue as an active secretary organ and an active participant in regulating the organism's physiologic and pathophysiologic processes (Fantuzzi 2005) (Fig. 74.3).

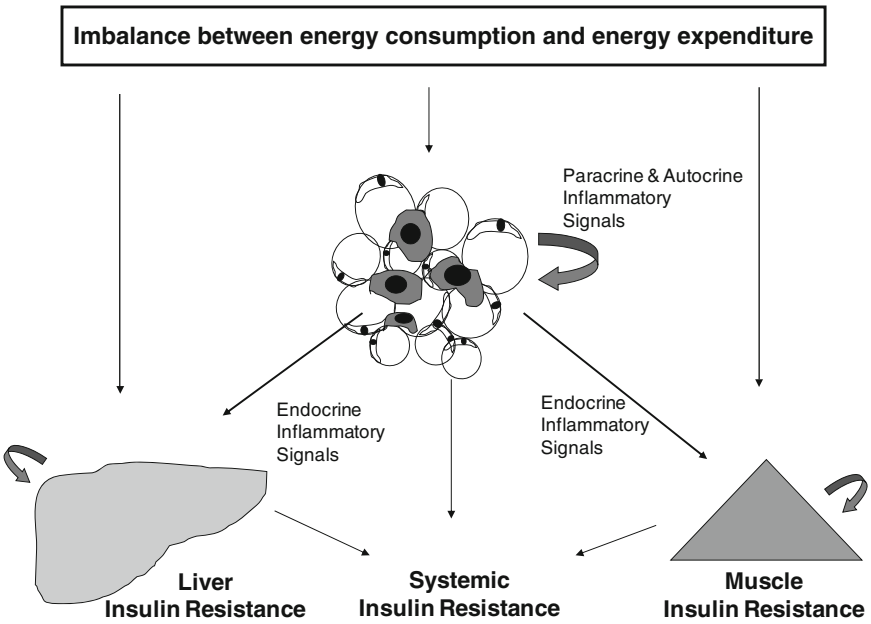

Fig. 74.3 Autocrine, paracrine, and endocrine function of the adipose tissue and the development of systemic insulin resistance in obesity. In obesity, adipocytes release cytokines, adipokines, and free fatty acids. These molecules act in a paracrine or autocrine function to augment the proinflammatory state within adipose tissue and cause localized insulin resistance. Furthermore, adipose tissue is considered as an endocrine organ, since these molecules act in liver and muscle and may decrease insulin sensitivity. In addition to the adipokines, independent inflammatory signals within the liver and muscle can result in local insulin resistance

Table 74.2 The pathophysiologic role of molecules secreted by the adipose tissue (in alphabetical order)

Adiponectin	Metabolic regulator; anti-inflammatory role; inhibition of monocyte adhesion to endothelial cells–macrophage transformation to foam cells
Agouti protein	Adipocyte lipid metabolism and differentiation
Adipsin	Stimulation of glucose transport; Stimulation of triglyceride storage in adipose cells; inhibition of lipolysis
Apelin	Regulator of cardiovascular functions; upregulated in obesity
FABP4/AFABP	Fatty acid–binding protein; lipid transport
IL-6	Inflammatory cytokine; promotes angiogenesis; regulates insulin sensitivity; increases hepatic *de novo* synthesis of fatty acid and cholesterol
Leptin	Metabolic regulator; promotes proliferation and angiogenesis; satiety signal; stimulation of lipolysis; inhibition of lipogenesis; improvement of insulin sesnsitivity
Lipocalin-2/NGAL	Antagonist of inflammatory adipokine secretion
MIF	Inflammatory cytokine
PPAR gamma/NRIC3	Nuclear regulator of metabolism
Retinol-binding Protein 4 (RBP4)	Regulator of insulin sensitivity
Resistin	Metabolic regulator; proinflammatory role
Serpin A8/Angiotensinogen	Serine protease inhibitor; promotes adipose tissue growth
Serpin A12/Vaspin	Serine protease inhibitor; regulates insulin sensitivity
Serpin E1/PAI-1	Serine protease inhibitor; extracellular matrix remodeling
Serum amyloid A1/SAA1	Apolipoprotein; low-grade inflammation
TGF-beta	Inhibitor of adipocyte differentiation
TNF-alpha	Inflammatory cytokine; regulates leptin; Promotes angiogenesis; regulates insulin sensitivity
Visfatin	Insulin-like and proinflammatory effects

This table summarizes the main actions of the molecules secreted by the adipose tissue in alphabetical order

The adipose tissue consists of white adipose tissue (WAT), which is the most prevalent type, and brown adipose tissue, participating mainly in thermogenesis. WAT consists mainly of adipocytes and a small number of macrophages. The number of macrophages infiltrated in WAT is directly associated with adiposity and with adipocyte size in human and rats (Weisberg et al. 2003). Adipocytes and macrophages are distinct types of cells. Macrophages are the major source of WAT derived TNF-alpha and IL-6 whereas circulating concentrations of these molecules are directly associated with adiposity, insulin resistance, and the metabolic syndrome. The pathophysiologic role of molecules secreted by the adipose tissue is presented in Table 74.2.

74.6 Leptin

Leptin (Greek word *leptos* meaning thin) is a 16 kDa protein encoded by the *ob* gene and it belongs to the class 1 cytokine superfamily, consisting of a bundle of four α-helices (Zhang et al. 1994). It is mainly produced by adipocytes, and circulating leptin levels are directly correlated with the mass of adipose tissue. Leptin is mainly involved in the control of appetite: it decreases food intake and increases energy consumption by acting on hypothalamus and inducing anorexigenic factors and inhibiting orexigenic neuropeptides (Lago et al. 2007) (Figs. 74.4 and 74.5). The synthesis of leptin is mainly regulated by food intake and eating-related hormones but also by sex steroid hormones and a variety of inflammation mediators. Leptin levels are higher in women than in men even after

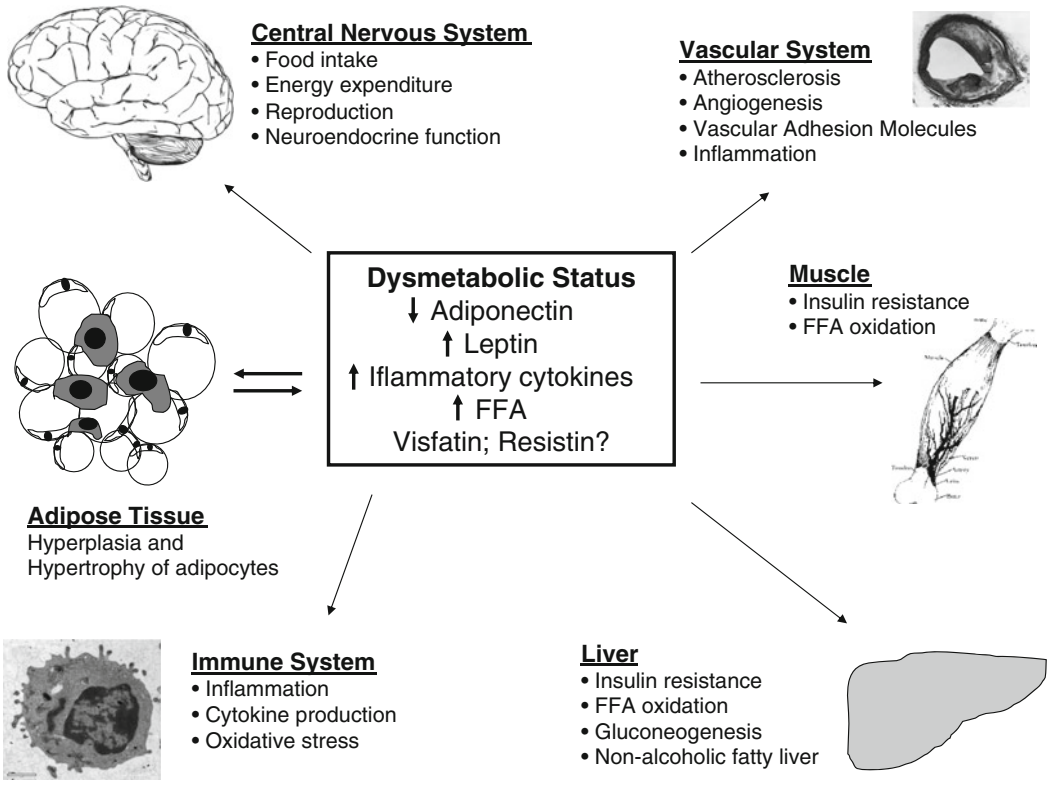

Fig. 74.4 Effects of obesity-related dysmetabolic status on other organs and systems. Hyperplasia and hypertrophy of adipocytes, caused by obesity, lead to an unfavorable metabolic status, with low adiponectin, high leptin, high inflammatory cytokines, and high free fatty acids. This dysmetabolic status effects on different organs and systems, such as the central nervous, the vascular, and the immune system as well as the muscle and the liver, regulating a variety of physiologic processes, as indicated in the figure

adjusting for BMI, as a result of sex steroid hormones' action (being inhibited by testosterone and increased by ovarian sex steroids).

Leptin exerts its biological actions by binding to its receptors, which are encoded by the gene *diabetes* (*db*) and belong to the class I cytokine receptors superfamily. Mice with a mutation in the leptin (*ob/ob*) or leptin receptor (*db/db*) genes, as well as humans with a mutation in the same genes have excessive obesity. Leptin is now considered as a pleiotropic hormone involved in a variety of physiologic processes, such as regulation of food intake, glucose metabolism, synthesis of glucocorticoids, the proliferation of CD4+ T lymphocytes, cytokine secretion, phagocytosis, endocrine functions, inflammation and immune response, and reproduction and angiogenesis (Lago et al. 2007).

A vast majority of studies has investigated the role of leptin in childhood and adolescent obesity and obesity-related disorders. A recent study (Zhang et al. 2009) examining plasma leptin concentrations in relation to different adiposity measurements has shown similar associations of leptin with BMI, WC, fat mass index (FMI), and percentage body fat (%BF) in females. In males, %BF and FMI were more strongly associated with leptin levels than BMI and WC. Trunk fat (%TF) had the weakest associations with leptin in both genders.

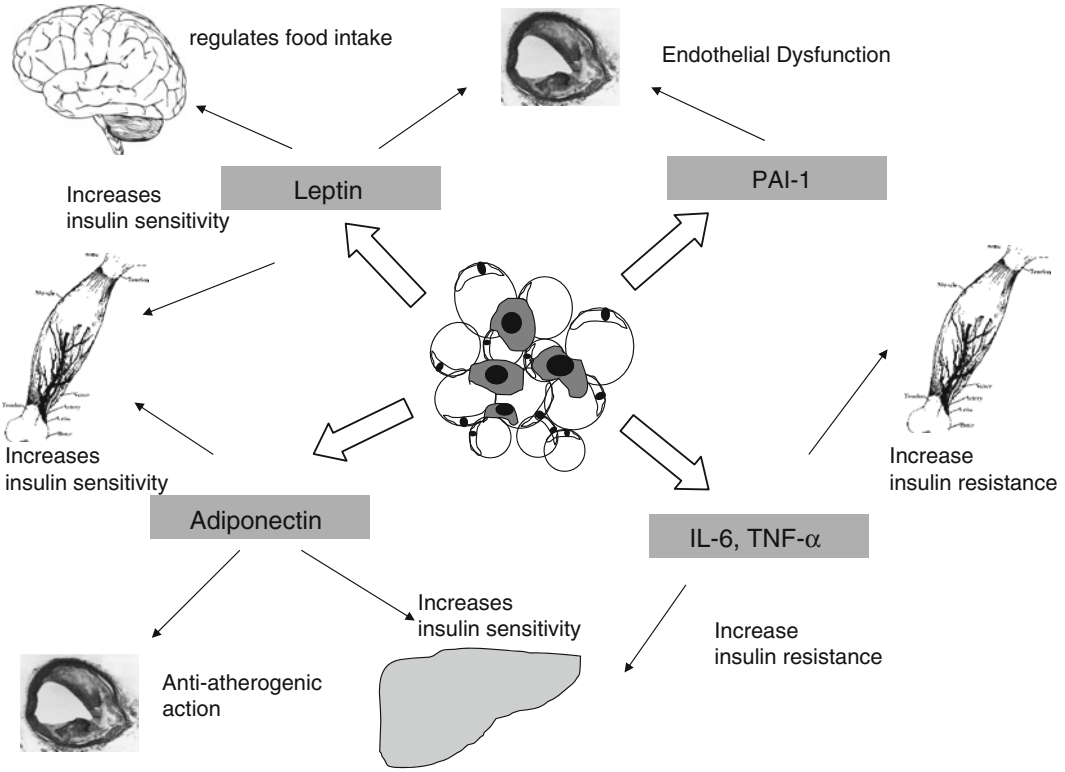

Fig. 74. 5 Actions of leptin, adiponectin, PAI-1, IL-6, and TNF-alpha. This figure indicates the diverse actions of each adipokine and inflammatory cytokine on different organs and systems

74.7 Adiponectin

Adiponectin is a 244-residue protein prevalently produced in the white adipose tissue. It increases the oxidation of fatty acids and reduces the synthesis of glucose in the liver (Berg and Scherer 2005). Adiponectin circulates in human blood in the form of multimers, with specific molecular sizes, a trimeric low-molecular-weight (LMW), a hexameric medium-molecular-weight, and a high-molecular-weight (HMW) adiponectin (Araki et al. 2006). It has been suggested that adiponectin molecules have different biological actions and that the HMW-form is the one with the higher activity. It acts, as far as it is known, via two receptors, the AdipoR1, mainly found in skeletal muscle, and the AdipoR2 found in the liver. It has profoundly insulin-sensitizing effects and an important role in regulating energy metabolism. Studies in knock-out mice have shown that ablation of the adiponectin gene has no dramatic effects on animals being in a normal diet. However, when those mice are given a high-fat, high-sucrose diet they develop severe insulin resistance and lipid accumulation in muscles (Whitehead et al. 2006).

Circulating levels of adiponectin are lower in obese than nonobese individuals (Arita et al. 1999). A significant negative correlation has been found between serum adiponectin levels and BMI, percent body fat, waist-to-hip ratio, and intra-abdominal fat. Adiponectin levels have also been studied in obesity-related disorders such as type 2 diabetes, where plasma adiponectin concentrations are lower than in age- and BMI-matched individuals. Finally, plasma adiponectin concentrations are lower in

patients with clinical manifestations of coronary heart disease (Ouchi et al. 2003) and several cardiovascular risk factors, including hyperlipidemia, high blood pressure, and C-reactive protein (CRP) levels. In addition to traditional obesity-related risk factors, such as lipid profile, glucose, and insulin, it appears that this cytokine has emerged as a powerful cardiometabolic risk factor.

One of the first studies in pediatric obesity examined the role of adiponectin (Winer et al. 2006) in childhood obesity and its associations with inflammatory markers and the metabolic syndrome. This study involved a multiethnic cohort of 589 obese children and adolescents. An association was found between adiponectin and CRP levels, which was independent of insulin resistance and adiposity. Low levels of adiponectin were associated with high levels of CRP and with components of the metabolic syndrome, such as low high-density-lipoprotein (HDL) and high triglyceride-to-high-density-lipoprotein ratio. Hypoadiponectinemia appeared to be related to a low-grade systemic chronic inflammatory state and it was suggested as a signal linking inflammation and obesity. Furthermore, high adiponectin levels were associated with a favorable lipid profile (high HDL and low triglyceride to HDL ratio). It has been suggested that these effects might result from the significant positive relation to lipoprotein lipase activity.

Few other studies have investigated the relation between adiponectin and the metabolic syndrome in children and found that hypoadiponectinemia is an independent risk factor for MetS (Gilardini et al. 2006) and adiponectin has been proposed as a potential biomarker of metabolic syndrome in children. Ethnic differences have also been reported in adiponectin levels in children: It has been shown that obese African-American and Hispanic children have lower adiponectin concentrations and this may be related to insulin sensitivity and may contribute to an increased risk for developing type 2 diabetes in these ethnic groups (Bush et al. 2005; Winer et al. 2006). Age and puberty seem also to impact on adiponectin levels: among children and adolescents, adiponectin levels were lower in older children (Winer et al. 2006) whereas another study found that adiponectin levels decline with age in relation to changes in sex steroid hormones and growth factors. These "normal" changes of adiponectin during puberty may contribute to the "normal" pubertal insulin resistance (Butte et al. 2005).

A few recent studies also suggest a positive association between adiponectin and the N-terminal pro-brain natriuretic peptide (NT-proBNP). NT-proBNP is considered a well-established diagnostic and prognostic marker of heart failure and coronary heart disease in adult patients with peripheral arterial disease, chronic heart failure, and coronary heart disease (Pervanidou et al. 2009). In investigating associations between adiponectin and NT-proBNP in obese adolescents, we found a significant positive correlation between NT-proBNP and adiponectin concentrations only in females. This association was stronger in adolescents with a greater degree of obesity, in girls having a BMI-z-score >2.5. In the same study, adiponectin showed a significant negative correlation with BMI-z-scores, triglycerides, HDL, and fasting insulin levels. This association was not found in males, suggesting a potential role of sex steroid effects during puberty. Although associations between adiponectin and NT-proBNP concentrations cannot be fully understood, a lipid-mobilizing effect of NT-proBNP that indirectly stimulates adiponectin could be a possible explanation. Indeed, in a recent study, intravenous infusion of natriuretic peptide increased glycerol concentrations in human subcutaneous adipose tissue suggesting a direct lipid-mobilizing effect.

A number of studies have also investigated circulating levels of adiponectin in neonates, in relation to gestational age and birthweight. In a sample of preterm infants at discharge, lower levels of adiponectin were found in the preterm than the full-term group. However, after adjustment for body weight, the influence of prematurity was no longer significant. Levels of adiponectin were influenced by being born small for gestational age, weight gain, and possibly by dietary intake of long-chain polyunsaturated fatty acids (LCPUFAs). In the same group, serum adiponectin levels did not correlate with insulin or leptin levels. Another study in preterm neonates showed that adiponectin was higher

in those infants fed long-chain polyunsaturated fatty acids (LCPUFA)-supplemented formula, than infants fed the LCPUFA-free formula, indicating that early dietary manipulation – supplementation with LCPUFA – may have a beneficial effect on serum adiponectin in preterm infants (Siahanidou et al. 2008). Regarding the distribution of adiponectin multimers in infants, a recent study in full- and preterm infants showed that high-molecular-weight adiponectin is the most prevalent form in infants, while the distribution of low- and medium-molecular-weight molecules differ between full- and preterm molecules (Siahanidou et al. 2009).

74.8 Resistin

Resistin is a 12 kDa peptide that was originally discovered when examining differential gene expression of mouse adipose tissue after treatment with thiazolidinedione (TZD) (Steppan et al. 2001). Resistin was increased in insulin resistant mice and decreased by TZD treatment. Additionally, treatment with a antiresistin antibody improved insulin sensitivity and glucose transport in mice and mouse adipocytes. However, data in humans are less clear: a number of studies investigated resistin concentrations in plasma or adipose resistin expression and have found variable results. In summarizing experimental and clinical data till now, resistin is an important adipokine in the development of insulin resistance; however, it seems to be quantitatively less important in humans in comparison with other adipokines (Rasouli and Kern 2008).

74.9 Visfatin

Visfatin was originally identified as a protein involved in B-cell maturation (Resouli and Kern 2008) and most recently was discovered as a protein with insulin-like functions. Visfatin is predominantly found in visceral adipose tissue, from which its name was derived (Fukuhara et al. 2005). Studies in mice revealed that injection of visfatin decreases blood sugar, while animals with a mutation in visfatin gene have high glucose levels.

74.10 Retinol-Binding Protein 4 (RBP4)

RBP4 is a small, 21 kDa protein that circulates bound to transthyretin (TTR) in a form of 80 kDa protein complex. RBP4 was initially considered to be only the transporter of retinol (Vitamin A), but recent experimental and clinical studies have shown that the soluble form of RBP4 is an adipokine involved in systemic insulin resistance: Studies in obese, insulin resistant, type 2 diabetic adults revealed high levels of this adipokine, while reduced concentrations of RBP4 were associated with improved insulin action. Two recent studies reported increased RBP4 concentrations in obese adolescents, although a correlation between RBP4 and the HOMA was not demonstrated. In children, a study in 80 girls (Kanaka-Gantenbein et al. 2008) showed that, in contrast to adult studies, RBP4 concentrations correlated negatively with BMI-SDS (Fig.74.6). This discrepancy in findings of RBP-4 levels between adult and pediatric obesity, may be due to the development of protective mechanisms of the organism during childhood.

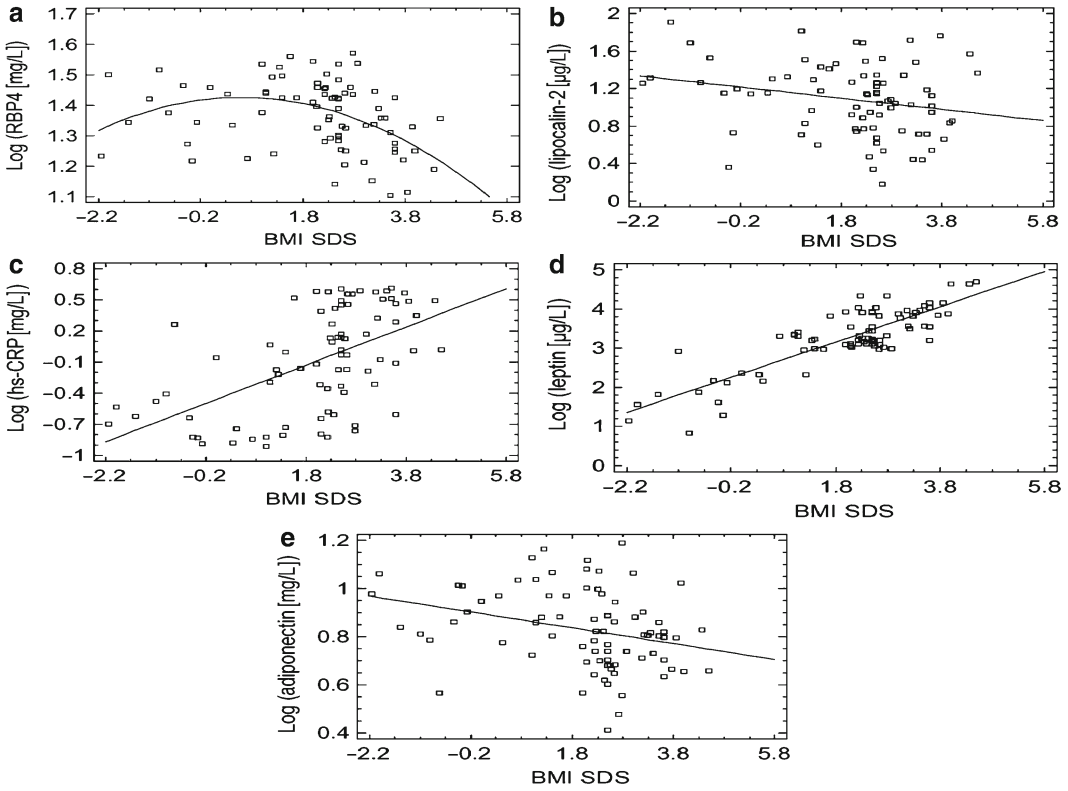

Fig. 74.6 Associations between childhood obesity and adipokines. Relations between childhood obesity, expressed in BMI-SDS, and leptin, adiponectin, ultra-sensitive CRP, RBP4, and lipocalin-2. This pediatric study suggests that with the exception of RBP4 and lipocalin-2, other cytokines follow the adult pattern of association (Kanaka-Gantenbein et al. 2008)

74.11 Lipocalin-2

Lipocalin-2 is a protein, belonging to the same family as RBP4, with inflammatory actions. It is positively correlated to BMI and several parameters of the MetS. Similarly to RBP4, lipocalin-2 was found to promote insulin resistance. In a recent pediatric study (Kanaka-Gantenbein et al. 2008), and similar to RBP4, lipocalin-2 concentrations correlated negatively with BMI-SDS. This finding was in contrast to adult studies, and a counter-regulatory effect was hypothesized to protect the organism from insulin resistance.

74.12 Applications to Other Areas of Health and Disease, and Conclusions

A large amount of clinical and experimental data supports that WAT is an active secretory organ, participating in a variety of physiologic and pathophysiologic processes. It is now clear that adipokines play multiple roles and participate in the function on several organs and systems, revealing a

continuous interplay between the adipose tissue and metabolic and inflammatory disorders. Research in adipose tissue and adipokines has enhanced our understanding of the relations between obesity, inflammation, insulin resistance, and the development of diabetes type 2 and cardiovascular disease and has led to the development of new therapeutic approaches. Prevention of leptin-induced inflammation is a potential therapeutic aim, through the development of a leptin-binding protein or by blocking the leptin receptor. Adiponectin, the promising molecule with antiatherosclerotic effects, is another obvious target for therapeutic interventions. The development of drugs acting in enhancing the endogenous production of this molecule would be of great importance for the treatment of obesity and obesity-related disorders. Further studies focused on mechanisms related to the infiltration of adipose tissue with macrophages and the secretion of inflammatory cytokines and adipokines are needed. However, the field is still too young to allow for therapeutic interventions related to adipokine and cytokine production, especially in childhood and adolescent obesity.

Summary Points

- The adipose tissue is no longer considered as an inert reservoir of energy but as an active secretory organ, releasing a variety of peptides and other molecules, the adipokines, into the circulation.
- In the presence of obesity, the adipose tissue, with enlarged adipocytes and macrophages inserted within them, secretes more proinflammatory cytokines, such as TNF-alpha and IL-6, and fewer antiinflammatory peptides, such as adiponectin.
- The Metabolic Syndrome, a clustering of clinical and metabolic manifestations related to obesity, is associated with an imbalance in the secretion of molecules secreted by the adipose tissue. These molecules act on several organs and systems, such as the central nervous, the immune, the vascular system, the muscle, and the liver, and regulate a variety of pathophysiologic functions.
- In children and adolescents, the same pathophysiologic mechanisms link obesity to the Metabolic Syndrome, however, there is some evidence that the effects of growth and puberty in these critical periods of change may differentiate the normal values as well as the physiologic role of the adipokines.
- Leptin, the prototypic adipokine, is mainly involved in the control of appetite: by acting on the hypothalamus, it decreases food intake and increases energy consumption. Leptin is higher in women than in men, independently of BMI, and higher in obese than normal-weight individuals, adults, and children.
- Adiponectin increases the oxidation of fatty acids and reduces the synthesis of glucose in the liver. Circulating levels of adiponectin are lower in obese adults and children and low levels of this cytokine are also associated with diabetes type 2.
- Retinol-Binding Protein 4 (RBP4) and lipocalin-2 are two novel adipokines involved in insulin resistance. In contrast to adult studies, where RBP4 and lipocalin-2 are high in obesity, it was found that these adipokines correlated negatively with BMI-SDS in obese children.

Chapter 75
Anthropometric Measures in Children with Renal Failure

Andreas Nydegger and Julie E. Bines

Abstract Anthropometric and body composition assessments provide important information about the nutritional status of dialysis patients. A nutritional assessment by a trained dietitian is therefore recommended for patients diagnosed with renal disease because they are frequently in poor nutritional health. Knowledge of the nutritional health of patients with renal disease is necessary to prescribe and monitor appropriate clinical and nutrition therapies. Anthropometrical methods occupy a meaningful role in assessing the nutritional status of patients with renal disease, are cost-effective screening techniques for describing body size, and they are well suited for identifying levels of body composition, nutritional status or risk for disease. However, children with renal disease present special problems for anthropometry, including decreased functional status and increased comorbidity, which challenge nutrition assessment methodology. Measures of weight, stature, calf circumference, arm circumference and triceps and subscapular skinfolds have therefore been reported for dialysis patients, who tend to be shorter, lighter and have less adipose tissue than healthy persons of the same age. Other techniques to assess body composition are dual energy X-ray absorptiometry (DEXA), bioelectrical impedance, total body water (TBW) and prediction equations. However, irrespective of the technique to be used, all are validated in healthy individuals based on the assumption that body composition parameters are relatively static, which isn't the case in renal patients. Anthropometric measurements should be an integral component of the routine care of the child and adolescent with renal disease.

Abbreviations

CRF	Chronic renal failure
ESRD	End stage renal disease
BMI	Body mass index
DEXA	Dual energy x-ray absorptiometry
TBW	Total body water
FFM	Fat free mass
BIA	Bioelectrical impedendance

75.1 Introduction

Accurate assessment of nutritional status is an essential component in the management of children with chronic renal failure (CRF) and following renal transplantation. Despite advances in dialysis technique and in adjunct therapies, protein-energy malnutrition is still encountered in up to 50% of children on chronic hemodialysis and may progress despite regular dialysis (Nydegger et al. 2007). The etiology of malnutrition in children with renal failure is multifactorial. Anorexia, side-effects of medications and uraemia can contribute to the development of malnutrition in children with renal disease. Hyperglucagonemia, hyperparathyroidism, or metabolic acidosis is associated with accelerated protein catabolism and a reduction in muscle mass (Kuizon et al. 1997). Alterations in nutritional, metabolic and fluid homeostasis negatively impact the long-term clinical outcome and quality of life of patients with CRF (Rigden et al. 1987). Assessment of nutritional status and body composition in the early stages of renal disease is important to detect nutritional disturbance at its onset and target interventions aimed at preventing the development of malnutrition.

Assessment of weight and height is routinely performed in children in both inpatient and outpatient settings. Using standardised growth charts, growth and weight, body mass index and growth velocity in a child with renal disease can be compared to normal expectations based on age and sex. These simple and practical measures can identify changes in nutritional status and growth impacting the normal growth of the child with CRF (Norman et al. 2000) (Fig. 75.1). However, faltering in

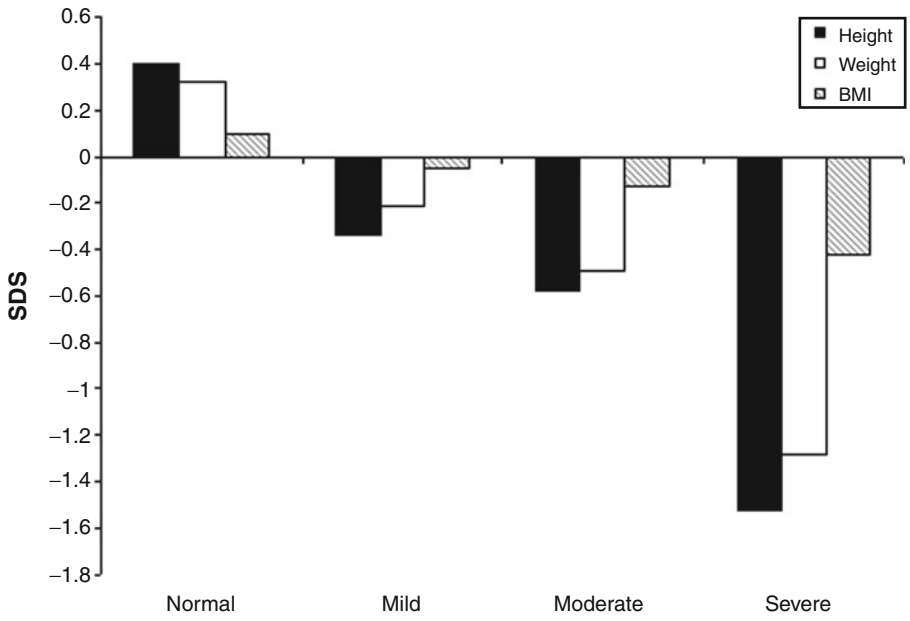

Fig. 75.1 Comparison of weight, height and body mass index standard deviation score (BMI SDS) in relation to severity of chronic renal insufficiency. Anthropometric assessment is a simple and practical measure to identify changes in nutritional status and growth impacting on the normal growth of the child with chronic renal failure (Reprinted from Norman et al. (2000), with permission)

●●●● Very high
●●● High
●● Moderate

height growth often lags 3–6 months after weight loss or failure to gain and is not considered a sensitive, early marker of decline in nutritional status. In view of the frequency of growth impairment in children with renal disease, correction for "height-age" is important in monitoring growth expectations in children with CRF (Wells 2001). Measurements of skinfolds and limb circumference are practical, cost-effective techniques that describe body size and can identify levels of fatness and leanness in patients with renal failure. The accuracy and reliability of these measurements in children on dialysis have been adapted from data in adults and children and are summarised in Table 75.1 (Chumlea 2004).

75.2 Effects of Renal Disease on Anthropometric Measurements and Interpretation in Children and Adolescents with Renal Disease

Anthropometric measurements are standardised and validated for age, gender and ethnicity in the healthy population (Lohman et al. 1988). However, when extrapolating this data to children with renal disease a number of key considerations need to be considered.

75.2.1 Site of Measurement

Traditionally, measurements are performed on the right side of the body based on the methodology used to establish the reference data. However, in a patient with a vascular access for dialysis or any other limitations of the right side (i.e. past cerebrovascular accident, localised oedema) (Fig. 75.2), measurements may need to be performed on the left side. The change in location of the vascular access for hemodialysis may necessitate changing the location for subsequent measurements of circumferences and skinfolds.

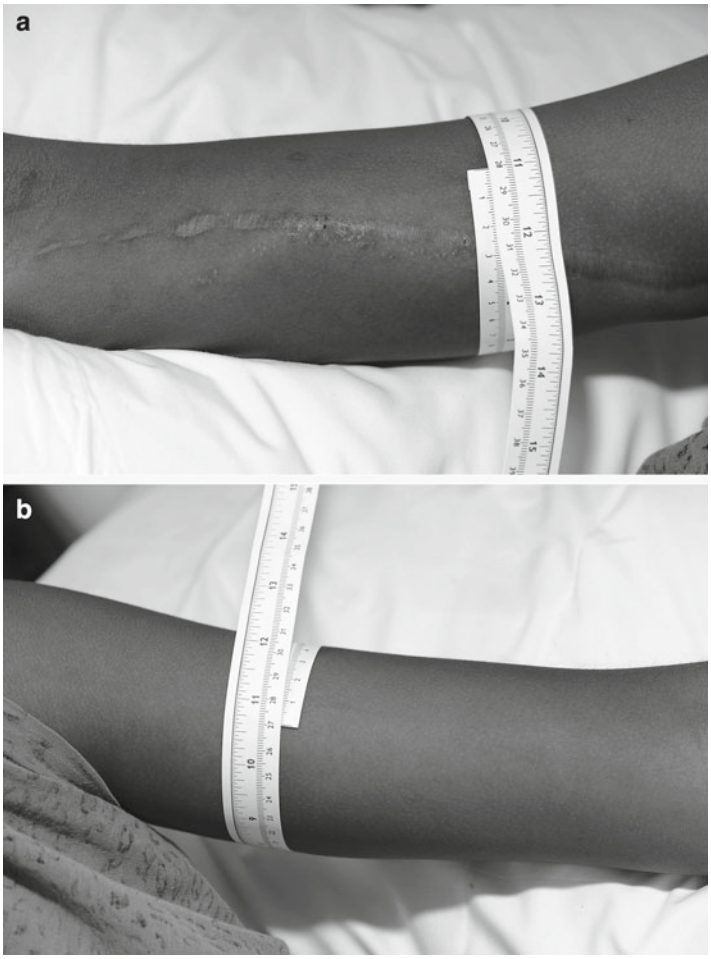

Fig. 75.2 Patient with a vascular access for dialysis on the right arm. (**a**) Increasing its diameter and rendering correct measurement impossible, (**b**) left arm of the same patient (with written consent of the patient)

75.2.2 Hydration Status

Changes in weight reflect changes in hydration status, energy and protein balance. This presents a challenge in patients on regular dialysis where large shifts in extracellular fluids may occur over a few hours. It is recommended that serial measurements be performed at the same time in the dialysis cycle, usually after dialysis is completed. Fluid overload in CRF can affect both skinfold and midarm circumference measurements as well as altering the assumptions for body composition validated in healthy individuals. Hydration status, abnormal regional body composition or an abnormal ratio of subcutaneous to visceral fat could also result in an overestimation of fat mass estimated from skinfold measurement. Estimates of fat free mass (FFM) are based on the assumption that the body water content is 73%; therefore, an estimate of edema-free FFM may be a more useful nutrition parameter than FFM in children with CRF.

75.2.3 Skeletal Disproportion in Children with CRF

Impaired linear growth is a major complication of childhood-onset CRF and is a significant obstacle to successful long-term rehabilitation. Growth failure in children with CRF can be caused by effect

of the disease and its treatment on the somatotrophic axis. It may also occur as a direct result of uremia at the level of the growth plate (Schaefer and Mehls 1998). An improved understanding of the factors affecting growth in CRF and following transplant has led to the introduction of growth-promoting strategies with recombinant human growth hormone (Haffner et al. 2000; Maxwell and Rees 1998). But, even with recombinant GH treatment, children and adolescents with CRF may not grow well during puberty and catch-up growth following renal transplantation may be suboptimal (Haffner et al. 2000; Fine 1997).

The spine has a greater number of epiphyses than any other part of the axial skeleton. Therefore, spinal measurements may be a more sensitive indicator of abnormal growth than total height, especially in the assessment of differential growth. A significant proportion of spinal growth occurs during puberty and delayed puberty may be associated with skeletal disproportion, impacting final height. Skeletal disproportion is assessed by calculating the ratio of sitting height to standing height (SH:HT). A significant proportion of children with CRF have relative shortening of the spine (Qayyum et al. 2003). Altered skeletal proportions can be identified at puberty and can persist, despite renal transplantation (Qayyum et al. 2003). Medications, in particular corticosteroids, inhibit growth directly at the level of the growth plate or via the growth hormone axis (Mushtaq and Ahmed 2002). The impact of corticosteroids on bone resorption is marked in cancellous bone and glucocorticoid-induced osteoporosis may present with loss of vertebral height as well as spinal deformity.

75.3 Effects of Age, Gender and Ethnicity on Interpretation of Anthropometric Data in Children and Adolescents with Renal Disease

The normal variability in anthropometric measurements occurring with age, gender and race further confounds the interpretation of anthropometric measurements in children with renal disease. Changes in body composition occur throughout the lifespan and are associated with changes in metabolism, nutrient intake, physical activity and the risk of chronic disease. Throughout childhood, there is an increase in the mineralisation of the skeleton with growth and increase in the density of FFM (Lohman 1986). In addition, the changes in the hormonal milieu alter the distribution and proportions of adipose, muscle and skeletal tissues in children as they mature into adults. These changes are further affected by the variation in the onset and duration of puberty.

Bone mineral accounts for as much as 6% of FFM but decreases substantially after menopause. However, levels of FFM and bone mineral also decrease as physical activity decreases with CRF and chronic hemodialysis and therefore, must also be considered in interpreting results of anthropometric measurements in children and adolescent with renal disease.

75.4 Effects of Hormone Deficiency on the Interpretation of Anthropometric Measurements in Children and Adolescents with Renal Disease

Although the etiology of growth failure in children with renal disease is multifactorial, endocrine-related factors, including abnormalities in the growth hormone (GH) and insulin-like growth factor-1 (IGF-1) axis may be may play an important role in the pathogenesis of growth impairment. Even after transplantation, alterations of the GH-IGF-1 axis are impacted by the use of corticosteroids, which suppress GH production and secretion and decrease cell responsiveness to IGF-1

(Hokken-Koelega et al. 1993). Whilst trunk and head measurements are usually preserved, the extremities are the most affected. Zivicnjak and colleagues reported a marked decrease in *z*-scores for bone dimensions of the legs (e.g. leg length –2.22; bicondylar femur diameter -1.87) and arms (e.g. arm length -1.996; bicondylar diameter of humerus –1.53) in children with CRF (Zivicnjak et al. 2000). However, these results need to be interpreted with caution as there was no correction for delayed puberty, which occurred in 34% of the study cohort. Nevertheless, growth hormone therapy was effective in improving impaired longitudinal dimensions of the body and the restoration of growth reported occurred predominantly in the extremities. Growth hormone therapy has been associated with improved growth and decreased the risk for death due to cardiovascular disease in children with CRF (Wong et al. 2000).

75.5 Other Limitations and Sources of Error

Measurement error may occur due to patient, observer and equipment factors. Children are notoriously difficult to measure and cooperation for repeat measurements can sometimes be challenging. The assistance of a parent and an experienced observer can help minimise these problems. Equipment should be well maintained and calibrated to limit the risk of malfunction. Estimation of fat mass and fat free mass should be based on established methodology validated in this specific patient group. The limitation of standardised data in normal children across a range of ages is a major barrier in the interpretation of measurements in children with renal disease. This may be further compounded by ethnic and disease specific factors that may influence linear growth potential or body composition. Also the treatment of an individual with renal disease may vary from year to year with alterations in medications, dialysis requirements or transplantation. This may limit the ability to interpret the influence of nutritional status on growth and body composition outcomes. In interpreting measurements of anthropometrics, both body size, irrespective of chronological age, and pubertal status are important variables that must be considered.

75.6 Other Techniques to Assess Body Composition in Children with Renal Disease

A range of methods is available to measure body composition and these provide options for monitoring nutritional status in children with renal disease. Direct methods use electro-magnetic radiation to quantify specific tissues and chemical and molecular elements in the body and include neutron activation, computer X-ray tomography and magnetic resonance imaging. Indirect methods involve measures of body density from water or air, dual energy X-ray absorptiometry (DEXA), total body water (TBW), bioelectrical impedance (BIA) and the use of predictive equations. However, irrespective of the technique to be used, all are validated in healthy individuals based on the assumption that body composition parameters are relatively static. For example, the measurement of TBW is based on the assumption that the average proportion of water in the body is 73%. However, body water in the normal adult can range from 67% to 80% (Chumlea et al. 1999). This range is even larger in infants and small children in whom the proportion of total body water changes dramatically in the first months of life (Davies 1993). As approximately 15–30% of TBW is present as extracellular fluid, variations in the distribution of TBW will also impact estimates of FFM and total body fat in patients with renal disease. Pre-dialysis patients have high levels of extracellular fluid and electrolytes. The impact of these variables on the accuracy of body composition methods is not well understood and may be clinically relevant in children with renal disease. Therefore, it is recommended that body

Table 75.2 Body composition of children with CRF and ESRF [*z*-scores; mean ± SD]

	CRF	ESRF	*P*-value
Number (%)	8 (53%)	7 (47%)	–

composition measurements be performed immediately after dialysis when body fluid compartments may be closer to healthy levels. The clinical use of isotope dilution in children with renal disease may be limited by fluid overload and may result in an underestimation of fat and lean mass. Techniques such as densitometry, neutron activation analysis and total body potassium measurement may offer some advantages (Nydegger et al. 2007) (Table 75.2). Fluid overload and altered body potassium and urea levels in children and adolescents with CRF may lead to an overestimation of lean body mass as was found in a study comparing methodologies for the assessment of body composition in children with CRF (Nydegger et al. 2007) (Fig. 75.3).

75.7 Anthropometric Measures as Predictors of Outcome and Mortality

Renal disease is associated with significant morbidity and mortality (Childhood mortality rate: Renal disease 1.9% versus total population 0.48%) (Guyer et al. 1998). Anthropometric measurements, including height, growth velocity, weight and BMI, can predict outcome in children with renal disease.

75.7.1 Height and Growth Velocity

Wong et al. reported that paediatric patients with end stage renal disease (ESRD, defined as glomerular filtration rate <10 mL/min/1.73 m^2) have a mean height 2.5 standard deviations less than the mean (Fig. 75.4), growth velocity 0.38 standard deviation less than the mean and BMI 0.24 standard deviation less than the mean of healthy children reported in the Third National Health and Nutrition Examination Survey (NHANES III) (Wong et al. 2000; NHANES-III 1996). Using multivariate analyses, height, linear growth velocity and BMI were identified as significant predictors of death among children with ESRD. However, height and growth velocity were better predictors of mortality in younger (0- to 5-years and 6- to 14-years) children, than in adolescents (15- to 18-years). Over all age strata, for every one standard deviation decrease in height, the adjusted risk for death increased by 14%. After adjusting for sex, age, race, treatment modality and duration of ESRD, for every one standard deviation decrease in growth velocity, the risk for death increased by 12%. Hemodialysis was associated with an 11-fold increase in risk for death compared to transplantation. Interestingly, weight, sex and ethnicity were not significantly associated with mortality in children with ESRD (Wong et al. 2000).

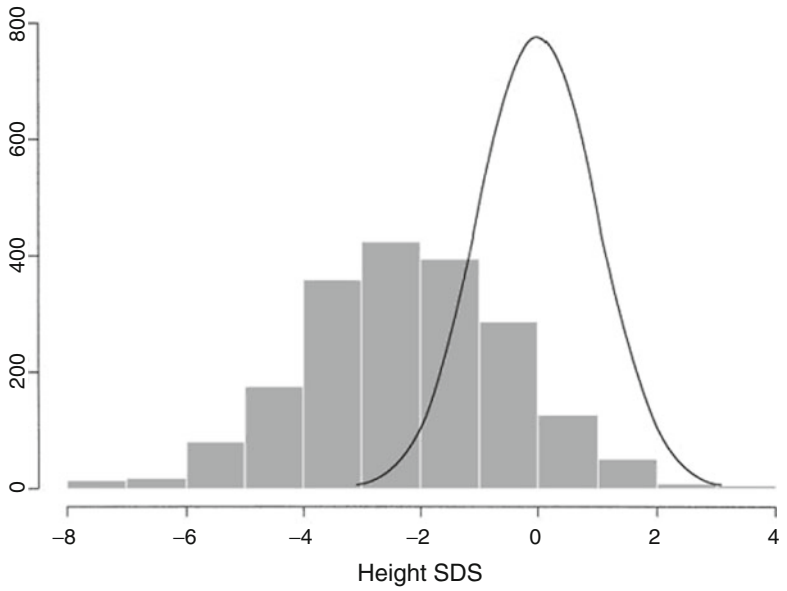

Fig. 75.4 Distribution of height standard deviation scores in patients with end stage renal failure compared with children in the US general population. The distribution of height standard deviation scores of 1949 patients in the study sample of Wong et al. compared with children in the US general population shows a mean height 2.5 standard deviation less than the mean (Reprinted from Wong et al. (2000), with permission)

75.7.2 Weight and BMI

Excessive weight gain in children with CRF may be associated with an increased risk of cardiovascular morbidity (Oh et al. 2002). Originally body mass index (BMI) was developed to assess body fat in community-based studies. Age-matched BMI data have aided the use of BMI in paediatric population studies and have increasingly been used to assess nutritional status in children with chronic disease (Cole et al. 1995; Wong et al. 2000). However, the clinical usefulness of BMI in the assessment of children with chronic diseases that place them at increased risk of growth retardation has been questioned (Schaefer et al. 2000). Reduced levels of physical activity, dialysis and glucocorticoid therapy may further confound the interpretation of BMI in children with renal disease. Wong et al. suggested that the relationship between BMI and mortality among both dialysis and transplant patients followed a "U" shaped distribution (Wong et al. 2000). Using the BMI standard deviation of 0.50 as the reference BMI, moving either above or below the referent point by two standard deviations was associated with a 26% increased risk for death. Moving from the referent point either above or below three standard deviations was associated with a 67% increased risk for death (Wong et al. 2000). However, caution must be used in interpreting BMI in children with renal disease. A high BMI may occur due to co-morbidities such as volume overload, edema or obesity, whereas a low BMI is likely to represent malnutrition. Rashid et al. showed that children with CRF and post renal transplantation have a high fat mass, which may be associated with an increased risk of cardiovascular morbidity, insulin resistance and diabetes (Rashid et al. 2006). Interestingly, these patients exhibited central obesity, suggesting that nutritional factors, chronic inflammation and lack of physical activity, as well as corticosteroid therapy, all contribute to the increased fat mass.

75.8 Applications to Other Areas of Health and Disease

The application of anthropometric techniques and the interpretation of results in children with CRF reflect similar challenges observed in children with chronic disease involving other organ systems. However, a key distinction in CRF is the specific impact of this disease on protein metabolism and bone mineralisation. Consideration of marked changes in hydration status with dialysis provides an insight into the interpretation of anthropometric measurements in children experiencing significant shifts in fluid balance such as occurs in assessing nutritional status in a child with acute gastroenteritis.

75.9 Conclusions

Renal disease in children is associated with significant morbidity and death. Not only can anthropometric measurements predict outcome in children with renal disease but they also provide a practical tool to detect early signs of nutritional and growth faltering and monitor response to nutritional and therapeutic interventions. However, the results of anthropometric measurements in children with renal disease need to be interpreted with consideration of hydration status, growth failure, skeletal abnormalities and delayed development. Early disturbance in growth and nutritional status can be identified even in children with mild chronic renal insufficiency. Identification and nutritional intervention at this early stage may present a window of opportunity to overt or limit the growth failure

often associated with CRF of childhood. Anthropometric measurements are safe, cost-effective and easy to perform and should be an integral component of the routine care of the child and adolescent with renal disease.

Summary Points

- Chronic malnutrition occurs in up to 50% of children on chronic hemodialysis and may progress despite regular dialysis
- Early assessment of nutritional status and body composition are important to detect nutritional disturbance at its onset and target interventions aimed at preventing the development of malnutrition
- Growth faltering often lags 3–6 months after weight loss or failure to gain weight and is not a sensitive, early marker of decline in nutritional status
- Key considerations in performing anthropometric measurements in children with CRF include the site of measurement due to vascular access needed for dialysis, hydration status and skeletal disproportion
- Key considerations in interpreting results of anthropometric measurements in children with CRF include age, gender, ethnicity, pubertal stage, bone mineral density, physical activity and hormone deficiencies such as growth hormone and IGF-1 deficiency
- Other methods of body composition measurement can provide useful data on early changes in nutritional status in children with CRF
- Anthropometric measurements including height, weight, growth velocity and BMI can predict outcome in children with CRF

Key Features of Chronic Renal Failure in Children

- Fluid retention
- High blood pressure
- Poor urine output
- Imbalance of blood electrolytes (high serum potassium and phosphate, low serum calcium)
- Imbalance of acid-base balance (metabolic acidosis)
- Poor appetite
- Lethargy
- Poor growth
- Disturbance in bone growth and strength
- Poor muscle mass

Chapter 76
Measures of Body Surface Area in Children

Janusz Feber and Hana Krásničanová

Abstract Body surface area (BSA) is an important index of body size in both adults and children. The use of BSA allows for standardization of the important physiological parameters such as cardiac function, glomerular filtration rate and proteinuria, which are indexed by BSA. This in turn enables comparison of these parameters among children of various ages and sizes. In addition, BSA has been frequently used in children for the dosing of diagnostic and therapeutic drugs. The estimation of a correct BSA is therefore of crucial importance in both diagnostic and therapeutic aspects of pediatric medicine.

Methods for direct estimation of BSA, such as coating methods, alginate methods or three-dimensional scanning, yield precise results but are not suitable for bedside use where only indirect methods for BSA estimation can be used. They are mostly based on mathematical formulae containing weight alone or both weight and height as parameters. Although there are numerous BSA formulae published in the literature, only few have been validated in children. Formulae with weight as the only parameter tend to underestimate or overestimate the BSA. Most published pediatric formulae with both weight and height yield similar results with only minor, yet not clinically important differences. Therefore, the BSA formulae are suitable for use in all children up to the age of 18 years, with the exception of newborns in whom the selection of suitable BSA formulae is limited. The formula by Mosteller et al., where the BSA (m^2) = square root of [height (cm) × weight (kg)/3,600], seems to be the most universal and user friendly formula for children of all age categories.

76.1 Introduction

Body surface area (BSA) is the total area of a human's skin. BSA changes significantly with age and growth, which is especially important in pediatric medicine where the patients' BSA gradually increases from 0.2 m^2 at birth to 1.73 m^2 in adulthood (Fig. 76.1) along with maturation of organ function. Consequently, BSA has been extensively used in clinical medicine as an index of physiologic processes (Table 76.1) such as glomerular filtration rate (GFR) (Bird et al. 2003; Blake and Grewal 2005), proteinuria (Nagasako et al. 2007), left ventricular mass (Daniels et al. 1988) and cardiac output (Bergstra et al. 1995). The indexation by BSA enables standardization of normal values and allows for the comparison of variables between individuals of different weight and height. Moreover, BSA is an important index for calculation of both maintenance and replacement fluid requirements in resuscitation setting and burn injury (Milner et al. 1993). BSA serves as a marker/guide for the therapeutic use of various drugs such as anticancer medications (Gao et al. 2008), prednisone (Feber et al. 2009), cyclophosphamide, cyclosporine, valganciclovir (Vaudry et al. 2009) and many others.

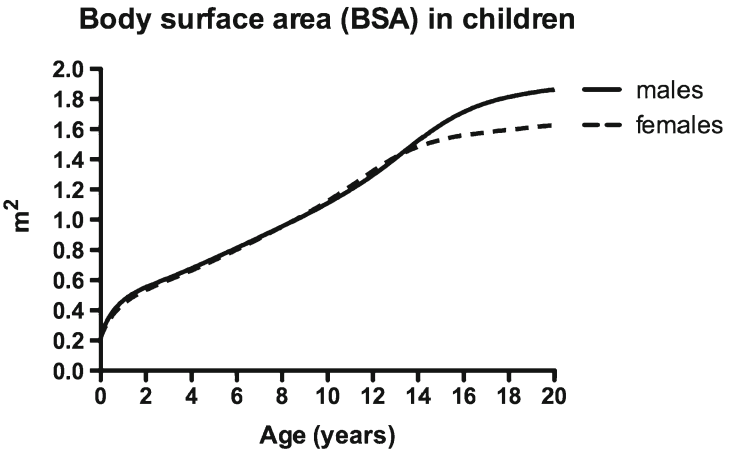

Fig. 76.1 Body surface area (BSA) in healthy persons aged from 0 to 20 years. This figure shows evolution of the BSA from the age of a newborn to the age of 20 years. The *x* axis represents age in years; the y axis represents BSA in m^2

Table 76.1 Examples of use of body surface area in pediatrics

Parameter	Description	Reference
Body structure	Liver volume	Yoshizumi et al. (2003)
	Central vein dimensions	Twardowski and Seger (2003)
	Left ventricular mass	Daniels et al. (1988)
Body functions	Glomerular filtration rate	Bird et al. (2003)
	Proteinuria	Nagasako et al. (2007)
	Cardiac output	Bergstra et al. (1995)
Fluid requirements	Maintenance fluids	
	Replacement fluids	Milner et al. (1993)
Medication dosing	Anticancer medications	Gao et al. (2008)
	Prednisone	Feber et al. (2009)
	Cyclophosphamide	
	Cyclosporine	
	Valganciclovir	Vaudry et al. (2009)
Diagnostic imaging	Radio contrast for CT scan	Bae et al. (2008)

This table illustrates various examples where body surface area is used as an index of body structure, body function, physiologic processes and medication doses. This allows for standardization of values/doses in patients with various body weight and height

BSA has also been used as a guide for estimation of liver volume (Yoshizumi et al. 2003) in transplant medicine and central vein catheter dimensions (Twardowski and Seger 2002). In addition, the use of BSA allows for the adjustment in dosage of radio contrast material for CT scanning (Bae et al. 2008).

The estimation of BSA belongs to the daily routine of clinicians, especially pediatricians who deal with constantly growing/changing body size and function. Therefore, the correct estimation of BSA is of primary importance for diagnosis and therapy in clinical medicine.

76.2 How Is BSA Measured?

The list of methods for measurement of BSA is shown in Table 76.2.

76.3 Direct Measurement of BSA

Typical practices used to measure BSA include coating methods (using paper, elastic tape, plaster bandage or aluminum foil), surface integration and geometric (or triangulation) methods (Lee et al. 2008). However, these methods are too laborious and tiresome for both subjects and researchers. Recently, three dimensional (3D) whole body scanning for estimating BSA has been proposed (Tikuisis et al. 2001; Yu et al. 2003). However, the accuracy of studies using 3D whole body scanning have also been questioned, because the method cannot recognize overlapping or shading body parts such as fingers, armpits, toes, and underneath the breasts. 3D scanning underestimates the BSA of overweight people because of the skin's folds. Lee and Choi suggested a new method using alginate to measure BSA (Lee and Choi 2006). This method has many advantages that are less time-consuming than traditional coating methods and can even measure skin folds of overweight and thin patients, in addition to small body parts such as fingers, toes and ears. Alginate (Jeltrate® Regular set. DENTSPLY LTD, England), a fine powder mainly used in forming artificial teeth in dentistry, is evenly coated on the skin. After only a couple of minutes, the material hardens to a certain degree and the alginate piece is separated from the surface of the skin. The alginate pieces are then copied on the paper, scanned by a 2D scanner and transformed into an electronic file containing the calculation of the surface area. The validity and reliability of the alginate method has been evaluated (Lee and Choi 2006). This precise measure of the BSA cannot be used

Table 76.2 Methods of estimation of body surface area in humans

Method	Details	Reference
Direct measurement	Coating method	Lee et al. (2008)
	Surface integration method	
	Geometric method	Tikuisis et al. (2001)
	3D scanning	Lee and Choi (2006)
	Alginate method	
Indirect measurement	Mathematical formulas:	Lee et al. (2008)
	Weight only	
	Square root of weight × height	
	$\text{Weight}^a \times \text{height}^b$	
	Weight + height	
	Weight, height, head circumference	

This table shows examples of direct and indirect measurements of body surface area in humans

in clinical practice due to its complexity, but serves as a reference measure for comparison of precision of various mathematical formulae used to calculate BSA in adults (Lee et al. 2008).

76.4 Indirect Measurement of BSA

76.4.1 BSA in Adults

The formulas for calculation of BSA can be divided into several categories based on the number of variables and the mathematical expression used (Lee et al. 2008) (Table 76.2):

weight only
square root of weight × height
weight^{a} × height^{b}
weight + height
weight, height and head circumference

Most of these formulae have been developed and validated for adults. In contrast, only few formulae have been validated for use in children. The list of formulae suitable for use in children is shown in Table 76.3.

76.4.2 BSA in Children

The most widely used formula of Du Bois and Du Bois (1916) increasingly underestimated BSA as the values fell below 0.7 m^2; the disparity was greatest in newborn infants (7.96%) (Haycock et al. 1978). Haycock et al. therefore developed a pediatric formula where BSA (m^2) = weight (kg)$^{0.5378}$ × height (cm)$^{0.3964}$ × 0.024265 (Haycock et al. 1978). This formula was derived from the measured data by multiple regression analysis and provided an adequate fit for all values of BSA from less than 0.2 m^2 to greater than 2.0 m^2 (r = 0.998). Consequently, this formula was used to construct nomograms for the estimation of BSA in infants, children and adults using a derivative from their height (length) and weight (Haycock et al. 1978).

In order to simplify the calculation of BSA for bedside use, Lindahl et al. proposed the following approach: for infants below 20 kg, the BSA (m^2) =3.6 × weight (kg) + 9, whereas for infants with a body weight between 20–40 kg, the BSA (m^2) =2.5 × weight (kg) + 33 (Lindahl and Okmian 1981). However, this formula was validated against the formula by Du Bois and Du Bois, which may underestimate the BSA as discussed above.

In 1987, Mosteller et al. (Mosteller 1987) described a simplified calculation where the BSA (m^2) = square root of [height (cm) × weight (kg)/3,600]. This formula gained wide acceptance in the pediatric community due to its precision and simplicity.

Also based on the formula by DuBois and DuBois, Ogunranti et al. (Ogunranti 1990) described a simplified method for BSA calculation in children based on their study of 920 Nigerian adults and children. Wang et al. studied 60 women and 148 neonates and concluded that several BSA formulas, including the DuBois and DuBois formulas, adequately predicted measured BSA over a wide range of patient populations. Although the original subjects studied by DuBois and DuBois excluded extremes of height and weight, their formula still appears to be a valid predictor (Wang et al. 1992). This is in contrast to an earlier study by Haycock et al. (1978), who stated that the formula by DuBois and DuBois is not suitable for children.

Table 76.3 Formulas for BSA estimation in children

Authors	Year of publication	Equation to calculate BSA
DuBois and DuBois	1916	BSA (cm^2) = 71.84 × height $(cm)^{0.725}$ × weight $(kg)^{0.425}$
Haycock et al.	1978	BSA (m^2)= weight $(kg)^{0.5378}$ × height $(cm)^{0.3964}$ × 0.024265
Lindahl and Okmian	1981	<20 kg: BSA (m^2) = 3.6 × weight (kg) + 9 20–40 kg: 2.5 × weight (kg) + 33
Meban	1983	BSA (m^2) = 6.4954 × weight $(g)^{0.562}$ × height $(cm)^{0.320}$
Mosteller	1987	BSA (m^2) = square root of [height (cm) × weight (kg)/3,600]
Current	1988	BSA (m^2) = (weight (kg) +4)/30
Shuter and Aslani	2000	BSA (cm^2) = 94.9 × [weight $(kg)^{0.441}$] × [height $(cm)^{0.655}$]

This table shows the most frequently used formulas for BSA calculation in children

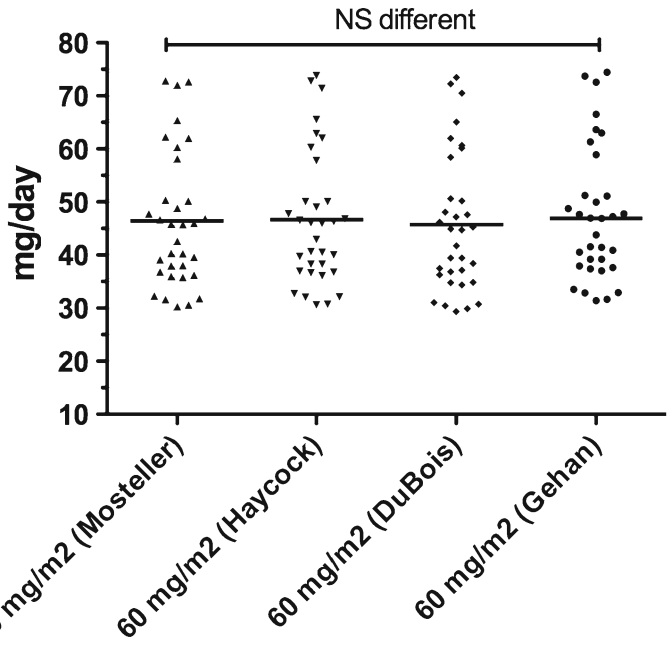

Fig. 76.2 Comparison of the oral prednisone dose (60 mg/m^2 BSA) calculated with various BSA formulae in children with nephrotic syndrome. The dose of oral prednisone was calculated as 60 mg/m^2 BSA using various formulas for BSA (*x* axis). The resulting total daily prednisone dose in mg/day is shown on the *y* axis. There is no significant difference in the total daily prednisone dose when calculated with various BSA formulae containing body weight and height as parameters for BSA estimation

Shuter et al. performed a critical revision of the DuBois and DuBois formula with modern statistical methods and stated that although the original equation obtained by Du Bois and Du Bois was found to be adequate in adults, it should not be used in daily practice based on the low number of subjects used in its derivation (Shuter and Aslani 2000).

More recently, Ahn et al. (Ahn and Garruto 2008) compared four different formulae for BSA in newborns against their mean and concluded that the formula by Meban (1983) is possibly the best BSA estimate for newborns among the existing formulae today; closely followed by the Mosteller formula (Mosteller 1987). Due to either overestimation or underestimation, the two formulae of Boyd (1935) and DuBois (1916) were not recommended for the surface estimation of newborns. The formula by Mosteller continued to provide very accurate estimates in newborns from Saudi Arabia (Nwoye and Al-Shehri 2005).

In older children with nephrotic syndrome, three commonly used BSA formulae (DuBois and DuBois 1916; Haycock et al. 1978; Mosteller 1987) that include weight and height in the calculation of BSA, were not significantly different – (Fig. 76.2). However, the formula using weight only

(Current 1998) significantly underestimated the BSA when compared to the formulae using both weight and height in the calculation of BSA (Feber et al. 2009).

Based on literature and personal experience, it seems that BSA is more of a function of both weight and height, rather than weight alone. The advantage in using both weight and height may override the single use of weight for surface estimation, regardless of the clinical and methodological simplicity of using only weight (Ahn and Garruto 2008).

The use of BSA rather than weight alone is likely more suitable for obese patients in whom the correct estimation of BSA and dosing of cytostatic drugs is a matter of debate (Verbraecken et al. 2006; Hunter et al. 2009). Similarly, adjustment of radio contrast-medium dosing for CT scanning by the BSA (which accounts for both the body weight and height factors) provides a more accurate iodine dosing over a wide range of body sizes (Bae et al. 2008).

In summary, accurate estimates of body surface area are clinically important in pediatric medicine for indexing cardiac and renal function, calculating maintenance and replacement fluid therapy and drug dosing. Although the formulae using both weight and height for the calculation of BSA are more mathematically complicated, they provide a more accurate estimation of the BSA when compared to formulae with weight as the only parameter. A simplified formula proposed by Mosteller et al. (Mosteller 1987) (BSA (m^2) = square root of [height (cm) × weight (kg)/3,600] offers the advantage of both parameters, which encompase the simplicity of use and precision over a wide range of body sizes. It may therefore be proposed as the preferred formula for bedside use in pediatrics.

76.5 Application to Other Areas of Health and Disease

An accurate estimation of body surface area (BSA) in children has a huge impact on many diagnostic and therapeutic procedures in pediatrics. BSA is frequently used as an index to standardize cardiac and renal function and to quantify urine protein excretion. The use of BSA therefore allows for comparison of results in children of various size and body composition. In addition, the dosing of many drugs and diagnostic substances such as radio contrast drugs for imaging used in pediatrics, is based on body surface area rather than weight alone.

76.6 Practical Methods and Techniques

BSA in children can be easily estimated from body weight and height using the following formula: BSA (m^2) = square root of [height (cm) × weight (kg)/3,600].

Summary Points

- The use of BSA allows for standardization of cardiac and renal function in children with various body compositions
- BSA is frequently used for the dosing of diagnostic and therapeutic drugs in pediatrics
- Direct measurements of BSA are not clinically useful
- BSA can be indirectly estimated with many mathematical formulae, with only a few having been validated in children

- Formulae for BSA containing weight and height as parameters, provide a more accurate estimate of the BSA when compared to formulae using weight as the sole parameter
- The formula proposed by Mosteller et al., BSA (m^2) = square root of [height (cm) × weight (kg)/3,600], offers reasonable precision and convenience for bedside use in pediatrics

Key Facts

Table 76.4 Key fact of body surface area estimation

1. BSA can be precisely measured using direct methods such as coating methods, the alginate method or 3D scanning
2. Only indirect methods for BSA estimation can be used in clinical practice
3. The selection of formulae suitable for calculation of BSA in children is limited, but the formula proposed by Mosteller et al. (Table 76.3) offers sufficient precision at all age categories and ease of use. It can be therefore recommended as the formula of choice for children

This table lists the key facts of measuring the body surface area in children

Table 76.5 Key facts of nephrotic syndrome in children

1. Nephrotic syndrome is characterized by an increased protein loss, low serum albumin level and high serum cholesterol level
2. The most common type of childhood nephrotic syndrome is associated with only minimal structural changes of cells along the glomerular basement membrane; it is also referred to as 'minimal change disease'
3. The therapy of childhood nephrotic syndrome consists of prednisone, with a standardized initial recommended dose of 60 mg/m^2/day or 2 mg/kg/day.

This table lists the key facts of childhood nephrotic syndrome

Chapter 77
Skinfold Thickness in Sri Lankan Children

V.P. Wickramasinghe

Abstract Skinfold thickness has been used as a method of assessment of body composition. It reflects the subcutaneous fat distribution of body. Assessment of the SFT is useful in nutritional assessment as well as in assessing changes in the distribution of fat in the body during treatment of certain illnesses. Furthermore, it provides information on regional body composition, which is important in certain illnesses, such as metabolic syndrome. Prediction equations can be used to assess body density, total FM and percent FM. Skinfold thickness is a user-friendly and cost effective method for assessment of body composition with significant accuracy. There are conventionally agreed sites for the measurement of skinfold thickness and they will represent central as well as peripheral fat distribution in the body. It is important to apply standardized techniques to assess the SFT for accuracy as well as for reproducibility of measurements.

Skinfold thickness shows ethnic variations which could be explained by the theories of evolution. Subcutaneous fat distribution also changes with age and gender. It is important to understand such changes when interpreting results of research studies. In Sri Lankan children, the peripheral (assessed by tricep + biceps SFT) and central (assessed by subscapular + suprailiac SFT) subcutaneous fat distribution was lowest at six years of age and increased with age with the increase being more marked in girls. In Sri Lankan children, while total fat mass was increasing with age, the ratio of peripheral SFT: total FM and central SFT: total FM showed a reduction denoting that more fat is deposited as visceral adipose tissue than subcutaneous adipose tissue.

Centile charts can be used to interpret measurements of SFT. Furthermore, SFT equations can be used in the assessment of body composition. It is important to first validate these prediction equations on the specific population under study before using them for body composition assessment. It would be most prudent to use prediction equations developed on the same study population as they would give more accurate assessments. SFT-based prediction equations available in the published literature did not provide accurate assessment of body composition in Sri Lankan children; therefore these were developed specifically for Sri Lankan children, which estimated body fat accurately not only in native Sri Lankan children but also in Australian children of Sri Lankan origin.

77.1 Introduction

History of body composition assessment can be traced back to the 5th century BC when Hippocrates proposed that the whole body is composed of blood, phlegm, black bile and yellow bile. (Wang et al. 1999). For many years people studied the structure of tissues of the body and determined whether it was of normal morphology or affected by any disease. The beginning of body composition analysis in early twentieth century enabled scientists to describe changes in a parameter that occur in different pathophysiological states. Although technically advanced methods for body composition analysis are available, anthropometric methods such as height, weight, skinfold thickness and circumferences are useful tools in day-to-day clinical practice. They are easy to use and cost effective. However, each anthropometric method has its own advantages and disadvantages in the assessment of body composition.

Scientists have appreciated the anthropometric value of subcutaneous fat in the assessment of nutritional status of humans for many years. In 1953 Tanner first described the use of Harpenden's skinfold caliper, enabling measurement of skinfold thickness which is a proxy measure of total body fat (Durnin et al. 1997). Since then the instrument has evolved, yet preserving its original mechanics and measurement techniques. Skinfold thickness represents a double layer of adipose tissue and skin. When measured at specific sites, it gives estimates of central (Sub-Scapular and Supra-Iliac) and peripheral (triceps and biceps) fat distribution. There are numerous equations described in the literature to predict fat mass as well as body density using skin fold thickness (vide infra).

Skinfold thickness is considered superior to mid upper arm circumference measurement for nutrition screening as the latter leads to errors in measurements due to soft tissue compression. Skinfold thickness measurements can be obtained with greater accuracy (Owen 1982). Skinfold thickness measurements taken at the NHANES I study in USA showed an inter-observer technical error of 1.89 mm (CV 15.4) for triceps and 1.53 mm (CV 15.4) for sub-scapular readings. Intra-observer technical error of 0.8 mm (CV 6.5) and 1.83 mm (CV 18.3) was observed for triceps and sub-scapular skinfold thickness measurements respectively (Owen 1982).

Subcutaneous fat deposition is influenced by sex, chronological age, race, state of maturation and nutritional status (Harsha et al. 1980; Shalitin and Phillip 2003). Skinfold thickness is more useful in the long-term follow-up of children with obesity and other medical conditions (growth hormone replacement) than for simple nutritional screening in the community (Owen 1982). Centile standards are used to compare data (Tanner and Whitehouse 1962, 1975). The new World health Organisation (WHO) growth reference charts are available for skinfold thickness assessment (http://www.who.int/childgrowth/en/). Regression equations are used to calculate body composition such as body density or percent fat mass (Annexure). However, as all these prediction equations were based on mathematical relationships, it will predict body composition only if the test population resembles the reference population that was originally used in the development of the equation. Most of the prediction equations were developed on Western European or North American populations of white Caucasian or black

African origins. There are a few equations that have been validated on populations of Chinese ancestry. These equations have been cross-validated on different populations and some showed satisfactory agreement while others did not (Janz et al. 1993; Reilly et al. 1995). There is no prediction equation developed on populations of South Asian origin. As fat distribution in body is influenced by the ethnic origin it is doubtful that currently available equations would predict body composition accurately in South Asian populations.

Skinfold thickness, which has the ability to directly assess the subcutaneous fat mass, would give a good estimate of body fat stores. However, concern over several technical issues has discouraged its use. The main concerns are in applying the technique, observer variability, influences of different types of callipers and difficulties in locating the correct measuring site.

Durnin and co-workers (1997) reviewed the published literature addressing technical errors on skinfold thickness measurements and found that inter-observer error accounted for less than 2–3% in estimation of percent fat mass. Furthermore, it was noted that the side of the body used for the measurement or instrument variability accounted for an error of less than 3%. They also looked at the effect of measuring skinfold thickness at imprecise locations other than what is considered to be standard sites for the measurement of four skinfold thickness measurements (triceps, biceps, subscapular and supra-iliac) in assessing percent fat mass. They showed that deviations as much as 20mm from the standard anatomical site gave an error of less than 3%. They concluded that the degree of error caused by picking up the wrong skinfold in assessing percent fat mass is of minimal importance. However, they expressed caution that precision is required if skinfold thickness is intended to examine local pathology. However in obese individuals locating the correct anatomical site as well as holding skinfold calliper jaws in place may be quite difficult.

Assessment of regional body composition is important in determining the onset of certain illnesses. This refers to anatomical variation in the distribution of major compartments of body mass, adipose tissue, skeletal muscle mass and skeletal tissues. Regional body composition varies with sex, age, development, physiological state and ethnicity. Regional fat distribution can be used as a determinant of risk for certain non-communicable diseases e.g. abdominal fat deposition associated with the metabolic syndrome (Alberti et al. 2006). Skinfold thickness is a good tool that can be used to assess regional body composition in detail. It is important to adopt standardized techniques in the assessment of skinfold thickness for reproducibility (Table 77.1). Standard equipment with standard caliper pressure needs to be applied. Standard pressure applied by caliper jaws is 10 g/cm^2 and should be kept for about 2–3 s before taking the measurement to the closest 1 mm. (Owen 1982). By convention certain sites have been identified for the assessment of skin fold thickness. It is important to adopt a standardized protocol in order to reproduce and compare measurements.

Table 77.1 Key feature in taking a skinfold thickness measurement

1. Identify the standard anatomical site to measure the skinfold thickness
2. Hold the skinfold between the thumb and the index finger.
3. Slide the skin with subcutaneous tissue over the underlying muscles to produce a skinfold just above or below the site marked for the measurement.
4. Apply the jaws of the calliper at the site marked to take the measurement.
5. Release your fingers from the skinfold.
6. Keep the calliper jaws for about 2–3 seconds to stabilize before taking the reading.

This table lists the key steps one has to follow when making a skinfold measurement

Following are the standardized techniques that have been described for making skinfold thickness measurement at some predetermined anatomical sites.

Triceps skinfold thickness is measured at the mid point between the lateral projection of the acromion and inferior surface of the olecranon process with the arm flexed to 90° at the elbow.

The measurement is taken with the arm hanging freely at the side of the trunk and the palm facing the lateral aspect of the thigh. A vertical skinfold over the triceps muscle is measured.

Biceps skinfold thickness is measured as the thickness of a vertical fold raised on the anterior aspect of the arm over the belly of the biceps muscle at the same level as is used for the triceps skinfold thickness measurement. Arm should be hanging by the side with the palm directed anteriorly while taking the measurement.

Forearm skinfold thickness is measured with the subject standing erect with arms relaxed and palms facing the lateral aspect of the thigh. A vertical skinfold in the midline of the posterior aspect of the forearm at the level of the maximum circumference is measured.

Mid anterior thigh skinfold thickness is measured by grasping a vertical fold of skin midway between the mid point of the inguinal crease and the proximal border of the patella. Measurement is taken with the subject standing erect and body weight evenly distributed on both legs.

Medial calf skinfold thickness is measured with the subject seated and the measured foot kept on the ground and flexed to 90° at the knee joint. A vertical skin-fold on the medial side of the calf at the level of maximum girth is measured.

Subscapular skinfold thickness is measured on an oblique line (approximately 45° to the horizontal plane), inclined infero-laterally, immediately below the inferior angle of the scapula.

Suprailiac skinfold thickness is measured in the mid axillary line. An inferomedially aligned oblique (45° to the horizontal plane) skinfold immediately superior to the iliac crest is grasped and measured (Harrison et al. 1988).

77.2 Ethnic Differences in Skinfold Thickness

Body composition varies with ethnicity, and Harsha and co-workers (1980) showed that there is a racial difference in subcutaneous fat distribution. Skinfold thickness measurement in a group of 7–15 year old American children of European and African origin showed differences in their fat distribution despite having similar weights and dietary habits. Black children had thinner skinfold thickness than white children except for the sub-scapular skinfold thickness which was similar in the two groups. This distribution could perhaps be explained by the influence of environment, both thermal and nutritional, on evolution. Europeans needed a heat conserving body composition. Therefore they have short limbs and long trunk with uniform deposition of subcutaneous fat for heat conservation and maintenance of energy stores. On the other hand Africans needed to dissipate more heat and keep body temperature down. This could be achieved by having a thin tall body with long limbs. Therefore they have lesser subcutaneous fat. However, they also need to stores energy with minimum interference to its cooling mechanism. This was achieved by depositing fat in the back of the trunk which would interfere only minimally with the cooling effort. This explains why Africans and Europeans have similar patterns of subcutaneous fat distribution in the subscapular region (Harsha et al. 1980). Robson and co-workers (1971) found similar results when comparing Caribbean island children of African origin with European children.

Body fat distribution of 12–17 year old American girls living in San Diego, of Mexican, European, Asian and African origins were compared by Malina and co-workers (1995). Based on skinfold thickness, girls of Asian and Mexican origins had more centrally distributed fat than girls of European and African origins. Central to peripheral skinfold thickness was larger in Asians. There was no significant ethnic difference between upper extremity (triceps) and lower extremity (medial calf) skinfold thickness. However, there were significant differences in upper trunk (sub-scapular) and lower trunk (supra iliac) skinfold thickness of children of Asian, Mexican and African origin when compared to children of white Caucasian origin (Malina et al. 1995).

77.3 Adipose Tissue Changes with Age and Sex

Physiologically normal amounts of fat mass depend on age and gender. Distribution of fat in the body also depends on age (Table 77.2). At birth, infants have equal amounts of central and peripheral subcutaneous adipose tissue. This ratio of central to peripheral tissue reduces to the lowest point at about 5 years of age. Up to about 13 years, similar increases are seen in both gender groups. During adolescence males gain more central subcutaneous adipose tissue than peripheral subcutaneous adipose tissue (C:P > 1), whereas females gain fat in both areas (C:P = 1) (Rolland-Cachera et al. 1990). This pattern of central to peripheral subcutaneous fat distribution remains thoughout life in both gender groups. Therefore males have proportionally more subcutaneous adipose tissue on trunk than extremity during adolescence and adulthood and females have similar subcutaneous fat distribution in both trunk and extremity (Table 77.3).

Subcutaneous adipose tissue to fat mass ratio is more or less similar for both boys and girls of 9–15 years of age. Thereafter, in males, it increases till about 20 years of age and then steadily declines. Therefore adult males have less subcutaneous adipose tissue and more visceral adipose tissue with advancing age. Contrary to this, female subcutaneous adipose tissue to fat mass ratio declines during adolescence and then remains static.

Table 77.2 Key features in changes in subcutaneous fat in with age

1. At birth infants have similar amount of subcutaneous fat in the central (trunk) and peripheral (extremity).
2. The ratio of central to peripheral skinfold thickness reduces and will be at its lowest point at around 5 years of age.
3. Till adolescence (about 13 years) both central and peripheral fat increases in similar amounts in both girls and boys
4. During adolescence, more subcutaneous adipose tissue gets deposited in the trunk than in the limbs in boys. Therefore central to peripheral subcutaneous fat ratio is more than one.
5. During adolescence, subcutaneous adipose tissue deposition in both trunk and limbs are seen in similar amounts in girls. Therefore central to peripheral subcutaneous fat ratio is equal to one.

This table shows main changes that occur in subcutaneous fat with age in both sex groups

Table 77.3 Key features in changes in body fat during puberty

1. Till puberty (about 9–15 years) subcutaneous fat (fat under the skin) to the total fat in the body (fat mass) are seen in similar proportions in both girls and boys.
2. In boys more subcutaneous fat deposition takes place till about 20 years. Therefore subcutaneous fat to fat mass ratio increases.
3. After 20 years this ratio decreases denoting that more fat get deposited inside (visceral) the body than under the skin (subcutaneous).
4. In girls subcutaneous fat to fat mass ratio increases till about 20 years denoting more fat is deposited under the skin.
5. Thereafter the ratio is static showing that fat deposition takes place in both subcutaneously as well inside body at an equal rate.

This table shows how body fat and subcutaneous fat changes during and after puberty in both girls and boys

In Sri Lankan children the peripheral subcutaneous tissue distribution measured by triceps and biceps skin fold thickness was shown to have the lowest distribution at six years of age and thereafter it shows an increase with age (Fig. 77.1). A similar pattern of distribution was seen in central adipose tissue measured by subscapular and suprailiac skinfold thickness. The increase is more marked in girls than in boys.

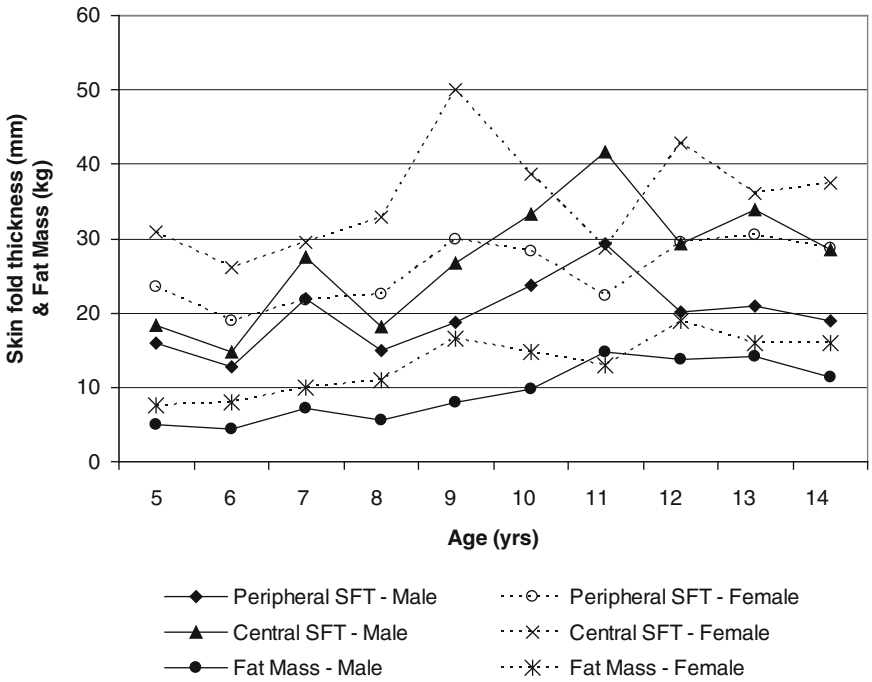

Fig. 77.1 Pattern of change in main skinfold thickness of the body and fat mass with age for each gender in a group of Sri Lankan children. Subcutaneous fat in both trunk and extremities are lowest at 6 years and gradually increases with age. Total FM also increased with age. Females always had a greater fat content than males

Central to peripheral skinfold thickness ratio remains more or less static during 5–14 years of age but it is more than one denoting that there is more central fat deposition than peripheral fat deposition (Fig. 77.2). Malina (1996) studied a group of female children from Quebec and noted that with maturation, from young pre-menarcheal to older post-menarcheal age, total fat mass increased. Although subcutaneous adipose tissue, as assessed by 6 skinfold thickness measurements at sub-scapular, supra iliac, abdominal, triceps, biceps and medial calf sites, increased while the subcutaneous adipose tissue to fat mass ratio reduced, denoting that more visceral adipose tissue accumulation occurred with advancing maturity. This denotes that females accumulate more visceral adipose tissue during sexual maturation (Malina 1996). Significant ethnic differences in body fat distribution have been noted. More central pattern of subcutaneous adipose tissue distribution is seen among adolescent girls of Asian and Mexican origin than their counterparts of European or African origin (Malina 1996).

Among Sri Lankan children also the total fat mass increased with age as assessed by isotope dilution technique using D_2O (Bell et al. 1998) (Please see Fig. 77.1.). The ratio of peripheral skinfold thickness to total fat mass and central skinfold thickness to total fat mass showed a reduction despite an increase in total fat mass with increase in age (Fig. 77.2). This denotes that more fat is deposited as visceral adipose tissue than subcutaneous adipose tissue.

77.4 Studies of Body Composition of Sri Lankan Children

South Asians are highly susceptible to metabolically related noncommunicable diseases and it is postulated to be directly related to regional body composition, namely abdominal fat distribution. South Asians have a higher amount of fat in the anterior abdominal wall for any given circumference

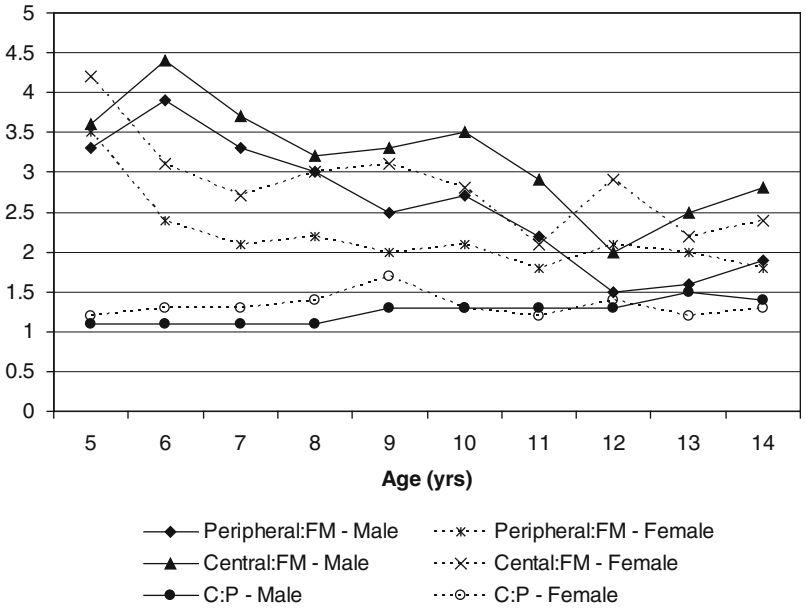

Fig. 77.2 Distribution of skinfold thickness ratios with age in both genders in a group of Sri Lankan children. Both peripheral subcutaneous fat to total FM and central subcutaneous fat to total FM are high at a younger age and decreases with advancing age. Central to peripheral subcutaneous fat ratio is static throughout growth in both gender groups

compared to other races (Alberti et al. 2006). Wider understanding of their body composition would help in controlling many of these illnesses. There had always been some doubt about the ability to use body composition assessment techniques without validating them on different ethnic groups. It is important to validate the existing body composition techniques and if not suitable, develop new equations/techniques for field use on populations.

As prediction equations for body composition assessment works best in the population they were originally developed for, it is important to validate them in the test population prior to their use. There are many skinfold thickness based prediction equations in the published literature for the assessment of body composition (Annexure). Several prediction equations were cross-validated on a group of Sri Lankan children to identify their suitability with this population. Nine skinfold thickness prediction equations in boys, described in the literature by five different authors and seven equations described by four authors for assessment of body composition in girls, were cross-validated on a group of 5–15 year old Sri Lankan children. Sarria and co-workers (1998) studied a group of Spanish boys and derived the equation to be used exclusively on boys. Therefore this equation was not included in the assessment of percent fat mass in girls. Some equations are ethnic specific (Slaughter et al. 1988) while some are gender specific (Deurenberg et al. 1990). Except for the equation of Yuan and co-workers (1987), other equations were developed on Western European or North American populations. Yuan et al. developed a set of equations on a group of Japanese children.

Table 77.4 shows the mean percent fat mass level for each gender of a group of Sri Lankan children assessed by different prediction equations (Annexure) and compared with the percent fat mass assessed by isotope dilution technique (D_2O) (Wickramasinghe et al. 2008a). All prediction equations in both

The mean bias or the difference between the percent FM assessed by the equation and the established method is given in the table. Limits of agreement show the range of bias with 95% confidence interval. The correlation shown is the relationship between the bias and the mean percent FM assessed by the two methods [(equation + established method)/2]

[a]"Bias"; difference of the %FM assessed by the indirect technique minus %FM assessed by isotope dilution technique.

[b]Correlation coefficient and 'significance, of the bias of percent fat mass between the two methods and the mean fat mass derived by the two methods (skin fold thickness and isotope dilution technique).

[c]Mean bias ± SD × *t* (*t* is the confidence coefficient at 95% level of confidence for *n* - 1 degrees of freedom in a two tailed test).

gender groups underestimated the percent fat mass. The equation of Brook had the highest estimate of percent fat mass out of the equations tested; 24.4% (9.5) and 29.2% (10.2) for boys and girls respectively. The correlations between percent fat mass assessed by criterion method and each skinfold thickness equations are shown in Table 77.4. Except for the equation described by Yuan and co-workers for the prediction of percent fat mass, all other equations in boys had a very good correlation with the percent fat mass assessed by criterion method (D_2O). Highest association in both groups was with the Brook equation. However, in females although there was statistically significant correlation the strength was low. Yuan and co-workers equation gave a low correlation in boys and a negative correlation in girls.

Percent fat mass assessed by criterion method and each skinfold thickness equation were compared using one way ANOVA (data not shown). Estimations made by the equations of Brook and Yuan agreed with the criterion method in males. However, none of the equations gave percent fat mass estimates agreeable with the criterion method in females (Wickramasinghe et al. 2008a).

Bias is used to evaluate the effectiveness of predicting a parameter (Bland and Altman 1986). It is calculated by subtracting the percent fat mass assessed by criterion method, from the percent fat mass estimated by prediction equations (predicted – actual) (Table 77.6).

Table 77.6 Key features in Bland Altman plot

1. A Bland and Altman plot is used to evaluate the agreement between the value predicted by a new diagnostic or test procedure and the assessment made by the established (criterion) method.
2. A graph (scatter plot) is drawn between the value obtained by the established method and the new method for each individual.
3. Correlation between the two methods is calculated to identify the closeness between the two assessment methods in giving the results.
4. Similarly the Bland and Altman plot is drawn to assess the distribution of bias between the value assessed by the new method and value assessed by the established method.
5. Bias is calculated by subtracting value obtained by the established method from the value obtained by the new method. This value is taken to the y axis.
6. Mean value for each parameter is calculated. That is the sum of the value obtained from the criterion method and new method, divided by 2. This value is plotted on x axis.
7. Correlation between the two parameters is calculated. It would be ideal to have no significant relationship. This means that the bias or difference is not affected by the value and therefore the new method is good to assess the parameter even at extremes.

This table lists the steps in performing a Bland Altman plot and its interpretation

Mean bias and limits of agreement for each method, for each gender is shown in Table 77.5. In boys the lowest mean bias was seen for estimation made by the equation of Brook. However, in boys, the limits of agreement were quite high denoting that values could be underestimated by 15.7% or overestimated by 12.1%. The narrowest limits of agreement was provided by the two equations described by Deurenberg et al. The equation which used the sum of triceps and susbscapular skinfold thickness, underestimated by 0.1% and overestimated by 17.1% while the equation which used the sum of four skinfold thickness overestimated by 18.4%. In girls also a similar pattern was observed. Whilst the equation of Brook gave the lowest bias, both equations of Deurenberg et al. gave the narrowest limits of agreement which was slightly wider in girls than in boys (Wickramasinghe et al. 2008a). Although Yuan and co-workers studied an Asian population it had very high limits of agreement, which perhaps denotes that significant differences exist between the body composition of populations of south Asian and Chinese origins.

The relationship between bias and mean percent fat mass, assessed by the criterion method and the specific prediction equation, is used to evaluate whether extremes of percentage fat mass in the

Table 77.7 Correlation between different skinfold thicknesses and fat mass/percent fat mass assessed by isotope dilution techniques (D_2O) in a group of Sri Lankan children

	Male		Female	
	Fat mass	Percent fat mass	Fat mass	Percent fat mass
Triceps SFT	0.85*	0.74*	0.72*	0.29**
Sub-scapular SFT	0.84*	0.67*	0.77*	0.40*
Supra iliac SFT	0.84*	0.71*	0.66*	0.41*
Biceps SFT	0.76*	0.76*	0.66*	0.30*

**$p < 0.01$

body would influence assessment made by skinfold thickness prediction equations (Bland and Altman 1986). Equations of Deurenberg et al. and Slaughter and co-workers did not show a relationship in both males and females. This denotes that extremes of percent fat mass did not influence the bias. The equation published by Brook had a statistically significant negative association denoting that at lower levels of percent fat mass the equation overestimates while at higher levels of percent fat mass the equation underestimates.

Brook gave the closest prediction value for percent fat mass when compared with the assessment made by isotope dilution method, which was considered as the criterion method in this study. Brook also used isotope dilution technique to develop the equation. The age groups were similar to our study but the sample size was only 23 children and some were obese and suffered from short stature. Therefore, the validity of such equations being used on the general public is questionable. Although Brook gave the lowest bias for the estimation of percent fat mass in both girls and boys the limits of agreement were quite wide. On the other hand both equations described by Deurenberg and co-workers had a fairly high bias, but 95% limits of agreement were the lowest. Furthermore, the correlation between bias and the mean percent fat mass assessed by criterion method and skinfold thickness equation was zero, denoting that there was no association between bias and percent fat mass assessed. In other words, extremes of measures of percent fat mass did not influence the bias. Equations of Slaughter and co-workers gave a relatively small bias in the assessment of percent fat mass, especially in males, but the limits of agreement were quite wide.

It is quite evident from this data that prediction equations cannot be used freely just because they have been developed on a group of children. The prediction equations we have tested were developed using 3 different ethnic groups namely white Caucasians (Brook 1971; Slaughter et al. 1988; Deurenberg et al. 1990; Sarria et al. 1998), black Americans (Slaughter et al. 1988) and those with Chinese ancestry (Yuan et al. 1987). Therefore it is possible to postulate that ethnic groups may have a significant influence on fat distribution of the body. Another factor that could lead to the difference in results would be the diversity in the age groups. Of the equations we validated, none of the equations matched each study population in its entirety with the age of the original population.

Table 77.7 shows the Pearson's correlation between different skinfold thickness measures and percent FM and FM assessed by isotope dilution techniques (D_2O). Statistically significant associations were seen in both groups but the power was weaker in females.

Although the equations predicted the percent fat mass poorly, the correlation between different skinfold thickness and percent fat mass was significant, denoting that skinfold thickness could be used to predict percent fat mass, but population/ethnic specific equations are required to do so.

Many factors could have contributed to the poor agreement of skinfold thickness prediction equations in the assessment of percent fat mass. Ethnic differences in body composition as well as

socioeconomic influence could have been the two main factors. Furthermore, a shortcoming of the study could be the criterion method we used. However, of the equations we validated, some used two-compartment body composition model with isotope dilution technique (Brook 1971) while some used underwater weighing (Sarria et al. 1998; Deurenberg et al. 1990). One study used a multi-component body composition model (Slaughter et al. 1988).

77.5 Development of Prediction Equations

As existing prediction equations showed poor estimation of percentage fat mass in Sri Lankan children, a prediction equation developed on this population would be very useful in the assessment of body composition.

Prediction equations are constructed by step wise multiple regression on an identified dependent variable(s) and a set of independent variables. Best predictive variables are selected by measure of goodness-of-fit statistics including coefficient of determination (R^2), root mean squared error (RMSE) and Mallows' Cp statistics. Best prediction equation should have a high R^2 with minimum RMSE. Mallows' Cp statistics give the appropriate number of independent variables to an equation. Mallows' Cp statistics is an index to identify the optimum number of independent variables. A prediction equation is considered suitable when the number of independent variables is close to the value of Cp statistics (Dawson and Trapp 2001). Increase in the number of independent variables increases the precision of the equation. However, the magnitude of improvement gradually decreases.

Several preliminary prediction equations were developed and after validating on an independent group of subjects, the best predictive equation was identified (Wickramasinghe et al. 2008b). After identifying the best independent predictor variables, the final prediction equation is developed. Final prediction equation is statistically validated using PRESS (prediction of sum of squares) statistical method (Guo and Chumlea 1996; Sun et al. 2003). The PRESS statistic is a measure of how well an equation performs when applied to an independent sample. The process of applying PRESS statistics is:

1. Regression equation is made after excluding one observation
2. Obtain the predicted value of the observation that was excluded
3. Calculate the residual or difference for that excluded observation (observed – predicted)
4. Steps 1–3 is repeated for all the observations
5. Sum of the squares of all the residuals are taken and
6. PRESS statistic is calculated by taking the mean square root of the sum of squared of the residuals divided by the total number of observations.

Validation using the PRESS technique is almost equal to validating against an independent sample as PRESS residual is obtained for the observation that was not included in forming the equation. Pure error was used to evaluate the predictability of the derived equation when applied to the Validation Group. It is calculated as square root of the mean sum of squared differences (bias) between observed and predicted value. Smaller values denote better prediction. There is no defined way to assess success of validation using pure error. However, the general rule is that the RMSE value obtained from the development group should be similar to the pure error obtained in the validation group (Guo and Chumlea 1996).

77.6 Development of a Skinfold Thickness Prediction Equation for Sri Lankan Children

Body composition assessment with skinfold thickness is based on prediction equations derived using statistical methods rather than biological properties of human anatomy and physiology. Therefore it is very important to choose the appropriate equation to convert the skinfold thickness to a body composition parameter. The best would be to have prediction equations derived from populations which are closely linked to the population under study. As most of the existing equations are developed on white Caucasian populations, it is very important to either derive a specific set of equations or validate the existing equations on the target population prior to its clinical use.

Two separate sets of preliminary equations based on skinfold thickness were constructed for the prediction of fat mass and percent fat mass (Wickramasinghe et al. 2008b). In each set there was a gender non-specific and gender-specific equation. Gender non-specific equation had a higher coefficient of determination in the prediction of both fat mass and percent fat mass than gender-specific equations. Root mean squared error did not differ significantly in any of these equations.

On cross-validation, results of mean fat mass and percent fat mass assessed by all equations, in both males and females, did not differ significantly from each other. However, gender non-specific equation gave minimum bias and minimum pure error when compared with gender-specific equations for the assessment of fat mass in both groups. In the assessment of percent fat mass, gender non-specific equation gave low bias but high pure error when compared with gender-specific equation. Gender non-specific equation either under- or overpredicted fat mass by very small amounts and it was always less than 1,000 g. Similarly gender non-specific equation for the prediction of percent fat mass also had prediction accuracy within 1.1% units. A statistically significant ($p < 0.001$) association existed between the criterion method and the predicted values of fat mass and percent fat mass assessed by each of the new prediction equations. Fat mass and percent fat mass was better predicted by gender combined equations than gender-specific equations. However, the variables in the prediction of fat mass were responsible for a variance of 70.2% while for prediction of percent fat mass it was only 40.8%.

Fat mass and percent fat mass assessed by each skinfold thickness equation and the criterion method showed statistically significant correlations. The association with fat mass was much stronger and results were similar in both gender groups. When preliminary prediction equations were validated they gave minimum bias and had significant agreement with the criterion method. A single gender combined equation for the prediction of fat mass and percent fat mass would also be more acceptable in day-to-day practice.

Table 77.8 shows the final prediction equation derived using the 282 subjects. The R^2 and root mean squared error (RMSE) showed good agreement between independent variables (impedance index, weight and sex) and dependent variables (fat mass and percent fat mass). Although PRESS statistics were closer to pure error in both gender groups, PRESS statistics were slightly higher than pure error for both fat mass and percent fat mass assessment in boys but slightly lower in girls. However, PRESS residual of final prediction equation was slightly higher than mean bias of validation of the preliminary prediction equations for fat mass and percent fat mass. PRESS R^2 is also comparable to the R^2 of the multiple regression of variables. PRESS residuals of the final prediction equation were compared with bias in validation of preliminary equations. PRESS residuals were higher than the mean bias in the assessment of both fat mass and percent fat mass in both gender groups. Variables showed strong agreement with the R^2 for the prediction of fat mass (75%) but low agreement for the prediction of percent fat mass (44.8%).

Fat mass and percent fat mass assessed by the criterion method plotted against the fat mass and percent fat mass predicted by each final prediction equations are shown in Figs. 77.3 and 77.4.

Table 77.8 Final, gender-combined, SFT prediction equation for FM and percent FM in Sri Lankan children

FM = (0.68 × age) + (0.246 × SFT-triceps) + (0.383 × SFT-sub-scapular) – (1.61 × Sex Code[a]) – 3.45
% FM = (–0.28 × Age) + (0.49 × SFT-triceps) + (0.34 × SFT-sub-scapular) – (7.97 × Sex Code[a]) + 26.8

The two equations developed on Sri Lankan children based on skinfold thickness are shown. These can be used to calculate the FM or Percent FM
[a]Sex code: male = 1; female = 0

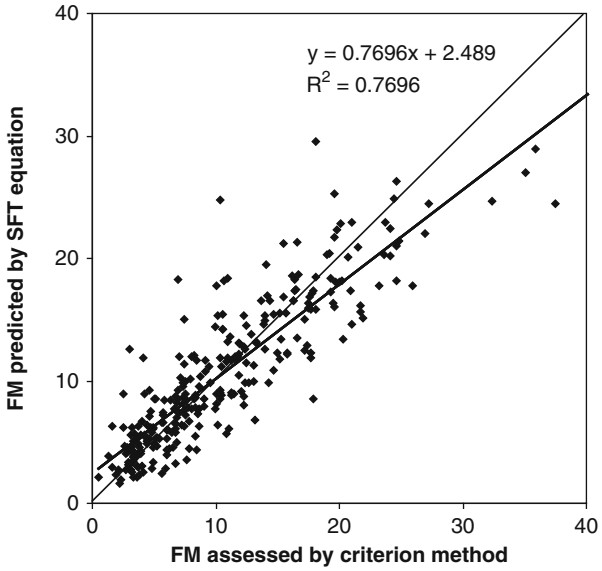

Fig. 77.3 Fat mass assessed by criterion method (D_2O) versus that predicted by final gender combined skinfold thickness equation, line of identity and regression line in a group of Sri Lankan children. FM assessed by established (criterion) method and new prediction equation is plotted on the graph. The values are concentrated closer to the mid line denoting that there is very good agreement between the two methods (Reprinted from Wickramasinghe et al (2008b), with permission)

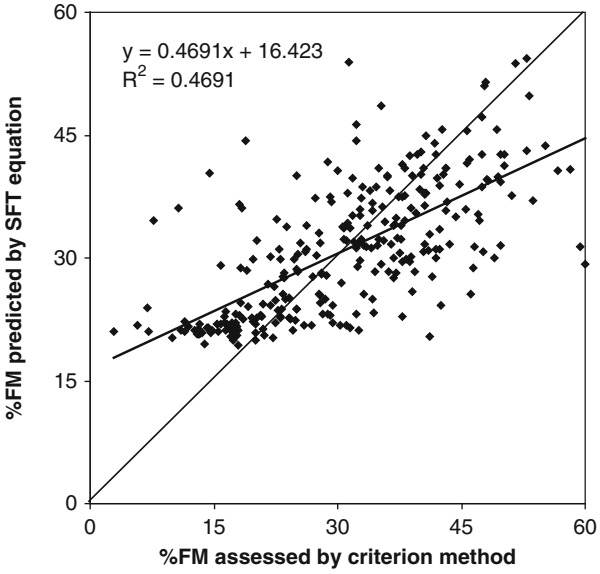

Fig. 77.4 Percentage fat mass assessed by criterion method (D_2O) versus predicted by final gender combined skinfold thickness equation, line of identity and regression line in a group of Sri Lankan children. Percent FM assessed by established (criterion) method and new prediction equation is plotted on the graph. The values are relatively concentrated to the mid line denoting that there is good agreement between the two methods. But it is not as impressive as in the assessment of FM (Reprinted from Wickramasinghe et al (2008b), with permission)

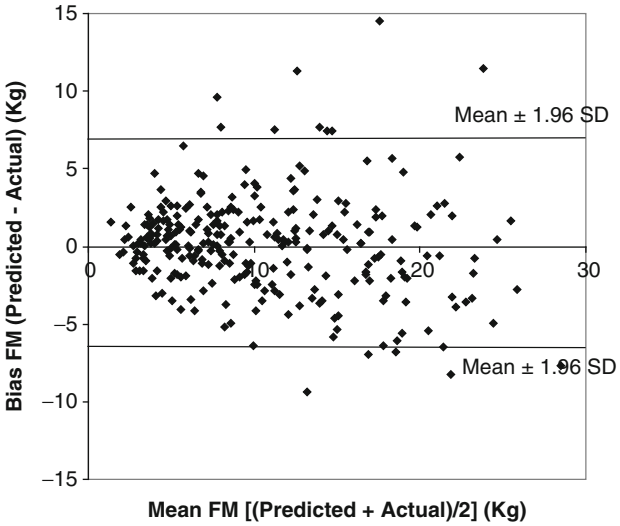

Fig. 77.5 Bland Altman plot for mean fat mass assessed by skinfold thickness prediction equation and D_2O method and fat mass assessment bias (predicted – actual) in a group of Sri Lankan children. Mean bias was 3.05×10^{-7} L (~0) and SD of 3.38. The bias in the assessment of FM (assessed by equation - established methods) is plotted against the mean FM assessed by the two methods [(equation + established methods)/2]. Values are scattered closer to mean and spreads across the whole of *X*-axis. This shows that bias in not dependent on the value of total FM of body (Reprinted from Wickramasinghe et al. (2008b), with permission)

Assessment of fat mass shows strong agreement with values obtained from the criterion method and most of the values were falling along the line of identity. However, in the assessment of percent fat mass values at extreme ends, there were deviations from the line of identity. Figure 77.5 shows the Bland Altman plot for mean fat mass assessed by the criterion method and final prediction equation and bias between the criterion method and final prediction equation. Most of the bias was close to zero. Figure 77.6 shows the Bland Altman plot for mean percent fat mass assessed by the criterion method and final prediction equation and bias between criterion method and final prediction equation. In this instance also the distribution was mainly around zero, but less condensed than for fat mass. In both instances most of the values remained within mean bias ± 1.96 SD.

Fat mass of the body as well as its distribution is influenced by maturity. Therefore, fat deposition of body could depend on pubertal stage of the individual. Thus, the prediction of body fat mass based on skinfold thickness equations could be influenced by the pubertal stage of the child. The initial prediction equation did not consider the influence of maturity on the assessment of fat mass and percent fat mass. A set of equations to assess fat mass as well as percent fat mass based on pubertal stage were also developed and validated to find the most appropriate set of skinfold thickness equation for Sri Lankan children (Table 77.9 and 77.10). The fat mass and percent fat mass were assessed by each of the maturation specific prediction equations. They are:

1. The gender and maturity non-specific common childhood equation (common equation to be used without taking pubertal stage and gender into consideration
2. Maturity-specific but gender non-specific common equation (equation is based on pubertal stage but irrespective of gender)
   and
3. Maturity and gender-specific equation (equation is selected taking into consideration both pubertal stage and gender).

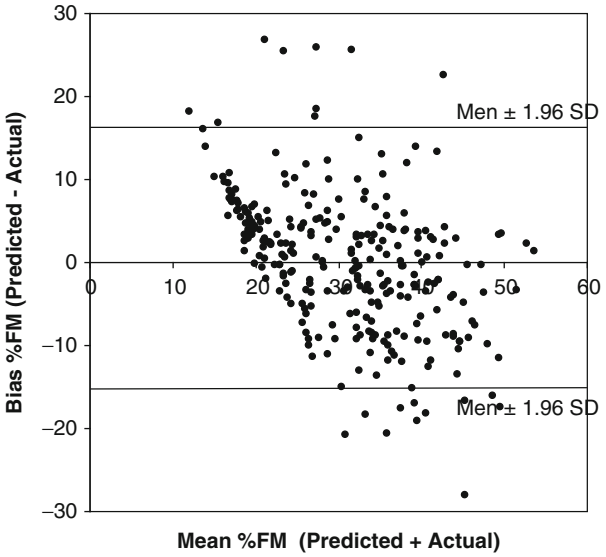

Fig. 77.6 Bland Altman plot for mean percent fat mass assessed by skinfold thickness prediction equation and D_2O method and percent fat mass assessment bias (predicted – actual) in a group of Sri Lankan children. Mean bias was $–1.11\times 10^{-7}$ L (~0) and SD of 8.6. The bias in the assessment of percent FM (assessed by equation – established methods) is plotted against the mean percent FM assessed by the two methods [(equation + established methods)/2]. Values are scattered evenly all over the graph denoting that bias is highly variable (Reprinted from Wickramasinghe et al. (2008b), with permission)

Table 77.9 Preliminary SFT equation developed on a group of Sri Lankan children: gender-combined and gender-specific equations for the prediction of fat mass and percent fat mass in *prepubertal children*

	Equation	R^2	RMSE
Fat mass prediction equations	**Gender non-specific**		
Fat mass	(0.41 × age) + (0.29 × SFT-triceps) + (0.28 × SFT-sub-scapular) – (2.2 × sex code[a]) – 0.48	75.9	2.09
	Gender-specific		
Fat mass: male	(0.26 × age) + (0.57 × SFT-triceps) + (0.026 × SFT-sub-scapular) – 2.26	72.0	1.8
Fat mass: female	(0.78 × age) – (0.08 × SFT-triceps) + (0.55 × SFT-sub-scapular) – 1.32	80.0	2.2
Percentage fat mass prediction equations			
	Gender non-specific		
Percentage fat mass	(0.09 × age) + (1.12 × SFT-triceps) + (0.10 × SFT-sub-scapular) – (10.4 × sex code[a]) + 22.0	50.2	8.9
	Gender-specific		
Percentage fat mass: male	11.53 – (0.53 × age) + (2.02 × SFT-triceps) – (0.42 × SFT-sub-scapular)	51.5	7.3
Percentage fat mass: female	22.46 + (1.48 × age) – (0.53 × SFT-triceps) + (1.02 × SFT-sub-scapular)	29.0	10.2

The table shows different equations developed to assess FM and percent FM in *prepubertal* children. Some equations are meant for a specific sex group (gender specific) while some equations can be used for both sex groups (gender non-specific)

[a]Sex code: male =1; female = 0

Table 77.10 Preliminary SFT equation developed on a group of Sri Lankan children: Gender-combined and gender-specific equations for the prediction of fat mass and percent fat mass in *pubertal children*

	Equation	R^2	RMSE
Fat mass prediction equations	**Gender non-specific**		
Fat mass: common	(0.57 × age) + (0.39 × SFT-triceps) + (0.27 × SFT-sub-scapular) – (2.17 × Sex code[a]) – 2.89	70.7	3.66
	Gender specific		
Fat mass: male	(0.69 × age) + (0.43 × SFT-triceps) + (0.8 × SFT-sub-scapular) – 5.7	75.1	3.1
Fat mass: female	(0.51 × age) + (0.37 × SFT-triceps) + (0.38 × SFT-sub-scapular) – 3.7	62.4	4.1
Percentage fat mass prediction equations			
	Gender non-specific		
Percentage fat mass: common	28.6 – (0.28 × age) + (0.5 × SFT-rtriceps) + (0.22 × SFT-sub-scapular) – (8.5 × sex code[a])	44.4	8.3
	Gender specific		
Percentage fat mass: male	9.7 – (0.5 × age) + (0.81 × SFT-triceps) – (0.07 × SFT-sub-scapular)	45.0	7.3
Percentage fat mass: female	48.8 – (1.53 × age) - (0.006 × SFT-triceps) + (0.37 × SFT-sub-scapular)	24.9	8.7

The table shows different equations developed to assess FM and percent FM in *pubertal* children. Some equations are meant for a specific sex group (gender specific) while some equations can be used for both sex groups (gender non specific)

[a]Sex code: male =1; female = 0

They were developed and validated on an independent group. Fat mass and percent fat mass predicted by each equation was quite similar to the results obtained by the criterion method (Table 77.11). One way ANOVA was used to compare the results obtained by the 3 different prediction equations and the criterion method in the validation group. None of the predicted values differed significantly from the values obtained from the criterion method (Table 77.11).

This denotes that although pubertal stage influenced the fat distribution in the body, the results obtained by pubertal stage specific and gender specific equation did not differ from the results obtained from gender and maturity non-specific equation in this group of children. It must be stressed that the assessment of maturity in a field or clinic setting is not easy. According to this study evaluations made by a common equation (that does not take gender and pubertal stage into account) does not seem to affect body fat assessment. Therefore, it would be more practical to use a single equation for children of both gender groups and without taking development stage into account. Therefore, body fat mass can be assessed using a single equation without having to assess the maturity of the child.

Of the equations that we validated, only the equations of Deurenberg and co-workers (1990) and Slaughter and co-workers (1988) used equations to suit different pubertal stages of subjects. Yuan et al (1987) used different equations based on age and sex, but not on pubertal stage. Brook (1971) used gender-specific equation while Sarria and co-workers (1998) developed equations only for boys. This shows the diversity of equations that are available in the published literature. Assessment of pubertal stages as well as applying gender-specific equations is not easy in busy clinics or field settings. Therefore, having a common equation which gives agreeable results is much more acceptable in day-to-day clinical practice.

Table 77.11 Validation results for the assessment of fat mass and percent fat mass using different skinfold thickness equations based on maturity (pubertal status) in a group of Sri Lankan children

	Fat mass	Percentage fat mass	Fat mass	Percentage fat mass
Pre-pubertal children	**Male (n = 25) Mean ± SD**		**Female (n = 16) Mean ± SD**	
Criterion method	6.6 ± 6.04	24.8 ± 10.8	8.02 ± 3.3	33.1 ± 8.5
Maturity specific common equation for prepubertal children	5.9 ± 4.7	24.6 ± 8.7	9.4 ± 3.6	37.6 ± 6.2
Maturity and gender specific equation for prepubertal children	5.7 ± 4.3	24.2 ± 10.4	9.9 ± 4.3	38.8 ± 6.7
Gender and maturity non specific common equation	6.1 ± 5.5	24.7 ± 6.2	9.1 ± 4.2	34.7 ± 5.5
Pubertal children	**Male (n = 28) Mean ± SD**		**Female (n = 25) Mean ± SD**	
Criterion method	11.7 ± 8.5	27.4 ± 13.1	16.4 ± 6.7	37.8 ± 10.9
Maturity specific common equation for prepubertal children	10.2 ± 6.5	27.3 ± 5.6	15.6 ± 4.8	37.6 ± 4.7
Maturity and gender specific equation for prepubertal children	11.0 ± 6.5	27.9 ± 11.4	15.6 ± 5.0	43.6 ±5.9
Gender and maturity non specific common equation	11.4 ± 6.5	27.3 ± 7.0	15.8 ± 4.8	38.1 ± 5.6

The above equations (in Tables 77.9 and 77.10) and the equation which was developed initially (Table 77.8) were tested on an independent group of children and results are shown in this table. Assessment by any of the equations did not significantly differ from the assessment made using established (criterion) method

77.7 Assessment of Body Composition of Sri Lankan Children Residing in Australia

Children of South Asia living in Western societies have been shown to develop metabolic derangements due to affluent life styles (Whincup et al. 2002). A significant Sri Lankan expatriate community lives in Australia. Therefore, having robust techniques to assess body composition of these groups of children is important. Equations developed on Sri Lankan children were validated on Australian children of Sri Lankan origin.

Table 77.12 shows the results obtained by each of the prediction equations and the criterion method. Except for the equation described by Yuan et al. to assess percent fat mass in both gender groups and estimation of percent fat mass in females children using fat mass estimation equation, all other equations gave high correlation for the assessment of percent fat mass in Sri Lankan children residing in Australia. Estimation of fat mass and percent fat mass in such Sri Lankan children residing in Australia, using skinfold thickness equations developed in Sri Lanka, provided a high degree of accuracy.

Skinfold thickness can be used in the assessment of body composition with fair accuracy. This is useful especially in low resource settings. Its accuracy in using on Sri Lankan children living in Australia suggests that ethnicity is a more influential factor on body composition assessment than the socio-economic environment that they are living in.

Table 77.12 Assessment of body composition in a group of Australian children of Sri Lankan origin, using Sri Lankan skinfold thickness equations

	Male (27)			Female (15)		
	Mean±SD	*r**	Bias	Mean±SD	*r**	Bias
Fat mass						
D_2O method	6.9 ± 4.6			10.2 ± 5.5		
Sri Lankan equation for fat mass estimation	6.9 ± 4.2	0.92	–0.3 ± 1.8	11.7 ± 5.5	0.88	1.5 ± 2.7
Percentage fat mass						
D_2O method	22.9 ± 8.7			29.0 ± 6.0		
Sri Lankan equation for fat mass[a]	22.4 ± 7.8	0.76	–0.4 ± 9.5	34.1 ± 8.1	0.40	5.4 ± 4.1
Sri Lankan equation for percent fat mass[b]	24.9 ± 4.3	0.86	1.9 ± 7.9	35.9 ± 5.0	0.80	6.9 ± 5.7
Slaughter et al. (Triceps+Calf)	17.2 ± 7.5	0.84	–5.7 ± 4.2	23.2 ± 5.5	0.82	5.8 ± 4.1
Sarria et al. 2	13.3 ± 6.6	0.83	–9.6 ± 5.3	–	–	–
Yuan et al.	21.4 ± 7.6	0.35	–1.5 ± 7.9	24.7 ± 6.1	0.46	–4.2 ± 6.7

The newly developed equation was tested on a group of Australian children of Sri Lankan origin with some other equations published in the literature. Results in the assessment of FM and percent FM using newly developed equations were quite similar to the results obtained by the established (criterion) method. Assessment results obtained from other equations did not agree

[a]Percent fat mass is calculated secondarily from the estimated fat mass based on Sri Lankan equation

[b]Percent fat mass is estimated directly from the equation derived to estimate the percent fat mass based on Sri Lankan equation

*$p < 0.001$

77.8 Clinical Application of Skinfold Thickness Measurements

Skinfold thickness measurements can be used in the assessment of nutritional status and also to assess improvement in nutritional rehabilitation of children with undernutrition. Although not very accurate, skinfold thickness also can be used to estimate the volume of muscle in a region of body such as a limb. When it is assumed that the cross-section of the limb is circular, skinfold thickness are equal to the thickness of subcutaneous adipose tissue and maintains a uniform thickness around the limb, then muscle bulk with the bone can be estimated. However, when compared to CT and MRI scans, it is less accurate (Roche 1996). Skinfold thickness is also useful in follow-up of patients with obesity. In the management of obesity one has to primarily reduce fat stores in the body. Therefore, fat stores could be objectively assessed based on skinfold thickness using either centile charts or prediction equations and calculating the absolute fat mass or percent fat mass of the body.

Children with growth hormone deficiency are obese with excess subcutaneous fat in the body. In such situations, response to growth hormone therapy could be assessed by serial skinfold thickness measurements.

Summary Points

- Subcutaneous fat deposits act as an energy store and reflect the nutritional status of the body.
- Measurement of skinfold thickness is useful in the assessment of nutritional status as well as follow-up of medical conditions for response to treatment.

- Skinfold thickness measures a double layer of skin and subcutaneous tissue and it can be used to assess muscle mass in a limb as well.
- Standard callipers should be used to measure skinfold thickness and the correct technique should be employed.
- Standard sites are used to measure skinfold thickness to improve accuracy and reproducibility.
- Subcutaneous fat distribution is dependent on age, sex, maturity and ethnicity.
- Centile charts can be used to compare data and new WHO reference charts are available.
- Skinfold thickness based prediction equations can be used for the assessment of body composition, mainly body density, fat mass and percent fat mass.
- Prediction equations need to be validated prior to their use on a given population if the equations were originally developed in a population different from the study population.

Annexure

Prediction equation of Deurenberg et al. for assessment of %FM

Boys	Prepubertal	= –14.61 + 26.51 × log (bicep + triceps)
		= –22.23 + 26.56 × log (biceps + triceps + SS + SI)
	Pubertal	= –9.78 + 21.9 × log (bicep + triceps)
		= –11.91 + 18.7 × log (biceps + triceps + SS + SI)
	Post pubertal	= –6.81 + 17.77 × log (bicep + triceps)
		= –15.58 + 18.88 × log (biceps + triceps + SS + SI)
Girls	Prepubertal	= –16.84 + 29.3 × log (bicep + triceps)
		= –25.87 + 29.85 × log (biceps + triceps + SS + SI)
	Pubertal	= –14.79 + 26.21 × log (bicep + triceps)
		= –18.89 + 23.94 × log (biceps + triceps + SS + SI)
	Post pubertal	= –27.71 + 36.53 × log (bicep + triceps)
		= –43.49 + 39.02 × log (biceps + triceps + SS + SI)

Prediction equation of Sarria et al. for the assessment of body density in boys

Equation 1 = 1.1579 – [0.0685 × log (biceps + triceps + SS + SI)] (13)
Equation 2 = 1.0728 + (0.0007 × BMI) – (0.0028 × triceps SFT) (14)

Conversation of body density to %FM

$$\%\text{FM} = \frac{\left[562 - 4.2\left(\text{Age} - 2\right)\right]}{\text{body density}} - \left[525 - 4.7\left(\text{Age} - 2\right)\right]$$

Prediction equation of Slaughter et al. equation for prediction of %FM

From triceps and calf SFT

Boys = 0.735 × (triceps + calf) + 1.0
Girls = 0.610 × (triceps + calf) + 5.1

From Triceps and Subscapular

Prepubertal	White males = 1.21 × (triceps + SS) – 0.008 × (triceps + SS) – 1.7
	Black males = 1.21 × (triceps + SS) – 0.008 × (triceps + SS) – 3.2

Pubertal	White males = 1.21 × (triceps + SS) – 0.008 × (triceps + SS) – 3.4
	Black males = 1.21 × (triceps + SS) – 0.008 × (triceps + SS) – 5.2
Post pubertal	White males = 1.21 × (triceps + SS) – 0.008 × (triceps + SS) – 5.5
	Black males = 1.21 × (triceps + SS) – 0.008 × (triceps + SS) – 6.8
	All females = 1.33 × (triceps + SS) – 0.013 × (triceps + SS) – 2.5

For sum of triceps and subscapular >35 mm, the following equation was used

$$\text{All males} = 0.783 \times (\text{triceps} + \text{subscapular}) + 1.6$$
$$\text{All females} = 0.546 \times (\text{triceps} + \text{subscapular}) + 9.7$$

Prediction equation of Brook equation for prediction of body density

$$\text{Males} = (1.1533 - 0.0643) \times \log (\text{biceps} + \text{triceps} + \text{SS} + \text{SI})$$
$$\text{Females} = (1.1369 - 0.0598) \times \log (\text{biceps} + \text{triceps} + \text{SS} + \text{SI})$$

Conversation of body density to %FM

$$\%\text{FM} = \left\{\frac{4.95}{\text{body density}} - 4.5\right\} \times 100$$

Prediction equation of Yuan et al. for prediction of %FM

10–12 years	Males = 9.0870 + 0.6616 × (triceps + SS)
	Females = 11.2657 + 0.5311 × (triceps + SS)
13–15 years	Males = 4.8942 + 0.5311 × (triceps + SS)
	Females = 10.8048 + 0.3614 × (triceps + SS)

Chapter 78
Use of Segmental Lengths for the Assessment of Growth in Children with Cerebral Palsy

Kristie L. Bell, Peter S.W. Davies, Roslyn N. Boyd, and Richard D. Stevenson

Abstract Measurement of height or recumbent length is essential for the assessment of linear growth in children. Children with cerebral palsy (CP) often grow poorly and assessment of growth in this population is further complicated by two main difficulties. Firstly, children may have joint contractures, muscular weakness, scoliosis, and/or involuntary movements that make standing or lying straight difficult, if not impossible. Hence, accurate and reliable measures of height or recumbent length are not always attainable in this population. Secondly, as a result of atypical growth patterns, generally accepted reference charts for typically developing children may not be appropriate for use in children with CP. Due to these difficulties segmental lengths such as knee height, tibial length or upper arm length are frequently used as alternatives. These measures are all reliable and valid alternative measures for height in children with CP. They have been recommended for inclusion in the routine growth assessment of this group when accurate or reliable direct measurements of height or recumbent length are difficult or not possible (Spender et al. 1989; White and Ekvall 1993; Chumlea 1994; Stevenson 1995; Gauld et al. 2004). Segmental lengths can be compared directly with growth charts developed from data collected from children with normal growth or children with CP (Spender et al. 1989; White and Ekvall 1993; Stevenson et al. 2006). Alternatively, they may be used to estimate height using published equations, thus enabling comparison with height-for-age reference charts developed from typically developing children or children with CP (CDC 2000; Stevenson et al. 2006; WHO 2006; Day et al. 2007).

78.1 Introduction

Physical growth is a fundamental aspect of health and an indicator of physical wellbeing in children. Abnormal growth may occur for a number of reasons and may be indicative of illness or chronic inadequate nutrient intake (Stevenson et al. 2006). Physical growth and development in children have been assessed for many years using classic anthropometric measurements. These include measures of height or supine length, weight and other simple measures (WHO Expert Committee on Physical Status 1995). In typically developing individuals, assessment of linear growth is relatively straightforward where values for recumbent length or height can be compared to a growth reference or standard (CDC 2000; WHO 2006). Measures of length or height are also frequently used with measures of body weight to assess body proportions through use the body mass index (BMI) or weight-for-height growth charts (WHO Expert Committee on Physical Status 1995). Other applications include calculation of predicted energy requirements using published formulae (Schofield 1985); and prediction of reference ranges for the assessment of pulmonary function and glomerular filtration rate (Gauld et al. 2004).

Growth and nutritional status of children and adolescents with CP have been the subject of numerous investigations over the past 50 years (Tobis et al. 1961; Spender et al. 1989; Stevenson et al. 1994; Krick et al. 1996; Stevenson et al. 2006; Day et al. 2007). In general, children with CP are shorter and lighter than their typically developing peers (Krick et al. 1996; Stevenson et al. 2006; Day et al. 2007). The largest study, to date, of the growth parameters of children and adolescents with CP was based on retrospective data relating to height and weight obtained from the patient records of 24,920 children and adolescents with CP aged 2–20 years (Day et al. 2007). A combination of cross-sectional and longitudinal data was included, totalling 141,961 different observations. The 10th, 50th and 90th percentile curves for height, weight and BMI were determined by age, sex, and five levels of functional ability. This study was the first to develop growth curves for children with CP stratified by gross motor skills and feeding ability (Day et al. 2007).

Height and weight percentile curves for the highest functioning groups (i.e. group 1: walks well alone for at least 6 m and balances well) approximated those of the general population. Trends for lower weight and height for age were apparent for the lower functional groups and deviated further from those of the general population with increasing functional impairment. Interestingly, in the lowest functioning groups (groups 4 and 5), the presence of a feeding tube was associated with greater height and weight (Day et al. 2007). The most significant limitation of this study was that the methods utilised to measure height were of unknown validity and reliability in this population. The authors acknowledge this limitation and conclude that the height curves presented for children with significant motor impairment (i.e. groups 3, 4 and 5) should be viewed with some caution.

Table 78.1 Key facts about the use of segmental lengths in children with cerebral palsy

Measurement of height or recumbent length in children with cerebral palsy may be difficult and sometimes impossible.
Segmental lengths are frequently used as alternative measures to height or length in children with cerebral palsy for the assessment of growth.
Commonly used segmental lengths in children with cerebral palsy are knee height, upper arm length and tibial length.
The landmarks for segmental lengths may be difficult to identify. Training and practice is required to develop skill and competence in their measurement.
All measurements should be taken twice and on the left hand side of the body. The average of the two measurements should be used.
Upper arm length and knee height should be measured using specialised equipment. Knee height should be measured using a sliding calliper or anthropometer. Upper arm length should be measured with an anthropometer or Vernier callipers, depending on the size of the child.
Tibial length can be measured accurately using steel or plastic measuring tapes.

This table describes some key facts related to the use of segmental lengths in children with cerebral palsy including those measures commonly used, equipment required and basic concepts

78.2 Difficulties with Conventional Assessment of Height or Length in Children with CP

Direct measurement of recumbent length or height may be inaccurate, unreliable and frequently impossible in children and adolescents with physical disabilities, such as cerebral palsy (CP), due to joint contractures, muscular weakness, scoliosis, involuntary movements or poor cooperation. Difficulty obtaining conventional measures of height or recumbent length have been reported in 53% of children with CP participating in a study of growth parameters (Spender et al. 1989); furthermore, reliable measurements of either recumbent length or height were unable to be obtained in 52% of a clinical population of children with CP (Stevenson 1995). In this study, the population in which a reliable measure of length or height was possible was those of the younger children with less severe motor impairment than the larger clinic population; suggesting that difficulties with obtaining direct measures of height or recumbent length in children with CP increase with increasing age and severity of motor impairment (Stevenson 1995). In order to overcome these difficulties, various segmental lengths including upper arm length, ulna length, forearm length, knee height and lower leg (tibial) length have been identified as potential alternatives or proxy measures in different populations. Key facts regarding the use of segmental lengths in children with CP are included in Table 78.1. To be clinically useful as a proxy measure for recumbent length or height in the population of interest, the measure must be (1) measurable in the population (2) reproducible (3) highly correlated with recumbent length or height and (4) able to be compared to a growth reference.

78.3 Use of Segmental Lengths in Children with Cerebral Palsy

Knee height, lower leg length and upper arm length have all been shown to be both reproducible and clinically useful as proxy measures for height or recumbent length in children and adolescents with CP (Spender et al. 1989; Chumlea 1994; Stevenson 1995; Hogan 1999; Bell and Davies 2006). In typically developing children, correlations between height and knee height, upper arm length and tibial length are very high (r = 0.97, 0.98 and 0.98, respectively) (Spender et al. 1989; Chumlea

Table 78.2 Reliability of segmental lengths in children with cerebral palsy

	Intra-observer error $N = 307$		Inter-observer error $N = 18$	
	TE (cm)	CV (%)	TE (cm)	CV (%)
Upper arm length[a]	0.27	1.07	0.52	2.32
Tibial length[b]	0.28	1.04	0.33	1.31
Knee height[a]	0.22	0.61	0.29	0.89

This table shows reliability data for measurements of segmental lengths in children with CP. All data presented here were obtained as part of the North American Growth in Cerebral Palsy Project

[a]Published data (Stevenson et al. 2006)

[b]Previously unpublished data. TE indicates the technical error = $\sqrt{\Sigma d^2/2n}$, where d = difference between paired measures on n subjects, CV is the coefficient of variation = 100 × (TE/mean of measures taken)

1994; Gauld et al. 2004). In children with CP, correlations between height or recumbent length and knee height, upper arm length and tibial length are similarly high ($r = 0.98$, 0.97, and 0.97, respectively, $p < 0.05$) (Stevenson 1995). In addition, knee height has been found to correlate significantly with recumbent length in a group of wheel chair dependent children, adolescents and adults with CP ($r = 0.88$, $p < 0.05$) (Hogan 1999).

78.4 Reliability

Reliability of anthropometric data may be expressed in many ways. Two commonly utilised statistics are the technical error of the measurement (TE) and the coefficient of variation (CV). The TE is calculated as $\sqrt{(\Sigma d^2/2n)}$, in which d is the difference between the same measure on the same child done by the same observer (intraobserver observer) or different observers (interobserver error) (Cameron 1986). The TE will be greater for measures of larger magnitude. For example, the TE for measurements of height will be greater than the TE for measurements of knee height due to the magnitude of the measure itself. The CV is the TE of measurement divided by the overall mean of all subjects for the particular variable under study. It is a measure of relative variability, i.e., variation relative to the overall magnitude of the measure (Malina et al. 1973).

Acceptable levels of intra- and inter-observer repeatability have been reported for measures of knee height, upper arm length and tibial length, when conducted by trained observers, in children with CP, as shown in Table 78.2 (Stevenson et al. 2006). The data reported here were obtained as part of the North American Growth in Cerebral Palsy Project (NAGCPP). This was a multicentre study that investigated the growth, body fat stores and physical development of children with moderate to severe CP (Gross Motor Function Classification System (GMFCS) Levels III–V). Data were collected across six different sites throughout the United States and Canada. Values reported for TE and CV for segmental lengths were similar to those obtained for measurement of height in typically developing children from the National Health Examination Survey cycle II. This large scale study reported TE and CV for height measured by the same observer (TE = 0.68 cm, CV = 0.42) and different observers (TE = 0.49 cm, CV = 0.30) (Malina et al. 1973).

78.5 Interpretation of Segmental Lengths

78.5.1 Use of Growth Charts for Segmental Lengths

The interpretation of anthropometric data is facilitated by comparison to a growth reference and/or to earlier measurements from the same child. Reference charts for lower leg length, upper arm length, knee height, and ulna length have been developed for healthy typically developing children and can be used to assess the linear growth of children with CP and other physical disabilities (Spender et al. 1989; White and Ekvall 1993; Gauld et al. 2004). For example, growth charts for upper arm length and tibial length were developed by Spender and colleagues using data obtained from 1,298 typically developing children (Snyder et al. 1977; Spender et al. 1989). These growth charts have not been commercialised and are not readily available in most clinical settings.

Growth charts for knee height have been developed from data collected specifically from children with CP as part of the NAGCPP (Stevenson et al. 2006). These charts, and additional charts for tibial length and upper arm length for boys and girls, are the first charts to allow clinicians to make comparisons with segmental length measurements obtained from a group of children with CP (Appendix 1–6). They were developed from data collected from 156 boys and 114 girls aged 2–18 years. All children were diagnosed with CP and classified as having moderate to severe motor impairment (GMFCS levels III–V only). The reference curves were estimated using the LMS method (Cole and Green 1992) Some key facts regarding the NAGCPP are included in Table 78.3.

78.5.2 Equations to Predict Height from Segmental Lengths

An alternative to direct comparisons with growth charts for segmental lengths is to predict height from the segmental length measure using published equations. Formulae have been developed from data collected from healthy, typically developing individuals to predict height from segmental lengths in different ethnic groups (Chumlea 1994; Cheng et al. 1998; Gauld et al. 2004) and from data collected specifically from children with CP (Stevenson 1995). These allow comparisons of predicted height with standard height-for-age growth references or standards for typically developing children (CDC 2000; WHO 2006) and children with CP (Day et al. 2007).

Equations to predict height from ulna, forearm, tibial and lower leg lengths have been developed from a large dataset of 2,343 healthy, typically developing Australian school children and adolescents aged 5–19 years as shown in Table 78.4 (Gauld et al. 2004). In addition, prediction equations for height from radius, humerus, tibia and ulna lengths have been developed from measurements conducted in a group of 3,647 healthy, typically developing Chinese elementary, middle and high school children and adolescents aged 3–18 years (Table 78.5) (Cheng et al. 1998). However, the largest data set to date from which equations to predict height have been developed was collected from 1960 to 1970 in cycles I, II and III of the United States National Health Examination Survey (Table 78.6) (Chumlea 1994). These surveys included nationally representative samples of free living United States civilian adults (cycle I, $n = 5{,}414$), children aged 6–11 years (cycle II, $n = 7{,}087$) and adolescents aged 12–18 years (cycle III, $n = 6{,}734$). Equations were developed by age, sex and ethnicity (Caucasian and African-American). Population specific equations have been developed to predict height from knee height, upper arm length and tibial length from data obtained from a group of 172 children with CP aged 2–12 years, 48% of which were non-ambulatory (Stevenson 1995) and are included in Table 78.7. Available reference data for measurements of segmental lengths are summarised in Table 78.8.

Table 78.3 Key Facts of the North American Growth in Cerebral Palsy Project

Study Design	The North American Growth in Cerebral Palsy Project (NAGCPP) was a multicentre, region based study established in 1996.
Location	Six regional geographic locations throughout the United States and Canada
Aims	The long term goal of NAGCPP was to optimise the growth, nutrition, functional outcome and overall quality of life in children with CP by: 1. Defining expected growth patterns 2. Determining the nutritional, endocrinological, neurological and physical factors that influence growth, and 3. Determining how growth affects function, general health status, cognitive and motor development, family stress, health care use, morbidity and mortality.
Eligibility	All children with CP between the ages of 2 and 18 years residing in the designated geographical regions and classified as Gross Motor Function Classification Levels III, IV or V were eligible to participate.
Participants	235 children participated. Average age was 9.7 ± 4.6 years. 59% were male GMFCS Levels were: III – 56; IV – 55; V – 122
Measures	• Anthropometry: weight, head circumference, length, upper arm length, tibial length, knee height, calf circumference, mid-arm circumference, triceps skinfold thickness, calf skinfold thickness, subscapular skinfold thickness • Child Health Questionnaire • Medical history • Feeding abilities • Cognitive functioning • Health care use • General health

This table describes some of the key features of the North American Growth in Cerebral Palsy Project (NAGCPP) (Liptak et al. 2001)

Table 78.4 Equations to estimate height from segmental lengths in typically developing children and adolescents

Segmental measure	Estimation equation (cm)	RMSE
Males		
Ulna length	Height = (4.605 × UL) + (1.308 × A) + 28.003	3.896
Forearm length	Height = (2.904 × FL) + (1.193 × A) + 20.432	3.556
Tibial length	Height = (2.758 × TL) + (1.717 × A) + 21.818	3.791
Lower leg length	Height = (2.423 × LL) + (1.327 × A) +21.818	3.062
Females		
Ulna length	Height = (4.459 ×UL) + (1.315 × A) + 31.485	3.785
Forearm length	Height = (2.908 × FL) + (1.147 × A) + 21.167	3.344
Tibial length	Height = (2.771 × TL) + (1.457 × A) + 37.748	3.383
Lower leg length	Height = (2.473 × LL) + (1.187 × A) + 21.151	2.717

This table shows key information relating to currently available reference data for segmental lengths in various populations. Included in the table are: descriptions of the populations in which measurements have been conducted (sample size, nationality, diagnosis of cerebral palsy), as well as identification of datasets used to develop growth charts for segmental lengths and equations to estimate height from segmental lengths

GMFCS Gross Motor Function Classification System

78.5.3 Evaluation of Prediction Equations

The accuracy of equations to predict height from segmental lengths in individuals with CP has been evaluated (Spender et al. 1989; Hogan 1999; Bell and Davies 2006). The ability of the Chumlea equations (Chumlea 1994) and the Stevenson equation (Stevenson 1995) to predict height from knee height was investigated in a group of 17 ambulatory children with CP (Gross Motor Function Classification System I and II) and 20 typically developing children (Bell and Davies 2006). At the population level, the Stevenson (1995) equation performed best with height predicted to within, on an average, 0.4% of measured height. Again, at the population level, the Chumlea equation also performed well with height predicted to within 1%; however, the bias in predicted height using the Chumlea equation increased with increasing height. Importantly, whilst the mean bias produced by the equations may have been acceptable, the limits of agreement for both equations remained relatively large. As a result, at the individual level height predicted by the Stevenson equation can vary by as much as 12.7 cm (10%) below to 11.8 cm (9%) above actual measured height for children with CP and 10.9 cm (9%) below to 12.3 cm (10%) above that for typically developing children. Thus the equations may be accurate at the group level; however, they may lead to unacceptable error for any one individual and caution should be exercised when using these equations in that way. Johnson and Ferrara (Johnson and Ferrara 1991) also found equations derived from healthy typically developing individuals to predict height from knee height were not sufficiently accurate for use in a group of adolescents with CP (Table 78.7 and 78.8).

These studies highlight the long known and well accepted concern relating to the application of equations to populations from which they were not derived. Equations to predict height or recumbent length from segmental lengths assume a strong relationship between the segmental length and height or recumbent length. Due to the heterogeneous nature of CP and known alterations in growth patterns, it is unlikely that this relationship is constant between children with different types and severities of motor impairment, let alone in children with CP and typically developing children (Krick et al. 1996; Stevenson et al. 2006; Day et al. 2007). Obviously, the Stevenson (1995) equations were derived from a group of children with CP where measurement of recumbent length or height was possible. The appropriateness of applying these equations to ambulatory children with CP has been confirmed (Bell and Davies 2006). Caution should be exercised when using these equations in children with more severe motor impairments where measures of height or recumbent length are not possible, such as those with severe scoliosis and contractures, the precise group for whom an alternative assessment of linear growth is necessary. The validity of prediction equations for use in these populations may never be determined since direct measurement of height or length is not possible. For these children it would be more appropriate to use growth charts for knee height, upper arm length or tibial length to assess linear growth, thereby avoiding any of the potential error associated with prediction equations.

78.5.4 Choice of Segmental Length in Individuals with CP

When an accurate measure of height or recumbent length is difficult, or impossible, the choice of alternative measure is likely to be determined by the resources available and the abilities of the child. To be accurate and reliable, both upper arm length and knee height require specialised measuring equipment (anthropometer or knee height calliper), whereas, tibial length can be measured using a flexible measuring tape (Spender et al. 1989; Rogerson et al. 2000). Of the three alternatives, the landmarks for knee height are the easiest to identify and indeed knee height has been found to be the most reproducible (Stevenson 1995). Since measurement of tibial length does not require specialised equipment, is not impacted on by knee and ankle contractures and the landmarks are relatively easy to palpate in lean individuals, it may be the most suitable alternative measure for height in children with CP. It is important to note however, that training of observers is required to ensure reliable and accurate results.

78.6 Practical Methods and Techniques

Detailed methods for the measurement of knee height, upper arm length and tibial length are described below (refer to Table 78.9). By convention, all anthropometric measures for the assessment of growth in children should be conducted on the left hand side of the body and in duplicate with the mean of the two measurements used for interpretation and analysis (WHO Expert Committee on Physical Status 1995). Where duplicates are not within an acceptable level of accuracy a third measurement may be taken and the mean of the two closest measurements used. In children with CP with marked asymmetry, investigators have conducted measurements on the less impaired side (Stevenson 1995; Bell and Davies 2006).

Table 78.9 Measurement of segmental lengths

Segmental measure	Equipment required	Distance of measurement
Upper arm length	Anthropometer or Vernier calliper in smaller children (Spender 1989)	From the acromium process to the head of the radius (Cameron 1986)
Tibial length	Flexible tape measure or Anthropometer (Stevenson 1995)	From the superomedial edge of the tibia to the inferior edge of the medial malleolus (Stevenson 1995)
Knee height	Anthropometer or Knee height calliper (Rogerson 2000)	From the heel to the anterior surface of the thigh over the femoral condyles (Cameron 1986)

This table describes the equipment required for measurement of different segmental lengths as well as the distance to be measured

Fig. 78.1 Measurement of knee height in a child with CP in the supine position. Measurement of knee height in the recumbent position requires two observers. Care must be taken to ensure that the child's knee and ankle should both be held at 90° angles

78.6.1 Knee Height

Knee height is the distance from the heel to the anterior surface of the thigh over the femoral condyles. Both the knee and ankle must be flexed at 90° angles with the subtabular joint in neutral. This can be achieved in one of two ways:

(a) The child may be seated upright with feet flat on the floor and both the knee and ankle joints flexed at 90° angles. In this instance, the measurement is taken as the distance from the floor, or foot rest, to the anterior surface of the thigh just proximal to the patella. The shaft of the caliper should be held parallel to the tibia and gentle pressure applied to the blades of the caliper to blanch the skin and compress the tissue (Chumlea 1994).

(b) Recumbent knee height is measured with both the knee and ankle held at 90° angles while the child is in a supine position (see Fig. 78.1). One of the blades of the calliper or anthropometer should be positioned under the heel of the left foot and the other placed over the anterior surface of the thigh above the femoral condyles, just proximal to the patella. Once again, the shaft of the calliper is held parallel to the shaft of the tibia and gentle pressure is applied to the blades of the calliper to compress the tissue (Stevenson 1995).

Fig. 78.2 Measurement of upper arm length in a child with CP. For children who are unable to sit independently, adequate positioning for measurement of upper arm length may be best achieved with the child lying on their right side

Accurate and reliable measurements of knee height may be difficult to achieve in children with contracture of the soleus resulting in equinovarus deformity or in children with a proximally displaced patella. Knee height should be measured using a sliding calliper or anthropometer, as accuracy is impaired when using a flexible measuring tape. Values for knee height collected using a flexible tape measure have been found to be on average 1.3 cm greater than those conducted using specialised equipment in a group of 56 non-ambulatory adults with developmental disabilities ($p < 0.001$) (Rogerson et al. 2000).

78.6.2 Upper Arm Length or Humerus Length

Upper arm length is the distance from the acromion process to the head of the radius (Cameron 1986) (see Fig. 78.2). The measurement should be made when the child is upright (either seated or standing) with their back to the observer, arms relaxed and vertical and the elbow flexed to 90°. This position can be difficult to achieve in children with physical disabilities who are unable to sit independently. The landmarks can be challenging to identify, and the measure requires significant practice to develop competence. Upper arm length should be measured with an anthropometer or may be measured with Vernier callipers in smaller children. Steel and plastic measuring tapes should

Fig. 78.3 Landmarks for the measurement of tibial length in a CP in the supine position. Landmarks for measurements of segmental lengths should be identified and marked prior to the measurement being taken

Fig. 78.4 Measurement of tibial length in a child with CP in the supine position. Adequate positioning for measurement of tibial length may be achieved with the child in a supine position with their left leg held so that the medial aspect of the tibia faces upwards

be avoided when measuring upper arm length as accuracy is impaired with their use (Spender et al. 1989). In children with CP, measurements of upper arm length obtained using steel and plastic measuring tapes have been found to be on average 1.03 cm (±0.2 cm) and 1.1 cm (±0.25 cm) greater than those obtained using an anthropometer (Spender et al. 1989).

78.6.3 Tibial Length

Tibial length is the distance from the superomedial edge of the tibia to the inferior edge of the medial malleolus (Stevenson 1995). The measurement should be conducted with the child in a seated position facing the observer with the left ankle or calf resting on the right knee so that the medial aspect of the tibia faces upwards (see Figs. 78.3 and 78.4) (Cameron 1986).

78.7 Applications to Other Areas of Health and Disease

Segmental lengths have proven to be clinically useful in other populations of children with physical disabilities such as Duchenne muscular dystrophy and myelomeningocele. The use of segmental lengths (ulna length, forearm length, tibial length, lower leg length) was investigated in a group of 20 children with Duchenne muscular dystrophy between 7 and 19 years of age, 17 of whom were wheelchair dependant (Gauld et al. 2004). Adequate positioning was not attainable for forearm and lower leg length measures in children with wrist or ankle deformities. Measurement of tibial length was difficult in children with equinovarus deformities of the ankle. Ulna length measurements were possible in all children and were not affected by wrist contracture; however, reliability was not reported. The usefulness of forearm length, ulna length, and arm span in children with idiopathic scoliosis and children with Duchenne muscular dystrophy was evaluated by Miller and colleagues (Miller and Koreska 1992). They concluded that for children who were unable to stand and who had proximal upper extremity contractures, height should be calculated from measurement of forearm segment. If there are finger or wrist contractures, height can be calculated from measurement of ulna length.

Arm span measurements are frequently used for the assessment of linear growth in children with myelomeningocele; however it is difficult to obtain accurate and reliable measurements in children with high level spinal lesions (Belt-Niedbala et al. 1986). For this reason other upper limb measurements have been proposed as alternatives including upper arm length, forearm length and total arm length, for use in this population (Belt-Niedbala et al. 1986). These measures have been shown to correlate significantly with recumbent length in a group of 44 children with myelomeningocele between three and 12 years of age ($r = 0.96$, 0.95 and 0.85, respectively), suggesting that these may be suitable proxy measures for linear growth in this population. Equations to predict height from segmental lengths are yet to be evaluated in children with myelomeningocele.

78.8 Clinical Usefulness of Measures of Body Height or Body Segments

Assessment of physical growth is an important aspect of routine health care maintenance for all children and is used by physicians primarily (1) as a screen for general endocrine and medical integrity and health and (2) as a marker of nutritional status (Stevenson 1996). For the assessment of physical growth *per se*, direct comparison of the segmental measure with its corresponding growth reference is recommended (Spender et al. 1989; White and Ekvall 1993; Gauld et al. 2004; Stevenson et al. 2006). This will avoid any potential error associated with the use of prediction equations. There is growing evidence that children with CP have different growth patterns as compared to typically developing children and that growth patterns in this population are influenced by both nutritional factors as well as factors related to the severity of CP (frequently referred to as non-nutritional factors) (Stevenson et al. 1994; Day et al. 2007). Due to the influence of non-nutritional factors on growth in this group, even well-nourished children with CP should not be expected to exhibit the same growth patterns as the general paediatric population. One major issue facing clinicians who treat children with CP is determining whether a child who is growing poorly according to a growth reference, is actually growing as expected for a child with CP, or whether a potentially treatable medical problem, such as malnutrition, is present that is limiting growth.

Most readily available growth references or growth standards have been derived from the general paediatric population and application to children with growth disorders may be problematic. In rec-

ognition of the requirement for diagnosis specific reference data, specialised growth charts have been developed for children with CP, as previously discussed (Krick et al. 1996; Stevenson et al. 2006; Day et al. 2007). These charts are not necessarily reflective of the "optimal growth" of well-nourished children as they were derived from populations with potentially high degrees of undernutrition. As a result they should be viewed with some caution. They do allow comparisons of the growth of individuals with CP with other large groups of children with CP; however they should by no means be used to determine "ideal" growth in this population.

78.9 Use of Segmental Lengths in the Assessment of Nutritional Status in Children with CP

For the evaluation of nutritional status in the clinical setting, measures of length or height are frequently used in combination with measures of body weight. Indices have been developed to provide simple estimates of body size, in both children and adults, and also to infer levels of body fatness (Benn 1971). Those most commonly utilised indices are weight-for-height (i.e. weight/height^1) and the BMI (weight/height^2). The BMI is the index which removes the most influence of height on weight and is highly correlated with skinfold thicknesses and total body fatness in typically developing children (Mei et al. 2002). As a result, BMI cut points to identify overweight, obesity and underweight in children and adolescents have been determined and are commonly utilised in clinical settings (WHO Expert Committee on Physical Status 1995; Cole et al. 2000, 2007). Use of these cut points in children with CP is problematic for a number of reasons. Firstly, the prediction of height from segmental lengths in children where this is necessary, introduces potential error associated with the prediction equation. Secondly, the BMI may not be a sensitive measure of body fatness in children and adolescents who are particularly short for their age or who have an unusual body composition. For example, a wheel chair dependent child with CP may have a low BMI but may in fact have a high level of body fatness in comparison to a typically developing child. In this instance, limitations in physical activity participation would result in a reduction in lean body mass and a subsequent increase in the proportion of body fat. Use of the BMI and other weight for height indices as indicators of adiposity in children with CP is an area that requires further investigation (Table 78.9).

The inclusion of a more direct measure of body fat when assessing the nutritional status of children with CP will allow for more accurate identification of poorly nourished children. Measures such as skinfold thicknesses are frequently utilised in this group; however, they do require specialised equipment and adequate training to be performed accurately and reliably. Further research is required to determine the most appropriate methods for the assessment of nutritional status in children with CP, in the clinical setting, and to establish links between nutritional status and health related outcomes in this group; with a view to establishing standards that reflect "ideal" patterns of growth for this population.

Summary Points

- Measurement of height or recumbent length in children with CP may be difficult and sometimes impossible due to joint contractures, muscular weakness, scoliosis, involuntary movements and poor cooperation.

- Correlations between height or recumbent length and knee height, upper arm length and tibial length are high in both typically developing children and children with CP.
- Knee height, lower leg length and upper arm length have been shown to be both reproducible and clinically useful as alternative measures for height or recumbent length in children with CP.
- Reference charts for lower leg length, upper arm length, knee height, and ulna length have been developed from data obtained from typically developing children.
- Reference charts for knee height, tibial length, and upper arm length have been developed from data obtained from children with CP.
- Height can be predicted from knee height, upper arm length or tibial length in children with cerebral palsy to facilitate comparison with standard height-for-age growth charts.
- Population specific equations to predict height from knee height perform better in children with cerebral palsy than equations developed from typically developing children.
- Whilst knee height is the most reproducible proxy measure and the landmarks are easily identified, it may be difficult or impossible to obtain an accurate measurement in some children with severe contractures of the lower limb, as the distance to be measured crosses two joints.
- Upper arm length and knee height should always be measured using either an anthropometer or a knee height calliper. Tibial length can be measured using a flexible measuring tape.

Chapter 79
Anthropometric Indices and Cardiovascular Disease Risk in Children and Adolescents: CASPIAN Study

Roya Kelishadi

Abstract For the first time in the Eastern Mediterranean region, we assessed the anthropometric indices most closely correlated to cardiovascular disease risk factors in a large nationally representative sample of children and adolescents to be used as a simple tool for identifying those at risk. We also developed the first age- and gender-specific reference curves for waist and hip circumferences in an Asian population of children and adolescents. This cross- sectional population survey was conducted in 2003–2004 on a nationally representative sample of 21,111 school-students living in urban (84.6%) and rural (15.4%) areas of 23 provinces in Iran. Biochemical variables were determined in a subsample of 4,811 participants. The correlation of anthropometric indexes and cardiovascular disease risk factors were determined by using Receiver Operator Characteristic (ROC) curves and partial correlation. Furthermore, smoothed reference curves for waist and hip circumference and waist-to-hip ratio were developed by the LMS method. In both genders, waist and hip percentile values increased with age. For girls, the 50th–95th percentile curves for waist circumference had a sharp increase between 8 and 13 years and 11–15 years, respectively, and began to plateau after this age, whereas for boys, these curves had a persistent and less sharp increase with age until the age of 18 years. The most prevalent cardiovascular disease risk factors were low levels of high-density lipoprotein-cholesterol (28%), followed by hypertriglyceridemia (20.1%), and overweight (17%). Among anthropometric indexes, body mass index (BMI) and waist circumference (WC) had the highest correlation ($r = 0.77$, $p < 0.0001$ in boys, and $r = 0.82$, $p < 0.0001$ in girls).The ROC analyses showed that among boys, all anthropometric indices had the same association with cardiovascular disease risk factors in 6–9.9-year-age group, while in the 10–13.9 and 14–18-year-age groups, respectively WC and BMI had the strongest association. Among girls, these indices were BMI and waist to stature ratio (WSR), WC and WSR, and WC, respectively. The obtained curves can provide baseline data for analysis of time trends, as well as for international comparisons. In the CASPIAN study, BMI, WC and WSR were more closely correlated with cardiovascular disease risk factors. Considering the close correlation between different anthropometric indices studied, and differences in the best predictive index according to age and gender, it may be clinically useful in the pediatric population to routinely measure WC and WSR in addition to BMI as a screening tool to identify high risk youths.

79.1 Introduction

Childhood obesity is reaching a global epidemic, but the dispute about the most valid anthropometric index related to its health hazards remains to be resolved. An improved understanding of body composition and factors influencing its development may help to plan strategies for reducing the risk factors of various diseases from early life onward. For early screening, various anthropometric measurements have been proposed to identify children and adolescents at risk. Body mass index (BMI) is perhaps the index most thoroughly studied; its relation with cardiometabolic risk factors and outcomes has been well documented. Nonetheless, as this index cannot distinguish fat from muscle mass and cannot represent the body fat distribution, the appropriateness of this overall obesity index in predicting cardiometabolic risk factors has been investigated in several studies.

Population-based surveys have documented that, similar to adults, in children and adolescents, abdominal or upper body fat is associated with an increased risk for cardiometabolic complications (Daniels 2000).

Ethnic differences are documented in several aspects of body size and proportions. Ethnic-specific references of anthropometric measures are generated, and are considered suitable for their respective populations, and corresponding to increases in body fat and associated health risks. Because of such ethnic differences in body size, especially in height, and variation in body fat distribution, different cutoff values are considered for anthropometric measures among diverse populations, and ratios of these measures are considered to provide a more appropriate index than simple measures in predicting cardiometabolic risk factors. This is of special concern for Asian populations with smaller body size, notably shorter statures than Western populations, and a genetic predisposition to visceral or abdominal obesity (WHO 2000). Similar to adults, anthropometric indices such as waist-to-hip ratio (WHR) and waist-to-stature ratio (WSR) and various cutoff values for anthropometric measures have been considered in children and adolescents as well (KC 2004).

Although the epidemiologic transition along with rapid lifestyle changes resulted in a rapidly growing prevalence of childhood obesity in the Eastern Mediterranean region (Kelishadi 2007a), experience regarding anthropometric indices of children and adolescents is very limited in this region. Therefore, for the first time in this region, we determined the anthropometric index most closely correlated to cardiometabolic risk factors in a large nationally representative sample of children and adolescents in Iran to be used as a simple tool for identifying those at risk.

79.2 Study Methods

79.2.1 Participants

The present study was performed as part of the baseline survey of a longitudinal national project titled: "***C****hildhood &* ***A****dolescence* ***S****urveillance and* ***P****revent****I****on of* ***A****dult* ***N****on-communicable disease*"*:* ***CASPIAN***[1] Study (Kelishadi et al. 2007b, c).

The first phase of this multicenter study was conducted at the national level in 2003–2004 among 21,111 school students (96% participation rates) living in urban and rural areas of the central cities of 23 (out of 28) provinces, as a joint collaboration of the World Health Organization (WHO/EMRO) and the National Ministry of Health and Ministry of Education. The present paper describes the findings obtained from a subsample of 4,811 school-students selected from six provinces located in diverse parts of the country (a 91% participation rate). In these counties, biochemical variables were examined in addition to the risk behaviors and biological risk factors evaluated in all the subjects studied.

Students were selected by multistage, random cluster sampling from elementary, middle, and high schools of urban and rural areas of different counties. These areas were defined according to the national population census. Initially, census blocks based on data from the Ministry of Health were randomly selected. Schools were randomly selected from different randomly selected clusters of these blocks, and, within schools, the students were selected at random. Schools were stratified according to location (urban/rural) and the socioeconomic character of its uptake area, with consideration of the proportion of the different types of schools (public/private) in order to avoid socioeconomic bias. From each stratum, a proportional, two-stage cluster sample of students was selected. The primary units (clusters) were the schools. The secondary units were the students within the schools. Students were allocated code numbers and randomly selected using random number tables.

Ethics committees and other relevant national regulatory organizations approved the study. Written informed consent was obtained from parents and oral assent from students, after full explanation of the procedure involved.

79.2.2 Quality Control/Quality Assurance

Considering that collecting data of high quality was critical to the success of our multicenter project, The Data & Safety Monitoring Board (DSMB) of the project has taken into account different levels of quality assurance and quality control (QA/QC). In addition to training, we developed a detailed operation manual and distributed it among the project team. A supervisor and a team of external evaluators nominated by the two collaborating ministries regularly monitored the performance of the personnel, and checked and calibrated equipment according to standardized protocols. Repeat studies were designed and conducted at specified time points on a student subsample. These repeat studies required taking multiple measurements on the same participant in order to quantify variability and to identify its sources, as well as to implement corrective action, as appropriate, in a timely manner to minimize measurement errors. The data entry staff entered data for all forms and questionnaires twice and checked for completeness and inconsistencies.

[1] Caspian is the name of the world's largest lake, located in Northern Iran.

79.2.3 Physical Examination

The field examinations of the survey were carried out by a specially trained team consisting of expert healthcare professionals trained for the survey. The questionnaires were filled out confidentially under the supervision of trained nurses. The age and birth date of subjects were recorded. Height and weight were measured twice to ±0.2 cm and to ±0.2 kg, respectively, with subjects being barefoot and lightly dressed; the averages of these measurements were recorded. Body mass index (BMI) (weight in kilograms divided by the square of height in meters) was calculated. Waist circumference (WC) was measured with a non-elastic tape at a point midway between the lower border of the rib cage and the iliac crest at the end of normal expiration. Hip circumference (HiC) was measured at the widest part of the hip at the level of the greater trochanter to the nearest half-centimeter. Next, WHR and the WSR were computed by dividing the WC by the HiC and Ht, respectively.

Blood pressure (BP) was measured using mercury sphygmomanometers after 5 min of rest in the sitting position. The subjects were seated with the heart, cuff, and zero indicator on the manometer at the level of the observer's eye. All readings were taken in duplicate on the right arm. Appropriate size cuffs were used with cuff width 40% of mid-arm circumference, and cuff bladders covering 80–100% of the arm circumference and approximately two-thirds of the length of the upper arm without overlapping. The procedure was explained to the students and the cuff inflated and deflated once; the first BP measured was not used in the analysis of this study. The readings at the first and the fifth Korotkoff phase were taken as systolic and diastolic BP (SBP and DBP), respectively. The average of the two BP measurements was recorded and included in the analysis.

79.2.4 Laboratory Examination

For blood sampling, students were invited to the health center nearest the school, in accordance with the rules of the national MoE. The students were instructed to fast for 12 h before the screening; compliance with fasting was determined by interview on the morning of examination. While one of parents accompanied his/her child, blood samples were taken from the antecubital vein between 8:00 and 9:30 a.m. After collecting blood samples, the participants were served a healthy snack provided by the project team.

The blood samples were centrifuged for 10 min at 3,000 rpm within 30 min of venipuncture. In each county, the biochemical analysis was performed in the Central Provincial Laboratory, which met the standards of the National Reference Laboratory, a WHO collaborating center in Tehran. Fasting blood sugar (FBS), HDL-C, and triglyceride (TG) were measured enzymatically by autoanalyzers. HDL-C was determined after dextran sulfate-magnesium chloride precipitation of non-HDL-C (Mc Namara 1987). Low-density lipoprotein-cholesterol (LDL-C) was calculated in serum samples with TG ≤ 400 mg/dL, according to the Friedwald equation (Friedewald 1972).

79.2.5 Definition of Risk Factors

The BMI percentiles provided by the Centers for Disease Control and Prevention (CDC) were used for the classification of the children and adolescents as undernourished, normal, and overweight and obese (Kuczmarsk 2000). Abnormal serum lipids were defined as TC, LDL-C, and TG higher than

the level corresponding to the age- and gender-specific 95th percentile, as well as HDL-C lower than age- and gender-specific 5th percentile (Lipid Research Clinics 1980). FBS levels equal or more than 100 mg/dL were considered high (Genuth et al. 2003). Elevated BP was defined as the mean SBP or DBP above the 90th percentile for that age and gender, after adjusting for weight and height (Task Force 1996).

79.2.6 Statistical Analysis

After editing, we transferred the data by the Stat Transfer 7 software to the SPSS version 13.0 software (SPSS, Inc., Chicago, IL).

Smoothed age- and gender-specific percentiles were constructed by the LMS Chart Marker software package (version 2.0, 2005, UK). The LMS method assumes that the data can be normalized by using power transformation. The percentile curves are the result of smoothing the age-specific curves: L for skewness, M for median, and S for coefficient of variation. In order to compare the mean values of the anthropometric measures in different age groups, the subjects were categorized to three age groups (6–9.99, 10–13.99, and 14–18 years) and by using univariate analysis, the mean values of BMI, WC, HiC, and WHR of both genders were compared between the age groups studied, and their living area (urban/rural). Partial correlation was used to examine the correlations between the age-adjusted anthropometric measures.

In order to determine the best anthropometric index associated with CVD risk factors, two statistical methods were used. First, receiver operating characteristic (ROC) curve analyses were used to calculate the area under ROC curves between each CVD risk factor and anthropometric index. Each value of an anthropometric index was used as a cutoff value to calculate its sensitivity and specificity in classifying a CVD risk factor. The ROC curve is a plot of the sensitivity against specificity for each cutoff value, and the area under curve (AUC) is an indicator of how well the anthropometric indices can distinguish a positive test outcome. AUC ranges from 0 to 1, with 0.5 (diagonal line) indicating that the anthropometric index has no predictive power and 1 indicating perfect power. After determining which the best anthropometric index was, the optimal cutoff value was denoted by the value that had the largest sum of sensitivity and specificity. In addition, partial correlation analysis was performed between CVD risk factors and anthropometric indices. The statistical significance was set at $p < 0.05$.

79.3 Findings

Figure 79.1 shows the smoothed reference curves of BMI, WC, HiC, and WHR for the 5th, 10th, 25th, 50th, 75th, 90th, and 95th percentile in both genders. The BMI percentile curves of girls had a sharp increase from 8 to 15 years of age, and then began to plateau; but, among boys, these curves had a persistent increase until the age of 18 years. For girls, the 50th–95th percentile curves for WC had a sharp increase from 8 to 13 years of age, and began to plateau after that, whereas, for boys, these curves had a persistent and less sharp increase with age until the age of 18 years. In girls, the 50th to 95th reference curves for HiC had a sharp increase, similar to that observed for WC curves, but at a later age, for example, 11–15 years, and began to plateau after that age. In boys, these curves had a persistent increase with age and ran nearly parallel to the WC percentile curves. The WHR curves of girls decreased with age until 15 years and began to plateau thereafter, whereas, for boys,

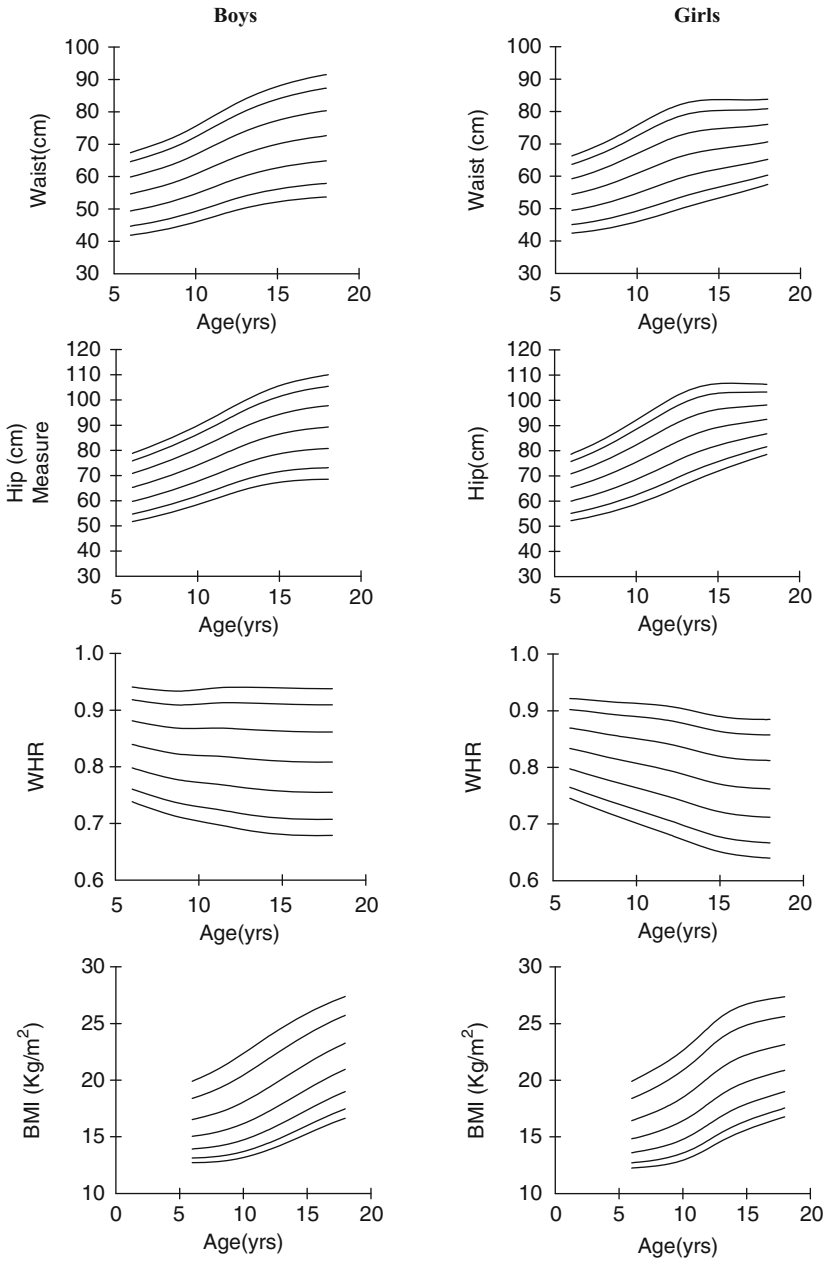

Fig. 79.1 Age- and gender-specific smoothed reference curves of waist and hip circumferences, waist-to-hip ratio (WHR), and body mass index (BMI) of a national sample ($n = 21{,}111$) of Iranian children aged 6–18 years: CASPIAN Study

the 25th–95th percentile curves for WHR had a plateau pattern and the 5th and the 10th percentile curves decreased slowly until 15 years of age.

The age-adjusted correlation between the anthropometric indices was significant in both genders. BMI and WC had the highest correlation ($r = 0.77$, $p < 0.0001$ in boys, and $r = 0.82$, $p < 0.0001$ in girls). The weakest correlation was found between BMI and WSR ($r = 0.56$, $p < 0.0001$ in boys, and $r = 0.63$, $p < 0.0001$ in girls).

ROC analysis showed that, among boys, the AUC of all anthropometric indices was the largest for 2 of the 8 risk factors in 6–9.9 year-old students. The AUC for WC was the largest for 5 of the 8 risk factors in subjects aged 10–13.9 years, and that for BMI was the largest for 6 of the 8 risk factors in the 14–18-year age group (Table 79.2).

Among girls, BMI and WSR were the best in distinguishing an abnormality in 3 of the 8 CVD risk factors in subjects aged 6–9.9 years. The largest AUC was found for WC and WSR (for 3 of the 8 risk factors) and for WC (for 6 of the 8 risk factors) in the 14–18-year age group (Table 79.3).

The ROC curves of the four anthropometric indices in relation to one or more risk factors according to gender and age group are depicted in Fig. 79.2.

Tables 79.4 and 79.5, respectively, present the optimal cutoff values, as well as the sensitivity and the specificity of the anthropometric indices in relation to each CVD risk factor in boys and girls, according to age group. Overall, the cutoff values in boys ranged from 13.91 to 22.04 for BMI, from 45.5 to 79.5 for WC, from 0.75 to 0.92 for WHR, and from 0.39 to 0.46 for WSR. Among girls, they ranged from 15.53 to 21.49 for BMI, from 48.5 to 76.5 for WC, from 0.75 to 0.86 for WHR, and from 0.40 to 0.48 for WSR.

Table 79.6 shows the partial correlation coefficients between anthropometric indices and CVD risk factors according to gender and age group. In boys, BMI had the highest coefficient in 5 of 8 risk factors among 6–9.9-year-old subjects; in the 10–13.9-year age group, BMI and WC had the highest coefficient (4 of 8), and in 14–18-year-old subjects, WC and WSR had the highest coefficient (3 of 8).

In girls, BMI had the highest coefficient in 4 of 8 risk factors in subjects aged 6–9.9 years; in the 10–13.9-year age group, WC and WSR had the highest coefficient (3 of 8), and in the 14–18-year-old subjects, BMI had the highest coefficient (4 of 8).

79.4 Correlations of Anthropometric Indices with Cardiovascular Disease Risk Factors

In the present study, the correlations between the anthropometric indices including BMI, WC, WHR, and WSR were strong in both genders, the highest correlation being between BMI and WC and the lowest between BMI and WSR. Contrary to studies among adults that determined a single anthropometric parameter as the best predictive index for CVD risk factors, in our study, this index varied well according to gender and the age group. Among boys, in subjects aged 6–9.9 years, all anthropometric indices had similar predictive value, whereas, in the 10–13.9-year- and the 14–18-year-age groups, respectively, WC and BMI were the best predictive factors. Among girls, respectively, in the 6–9.9-year age group, BMI and WSR; in the 10–13.9-year age group, WC and WSR; and, in the 14–18-year age group, WC were the best in distinguishing CVD risk factors. Although the best anthropometric indices were identified, it should be noted that the differences for the anthropometric indices were often small, with overlapping confidence intervals.

Most previous studies have determined the correlation of different anthropometric indices with CVD risk factors among adults. Some studies performed in South Asian adult population found WSR as the best anthropometric parameter. For instance, the study of Pua et al. (2005) among Singaporean women and the study of Ho and colleagues (Ho 2003) in Hong Kong Chinese found that WSR might be the best anthropometric index in relation to CVD risk factors. A study in Japan showed that WSR is more sensitive than BMI or WC to evaluate clustering of coronary risk factors among non-obese men and women (Hsieh 2005). However, some studies in Western countries found that other anthropometric parameters have better correlation with CVD risk factors than WSR has. The study of Ledoux et al. among Canadians revealed that WC and BMI correlate most closely with

BP and plasma lipids (Ledoux et al. 1997). In the study of Zhu et al. among Americans of three race–ethnicity groups, WC was more sensitive than BMI in predicting CVD risk (Zhu et al. 2005).

Population-based studies concerning the correlation of anthropometric indices and CVD risk factors in children and adolescents are limited, and comprise different age groups, making the comparisons difficult. The recent study of Kahn et al. among a population drawn from the third National Health and Nutrition Examination Survey (NHANES III) in USA showed that WHR is a simpler anthropometric index than sex- and age-specific BMI percentiles, and better identifies youth with adverse CVD risk factors (Kahn 2005).

In Cyprus, Savva and colleagues found that, in children (with a mean age of 11.4 years), WC and WSR are better predictors of CVD risk factors than BMI (Savva et al. 2000).

The study of Maffeis et al. in Italy showed that WC as well as subscapular and triceps skinfolds could be helpful parameters in identifying prepubertal children with dyslipidemia and high BP (Maffeis 2001).

In Portugal, Teixeira and colleagues showed that, among 159 children with a mean age of 13 years, measures of central adiposity, such as WC and WSR, significantly correlated with serum lipid levels in obese children and adolescents but not in leaner individuals (Teixeira et al. 2001).

Similar to studies performed among adults in Japan, the study of Hara et al. showed that WSR is the best predictor of CVD risk factors in Japanese schoolchildren 9–13 years of age (Hara 2002).The study of Asayama and colleagues among obese Japanese girls confirmed such a correlation, and found that only WSR/Ht showed high-enough sensitivity and specificity to predict CVD risk factors (Asayama 2000).

In the CASPIAN Study, BMI, WC, and WSR were more closely correlated with CVD risk factors. Considering the close correlation between different anthropometric indices studied, and differences in the best predictive index according to age and gender, it may be clinically useful in the pediatric population to routinely measure WC and WSR in addition to BMI as a screening tool to identify high-risk youths.

79.4.1 Applications to Other Areas of Health and Disease

Usually for clinical practice and epidemiological studies, child overweight and obesity are assessed by indicators based on weight and height measurements, such as weight for height or BMI. The present study documented BMI as a predictor of cardiovascular disease risk factors in children and adolescents; this finding is consistent with previous studies confirming the predictive value of BMI for cardiovascular disease risk factors. However, as this index cannot distinguish fat from muscle mass, and cannot represent the fat distribution, some scientific groups stated that, as an overall obesity index, BMI could not be appropriate in predicting chronic diseases.

Different studies have documented that, similar to adults, WC is an indicator of abdominal fat content, and, consequently, is a good predictor of cardiometabolic risk factors among children and adolescents, as well (Weiss 2003). However, there is still no global standard for WC in youth. The cutoff values differ between genders, races, and ethnic groups.

Our findings are in line with the recent study of Janssen and colleagues among the Bogalusa Heart Study population, indicating that BMI and WC did not have independent effects on CVD risk factors in youth aged 5–18 years (Janssen 2005).

In a previous study, we compared the reference curves for anthropometric indices in the 6–11-year age group of the CASPIAN study and a population-based sample of German children (Kelishadi et al. 2008). Comparison of our data with British children (McCarthy 2001) are presented in Table 79.1 and Fig. 79.3, and show that the reference curves for BMI and WC were higher and had a sharper increase in Iranian than in British children.

It is suggested that, in adults, lower cutoff points of BMI should be retained for Asians because the risk factors for CVD at a given BMI are generally higher among Asians compared with Western populations (WHO 2004). Because growth rate and fat patterning vary among different populations (Goran 1997), it is important to develop simple and effective anthropometric indices for the screening of higher metabolic risk subjects in different populations until they reach internationally accepted measures.

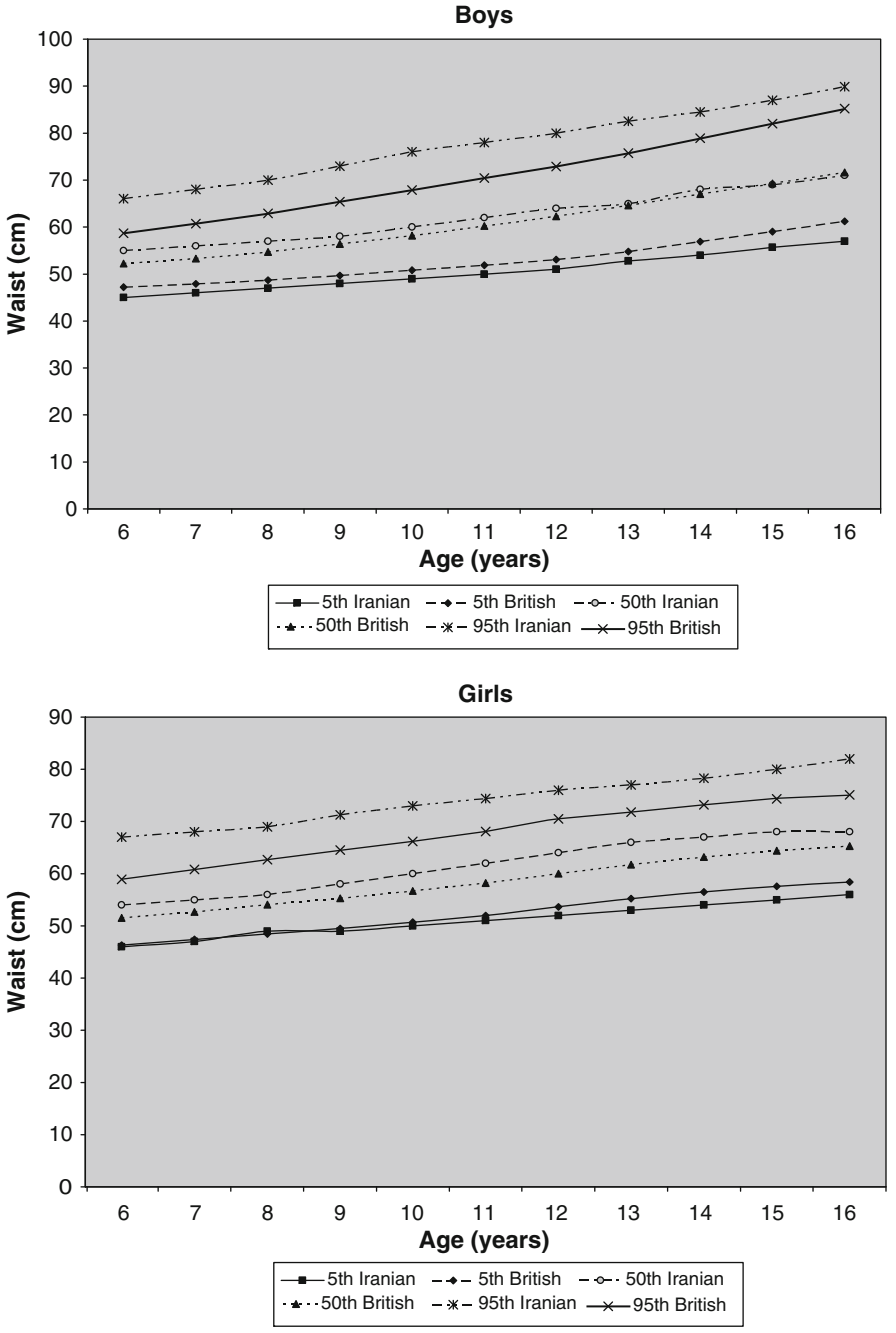

Fig. 79.3 Age- and gender-specific 5th, 50th, and 95th percentile curves of waist circumference (WC) of a national sample of Iranian children and adolescents (2003–2004) in comparison to the British percentiles (McCarthy 2001): CASPIAN Study

79.4.2 Features of the Association of the Anthropometric Indices and Cardiovascular Disease Risk in Children and Adolescents: CASPIAN Study

- It may be clinically useful in the pediatric population to routinely measure WC and WSR, in addition to BMI, as a screening tool to identify youth at risk of future cardiovascular diseases.
- Ethnic differences in anthropometric indices and their association with cardiometabolic risk factors are observed from early life onward.
- Among the children and adolescents examined in the CASPIAN Study, BMI, WC, and waist-to-stature were more closely correlated with cardiovascular disease risk factors.

Summary Points

- Age- and gender-specific reference curves as well as cutoff values should be provided for anthropometric indices of children with different ethnicities.
- Contrary to studies among adults that determined a single anthropometric parameter as the best predictive index for cardiovascular disease risk factors, among Iranian children and adolescents analyzed in the CASPIAN Study, this index varied well according to gender and age groups.
- The CASPIAN Study documented BMI as a predictor of cardiovascular disease risk factors. However, as this index cannot distinguish fat from muscle mass, and cannot represent the fat distribution, it is suggested to measure indices of abdominal obesity in addition to this measure of generalized obesity.
- The 5th and 50th percentile curves for WC obtained in the CASPIAN Study were similar to the British ones, but the obtained 95th percentile curve was higher than the British curves. For girls, the obtained 50th and 95th percentile curves were higher than the British ones.
- Because of smaller size and shorter stature of Asian children and adolescents compared with their Western counterparts, WSR can be considered as an appropriate index for abdominal obesity and associated cardiometabolic risk factors.

Chapter 80
Secular Trends in the Anthropometry of Adolescents and College Students: Polish Perspective

Boguslaw Antoszewski and Aneta Sitek

Abstract Socio-economic disparities lead to biological consequences manifested in the differences in anthropometric traits as well as in pubertal timing within a population, which is the case not only in Poland, but all over the world. The screening of the development of somatic traits in the Polish population has been conducted for over 100 years. Furthermore, some studies on stratification trends, i.e. intergenerational changes occurring in social groups singled out from the general population, have been conducted. Such analyses allow observing social stratification changes over a given period and determining the intensity of the biological consequences of these disparities.

The analysis of intergenerational changes in respect of body height (stature) of Polish males based on a representative sample of military conscripts shows that the genetically determined growth potential of Poles has not been fully exploited yet, and thus a further increase in mean body height may be anticipated. However, it seems that the increase in adult stature will be in the near future less considerable than the intergenerational changes leading to BMI (Body Mass Index) increase. The continuing presence of social gradients in respect of body height and relative mass reflect the stability of social divisions in Polish living standards. The results of studies on earlier pubertal timing in Polish girls demonstrate that the lowering of age at menarche will continue, as the genetically determined limit has not been achieved yet, either.

Abbreviations

B-v	Body height
BMI	Body Mass Index
°C	Degree centigrade
GH	Growth Hormone
GDP	Gross Domestic Product
ng/mL	Nanogram per milliliter
R	Pearson correlation coefficient
Y	Years

80.1 Introduction

The factors that make up the socioeconomic status result in two kinds of variation in the measures of the human biological condition: social gradients and secular trends (Łaska-Mierzejewska and Olszewska 2007).

The term "social gradients" denotes a change in the value of biological parameters and their direction at the rate that reflects the economic situation of the groups studied (Łaska-Mierzejewska and Olszewska 2007). In the description of social disparities, paired groups differing in respect of the "quality" of factors influencing them (such as big cities and villages, and small and large families) are usually contrasted.

A secular trend (the word "secular" derives from the Latin word *seculum*, which means a 100 years old, ancient) means intergenerational, directional changes of morphological, physiological, and motor traits. The elements of time variation occurring in human biological traits include the acceleration of development and earlier puberty timing, modifications in the sequence of certain developmental events (e.g., ossification and dentition) as well as retardation of involutionary processes. The secular trend is considered to result from the progress of civilization, involving socioeconomic changes, leading to improvement in the general living conditions. It is also thought that genetic factors related to an increase in the distance between parental birthplaces due to migrations, which result in the heterosis effect, are crucial in this respect (Malinowski 1977). Moderate heterosis leads to larger sensitivity to external factors. When these factors are favorable, the body develops at increasingly higher levels in respect of the individual norm of reaction in order to exploit its full genetic potential. Short persons' tendencies in perinatal and marital selection (Malinowski 2003) are thought to have certain significance within the genetic determinants of the secular trend. Koh (citation after Malinowski 1977) ascribed the existence of secular changes to the larger effect of the sun's rays on contemporary humans and emphasized the role of ultraviolet radiation in the activation of vitamin D. However, this concept has not been confirmed in the face of, for example, the lower average body height (B-v) in the rural population, which is generally more exposed to the sun's rays as compared with the big-city population (Malinowski 1977). According to a number of researchers, intergenerational changes are related to specific generational factors, which influence the determinative and regulatory functions of the genes responsible for body size. These may include various vaccinations, antibiotics, and biological and chemical substances used in breeding animals to accelerate their growth and body mass as well as chemicals used to improve crops in growing plants. Consequently, meat products and animal-based foods, such as milk or butter, as well as some plant-based foods, represent a potential capacity to stimulate and modify the functioning of the endocrine system, primarily in respect of the secretion of the human growth hormone (GH).

The study of intergenerational changes with respect to social gradients sheds some light on changes in living standards over time and the degree of social stratification. Secular changes are usually more distinct in the least developed social groups and populations. Thus, this process is very intensive, particularly in a number of developing countries as well as in groups with the lowest social status. As regards the affluent social groups in Western Europe, body height in successive generations is not subject to significant variation. The differences between social strata are also declining. The disappearance of environmental differences results primarily from a larger rate of somatic trait gains in the groups of children from poor families with a lower economic status. Intergenerational transformations are usually more distinct in males than in females, which results from the different threshold sensitivity of boys and girls in terms of the influence of environmental variables (Bielicki and Charzewski 1977). However, a number of studies reveal the opposite direction of sex differences in respect of the extent of morphological intergenerational changes (Ignasiak and Sławińska 1993).

This is probably the effect of the difference in the above-mentioned biological sensitivity of males and females. Boys, who are more eco-sensitive, react to changes in their living conditions more promptly and approach the upper limit of their genetic capabilities earlier, which results in the decline of the rate of their secular trend. Girls, who are less eco-sensitive, react to the stimuli later; therefore, when favorable environmental conditions persist, they achieve the upper limit of their genetic capabilities later, and thus their process of intergenerational changes also stops later.

As numerous studies reveal, the Polish population is highly homogeneous and, consequently, no distinctive genetic differences are found (Bielicki et al. 2000). Such a population provides excellent material for observing intergenerational changes, as any differences in the biological development primarily reflect a large diversification in terms of family living conditions, social strata, and local populations.

80.2 Acceleration of Body-Height Increase

Body height represents a typical example of a continuous trait whose variation develops under the influence of genotype as well as the environmental characteristics of the places where the individuals are raised. Studies show that the final body height of individuals is determined genetically, in about 60%, and after taking into account the additional influence of uterine environmental factors during fetal development as well as cultural factors, this figure amounts to 71% (Byard et al. 1993). The environmental variables directly affecting B-v throughout an individual's development include nutritional habits (food quantity and quality) in proportion to energy expenditures of the body as well as the degree of disease impact on the progressive stage of ontogenesis (Bielicki et al. 2005). The environmental factors listed earlier are strictly connected with family living standards, which largely result from the country's economic situation.

Body height has been recorded in a number of European countries since 1750. Recently, this trait has been commonly used to describe the economic development of different countries. Komlos (1994) analyzed economic fluctuations in a number of countries, using the state of nutrition and health, and economic status of social strata and groups based on body-height changes over 205 years. In his opinion, data on body height may replace information on gross national product per capita, which was previously used in the evaluation of affluence of social strata and groups.

80.3 Secular Trend in Body Height of Polish Conscripts

In Poland, studies involving 19-year-old conscripts provide the most extensive and representative data for the assessment of intergenerational changes with respect to body height. Pursuant to the Polish law, every year, all 19-year-old males are involved in conscription procedures, regardless of whether they are to be subsequently enlisted. Based on the data gathered in this manner and prepared at the beginning of the twentieth century by Mydlarski (1933), and subsequently by Bielicki et al. (2000, 2005), it is possible to state that, over 74 years (1927–2001), the mean body height of Polish males increased by 11.3 cm (Table 80.1). The increase in body height over this period, perceived as an increasingly fuller exploitation of the genetic growth potential, was caused by the improvement in living and development conditions of children and adolescents. During these years, Poland suffered from economic crises resulting from World War II and an economic downturn in the 1980s,

Table 80.1 Secular trend in body height of Polish conscripts in the years 1927–2001

Year of study	*n*	$\overline{x}$	SD	*v* (%)	Gain per decade (cm/decade)	Author
1927	–	166.1	6.3	3.79	–	Mydlarski (1933)
1928	–	166.1	6.3	3.79	–	Mydlarski (1933)
1929	–	166.3	6.2	3.73	–	Mydlarski (1933)
1930	–	166.6	6.1	3.66	–	Mydlarski (1933)
1965	21,155	170.5	5.9	3.46	–	Bielicki et al. (2000)
1976	12,711	173.2	6.3	3.64	2.4	Bielicki et al. (2000)
1986	29,275	175.3	6.2	3.54	2.1	Bielicki et al. (2000)
1995	30,940	176.9	6.4	3.62	1.8	Bielicki et al. (2000)
2001	30,850	177.4	6.7	3.78	0.8	Bielicki et al. (2005)

The table shows the height increase in Polish conscripts in the years 1927–2001 including height gains in particular decades

n number of conscripts examined; $\overline{x}$ average body height of conscripts in a given year; SD standard deviation of body height; *v* (%) coefficient of variation ((SD/ $\overline{x}$)100%). 8

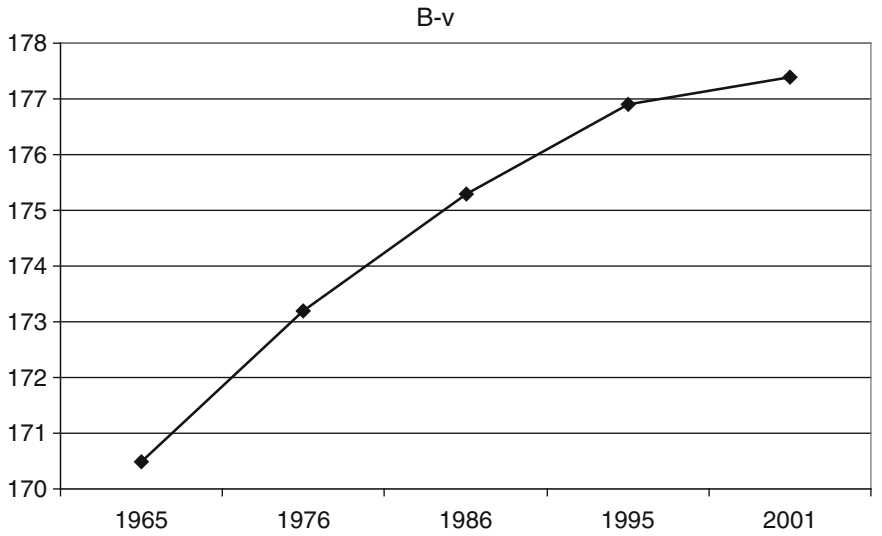

Fig. 80.1 Secular trend in body height (B-v) of Polish conscripts in the years 1965–2001 (Bielicki et al. 2000, 2005). Arithmetic mean values of body height demonstrate a height increase in Polish conscripts in the years 1965–2001 (Based on, Bielicki et al. 2000, 2005, by permission)

and underwent a socioeconomic transformation in the 1990s. A precise estimation of body-height gains per decade was possible, as the studies were repeated in approximately 10-year time intervals. Such results calculated per decade on the basis of data from, for example, a 35-year period, would lead to excessive averaging of the values of these changes, which are not a monotonic phenomenon. Thus, the data gathered allow for the precise determination of the rate of height increase of Polish males only over the past 4 decades. A gradual slowdown in the rate of increase in the mean body height among conscripts was observed in this period, as it fell from 2.4 cm/decade in the years 1965–1976 to 0.8 cm/decade in the years 1995–2001 (Table 80.1, Fig. 80.1). There are two hypotheses as regards the reasons for the slowdown, which has been observed since 1986: the so-called "crisis hypothesis" and the "genetic limit hypothesis" (Bielicki et al. 2005). The cohort studied in 2001 was affected by both the economic crisis (1980s) in their childhood and "the shock" caused by the transformation (1990s) during their puberty (Bielicki et al. 2003). It should be noted, however,

Table 80.2 Body height of Polish conscripts by degree of urbanization of their place of residence (Reprinted from Bielicki et al. 2005, by permission)

	1965		1986		1995		2001	
Type of settlement	$\bar{x}$	SD	$\bar{x}$ (cm)	SD	$\bar{x}$ (cm)	SD	$\bar{x}$ (cm)	SD
Cities over 500,000	172.7	6.0	176.9	6.5	178.0	6.7	178.8	6.8
Cities 100–500,000	171.3	5.9	175.6	6.3	177.4	6.7	178.2	6.7
Cities 25–100,000	171.0	6.0	175.9	6.4	177.3	6.4	177.8	6.6
Towns under 25,000	170.8	5.9	175.5	6.4	177.0	6.5	177.5	6.6
Rural areas	169.8	5.8	174.0	6.1	175.7	6.3	176.4	6.5

The table shows height increase in Polish conscripts by the size of their place of residence. Throughout the study period (1965–2001), the mean body height of males manifests a distinct gradation by the size of the place of their residence

$\bar{x}$ means body height of conscripts in a given year; SD standard deviation of body height

that despite food rationing and a drop in consumption resulting from the shortages of products, a marginal GDP increase was still observed in the 1980s. Moreover, the rapid educational advancement of the conscripts' parents continued and the percentage of mothers with secondary and university education in the cohort of conscripts in 2001 doubled as compared with 1986; mother's education is considered to have a particularly strong influence on family living standards (Bielicki et al. 2005). Consequently, these factors may have provided protection against the influence of the economic crisis on height increase in the young generation of Poles. The "genetic limit" hypothesis assumes that every individual represents a genetically determined upper value of the trait, which may theoretically be achieved provided an individual's development is not disturbed by any environmental deficits. It seems that in the event that the secular trend in the body height of Poles is inhibited, both hypotheses concerning the reasons for this phenomenon are probable and do not exclude each other.

The analysis of intergenerational changes in the groups singled out with respect to the degree of urbanization of their place of residence reveals a gradual increase in the mean body height in all cohorts. At the same time, a distinctive social gradient of body height is noticeable and represents the same direction throughout the period analyzed. The mean body height of conscripts increases along with the increase in the size of the place of residence, and the difference between extreme groups isolated with respect to the urbanization factor (big cities and villages) over 35 years generally remained unchanged (2.9 cm in 1965 and 2.4 cm in 2001). This proves the lasting living standard diversification (consumption, health, and parents' education) in cities and villages (Table 80.2, Fig. 80.2).

The secular trend in body height in the groups singled out with respect to father's socio-professional status showed that, in all cohorts, average body height increased along with social advancement. Furthermore, intergroup disparities did not undergo major changes over 36 years (1965–2001). Conscripts from big-city, well-educated families are the only exception, as height increase was not observed in them between 1995 and 2001 and, thus, in 2001, their mean body height was not different from big-city conscripts whose fathers had secondary education. A similar situation was observed in 1986 following the rapid body-height increase trend in the sons of fathers with secondary education from big cities (Fig. 80.3). Body-height stabilization in the conscripts from big-city, well-educated families, distinct particularly after 1995, might show that the group achieved its "genetic limit" in terms of body height, if it were not for the fact that, in 2001, they were surpassed by a new social group – entrepreneurs. The presence of social gradients without tendencies for bridging the disparities between the elites and social groups with a lower economic status, as well as the appearance of a new elite, demonstrates that the Polish population still represents considerable "genetic reserves," which can enable a further increase in average body height. Consequently, the deceleration of body-height increase, which has recently been observed, most likely results from a series of socioeconomic crises, which is emphasized by Bielicki et al. (2005).

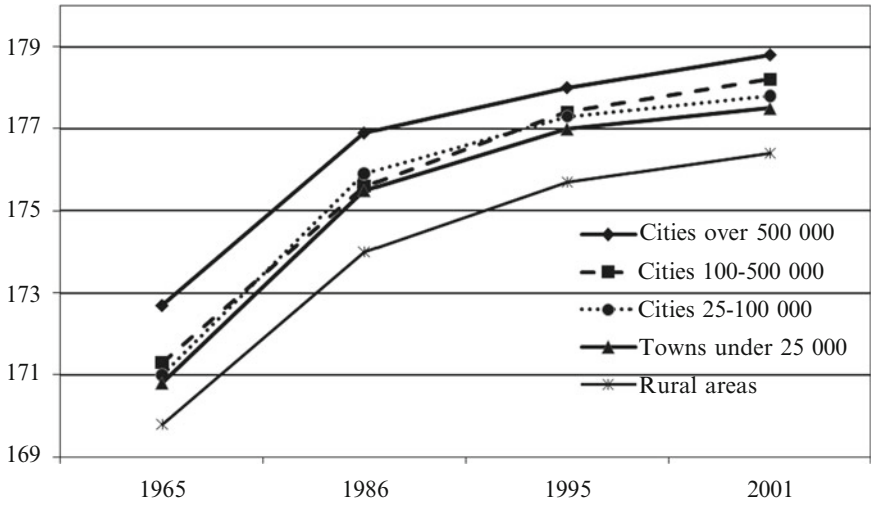

Fig. 80.2 Body height of Polish conscripts in the years 1965–2001 by size of their place of residence. Height increase of Polish conscripts in the years 1965–2001 occurred regardless of the degree of urbanization of the place of residence. However, throughout the study period, distinct environmental differences with respect to the size of the place of residence persisted. (Reprinted from Bielicki et al. 2005, by permission)

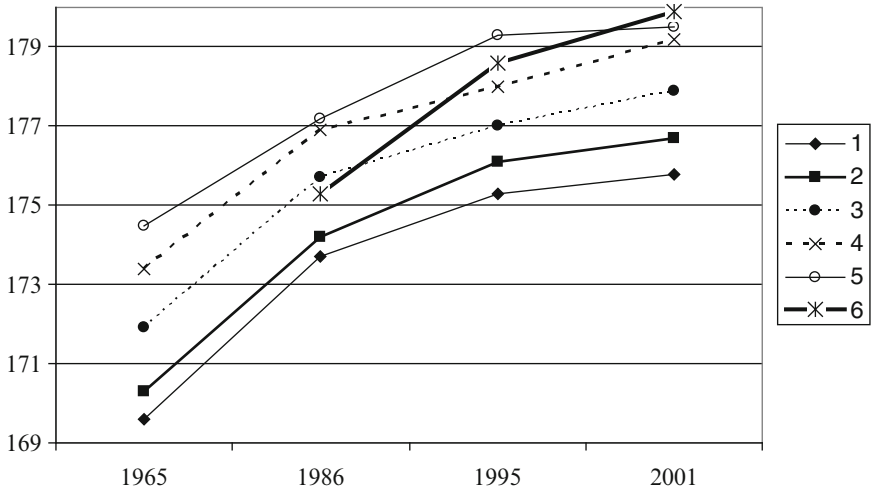

Fig. 80.3 Body height of conscripts by degree of urbanization of their place of residence and social status of father. In the years 1965–2001, the mean body height of Polish conscripts increased, which demonstrates socio-environmental disparities determined by father's education and the degree of urbanization of the place of residence. Entrepreneurs constituted a new social stratum, which was first recorded in 1986. In 2001, their sons were found to be taller than the tallest conscripts from big-city families whose fathers had university or secondary education. This demonstrates the continuing presence of "genetic reserves," which, in favorable conditions, will result in further height increase of the Polish people. (*1*) Village, father – farmer, primary education; (*2*) village, father – farmer, secondary education; (*3*) city over 100,000, father – skilled worker, vocational education; (*4*) city over 100,000, father – technician, secondary education; (*5*) city over 100,000, father – specialist, university education; (*6*) city over 100,000, father – entrepreneur, university or secondary education. (Reprinted from Bielicki et al. 2005, by permission)

80.4 Secular Trend in Body Height of Polish Students

The comparison of body heights of Polish conscripts and students of the Medical University of Poznań provides another confirmation that social gradients do exist. Throughout the study period, students of the Medical University were, on average, much taller than Polish conscripts, which shows that there is a positive selection, as students presumably come from well-educated families with a good economic situation and high living standards. The slowdown of the upward body-height trend observed in 1988 as compared with the data from 1976 demonstrates that living conditions deteriorated to a certain extent during the development of this cohort (Table 80.3, Fig. 80.4). This is a surprising phenomenon, as, at the same time, a continuing body-height increase in Polish conscripts was observed. It seems that this results from the relatively small size of the sample of students examined in 1988 (92 persons).

Table 80.3 Secular trend in body height of students of the Medical University of Pozna in the years 1965–1994

Year of study	*n*	$\overline{x}$	SD	*v* (%)	Gain per decade (cm/decade)	Author
1966	134	176.0	4.4	2.5	–	Malinowski and Strzałko (1970)
1977	126	177.4	5.9	3.3	1.3	Drozdowski et al. (1980)
1988	92	177.8	6.1	3.4	0.4	Deckert (2000)

The table shows height increase in the students of the Medical University of Pozna
n number of students examined; $\overline{x}$ mean body height of students in a given year; SD standard deviation of body height; *v* (%) coefficient of variation, ((SD/ $\overline{x}$). 100%) together with body-height gains per decade

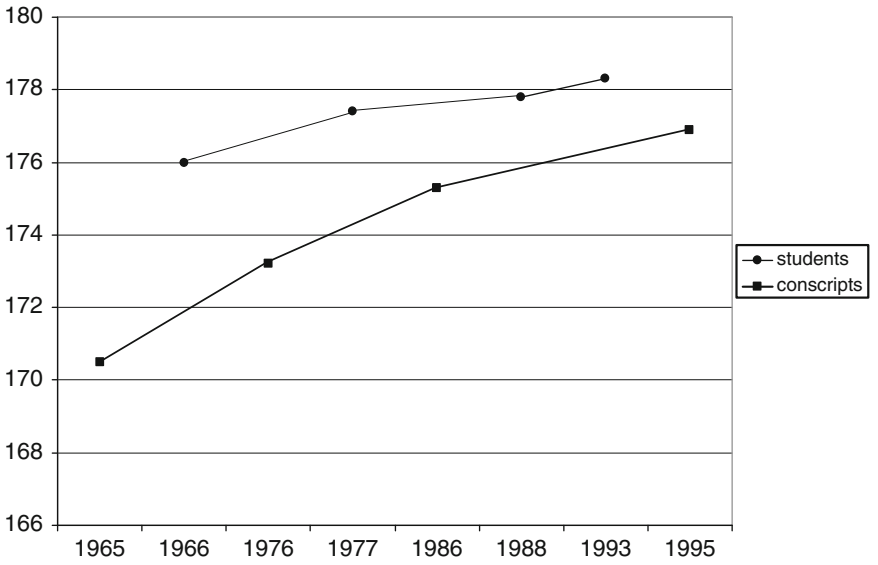

Fig. 80.4 Secular trend in body height in students against intergenerational changes in conscripts in the years 1965–1995. The diagram shows stature increase in the students of the Medical University of Pozna and the population of Polish conscripts. As regards body height, distinct differences prove the existence of a discrepancy with respect to socioeconomic conditions in both groups. The figure shows mean body-height values. (Based on data from Malinowski and Strzałko 1970; Drozdowski et al. 1980; Deckert 2000; Bielicki et al. 2000, 2005)

80.5 Acceleration of Relative Body Mass (BMI) Increase

Body mass is strongly correlated with body height and, usually, demonstrates secular variability as well. The examination of body mass as an absolute trait significantly impedes the interpretation of the results; hence, analysis of the secular trends of this trait was based on BMI, which reflects its relative value. Studies show that BMI is less genetically determined than body height and, consequently, is more influenced by environmental conditions. The heritability of relative body mass is estimated at 30%. The index demonstrates exceptional lability, which means it rapidly reacts to even short-time changes in the environmental factors, such as nutrition, physical activity, or diseases. Its major advantage is that it carries significant information value for the assessment of the organism's health, as it correlates with different measures of body fat and obesity.

80.6 Secular Trend in the Body Mass Index (BMI) in Polish Conscripts

The mean value of BMI in the population of conscripts throughout the 36-year study period increased by 0.53 units and represented the values as follows: 0.12 units/decade in the years 1965–1986, zero in the decade 1986–1995 (political and socioeconomic transformation period), and as much as 0.48 units in 1995–2001 as expressed per 10 years. The upward trend as regards the mean value of BMI shows a distinctive improvement in the living conditions, particularly over the recent years (1995–2001) (Table 80.4, Fig. 80.5.). This is confirmed by economic data, which reveal that, in the years 1995–1997, a rapid economic growth of 6–7% GDP was observed, which resulted in an increase in the population'sincomes, albeit unequal in particular professional groups. It should be noted that, at the same time, the upward trend in height was small, which demonstrates the considerable stability of this trait, which is in fact an irreversible reaction to the cumulative influence of factors operating throughout the period of growth of an individual. BMI depends considerably on absolute body mass and reflects much sooner the effects of an even short influence of environmental factors. Throughout the study period, mean values of BMI in 19-year-old males decreased relative to city size, where the biggest cities with the population of 100,000–500,000 were at the top as regards BMI, small towns with the population below 25,000 in the middle, and medium-sized towns with the population between 25,000 and 100,000 at the bottom. In 1965, conscripts from villages (food producers) represented the highest BMI value, whereas, after 25 years, they were caught up with by big-city

Table 80.4 Intergenerational changes in the body mass index (BMI) in Polish conscripts in the years 1965–2001 (Reprinted from Bielicki et al. 2005)

Year of study	n	$\overline{x}$ (kg/m^2)	SD	v (%)	Gain per decade
1965	21,145	21.73	1.98	9.10	–
1986	26,440	21.98	2.40	10.90	0.12
1995	26,245	21.97	2.76	12.58	–0.01
2001	26,528	22.26	3.09	13.86	0.48

The table shows intergenerational BMI increase in Polish conscripts in the years 1965–2001, including the rate of increase per decade. The mean values show that the trend came to a standstill during the period of political and economic transformation of Poland (1986–1995)

n number of conscripts examined; $\overline{x}$ BMI mean value for conscripts in a given year; SD standard deviation of BMI; v (%) coefficient of variation $\overline{x}$

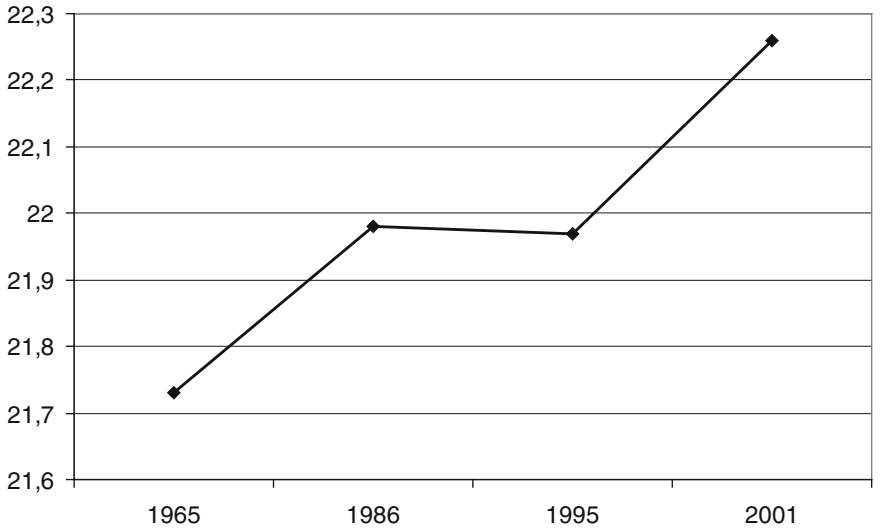

Fig. 80.5 Changes in BMI mean value in Polish conscripts in the years 1965–2001. The diagram shows body-weight increase in proportion to body height in Polish conscripts in the years 1965–2001, with a distinct standstill in the years of the political and economic transformation (1986–1995). The above relationship confirms the socioeconomic conditions of this secular trend. (Reprinted from Bielicki et al. 2005, by permission)

Table 80.5 Relative body mass of Polish conscripts by degree of urbanization of the place of residence (Reprinted from Bielicki et al. 2005, by permission)

	1965		1986		1995		2001	
Type of settlement	$\bar{x}$	SD	$\bar{x}$	SD	$\bar{x}$	SD	$\bar{x}$	SD
Cities over 500,000	21.58	2.58	22.05	2.65	22.25	3.00	22.39	3.24
Cities 100,000–500,000	21.73	2.06	21.97	2.48	21.97	2.93	22.30	3.09
Cities 25,000–100,000	21.54	2.00	21.90	2.51	21.78	2.85	22.10	3.15
Towns under 25,000	21.69	2.00	21.94	2.43	21.86	2.74	22.17	3.15
Rural areas	21.82	1.89	22.04	2.25	22.05	2.65	22.28	2.99

In the years 1965–1986, a strong increase in the BMI value was observed in conscripts from big cities (over 500,000). These conscripts have consistently represented the highest value of this index since 1995. High BMI values in conscripts from rural areas (food producers) demonstrate that, unlike body height, absolute body mass is more sensitive to the influence of environmental factors. Throughout the study period, the dispersion of the index values (SD) increased markedly

(500,000+) conscripts, who represented a rapid increase in the index value in the years 1965–1986. In subsequent years, big-city conscripts represented the highest BMI values. Data from 1995 show a distinctive deceleration in respect of the relative body mass in almost all social groups, which is undoubtedly the result of deterioration of living conditions caused by the transformation in the 1990s. Big-city conscripts provide an interesting exception with respect to BMI values, which, instead of decelerating or regressing, gradually increased. The trend demonstrated a noticeable revival in all examined urban categories except for big cities in the years 1995–2001 (Table 80.5, Fig. 80.6). It seems that the changes in nutritional behaviors toward a diet with a large content of fats and carbohydrates, coupled with a decrease in physical activity in favor of more time spent in front of a computer or television set, account for a rapid increase in BMI mean values.

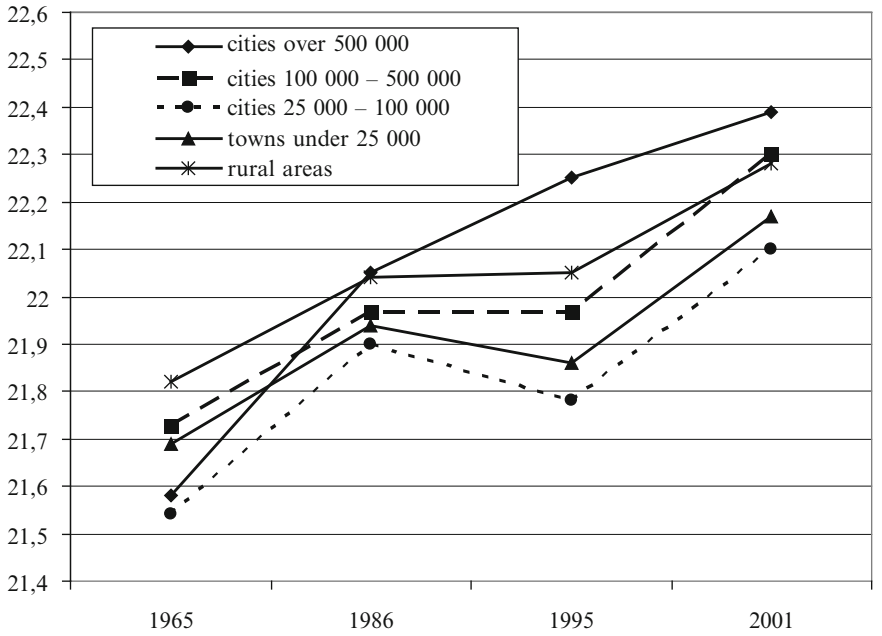

Fig. 80.6 Changes in the body mass index (BMI) in Polish conscripts in the years 1965–2001 by degree of urbanization of their place of residence. Regardless of the degree of urbanization of the place of residence, conscripts represented an upward BMI trend. In the years 1986–1995 (during the economic transformation in Poland), a deceleration of relative body mass was observed in the majority of males, except for big-city dwellers (500,000+). Renewed BMI acceleration was observed in the years 1995–2001, which reflected the changes in nutritional behaviors toward a diet with a large content of fats and carbohydrates coupled with a decrease in physical activity. (Reprinted from Bielicki et al. 2005, by permission)

80.7 Secular Trend in the Body Mass Index (BMI) in Polish Students

A comparison of the relative body mass trend in the Polish population of conscripts and students of the Medical University of Pozna reveals that the students' BMI mean value was on the decline until the late 1980s and then demonstrated a rapid increase (1.88 units as calculated per decade in the years 1988–1993). Interestingly, the increase occurs during the period of the socioeconomic transformation in Poland, which led to a regression in the increase of the BMI value in conscripts (Tables 80.4, 80.6, Fig. 80.7). It should be noted that substantial BMI values may be caused not only by excessive body fat but also by a muscular, mesomorphic body build. It is possible that individuals' intentional care about their physical appearance accounts for the above-mentioned differences in respect of relative body mass between students and conscripts. As men intend to keep a muscular body build, they may consequently do appropriate physical exercises and select food products appropriate in terms of quantity and quality. However, it seems that study results for the cohort of students in 1988 are not fully representative on account of their limited number, which was mentioned earlier. To sum up, BMI values seem to have been on the decline in 1966–1988, but the decrease was not considerable; hence, the change in the trend after 1988 was not rapid, either. However, this hypothesis requires more extensive analysis, which would in particular take into account the socioeconomic status of students. However, this is impossible due to the nature of the source, which provided data on the male students.

While assessing the stabilized value of changes in body height and relative body mass between successive cohorts of conscripts, it is easy to notice that males examined in 1986 were different from their peers 21 years earlier more in terms of height than the BMI value. This difference declined over

Table 80.6 Secular increase in the relative body mass in students of the Medical University of Poznań (Own calculations based on data from Malinowski and Strzałko 1970; Drozdowski et al. 1980; Deckert 2000)

Year of study	*n*	BMI*	Gain per decade
1966	134	22.38	–
1977	126	22.11	–0.24
1988	92	21.61	–0.46
1993	132	22.55	1.88

The table shows BMI deceleration in students of the Medical University of Poznań in the years 1966–1988, followed by a rapid increase in their relative body mass. BMI changes per decade are also provided

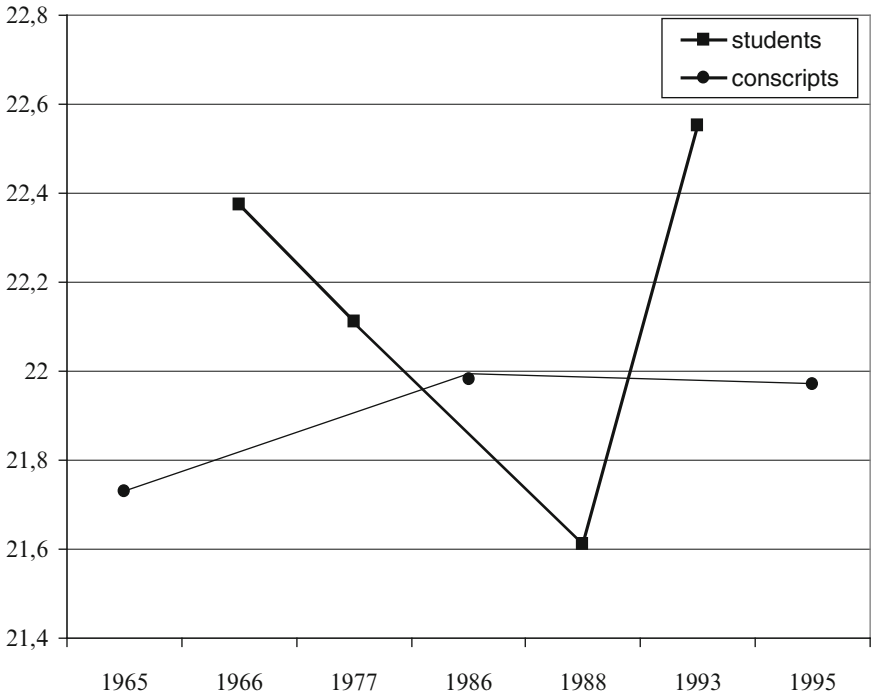

Fig. 80.7 Secular increase in the body mass index (BMI) in students against intergenerational changes in conscripts in the years 1965–1995. Except for the students examined in 1988, throughout the study period, students invariably represented a higher BMI than conscripts, although the representativeness of the 1988 sample may raise doubts on account of its small size ($n = 92$). (Based on Deckert 2000; Bielicki et al. 2005)

the subsequent 9 years, but, in 2001, the conscripts outdistanced their peers examined 21 years earlier in respect of both traits to a similar degree (Fig. 80.8). This demonstrates a gradual decline in the body-height increase trend in favor of an increase in the relative body mass of successive generations.

80.8 Intergenerational Changes in Other Somatometric Traits

Scientific literature describes secular trends more frequently on the basis of body height than body mass. Other somatic traits are analyzed extremely rarely. Current studies reveal that acceleration does not concern all traits to the same degree. The literature reveals that diversification in respect of

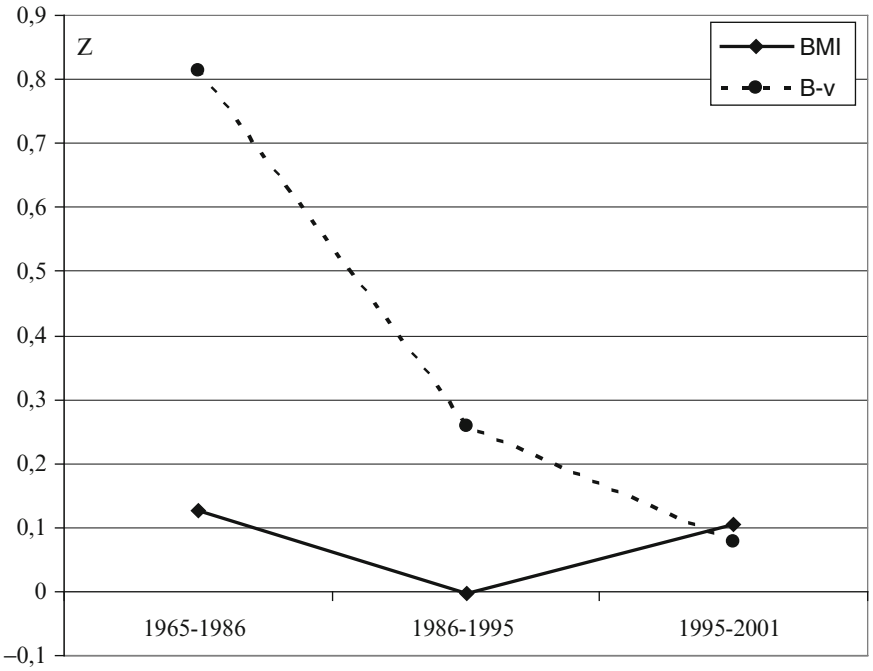

Fig. 80.8 Normalized values of gains of body height and the body mass index (BMI) in conscripts in successive time intervals. Normalized values of body height and BMI in Polish conscripts manifest deceleration of body-height increase and an upward relative body mass trend in successive generations. Mean value of trait/index from 1986 was normalized for mean and standard deviation of trait/index from 1965, etc. (Based on Bielicki et al. 2005)

acceleration in the development of body height and mass leads to a more slender average body build (Szczotkowa 1970; Malinowski 1978; Ignasiak and Sławińska 1993). Acceleration is also thought not to concern trunk length (Szczotkowa 1970, Malinowski 1978) and chest depth (Malinowski 1978). Conversely, the broadening of shoulders (Szczotkowa 1970; Malinowski 1978; Sitek et al. 2007), chest broadening, as well as the narrowing of the hips have been observed over a number of years (Szczotkowa 1970; Malinowski 1978). The change in the proportions of limb length caused by the lengthening of lower limbs is noticeable as well (Szczotkowa 1970).

80.9 Conditionings of Acceleration of Menarche

On average, menarche occurs a year after pubertal growth spurt. This is the most characteristic and critical moment in female puberty. The occurrence of menarche manifests their ability to reproduce, with a balanced development of external sex characteristics, and depends largely on the functioning of the hormonal system. Biologically, menarche means the commencement of hypothalamus control of the gonadotrophic activity of the pituitary gland as well as the cyclic activity of ovaries. The age when menarche occurs is affected by genetic and environmental factors. It is widely thought that age at menarche is a very sensitive indicator of the socioeconomic situation of the population, a kind of a litmus paper reacting to the slightest changes in living conditions. The socioeconomic factors are found to have a more considerable impact on pubertal timing in children than chemical and physical pollution of water, soil, and air (Hulanicka et al. 1994). It is girls who are well nourished, raised in good living conditions, and have parents with larger incomes, who attain the ability to reproduce earlier (Hulanicka et al. 1994;

Wolański 2006). Conversely, early reproductive ability is also related to difficult psychosocial situations related to parental conflicts, divorce, absence of the biological father, step parents, or lack of affection and attention on the part of the mother or father (Cichocka and Żarów 2002). Early reproductive ability was also found in girls with vision or hearing disorders (Umławska 2006) as well as in the daughters of parents who smoked (Umławska and Kolasa 2002). Hulanicka (1986) proposed the following model of relationship between pubertal timing and psychological stimuli: "Lack of psychological stimuli inhibits puberty. A large intensity of stimuli and frequent stressful situations accelerate puberty, but when stressful situations become excessively frequent and stimuli excessively strong puberty is inhibited." Given the above, Hulanicka et al. (1994) present the opinion that early puberty should not be perceived a priori as a symptom of good biological condition of individuals or the population.

Pubertal timing is also related to the climate. The earliest onset of puberty is observed in moderate climate areas, that is, with the average annual temperature ranging between 5°C and 10°C (e.g., Mediterranean countries), whereas the latest onset of puberty is observed in the areas with a low average temperature (e.g., Inuit and Sami people) (Wolański 2006).

Age at menarche is related to the body build as well (Łaska-Mierzejewska and Łuczak 1996). Girls with a very slender body build menstruate 1.8–2.58 years later than their peers with an extremely stout body build (Łaska-Mierzejewska and Łuczak 1996). In the 1970s, Frisch and Revelle declared that menarche may be initiated when the so-called critical body mass is attained or the metabolism rate declines. Over many years, this hypothesis was revised and criticized by numerous authors (e.g., Billewicz et al. 1976). At the same time, some papers that confirmed the decisive role of adipose tissue in initiating the first menstruation were published. It is currently thought that conversion of androgens to estrogens in adipose tissue is the reason for earlier menarche in obese girls. An intermediary factor in the interaction between the body build and age at menarche is leptin, which represents a positive correlation with the quantity of adipose tissue ($r = 0.81$) and an inverse correlation with the pubertal age. Studies revealed that a body-fat increase by 1 kg accelerates menarche by 13 days and an increase in leptin concentration by 1 ng/mL accelerates menarche by 1 month (Matkowic et. al. 1997).

Physical exercise is another factor related to age at menarche. Studies demonstrate that excessive physical load caused by sport training delays menarche (Malina 1983; Skierska 1998). There are different hypotheses concerning the reason for this phenomenon. Physical load is frequently thought to be a direct factor that delays menarche (Malina 1983), which would be plausible only in the event of girls who exercised intensively prior to menarche. However, this correlation also concerns girls who commenced practicing sports after their first menstruation. Consequently, the most probable hypothesis seems to be the one suggesting selection for sports in terms of body build. As it is widely known, a slender body build is necessary in sports, such as gymnastics or long-distance running, and it is those girls practicing these sports who are characterized by the latest menarche (Malina 1983; Skierska 1998). It was even found that the better sport results girls achieve, the more delayed their puberty timing is (Skierska 1998).

A secular trend in the form of earlier pubertal timing in successive generations has been observed for over 100 years (Cichocka and Żarów 2002; Łaska-Mierzejewska and Olszewska 2007). Over the past 150 years, the onset of puberty has been globally lowered by 3 years, which is 0.2 year/decade. It should be noted that this phenomenon significantly varies among different parts of the world (Wolański 2006). A noticeable drop in age at menarche in successive generations is thought to result from improvement in living conditions, hygiene, increasing consumption of animal protein, and the lifestyle change triggered by urbanization (Bielicki 1999; Wolański 2006). According to other authors, the factor which accounts for menarche acceleration is the right body size, which girls now attain earlier, including critical body mass (i.e., weight and characteristic composition of the body, which is necessary to menstruate) (Frisch and Revelle 1970). Along with frequent acceleration of puberty, an inverse process, that is, its regression or deceleration, is observed as well.

80.10 Acceleration of Menarche in Polish Girls

Age fluctuations with respect to menarche occurrence in Polish girls, observed after World War II, clearly reflect political and economic changes that Poland experienced in this period. Postwar Poland was in the possession of modest capital, social, and cultural resources and suffered from civilizational backwardness, which led to delayed industrialization. The rapid development of industry and an increase in employment have been observed since the 1950s, which has led to the improvement of living conditions, particularly in large urban areas. The emphasis on industry hampered the development of other economic sectors, and, in particular, agriculture. This is reflected in the acceleration of puberty in girls, which was primarily noticeable in big cities (0.51 years; 6.12 months). The most beneficial in economic terms was the period 1971–1975, when, due to mechanization and widespread use of fertilizers, agriculture represented a considerable rate of development. Age at menarche, being an exceptionally eco-sensitive measure of living conditions, illustrated this advantageous situation for Polish villages, as it demonstrated the most considerable decrease (0.48 year – 5.76 months). Small towns also saw a substantial acceleration of menarche (0.43 year – 5.16 months). Subsequent years (1977–1989) witnessed a severe economic crisis, including the rationing of food, as well as of a number of non-food products. This was reflected in pubertal timing in girls, which manifested delayed age at menarche in three social groups. Except for the above-mentioned period, this phenomenon was not observed in any anthropological studies conducted in Poland after World War II. The largest delay of age at menarche affected girls living in small towns (0.25 years – 3 months) and those living in big urban areas (0.12 years – 1.44 months). Deceleration of puberty timing in girls living in villages was negligible (0.06 years – 0.72 month), which seems to be obvious as food rationing must have hardly affected its producers. The years 1987–2001 witnessed a political and economic transformation related to the change in the system of ownership (privatization of state-run enterprises). Numerous industrial enterprises were liquidated and unemployment increased considerably, which had a greater effect on villages than cities on account of the liquidation of state-run farms. These changes led to a huge increase in social disparities, as impoverishment of a considerable part of the society was accompanied by an increase in the affluence of a relatively small group of the population. The results of studies conducted in 1997 and 2001 demonstrate a further acceleration of puberty timing in girls as compared with the 1980s (0.20 years – 2.4 months/decade for big cities and 0.24 years – 2.88 months/decade for villages), which demonstrates that political and economic transformation was more favorable for the development and puberty of girls than the period of the economic crisis at the turn of the 1980s (Table 80.7, Figs. 80.9 and 80.10).

The economic situation of the country had a varied impact not only on young generations living in environments with different degrees of urbanization but also on children and adolescents living in the same environments but coming from families with different socioeconomic status. This is confirmed by studies on age at menarche in Polish girls living in the countryside

Table 80.7 Secular trend in age at menarche in Poland by degree of urbanization of the place of residence (Based on Hulanicka and Waliszko 1991; Charzewski et al. 1998; Łaska-Mierzejewska and Olszewska 2007)

Type of settlement	1955	1966	1978	1988	1997	2001
Big cities of over 500,000	13.41	12.90	12.84	12.96	12.76	–
Small towns of about 10,000	13.94	13.58	13.15	13.40	–	–
Rural areas	14.28	13.95	13.47	13.53	–	13.22

Arithmetic mean values for the age at menarche demonstrate acceleration of age at menarche in all environments under analysis

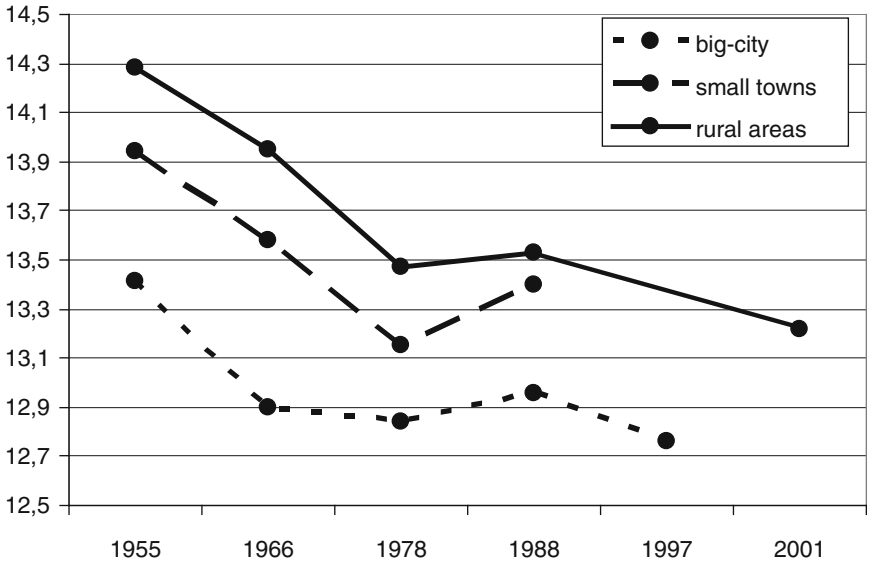

Fig. 80.9 Changes in age at menarche in girls, Poland 1955–2001. Throughout the period under analysis, lowering of age at menarche was observed along with increased degree of urbanization of the place of residence. (Based on Hulanicka and Waliszko 1991; Charzewski et al. 1998; Łaska-Mierzejewska and Olszewska 2007)

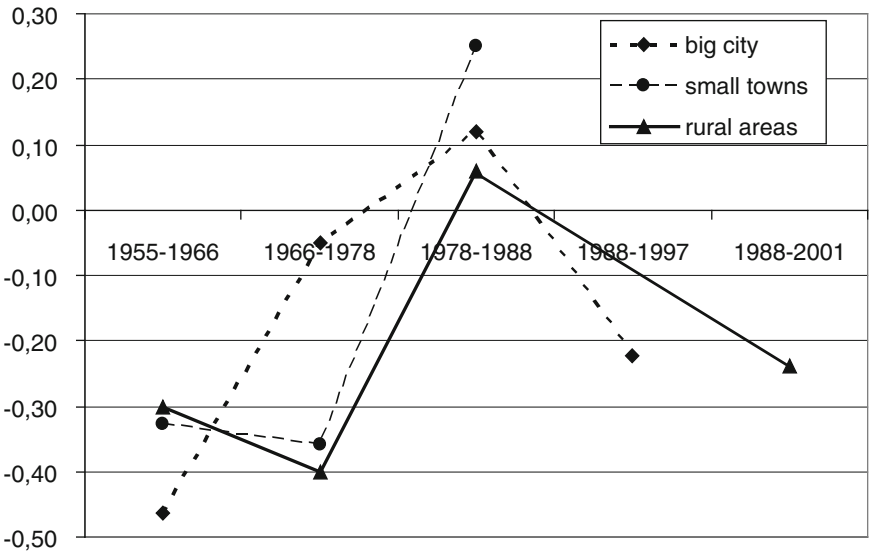

Fig. 80.10 Changes in age at menarche in Polish girls in the years 1955–2001 by degree of urbanization of the place of residence. In 1966, big cities saw the largest acceleration of age at menarche, which was the consequence of industrial development and higher employment resulting in living conditions improvement. The subsequent decade saw rapid agricultural development, which resulted in acceleration of age at menarche in villages and small towns; the years 1977–1989 witnessed an economic crisis resulting in the deceleration of age at menarche in all social environments. Lowering of the age at menarche in Polish girls was observed in subsequent years, despite the political and economic transformations. (Based on Hulanicka and Waliszko 1991; Charzewski et al. 1998; Łaska-Mierzejewska and Olszewska 2007)

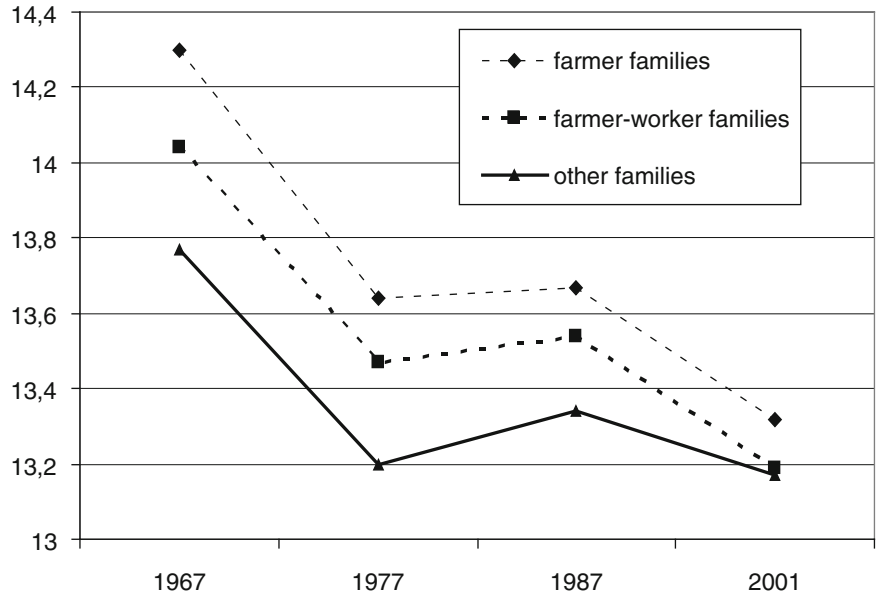

Fig. 80.11 Age at menarche in girls from Polish villages by socio-professional groups. Poland's economic situation has an unequal impact on children and adolescents living in the same environment but in families of different socio-professional status. Throughout the period under study, the latest onset of puberty was observed in the daughters of farmers, whereas girls in rural families possessing no land menstruated earliest. The above gradients demonstrate the bad economic situation of Polish farmers in the study period. (Reprinted from Łaska-Mierzejewska and Olszewska 2007, by permission)

(Łaska-Mierzejewska and Olszewska 2007). Throughout the study period (1967–2001), the daughters of villagers who were not landowners attained the ability to reproduce earlier than girls from families consisting of both farmers and workers, whereas the daughters of farmers were the last to become sexually mature. In 1967, the average pubertal age was 14.3 years for the farmer group, 14.04 years for the farmer–worker group, and 13.77 for the non-agricultural group. The difference between extreme groups amounted to 0.53 years. In the decade of prosperity purchased with bank loans, a rapid acceleration of puberty was observed in all the three socio-professional groups, although the largest drop in age at menarche was noted in girls from farming families (0.66 year), whereas, in the other two groups, it amounted to 0.57 years. The villagers, who were not landowners, were the most severely affected during the period of economic crisis and food rationing. The rate of deceleration of age at menarche in girls from this group amounted to 0.14 in the decade 1977–1987, whereas, in girls from farmer–worker families, it was 0.07, and, in the group of food producers (which was then most privileged), only 0.03. Although this diversification with respect to the deceleration of age at menarche reduced the gradient between these socio-professional groups, which amounted to 0.33 in 1987, the disparities still persisted and had the same direction. The studies repeated by Łaska-Mierzejewska and Olszewska in 2001 involved only four out of eight Polish rural areas studied previously. The results confirmed continuing diversification with respect to age at menarche in girls from different social groups, although the difference between extreme groups decreased to 0.15 years (Fig. 80.11).

The presented changes, in respect of menarche timing, demonstrate the continuing lowering of pubertal age in Polish girls, regardless of the degree of urbanization of their place of residence or social background. However, disparities between different social groups and areas still persist. Considerable differences in terms of age at menarche between big-city-, small-town-, and village

dwellers as well as between girls from different social strata within the same environment with respect to the degree of urbanization are the biological manifestation of disparities in living conditions and undoubtedly demonstrate poor living conditions of Polish villagers, and farmers in particular. The results demonstrate that Polish girls do not fully exploit their genetic potential as regards the age when they attain the ability to reproduce. This age will continue to decrease along with improvement in the socioeconomic conditions in Poland.

80.11 Conclusions

Over a period of 74 years (1927–2001), the mean body height of Polish males increased by 11.3 cm, of which as much as 61% (6.9 cm) occurred over the past 36 years. During the same time (36 years), the BMI mean value increased by 0.53 units. This trend demonstrates a fuller exploitation of the growth potential in the Polish population, which reflects the continuing improvement in the socioeconomic conditions of the society. The slowdown with respect to body-height increase in the Polish population, which has been noted in the past 9 years, results from the slower rate of improvement in the living standards of a number of social groups and from the attainment of the "genetic limit" of body height. It seems that, in the nearest future, the trend of increasing relative body mass will surpass body-height increase. In the years 1955–1988, age at menarche in Polish girls was lowered by 0.45 years (big cities), 0.54 years (small towns), and as much as 0.75 years (villages). The acceleration of age at menarche is still in progress, as, in this respect, the female population has not exhausted its genetic possibilities yet. The social gradients of body height, relative body mass, and age at menarche, persisting in the period studied, demonstrate a lasting diversification of the living standards of Poles.

Table 80.8 Key features of secular trend

1. In successive generations, a number of human biological traits are subject to adaptation-based, non-evolutionary changes called a secular trend.
2. These changes cause intergenerational phenotype variability of morphological–functional traits affected by civilizational development.
3. The changes include the following:
   - Acceleration of development and earlier puberty timing
   - Change in the sequence of a number of development stages (e.g., secondary dentition sequence), and
   - Retardation of involutionary processes – delay in aging processes
4. Developmental acceleration, which is the best-known component of the secular trend, consists of the acceleration of biological development and earlier puberty timing, which entails earlier completion of particular development stages and a larger body size.
5. Acceleration affects primarily the traits representing weaker genetic determination, which means that this phenomenon is primarily caused by changes in external factors.
6. It is thought that secular changes manifest the determination of the body to fully exploit its genetic potential in view of environmental conditions improvement.
7. The consequences of the secular trend are generally positive and include improvement of physical development and skills in children and deceleration of aging, whereas its negative consequences include divergence between biological age, calendar age, and social maturity, temporary disharmonies in the development of internal systems and organs, for example, the size of heart during the so-called pubertal growth spurt, increased incidence of faulty postures, and lower age of occurrence of a number of diseases (e.g., diabetes).

The table lists the key facts concerning the secular trend, including its reasons and consequences

Chapter 81
Vitamin D, Exercise, and Body Composition in Young Children and Adolescents

Leng Huat Foo

Abstract Vitamin D is now more correctly categorized as a seco-steroid prohormone, rather than as a nutrient or a vitamin. The primary function of vitamin D is thought to be the maintenance of calcium and phosphate homeostasis and skeletal integrity throughout life. Although persistent severe vitamin D deficiency results in the bone disease rickets in children and osteomalacia in adults, low vitamin D status can influence musculoskeletal health at any age. Numerous epidemiological studies suggest that vitamin D deficiency and/or insufficiency are global problems for growing children and adolescents. An adequate vitamin D status in children and adolescents is associated with higher levels of lean body mass and muscle strength levels. On the contrary, vitamin D deficiency in children and adolescents is associated with elevation of PTH level, increased bone remodelling rates and a reduction in bone mass. Thus, avoiding vitamin D deficiency by ensuring an adequate supply throughout childhood and adolescence might enhance physical growth and bone mass accretion, which ultimately could reduce the risk of osteoporotic fracture later in life. Furthermore, in recent years, the positive association of vitamin D status with many non-skeletal metabolic processes such as antiproliferative, differentiation, and immunosuppressive effects, has been related a decreased risk of chronic diseases such as cardiovascular diseases, various types of cancers and type-I diabetes. However, this review will be focused on the importance of vitamin D status on body composition and bone growth in children and adolescents.

81.1 Introduction

Vitamin D is chemically a seco-steroid, which acts biologically as a prohormone and requires two hydroxylation processes, first in the liver and then in the kidney, before becoming active. Either vitamin D is obtained through photosynthesis in the skin upon exposure to sunlight or it may be obtained from food. Vitamin D in the blood is taken up by the liver, and its metabolite, 25-hydroxyvitamin D [25(OH)D], is further metabolized by the kidney to the biologically active metabolite, 1,25-dihydroxyvitamin D [1,25$(OH)_2$D]. This metabolite functions in calcium homeostasis by acting on the intestinal mucosal cells to increase the capacity for calcium absorption. It also has a role in decreasing renal calcium excretion and in mobilizing calcium from bone in conjunction with the actions of parathyroid hormone (PTH) and probably calcitonin to maintain extracellular ion calcium concentration within a narrow range (Fraser 1995). Other, more general functions include maintenance of skeletal integrity by influencing bone mineralization and growth in children and adolescents (Outila et al. 2001; Lehtonen-Veromaa et al. 2002a; Foo et al 2009a) and diminishing the loss of bone and of osteoporotic facture risk in postmenopausal women and the elderly (Dawson-Hughes et al. 1997; Lips 2001) by stimulating osteoblast function and promotion of mineralization of the osteoid, the unmineralized matrix. Furthermore, 1,25$(OH)_2$D also plays an important role in modulating the synthesis and secretion of PTH (Lips 2001).

81.2 Vitamin D Metabolism and Functions

Vitamin D is now more correctly categorized as a prohormone, rather than a nutrient or a vitamin. The most important source of vitamin D is that derived from the synthesis in the skin through the exposure of 7-dehydrocholesterol in the epidermis to ultraviolet radiation. This precursor undergoes photochemical isomerization to precholecalciferol (previtamin D) upon exposure to ultraviolet B radiation in the wavelength range of 300–320 nm. Precholecalciferol is thermodynamically unstable and undergoes thermal isomerization to form the more stable cholecalciferol or vitamin D_3 (Fig. 81.1). After vitamin D_3 is formed in the skin, it is transported by the vitamin D-binding protein, an α_2-globulin, in blood to the liver where vitamin D 25-hydroxylase introduces a hydroxyl group at carbon 25 to form 25$(OH)D_3$, which is the major circulating form of vitamin D; its concentration in blood gives a good indication of vitamin D status (Hollis 1996). There may also be some vitamin D in adipose tissue and muscle tissue, which may contribute substrate for the functional metabolism of vitamin D.

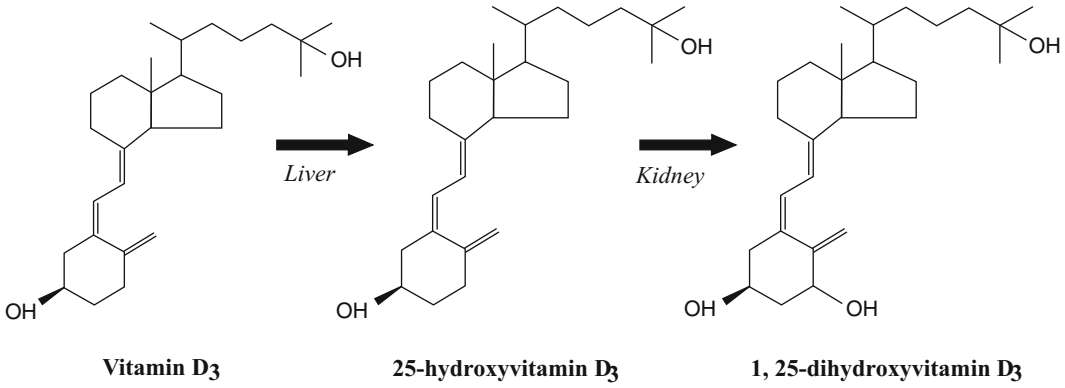

Fig. 81.1 Biosynthesis of vitamin D_3 in human body. This figure illustrates the bioconversion of vitamin D_3 to the biologically active metabolite, $1,25(OH)_3$, through two hydroxylation processes in the liver and the kidney, respectively

In order to become physiologically active, 25(OH)D is further metabolized in the mitochondria of the proximal renal tubules in the kidney, where 1α hydroxylation of 25(OH)D by 25(OH)D 1α-hydroxylase yields 1,25 $(OH)_2D_3$ (Fraser and Kodicek 1970). The renal hydroxylation to $1,25(OH)_2D$ is closely regulated by PTH, hypocalcemia, and hypophosphatemia. The compound $1,25(OH)_2D$ regulates gene transcription through a nuclear, high-affinity, vitamin D receptor (VDR) and initiation of rapid cellular response, including the synthesis of a calcium-binding protein through an interaction of $1,25(OH)_2D$ with VDR. The VDR has been found in cells of the intestine, colon, kidney, bone, brain, skin, prostate, and parathyroid, as well as other cells (lymphocytes, osteoblasts, β-islet cells, and mononuclear cells) (Holick 2004).

The biologically active form of vitamin D is now considered as a hormone because its production is at a site distant from the targets of hormone action, and it is carried to its target tissues by the blood. The conversion of 25(OH)D to 1,25(OH)D in the kidney is tightly controlled, and, except in vitamin D deficiency, is mainly independent of the supply of 25(OH)D (Fraser 1995).

The parent vitamin D is either vitamin D_2 (ergocalciferol) or vitamin D_3 (cholecalciferol), with identical chemical structure of three double bonds, at carbons 5, 7, and 10. The differences between vitamin D_2 and vitamin D_3 are in the side chain where vitamin D_2 has an additional double bond at carbon 22 and a methyl group at carbon 24. Both vitamins D_2 and D_3 undergo the same metabolic activation process by 25-hydroxylation in the liver, followed by 1α-hydroxylation in the kidney, to make the biological active compounds, $1,25(OH)_2D_2$ and $1,25(OH)_2D_3$, respectively. The biological activity of vitamins D_2 and D_3 are often considered to be equal in humans (Jones et al. 1998). However, it is also suggested that they may have different pharmacokinetics and that vitamin D_2 may have less biological activity than vitamin D_3 (Armas et al. 2004).

Historically, the role of vitamin D has been recognized in terms of the deficiency disease of rickets in children and osteomalacia in adults. However, it is now apparent that its physiological function is also related to bone mineral homeostasis. The primary function of vitamin D is thought to be the maintenance of calcium and phosphate homeostasis and skeletal integrity throughout life (Fraser 1995). In children, the regulation of calcium homeostasis is important to ensure an adequate growth and development of bone mass (Lehtonen-Veromaa 2002a; Heaney et al. 2000). Vitamin D may also play a crucial role in prevention of chronic diseases, in which deficiency in vitamin D has been implicated, as in the development of cardiovascular diseases, autoimmune diseases, certain types of cancer, and type-I diabetes (Holick 2004).

81.3 Vitamin D Deficiency and Its Health Consequences in Children and Adolescents

It is generally agreed that persistent, severe vitamin D deficiency results in the development of rickets in children and osteomalacia in adults. Unlike deficiencies of water-soluble micronutrients, vitamin D deficiency takes many weeks to develop and can be asymptomatic. Therefore, in the past two decades, research has focused on the influence of mild vitamin D deficiency on bone health. It is suggested that a low 25(OH)D concentration, also known as hypovitaminosis D, is not only a biochemical abnormality, but also associated with physiological, pathological, and clinical signs of vitamin D deficiency, along with secondary hyperparathyroidism, and increased bone remodeling. In elderly people, such deficiency may exacerbate age-related bone loss and the risk of osteoporotic fractures (Dawson-Hughes et al. 1997; Lips 2001). Vitamin D deficiency might arise from either an inadequate supply, impaired utilization, or enhanced excretion of vitamin D.

Elderly and postmenopausal women are susceptible to vitamin D deficiency and insufficiency, but vitamin D deficiency is also being found among apparently healthy growing children and adolescents (Docia et al. 1998; Du et al. 2001; Foo et al. 2009b; Guillemant et al. 1995, 1999; Lehtonen-Veromaa et al. 2002b; Looker et al. 2002; Gordon et al. 2004). Recent surveys indicate that rickets is reappearing in developed countries (Weisberg et al. 2004) and that the prevalence of hypovitaminosis D was also increasing in developed and developing countries (Chapuy et al. 1997; Looker et al. 2002; Fraser 2004). Surprisingly, hypovitaminosis D has been found in sunny countries at tropical latitudes where cutaneous production of vitamin D can occur throughout the year (Gannage-Yared et al. 2000; El-Hajj Fuleihan et al. 2001; Hatun et al. 2005).

Severe vitamin D deficiency is associated with increased PTH levels in blood. Persistent vitamin D deficiency results in a net loss of bone, and, in children, in the development of rickets. By contrast, little is known about the effects on body composition and bone health in children and adolescents with low vitamin D status without clinical signs of rickets. Nevertheless, several studies have found that vitamin D deficiency and insufficiency in children and adolescents resulted in secondary increases in serum PTH (Guillemant et al. 1999; Foo et al. 2009b; El-Hajj Fuleihan et al. 2001; Outila et al. 2001; Gordon et al. 2004), increased bone turnover (Lehtonen-Veromaa et al. 2002a; Cheng et al. 2003; Foo et al. 2009a), and a decrease in the rate of bone mass accumulation (Jones and Dwyer 1998; Lehtonen-Veromaa et al. 2002a; Foo et al. 2009a). These studies indicated a significant inverse relationship between serum 25(OH)D and PTH concentrations. Additionally, an increase in bone turnover and in secretion of PTH due to vitamin D deficiency may increase the rate of skeletal remodeling during periods of bone growth, thus resulting in reduced bone accumulation (Slemenda et al. 1997).

81.4 Prevalence of Vitamin D Deficiency in Children and Adolescents

The definition of vitamin D deficiency based on the serum 25(OH)D concentration varies among studies. When vitamin D deficiency is defined as a serum 25(OH)D concentration of <25 nmol/L, the prevalence of deficiency ranges from 2.4% to 72%, depending on the age groups, the latitude of the population assessed, and the season of the year (Table 81.1). When deficiency was defined at the higher threshold concentration value of <50 nmol/L, the prevalence rates increased upward to range about 10–91% for young children and adolescents. Even 11–10% of apparently healthy children at 6–24 months of age living in Alaska and New Zealand had serum 25(OH)D concentrations of <37 nmol/L

Table 81.1 Key Features of Vitamin D

1. Vitamin D acts biologically as a prohormone, in which it requires two hydroxylation processes that occur in the liver and the kidney, respectively, before becoming active as 1,25-dihydroxyvitamin D [1,25(OH)D].
2. Vitamin D is obtained either through photosynthesis in the skin through exposure to the sunlight or from food.
3. Main functions of vitamin D is involvement in calcium homeostasis by regulating the intestinal calcium absorption, renal calcium excretion and mobilization of calcium from bone in conjunction with the actions of parathyroid hormone (PTH) and probably calcitonin to maintain extracellular ion calcium concentration in the body.
4. A persistent severe vitamin D deficiency is associated with the bone abnormalities of rickets in children and osteomalacia in adults.
5. Suboptimal vitamin D deficiency in the elderly and in postmenopausal women is associated with rapid age-related bone loss and increase in the risk of osteoporotic fractures.
6. Vitamin D deficiency in growing children and adolescents is associated with an increase in PTH concentration in blood, increase rate of bone turnover, and a decreased rate of bone mass accumulation.
7. Preventive strategies should be implemented to maintain optimum vitamin D status by promoting the production of adequate cutaneous vitamin D through sunlight exposure and intake of vitamin D-rich foods, such as milk, or foods fortified with vitamin D.

This table lists the key facts of vitamin D including the biosynthesis of vitamin D, function of the vitamin in the body, health consequences of vitamin D deficiency, and recommended preventive strategies to maintain adequate vitamin D status

(Gessner et al. 2003) or <27.5 nmol/L (Grant et al. 2009), thus indicating that vitamin D deficiency can occur early in life. The prevalence rates of deficiency were found to be higher among adolescents from various regions of the world (Du et al. 2001; Foo et al. 2009b; Hatun et al. 2005; Gordon et al. 2004) compared to younger children (Grant et al. 2009; Stein et al. 2006).

It is generally agreed that higher rates of vitamin D deficiency or/and insufficiency are found in children and adolescents living at far northern or far southern latitudes compared to those in more equatorial regions. Such deficiency is seen particularly in the winter months because of the seasonal decrease in intensity of UV light (see details in Sect. 81.5). In equatorial countries, a high prevalence of hypovitaminosis D was also found among adolescent girls and women who wore full-length covered dresses (El-Hajj Fuleihan et al. 2001; Ganage-Yared et al. 2000; Hatun et al. 2005). Thus, such epidemiological evidence suggests that vitamin D deficiency and/or insufficiency are global problems for growing children and adolescents.

81.5 Factors Contributing to Vitamin D Deficiency in Children and Adolescents

Vitamin D deficiency in children can be associated with clinical signs, such as retarded growth and motor development, failure to thrive, short stature, bone deformities including tibial bowing and splaying of the anterior ribs, tetany, seizures, and dental enamel defects. Several factors, such as exclusive breastfeeding of infants, lack of sunlight exposure, darker skin pigmentation, living at temperate latitudes, and low intake of vitamin D and calcium as well as higher body adiposity levels, have been shown to contribute to vitamin D deficiency and the disease of rickets (Table 81.2). When the vitamin D status of pregnant women is low, their infants have a high risk of vitamin D deficiency in the neonatal period. In addition, limited exposure to sunlight due to religious, cultural, and lifestyles practices may also play a part in the etiology of vitamin D deficiency. It is reported that about 52% of Lebanese schoolchildren aged between 10 and 16 years, who wore full-length clothes, had vitamin D insufficiency (El-Hajj Fuleihan et al. 2001). Additionally, in apparently healthy Caucasian adolescent boys aged from 16 to 18 years, there was a significant association between sports-related

25(OH)D 25-hydroxyvitamin D; *RIA* radioimmunoassay; *CPB* Competitive protein-binding assay

This table shows the percentage of persons at risk of vitamin D deficiency or vitamin D insufficiency, as measured by the 25(OH)D in the blood of different age groups in children and adolescents living in countries of various latitudes throughout the world

sun exposure and serum 25(OH)D concentrations, indicating that adequate sunlight exposure in summer is important for optimal vitamin D status (Jones et al. 2005). Similarly, a study of Chinese adolescent girls aged 15 years also found that lifestyle factors, such as participation in organized sports and the time spent in physical exercise, both at school and in leisure time, showed significant independent positive association with 25(OH)D concentration (Foo et al. 2009b). In the multivariate analysis of this cohort, adolescent girls, who participated in organized sports, had a higher vitamin D status than those who did not engage in any sport. It is possible that the higher vitamin D status of those with greater exercise could a result of an increased exposure to sunlight. Conversely, there is an awareness of the hazards of ultraviolet-B light exposure in childhood and the subsequent risk of development of skin cancer in adulthood. This problem may cause difficulties for public health policy in advocating exposure to sunlight of children and adolescents, when there is a risk of skin cancer. However, only a small amount of ultraviolet exposure is needed to maintain vitamin D status, and this would have a low risk of development of skin cancer.

It is generally agreed that the dietary sources of vitamin D in most natural foods are very limited, being only present in significant amounts in oily fish and the yolks of eggs of domestic chickens provided with vitamin-D-fortified food (Gannage-Yared et al. 2000). Several studies have shown that low intake of vitamin D was significantly associated with decreased vitamin D status in children, adolescents, and adults (Weng et al. 2007; Ilich et al. 1997). Furthermore, low dietary calcium intake or reduced dietary calcium availability may also lead to rickets by inducing vitamin D deficiency. In animal studies, dietary calcium deprivation appears to affect the efficiency of vitamin D utilization. Low intakes of dietary calcium or diets high in phytate induce mild hyperparathyroidism and elevation of $1,25(OH)_2D$ concentrations, which enhances the catabolism (metabolic destruction) of 25(OH)D and decreases its half-life in the circulation (Clements et al. 1987a). The increased catabolism of 25(OH)D is mediated through elevated levels of $1,25(OH)_2D$, which have been shown to correlate inversely with the half-life of 25(OH)D (Clements et al. 1987b) with a resultant reduction in vitamin D status. It is thus likely that diets low in calcium content and high in calcium absorption inhibitors, such as phytate, might exacerbate vitamin D deficiency, leading to the development of rickets. Such a mechanism has been proposed as a factor in the high prevalence of rickets among the Asian community in the United Kingdom (Clements 1989).

People in temperate regions also show seasonal variations in vitamin D status as the angle of sunlight reaching earth's surface changes. Exposure to sun for part of winter is of no use in improving vitamin D status because the intensity of UV light drops, even though the visible light may be very bright. In addition, the seasonal variation in UV light is greater at higher latitudes than at lower ones. Apart from these factors associated with limited sunlight exposure and dietary practices, the role of body composition may also affect vitamin D status in children and adolescents (see details in Sect. 81.6).

Therefore, a decline in levels of serum 25(OH)D in children and adolescents from summer to winter has been well documented by several studies, in which the prevalence of vitamin D deficiency (low vitamin D status) is increased during winter in China (Du et al. 2001; Foo et al. 2009b), Finland (Lehtonen-Veromaa et al. 1999; Outila et al. 2001), France (Guillemant et al. 1995), Spain (Docia et al. 1998), and New Zealand (Rockell et al. 2005). Regardless of the definition of hypovitaminosis D, a high proportion of subjects had deficient levels of 25(OH)D during winter compared to summer because of low or no ultraviolet-B light of sufficient intensity to activate the conversion of 7-dehydrocholesterol to previtamin D in skin (Webb et al. 1988). Low vitamin D status in winter may increase PTH secretion and thus may decrease bone mass accumulation. The optimal concentration of 25(OH)D required for bone health in children and adolescents is unclear; however, optimal vitamin D status during childhood and adolescence is considered to be important for long-term benefits to musculoskeletal health.

81.6 Relationship of Vitamin D Status and Body Composition and Muscular Strength in Young Children and Adolescents

Although it is well established that obesity, expressed as excess body fat, has an adverse effect on vitamin D status in adults (Wortsman et al. 2000), there is limited data on the relationship of vitamin D status to body composition in growing children and adolescents. An understanding of any such relationships would be particularly crucial, given that the epidemic of childhood obesity is increasing worldwide. Two studies in Caucasian children and adolescents found an inverse relationship between vitamin D status and body mass index (BMI) (Gordon et al. 2004; Rockell et al. 2005). However, a significant positive independent association has been reported between vitamin D status and BMI in adolescent Chinese girls (Foo et al. 2009b). This positive association between 25(OH)D levels and BMI is contrary to the common view that vitamin D status declines as BMI increases (Gordon et al. 2004; Rockell et al. 2005). In the studies of Gordon et al. (2004) and Rockell et al. (2005), obesity was defined only by a high BMI rather than by using a direct estimate of body fat mass. The use of BMI to assess the degree of body fatness in children and adolescents is of limited value (Wells et al. 2002) compared to adults because, during growth, an increase in BMI in childhood and adolescence may also be related to an increase in the fat-free lean body mass (LBM), instead of body fat mass (Wells et al. 2002; Maynard et al. 2001). Hence, higher vitamin D status is found in children with a higher proportion of LBM. This is complicated further by variation in growth rates and maturity levels (Daniels et al. 1997).

Until recently, the mechanism by which vitamin D status impacts on body composition is not well elucidated. The relationship between vitamin D status and body composition has been examined in a representative population-based study of adolescent girls of Chinese-origin aged 15 years, by direct measurement with dual-energy X-ray absorptiometry (DXA). A significant positive association was found between 25(OH)D concentration and LBM, whereas there was no significant association between the percentage of body fat and vitamin D status, as indicated in Figs. 81.2 and 81.3, even after adjustment for other possible confounding factors (Foo et al. 2009b). When different body components, such as LBM and body fat mass, were compared according to vitamin D status groups, adolescent girls in the vitamin D sufficient group (>50 nmol/L) had significantly higher LBM than those who were vitamin D deficient (<25 nmol/L). By contrast, there was no association between vitamin D status and body fat mass, after adjusting for other confounding lifestyle and dietary factors. Thus, in these adolescent girls, the relationship of adiposity to vitamin D status was less pronounced than that between LBM and vitamin D status (Foo et al. 2009b). It is suggested that changes in BMI are related not just to changes in adipose tissue mass, but also to changes in the proportion of LBM during this stage of growth. This seems to be the first study to examine any relationship between differences in body composition profiles and vitamin D status in children and adolescents. Furthermore, this study also suggests that BMI is not as good an indicator of mild obesity in children and adolescents as it is in adults. By contrast, a recent study of 90 postpubertal Hispanic and Caucasian females aged 16–22 years with a mean BMI of 25.7 kg/m^2 showed a significant negative association between 25(OH)D levels and regional body composition of visceral and subcutaneous fat measured by computed tomography (CT) and also total body fat mass determined by DXA (Kremer et al. 2009). In the sub-analyses of vitamin D status groups, females who were vitamin D insufficient, as defined by 25(OH)D concentrations of ≤72.5 nmol/L (29 ng/mL), were found to have a significantly higher body weight and BMI, but were shorter than females, who were vitamin D sufficient with serum 25(OH)D levels more than or equal to 75 nmol/L. This indicated that females with 25(OH)D in the vitamin D insufficient range tend to be shorter and heavier (Kremer et al. 2009). Additionally, there was a surprisingly significant positive association between serum 25(OH)D levels and height in these populations (Kremer et al. 2009). This observation was in line with a previous study in adolescent girls aged 13–17 years that also found a significantly lower height in girls with low vitamin D status

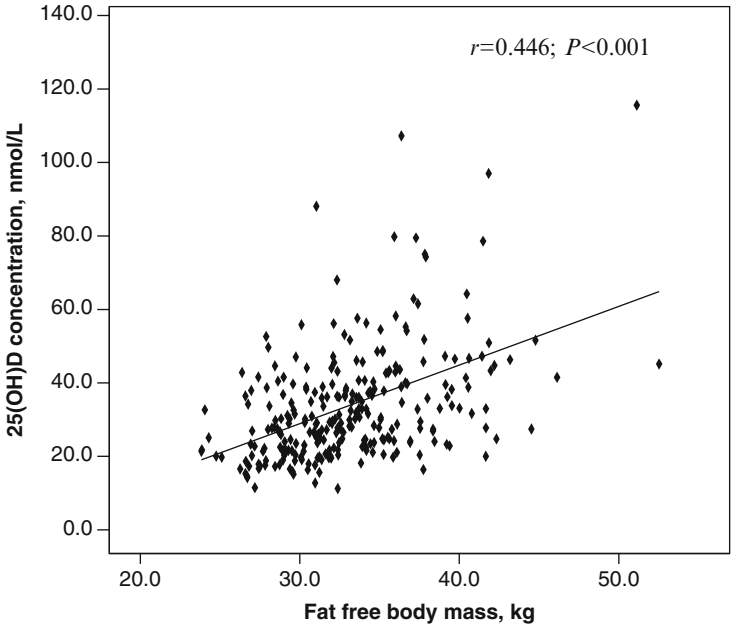

Fig. 81.2 Relationship between plasma 25(OH)D (nmol/L) and fat-free body mass (kg). Relationship between vitamin D status as measured by 25(OH)D levels in the blood and total body lean body mass (Reprinted from Foo et al. (2009b). With permission. 25(OH)D: 25-hydroxyvitamin D)

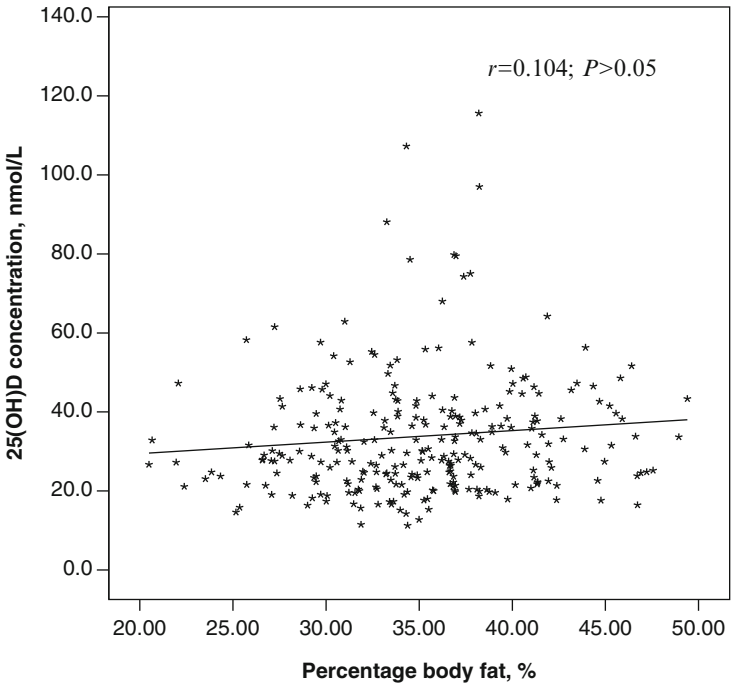

Fig. 81.3 Relationship between plasma 25(OH)D (nmol/L) and percentage body fat (%). Relationship between vitamin D status measured by 25(OH)D levels in the blood and percentage of body fat (Reprinted from Foo et al. (2009b). With permission. 25(OH)D: 25-hydroxyvitamin D)

compared to those with higher vitamin D status (Hatun et al. 2005). These positive relationships between vitamin D status and height warrant further population-based longitudinal studies to determine the possible mechanism by which vitamin D status affects longitudinal bone growth.

It is still uncertain whether (1) a higher vitamin D status is caused by increased LBM or (2) a higher vitamin D status leads to an increase in LBM. In a recent randomized clinical trial of vitamin D supplementation in healthy school-aged Lebanese girls, a significant beneficial effect on LBM was found in premenarcheal girls. By contrast, there were no such effects in postmenarcheal girls (El-Hajj Fuheihan et al. 2006), and it was postulated that any beneficial effect during the postmenarcheal period may be confounded by the powerful effects of pubertal growth. Several mechanisms have been proposed to explain why obesity is associated with lower vitamin D status. One theory is that low vitamin D status might diminish leptin secretion into the circulation, which, in turn, may contribute to the increase in adipose tissue mass (Menendez et al. 2001). Another possible mechanism is attributed to greater mass of adipose tissue may trap vitamin D so that it becomes unavailable for functional conversion to 25(OH)D (Wortsman et al. 2000). More longitudinal population studies in growing children and adolescents are needed to explain how changes in body composition during growth might be related to vitamin D status. A more comprehensive understanding of the mechanisms relating vitamin D deficiency and/or insufficiency and adipose tissue mass is required because obesity later in life is associated with serious health problems, such as osteoporosis, diabetes, cardiovascular diseases, cancer, and multiple sclerosis (Holick 2004).

Although it is well documented that long-term severe vitamin D deficiency can cause rickets, which is characterized as a failure of mineralization of the organic matrix of bone, particularly at the epiphyseal growth plate, with deformities of the skeleton, enlargement of the joints of the long bones and rib cage, curvature of the spine and thighs, muscle spasms, weakness, and atrophy in children. There is, however, little information about the effects of less severe vitamin D deficiency and/or insufficiency on muscle function in children and adolescents. A study in Chinese postpubertal adolescent girls aged 15 years found that subjects with 25(OH)D levels ≥50 nmol/L showed significantly greater handgrip muscle strength compared with those of lower vitamin D status (Fig. 81.4). This relationship was independent of pubertal growth parameter, body size, level of physical activity (PA), and dietary calcium and vitamin D intakes (Foo et al. 2009a). This finding is further supported by another study of 99 post-menarcheal girls, aged 12–14 years, where a significant positive association was found between serum 25(OH)D concentration and muscle strength in the lower limb, measured by jumping velocity, height and power, Esslinger Fitness Index, and maximum voluntary force (Ward et al. 2009). This suggested that muscle contractility is affected by vitamin D status. Adolescent girls with low 25(OH)D concentrations generated less muscle power, and, hence, jump height and velocity were lower compared to those with higher vitamin D status (Ward et al. 2009). These findings in adolescents are comparable to those in elderly subjects in whom higher serum 25(OH)D levels were significantly associated with increased muscle strength and improved lower extremity function (Bischoff et al. 2003; Dawson-Hughes et al. 1995). In the elderly, this improved muscular function and strength may lower the risk of falls and consequent osteoporotic fractures.

The mechanism responsible for the greater muscle strength, force, and power in subjects with better vitamin D status was not explored in these two studies. One possible mechanism may involve a direct role of vitamin D (either as $1,25(OH)_2D$ or 25(OH)D) in muscle action. Although such an effect has not been shown, there has been much research on the molecular action of vitamin D in muscle, in which 1,25(OH)D stimulates the growth and proliferation of muscle cells and regulates intracellular calcium in muscle cells (Boland 1986; Boland et al. 1995). It may be that vitamin D either has a role in modifying the transport of calcium in muscle cells or may have a role quite independent of that. For instance, low vitamin D status may result in fatigue and diminished muscle oxygenation, and, consequently, may affect muscle strength and function, and give rise to muscle weakness

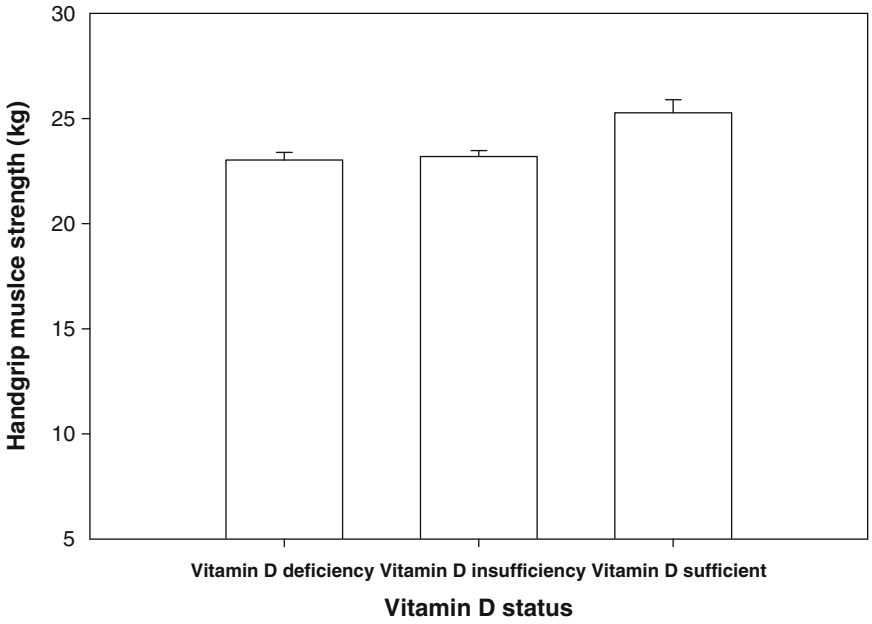

Fig. 81.4 Vitamin D status and handgrip muscle strength. Association between the stages of vitamin D status measured by 25(OH)D levels in the blood and muscle strength at the handgrip in Chinese adolescent girls aged 15 years after adjusting for body size, Tanner pubertal stage, dietary intakes of calcium, vitamin D and milk, organized sports participation status and total PA levels. Results are expressed as mean ± SEM. 25(OH)D: 25-hydroxyvitamin D

(Boland 1986). Conversely, a separate observation that 25(OH)D is apparently stored in muscle in newborn rats may indicate a special role of muscle in vitamin D homeostasis, which is quite independent of any role of vitamin D in muscle function (Clements and Fraser 1988). Therefore, more studies are required to identify the mechanisms for these interactions. Such information is much needed because the development of optimum muscle strength has an important influence on bone mass accrual as well as for the maintenance of bone mass integrity during this critical period of growth. For instance, several studies in children and adolescents found that increases in muscular strength were significantly associated with both changes in bone mass (Foo et al. 1998) and changes in bone geometry, and, hence, the structural properties of bone, independent of the bone mass properties (Haapasalo et al. 1998). This is compatible with the functional model of bone development, described as the mechanostat hypothesis, in which muscle and bone together form a functional unit, so that greater muscle strength leads to increased bone strength and mass (Frost and Schonau 2000).

81.7 Relationship Between Vitamin D Status and Bone Composition Growth in Young Children and Adolescents

It is well recognized that persistent severe vitamin D deficiency is associated with the bone abnormalities of rickets in growing children. There is now a growing body of evidence which suggests that mild vitamin D deficiency in children and adolescents may also be deleterious to bone health in this population. Achieving adequate vitamin D status is important for skeletal health because of a vitamin D role in calcium homeostasis and bone cells. Numerous studies in growing children and

adolescents have found that a persistently low vitamin D status with prolonged elevation of PTH and a subsequent increase in bone remodeling leads to suboptimal bone mass accretion. However, studies investigating the influence of vitamin D status on bone mass accretion in healthy growing children and adolescents have yielded inconsistent results, especially with adolescents at the time of pubertal growth development. In Caucasian adolescent girls, a positive association has been found in some studies between vitamin D status and bone mass measurements (Lehtonen-Veromaa et al. 2002a; Outila et al. 2001; Cheng et al. 2003). However, this association was not found in other studies (Kristinsson et al. 1998; Willett 2005). In a cross-sectional survey of adolescent girls aged 14–16 years, a positive association was found between serum 25(OH)D concentrations and forearm areal bone mineral density (aBMD), but only in subjects who had a 25(OH)D concentration of less than 40 nmol/L (Outila et al. 2001). Similarly, in a 3-year longitudinal investigation of bone development in Finnish adolescent girls aged 9–15 years, Lehtonen-Veromaa et al. (2002a) found a positive association between changes of serum 25(OH)D levels from baseline as well as the baseline 25(OH)D levels themselves on lumbar spine (LS) aBMD. Both studies used areal BMD as their bone outcome variable, but, in growing children and adolescents, this is now regarded as an inaccurate measure of bone mass accretion because it depends on bone size and body growth factors (Prentice et al. 1994). The increase in aBMD reported in these studies may have been related to differences in bone size between individuals rather than to vitamin D status. Hence, there is still uncertainty about the importance of vitamin D deficiency during childhood and adolescence on final bone mass at maturity.

Limited data exist about the influence of vitamin D status on bone growth in children and adolescents in non-Caucasian children and adolescents. In a population-based study of Chinese adolescent girls aged 15 years, adequate vitamin D status (≥50 nmol/L) was found to be associated with a significant increase in size-adjusted BMC of the total body, and distal and proximal forearm compared to those with poor vitamin D status (Foo et al. 2009a). These relationships persisted after adjusting for stage of pubertal development, dietary intake of calcium and vitamin D, and total time spent in PA, thus demonstrating that these variables did not influence the changes in bone measurements in relation to vitamin D status. By contrast, there were no significant differences in bone area (BA) as an indicator of bone size at the skeletal sites measured between the three groups of vitamin D status. Similar findings were also reported by Kristinsson et al. (1998) where Icelandic adolescent girls aged 16–20 years showed a significant positive association between 25(OH)D concentration and total forearm BMD and BMC. These findings are in line with the two recent intervention studies of vitamin D supplementation on bone growth in growing adolescents (Viljakainen et al. 2006; El-Hajj Fuleihan et al. 2006). In the study of 212 Finnish prepubertal adolescent girls aged between 11 and 12 years, who were randomly given different doses of vitamin D supplements of either 200 IU or 400 IU daily for a year, it was found that bone mineral augmentation of the proximal femur was 14% and 17% significantly greater in participants who received 200 IU and 400 IU of vitamin D per day, respectively, compared to control subjects (Viljakainen et al. 2006). Another investigation in Lebanese premenarcheal adolescent girls aged 10–17 years, supplemented with either 1,400 IU/week or 14,000 IU/week vitamin D_3 for 1 year had significantly increased bone mineral content (BMC) and BA of the total hip as compared to the controls (El-Hajj Fuleihan et al. 2006).

Most of the published reports investigating the influence of vitamin D status on bone mass in children and adolescents focused on BMC and/ or areal BMD, assessed by DXA as the endpoint bone variable. This assessment method does not measure bone geometry and structural properties of the skeleton and only provides a two-dimensional rather than a more complex three-dimensional analysis of the bones measured. There are two reports of investigations into the association between vitamin D status and bone geometry. One of these studied Caucasian prepubertal girls aged 10–12 years (Cheng et al. 2003) and the other examined Hispanic and Caucasian postpubertal females aged 16–22 years (Kremer et al. 2009). The study by Cheng et al. (2003) using peripheral quantitative computed tomography (pQCT) found that girls with vitamin D deficiency, defined as 25(OH)D levels

≤25 nmol/L, had significantly lower cortical volumetric BMD (vBMD) in the distal radius compared with subjects with higher vitamin D status. By contrast, however, no significant differences were found between vitamin D status and any BMC or BMD measurements for the total body, femur, and LS, measured by DXA (Cheng et al. 2003). The authors concluded that, when only DXA was used to determine the influence of vitamin D status on bone mass, there could be a misinterpretation of the role of vitamin D on bone mass accretion. When pQCT was used to measure volumetric bone density, vitamin D status was found to influence the results (Cheng et al. 2003). Conversely, no significant association was found between the adequacy of vitamin D status and bone growth, as measured by either computed tomography (CT) or DXA methods (Kremer et al. 2009).

Although it is well established that low vitamin D status in postmenopausal and elderly women is considered as a major risk factor associated with increased risk of rapid bone loss and osteoporotic fractures (Lips 2001; Dawson-Hughes et al. 2005), on the contrary, the precise beneficial effects of vitamin D status on bone mass growth and development in growing children and adolescents are still inconclusive. Interpretation of the effects of vitamin D status and bone mass accretion in growing children and adolescents is complicated and confounded by various biological growth factors, such as sexual maturation and changes in the rate of linear growth. The interaction between these variables is complex during this rapid growth period (Heaney et al. 2000; Saggese et al. 2001). For instance, there is a strong confounding effect of puberty on skeletal modeling and remodeling, where plasma calcium and phosphate concentrations may be affected by factors other than vitamin D status (Kristinsson et al. 1998; Saggese et al. 2001). This suggests that these biological variations may confound the independent influence of vitamin D on bone mass accretion. In a study of Chinese girls, the significant association between vitamin D status and bone mass remained unchanged, even after adjusting for pubertal stage (Foo et al. 2009a). This is not surprising as most of the subjects were at a postpubertal stage of development, where changes in sex hormones are less pronounced compared to those in subjects at an earlier stage of puberty (Saggese et al. 2001). This finding is strengthened by the homogeneity in age and sex of the population studied, which was similar to that of Kristinsson et al. (1998), where analysis was stratified according to individual age. Other explanations for inconsistency in the findings of studies in Caucasians and those of other ethnicities may be differences in study design, subject characteristics, their sexual maturity, data interpretation and/or baseline vitamin D status defined as deficient, the techniques used for bone measurements, and the skeletal sites measured.

The mechanism by which adequate vitamin D status leads to higher bone mass in healthy growing children and adolescents is not understood. However, current evidence suggests that the increased bone mass with adequate vitamin D status may be, in part, a consequence of lower secretion of PTH, followed by a decrease in the rates of bone remodeling, as indicated by the biochemical markers for bone formation and resorption (Outila et al. 2001; Foo et al. 2009a). Therefore, adequate vitamin D status is important and may contribute to attaining optimal peak bone mass in growing children and adolescents. Further longitudinal population studies are needed to evaluate what the optimal serum 25(OH)D concentration might be for maximal bone accretion during the time of rapid growth and also to identify the optimal levels of vitamin D intake in relation to greater bone mineralization and physical growth in children and adolescents.

81.8 Recommended Daily Intake of Vitamin D for Children and Adolescents

The US Dietary Reference Intakes (DRI) panel for calcium, phosphorus, magnesium, vitamin D, and fluoride was established in 1997 (Institute of Medicine 1997). Adequate intakes (AIs) for all nutrients except for vitamin D were set from the estimated average requirements (EARs), which are based on

Table 81.3 Factors contributing to low vitamin D status in children and adolescents

Low sunlight exposure
- Little time spent in outdoor activity
- Clothing due to religious and cultural practices that prevents skin exposure to sunlight
- Increased urbanization with more atmosphere pollution that absorbs ultraviolet light

Decrease in dietary intake of vitamin D and calcium
- Decreased consumption of dietary vitamin D and/or food fortified with vitamin D
- Low calcium diets

Higher levels of body fat mass or obesity
- Decreased bioavailability of vitamin D in the body

This table lists the lifestyle, dietary, and body composition factors that contributing to lower vitamin D status in children and adolescents

nutrient demands for accretion and obligatory losses through absorption, or are the intakes required for maximum retention (Weaver and Fleet 2004). However, this approach seems to be inappropriate for vitamin D, which is metabolized like a hormone and which is mainly acquired by solar irradiation of skin. Furthermore, EARs are difficult to set for vitamin D because inputs from sunlight and food are difficult to assess. Therefore, AI was used instead of EAR for vitamin D. This is defined as the intake necessary to achieve the normal range of serum 25(OH)D concentration. The current vitamin D intake recommendation established by the Food and Nutrition Board of The Institute of Medicine in 1997 for various age groups of populations is given in Table 81.3. The current recommendation of vitamin D intake for infants, young children, and adolescents, regardless of sunlight exposure, age, degree of skin pigmentation, geographic region, and gender, is 200 IU (5 μg)/day, and the upper limit levels were set at 2,000 IU/day (50 μg/day). The upper level was set to prevent hypervitaminosis D when serum 25(OH)D concentrations are in excess of 400 nmol/L. Since 1997, there has been debate about whether the AI level for vitamin D is really "adequate" and ideal for optimal bone health (Dawson Hughes et al. 2005; Vieth 1999). Since then, progress has been made toward determining the optimal vitamin D intake needed to produce changes in serum 25(OH)D concentration. Two direct functional measures for vitamin D adequacy were used, namely calcium absorption (Heaney et al. 2003; Vieth 1999) or bone resorption (Chapuy et al. 1992; Dawson-Hughes et al. 1997). Revised recommended AI of vitamin D for populations were proposed in 2004 (Table 81.3). As expected, the recommended AI for vitamin D for growing girls and for women are higher, and are approximately five times higher than the recommended levels set in 1997 to achieve and maintain a concentration of 25(OH)D at or above 80 nmol/L, a level found to prevent elevation of PTH concentration in various age groups (Chapuy et al. 1997; Dawson-Hughes et al. 1997). A recent estimate is that a daily oral cholecalciferol intake of ~12.5 μg/day (500 IU/day) would be required to maintain and prevent the winter fall in serum 25(OH)D level (Heaney 2005).

81.9 Dietary Sources of Vitamin D

Food sources of vitamin D are extremely limited. Vitamin D is not present naturally in most foods. The only food sources relatively rich in vitamin D are some oily fish, fish liver oils, and egg yolk. In developed countries, foods such as breakfast cereals, fruit juices, margarine, and some dairy products may be fortified with vitamin D. Dietary supplements containing vitamin D in amounts that will increase vitamin D status are also consumed (Table 81.4).

Table 81.4 Dietary reference intake (DRI) for vitamin D for populations based on 1997 and 2004

	US	
	1997[a]	2004[b]
Male		
0–11 years	5	NA
12–19 years	5	2
20–39 years	5	16
Female		
0–11 years	5	NA
12–19 years	5	22
20–39 years	5	25

This table lists the recommended amount for dietary vitamin D intake required, according to different age groups of children and adolescents in 1997 and 2004.

81.10 Conclusions

Vitamin D deficiency and insufficiency occur in a high proportion of growing children and adolescents worldwide, regardless of what 25(OH)D level is used to define vitamin D deficiency. Poor vitamin D status should be regarded as of universal concern. Low vitamin D status is not only a biochemical abnormality, but also associated with physiological, pathological, and clinical signs of vitamin D deficiency, along with secondary hyperparathyroidism and increased bone remodeling, which could have long-term detrimental effects on physical growth and skeletal development and mineralization. Vitamin D has also been found to impair optimal muscle function and action on the skeleton. These conditions would therefore compromise bone mass accretion and muscular strength and function during the growing years. Hence, an adequate nutritional vitamin D status during growth is particularly crucial for optimal musculoskeletal health.

It is strongly recommended that children and adolescent participate in intervention programs to combat vitamin D deficiency. Several preventive strategies to maintain optimum nutritional vitamin D status, such as promoting the production of cutaneous vitamin D through exposure to sunlight and intake of vitamin D rich foods, such as milk, or foods fortified with vitamin D, have been developed. Although there is some debate on the adverse effects of exposure to highly intense ultraviolet-B light and the risk of skin cancer, only a small amount of ultraviolet exposure is needed to maintain vitamin D status. For instance, exposure of hands, face, and arms to approximately one-third of a minimal erythemal dose (MED) of sunlight most days before 10 am and after 3 pm during the summer months is sufficient to enable adequate cutaneous synthesis of vitamin D (Working Group of the ANZBMS, Endocrine Society of Australia and Osteoporosis Australia 2005). This approach is very important, as natural dietary sources of vitamin D are limited. In addition, innovative health and nutrition education programs focused on vitamin D, PA, and dietary modification as well as skeletal health should be included in the school health-education curriculum, as most children and adolescents can be reached through schools.

Emerging evidence showing a significant positive effect of adequate vitamin D status on maintaining non-skeleton health, such as diminishing the risk of diabetes, obesity, some cancers, and other long-latency disease processes warrants further investigation in healthy growing children and adolescents.

Summary Points

- The main function of vitamin D is associated with calcium and phosphate homeostasis and skeletal integrity throughout life.
- Vitamin D status should be regarded as of universal concern.
- Vitamin D deficiency and insufficiency occur in a high proportion of growing children and adolescents worldwide.
- Risk factors attributed to vitamin D deficiency are prolonged exclusive breastfeeding of infants, lack of sunlight exposure, low intake of vitamin D and calcium, darker skin pigmentation, and living at temperate latitudes.
- Persistent severe vitamin D deficiency results in the bone disease, rickets, in children and in osteomalacia in adults.
- Adequate vitamin D status is associated with higher LBM and muscle strength levels in children and adolescents.
- Adequate vitamin D status throughout childhood and adolescence might enhance lean body physical growth and bone mass accretion, and consequently reduce the risk of osteoporotic fracture later in life.
- The beneficial effects of vitamin D status regarding many non-skeletal metabolic processes in the prevention of chronic diseases are being increasingly recognized.

Acknowledgments Sincere appreciation and gratitude are extended to Professor Dr. David Fraser, for his excellent mentorship and his sharing of critical comments and intellectual thoughts throughout the preparation of this chapter.

Chapter 82
Anthropometry of Adolescents: Brazilian Perspectives

Silvia Eloiza Priore, Renata Maria Souza Oliveira, Sylvia do Carmo Castro Franceschini, Silvia Nascimento de Freitas, and Cláudia Aparecida Marlière de Lima

Abstract Health status of Brazilian adolescents is directly affected by huge inequalities, considering the social and economic conditions they are submitted to. According to a national survey, 10% of adolescents present height-for-age deficit. The analysis of the secular trend of the nutritional profile of the group under discussion emphasizes the drop in height deficit for 30 years, although the prevalence observed is still considerable. On the other hand, there is increased prevalence of excess weight and obesity. Adolescents are in full transformation and the chronological age not always means similarity among peers. Hence, in some studies of female adolescents, the methodology includes a 1-year period after menarche to have a homogeneous sample and assure that the typical changes of adolescence influence less in the results. This methodology also enables adolescents assessed by non-medical professionals to have more specific orientations according to their sexual maturation stage. Despite the fact this methodology assesses sexual maturation close to real situation, it is known that there are limitations, mainly in males and in females who had no menarche yet.

82.1 Introduction

Adolescence is defined by the World Health Organization (WHO 2005) as the age group 10–19 years. It is a transition period between childhood and adulthood when many adult characteristics or lifestyle habits are acquired and/or consolidated.

It is characterized by intense growth and development and many morphologic and physiologic changes (WHO 2005). Among the biological alterations that better describe puberty, growth spurt, sexual maturation, and changes in body composition stand out.

In this phase, the individuals reach their peak of growth velocity, and there is no age specific for all adolescents. This stage depends on sexual maturation, and those who mature early or late achieve the velocity peak before or after the average population, respectively (Colli 1991). During adolescence, the individuals acquire approximately 25% of their final height and 50% of their definite weight (Colli 1991; Carvalho et al. 2001).

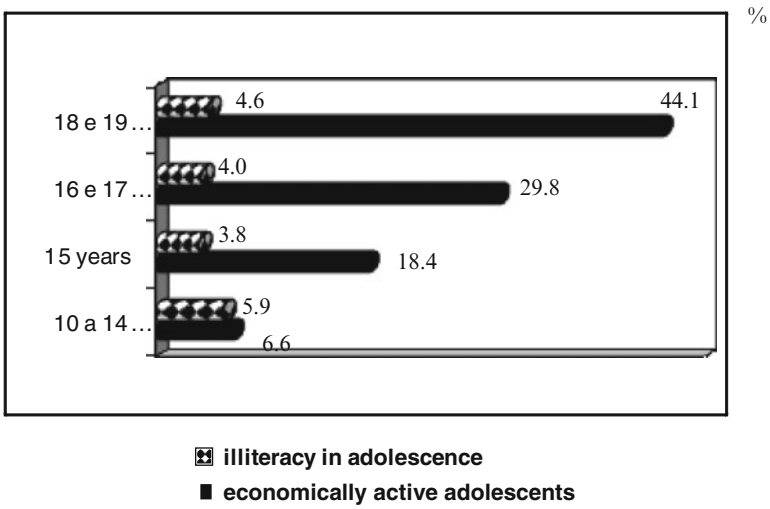
Some relevant aspects to be considered include anthropometric modifications and body composition. In both sexes, there is gain of fat and lean mass. Males, unlike females, gain more lean mass than fat tissue (Siervogel et al. 2000).

82.1.1 Brazilian Adolescents

Brazil is a country of large inequalities that influence the health status of its adolescents, who are directly affected by social and economic conditions they are submitted to.

According to the last demographic census data (IBGE 2000), 20.7% of the Brazilian population (n = 35,302,972) is aged between 10 and 20 years, of which 10,516,531 adolescents (29.7%) are economically active. Among the adolescents who have already performed any paid activity, 25% are aged under 15 years (Fig. 82.1) and 31.6% of them work over 40 h/week (IBGE 2000).

The Laws no. 8069 and 8242 guarantee the right to education of adolescents, aiming at their full development, preparing them to exercise citizenship and qualification for work, and prohibit any work for those aged under 14 years, except as apprentices (Brasil 1990, 1991).



Source: IBGE, 2000.

Fig. 82.1 Economically active and illiterate adolescents, per age group. This table list the key facts of inequalities that impact on the health status of its adolescents, who are directly affected by educational level and socioeconomic conditions (Source: IBGE 2000)

The repercussions of work in the development of adolescents may have consequences for their health. When dealing with child and adolescent work, family socioeconomic level has been repeatedly shown as the determining factor in entry into the job market. Poor families more frequently pressurize the younger members to enter the job market aiming to add to their income (Priore 1997).

The illiteracy rate is also relevant and it has been proved to influence health status. Approximately 6% of adolescents aged 10–14 years have never attended school (IBGE 2000).

There is a high prevalence (21%) of pregnancy in adolescence, according to the National Liveborn System. The Ministry of Health indicates that, regardless of information given about this issue, 45–60% of Brazilian adolescents initiate their sexual life without using any contraceptive methods (Gama et al. 2002; Brasil 2006).

82.2 Nutritional Profile

Three studies were conducted in the Brazilian population: the National Study on Family Expenses [*Estudo Nacional sobre Despesas Familiares*] – ENDEF, 1974/1975; the National Health and Nutrition Survey [*Pesquisa Nacional de Saúde e Nutrição*], at the end of the 1980s – PNSN 1989; and the Familiar Budget Survey [*Pesquisa de Orçamento Familiar*] – POF, 2002/2003 (POF 2003). These studies obtained the anthropometric indices for all age groups.

The National Health and Nutrition Survey – PNSN 1989 – demonstrated that Brazilian babies are born with height equal to or greater than Americans, but, before the age of 6 months, there is an inversion in this pattern. In 1996/1997, the National Survey on Standard of Living [*Pesquisa Nacional sobre Padrões de Vida*] – PPV, 1996/1997, carried out in two regions of the country – Northeastern (most deprived) and Southeastern (most developed) – also provided data on the nutritional status of

Minimum wage is similar – U$282
This table lists the key facts of low income in the nutritional status of adolescents and its distribution according to location of residence

the Brazilian population. Overweight in adolescents was more prevalent among females. In the Southeastern region, the prevalence of overweight ($p < 0.05$) and obesity in early adolescence ($p < 0.01$) and mean adolescence ($p < 0.05$) was also higher (POF 2003).

The most recent data on the nutritional status of the Brazilian population are described in Table 82.1.

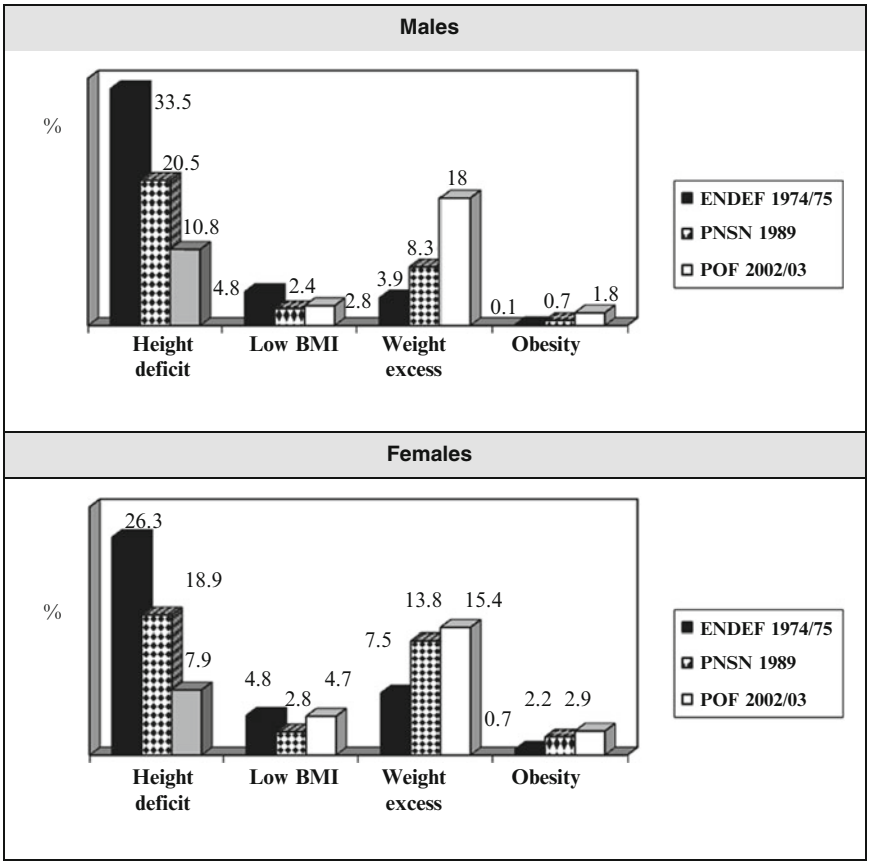
According to Table 82.1, approximately 10% of Brazilian adolescents present deficit of height for age. The frequency of height deficits is roughly threefold higher in regions with worse living conditions. Obesity among adolescents is more prevalent among females and in urban areas (POF 2003).

Table 82.2 demonstrates the influence of economic status on anthropometric indicators.

82.2.1 Secular Trend of Adolescent Nutritional Status

The secular trend of nutritional status of Brazilian adolescents is presented in Fig. 82.2.

The evolution of height-for-age deficit is characterized by a drop throughout the three Brazilian studies, although the prevalence is still higher than expected. The frequency of low-weight



Source: POF, 2003

Fig. 82.2 Secular trend of adolescent nutritional status. This figure shows, by sex, the secular trend in BMI of Brazilian adolescents, according to the three national studies that assessed the nutritional status of the group in question: Studies of Household Spending (1974/1975), National Survey of Health and Nutrition (PNSN 1989), and the Household Budget Survey (2002/2003) (Source: POF 2003)

adolescents, shown by the BMI for age, is below the expected 5%, in accordance with the cutoff point used to calculate the nutritional status, varying from 2.4% to 4.8%, regardless of sex; however, there is a different situation between the sexes – in males, the decline remains throughout 30 years (between studies), whereas, in females, the situation in 2000 is basically the same as in the 1970s. The increased prevalence of weight excess and obesity in this group is remarkable.

82.3 Application to Other Health and Disease Areas

82.3.1 Consequences of Weight Excess

The problems related to insufficient food intake are still relevant in Brazil, but health conditions resulting from weight excess deserve attention.

The scientific literature describes individuals with adequate BMI and excess fat tissue as metabolically obese normal weight (MONW). These individuals present a BMI within normal values, but have an increased risk to develop metabolic alterations, such as insulin resistance and hypercholesterolemia, indicating the important role played by fat tissue in the individual nutritional profile (Serrano 2008).

Due to increased overweight/obesity, adolescents already show metabolic alterations, such as hyperglycemia, dyslipidemia, and arterial hypertension, which are risk factors for coronary artery disease that were found only in adults in the past (Oliveira et al. 2004).

- *ARTERIAL HYPERTENSION*: It increases with aging, but the prevalence in adolescents is not negligible (Kuschnir and Mendonça 2007). In Brazil, the prevalence observed was 2.7% in children and adolescents in the State of Sao Paulo (Romaldini et al. 2004) and 6.6% in adolescents in the State of Rio Grande do Sul, which presented levels above the 95th percentile for diastolic pressure and 12.9% for systolic pressure (Barros and Victora 1999). Rosa and Ribeiro (1999) revised studies about arterial hypertension in adolescence and found evidence indicating that arterial hypertension (AH), which is more characteristic of adults, may initiate in childhood and adolescence. The authors reported that the prevalence of AH among children and adolescents is 2–3% and that increased arterial blood pressure levels in childhood and adolescence seem to be the most potent predictor of arterial hypertension in adults.
- *DIABETES MELLITUS*: The prevalence of diabetes in adolescents was lower, mainly of type 2 diabetes mellitus (DM), but, in the past two decades, there has been an increase of this disease in this age group, and the characteristics are similar to those found in adults (Gabbay et al. 2003). In Brazil, a study of adolescents aged 10–19 years found a prevalence of insulin resistance of 10.9%, in 23% of those overweight and in 43.5% of those obese (Silva et al. 2005).
- *DYSLIPIDEMIAS*: The association of obesity and dyslipidemia observed in adults has also been reported in children and adolescents. Faria et al. (2006) studied adolescents from a Brazilian city examined by the Adolescent Healthcare Program, and found that the lipid profile was inadequate in 63% and the highest percentage was for total cholesterol (47.4%); females presented higher and significant total cholesterol levels ($p = 0.009$), LDL ($p = 0.02$), and lower HDL levels ($p = 0.0009$). A study conducted by Giuliano et al. (2004) in another city in Brazil demonstrated cholesterol levels above the desired values in 28%, hypertriglyceridemia in 22%, LDL above the desirable levels in 14%, and low HDL in 5% of adolescents.
- *METABOLIC SYNDROME*: Its prevalence in childhood and adolescence varies according to the diagnostic criterion used as well as the definition adopted for cutoff points (Jessup and Harrell 2005).

In Brazil, Silva et al. (2005) studied the prevalence of metabolic syndrome and insulin resistance in adolescents. They adopted the BMI curves and arterial pressure levels adjusted to the Brazilian population; they considered as obese those with BMI > 97th percentile and as hypertensive those with systolic or diastolic blood pressure > 95th percentile. The metabolic alterations analyzed were triacylglycerols > 130 mg/dl, HDL ≤ 35 mg/dl, decreased glucose tolerance, abnormal fasting glucose, or type 2 diabetes according to the American Diabetes Association. They also included the criterion of presence of insulin resistance by the HOMA-IR (Homeostasis Model Assessment-Insulin Resistance), that is, [(fasting insulin (μU/ml) × fasting glucose [mmol/l])/22.5] > 2.5). The prevalence of metabolic syndrome according to the NCEP-ATP III (2001) was 6% in the total group of adolescents and 26.1% in the obese. Adolescents with normal BMI or overweight presented the necessary number of factors to diagnose this syndrome. Faria (2007) analyzed several criteria to classify metabolic syndrome in female adolescents who have already had menarche, and found a

prevalence of the syndrome ranging from 1% to 28%, depending on the criteria and cutoff points chosen. The WHO criterion (1998) adjusted to age group had a positive predictive value and a prevalence of metabolic syndrome of 16%.

82.3.2 Consequences in the Long Run

The major consequence of above-average nutritional status of adolescents is excess weight, which tends to persist in adult life, significantly contributing to morbidity and mortality.

According to Lamounier et al. (2000), about 50% of children who are obese at 6 months of age, and 80% of those at 5 years, will be always obese.

Aiming to investigate the influence of nutritional status in adolescence in the current nutritional situation of individuals when adults, Oliveira et al. (2009) carried out a study in Brazil with males, in three stages of life: at birth, at the end of adolescence (18 and 19 years), and at the beginning of adulthood. The BMI in adolescence related positively to weight and BMI in adulthood ($r = 0.634$; $p < 0.001$; $r = 0.678$; $p < 0.001$; respectively). The adults with metabolic syndrome presented, in adolescence, higher values for weight, waist circumference, and BMI, emphasizing the observed increased prevalence of overweight/obesity in adolescence, which corresponds to the observed rise in prevalence of metabolic syndrome in adulthood. It was concluded that adolescence, mainly at its end, seems to be very important in determining future nutritional status and health problems.

82.4 Anthropometric Indices in Post-Menarche Adolescents

With the development of secondary sexual characteristics, females have their first menstruation, called menarche (Colli 1991). It interferes with their social and psychic behavior and is biologically important. It is a landmark in the reproductive process of humans and a marker of growth. The first menstruation usually occurs between the maturation stages M3 and M4 (breasts) (Colli 1991), when adolescents continue to gain height, but growth velocity slows down, that is, when they are close to the end of spurt.

The assessment of infant–pubertal growth and development, observation of secondary sexual characteristics, and age at menarche are recommended in periodical growth evaluation (Zerwes 1993). Menarche is one of the sexual maturation indicators more often used in clinical and population practice by healthcare professionals, since it is a noninvasive method that requires no clinical examination and any professional is able to obtain this piece of information, which will help choosing the specific management (Horta 1991). Menarche has genetic and socioeconomic influences. It is found in the same group of adolescents at the same age, but with different maturation processes, demonstrating that chronological age of adolescents is not the main biologic indicator of health and nutritional status.

The variability of data regarding the first menses involves genetic characteristics and environmental influence, with complex interactions (Sedenho 1984). The literature indicates that, generally, menarche occurs between 12 and 13 years of chronological age (Crespin 1999). Data from the National Health and Nutrition Survey (PNSN 1989), a study with national representation, showed that the mean age of menarche in Brazil was 13.02 (±0.09) years (Picanço 1995).

The 1-year period after menarche as the inclusion criterion in population studies has been used to make the studied population homogeneous and to assure that hormone alterations and body composition characteristic of adolescence are not confounding variables in investigations. Moreover, adolescents who already had menarche are considered (in studies) because physicians specialized in adolescence are not always available to evaluate sexual maturation; and obtaining data based on self-assessment may have important biases. Hence, information on menarche is more reliable, enabling to have a more homogeneous population, even if it presents some differences, such as chronological age. The disadvantage is that studies are limited to females and those who are in more advanced stages of sexual maturation.

Weight and height are utilized to calculate the body mass index (BMI), waist circumference (WC), hip circumference (HC), and skinfolds, among other measurements. The anthropometric and body composition indices used in Brazilian studies on adolescents 1 year after a menarche are described in Chart 82.1.

Table 82.3 briefly describes some Brazilian studies on adolescents and 1-year period after a menarche.

Chart 82.1 Measures and body composition or anthropometric indices

Measurements and body composition or anthropometric indices	Description
Mid-arm circumference (MUAC)	Midway between the tip of the acromion process of the scapula and olecranon process of the ulna in the right arm
Umbilical circumference (UmC)	Measured under the navel
Leg length (LL)	Measured with the adolescent seating on a bench previously measured. The LL is the difference between the total height and the trunk-cephalic height (TCH).
Sagittal abdominal diameter	It corresponds to the distance between the back and the abdomen.
Coronal diameter	It corresponds to the distance between the iliac crests.
Trunk–cephalic height (TCH)	Height of a seated adolescent, in a bench previously measured. The bench height is then subtracted.
Central (CFM) and peripheral (PFM) fat mass	CFM: sum of central skinfolds (SSF + PSC) PFM: sum of peripheral skinfolds (TSF + BSF)
Central skinfold/fourfold sum ratio – ∑4P (CFM/∑4P)	It is calculated by adding up the central skinfolds (SSF + PSC) and dividing by the sum of four folds (SSF + SISF + BSF + TSF).
Central skinfold/peripheral skinfold ratio (CFM/PFM)	It is calculated by adding up the central skinfolds (SSF + PSC) and dividing by the sum of peripheral folds (TSF + BSF).
Conicity index (CI)	It is calculated using the formula: $CI = \frac{\text{umbilical circumference}}{(0.09)\sqrt{\text{weight / height}}}$
Fat body mass index (FBMI)	Ratio between body fat and squared height
Lean body mass index (LBMI)	Ratio between lean mass (LM) and squared height
Waist-to-hip ratio (WHR)	Ratio between WC and HC measurements
Waist-to-thigh ratio (WTR)	Ratio between UmC and thigh circumference (measured 3 cm above the patella)
Trunk cephalic height to height ratio (TCH/height)	It is calculated by dividing the TCH by height.

This table list the key facts used to assess the nutritional status of adolescents
MUAC mid upper-arm circumference; *LL* leg length; *UmC* umbilical circumference; *TCH* trunk–cephalic height; *CFM* central fat mass; *CI* conicity index; *FBMI* fat body mass index; *LBMI* lean body mass index; *BSF* bicipital skinfold; *SSF* subscapular skinfold; *SISF* suprailiac skinfold; *TSF* tricipital skinfold; *PFM* peripheral fat mass; *WTR* waist-to-thigh ratio; *WHR* waist-to-hip ratio

Table 82.3 Description of Brazilian studies using the 1-year period after menarche as inclusion criterion to investigate adolescents

References	Site	Sample	Objective	Results
Vieira et al. (2003a)	Viçosa-MG	*120 adolescents* One year after menarche *Study group (CFM)*: 60 adolescents with normal BMI (percentile 5–85) and with body fat percentage >25% *Comparison group*: 60 adolescents with normal BMI (percentile 5–85) and with normal body fat percentage	To study sociocultural nutritional variables and lifestyle habits of adolescents with elevated body fat	The study group presented higher weight, WC, HC, F in kg and BMI values It demonstrated the importance of assessing detailed body composition of adolescents with normal BMI and not only the BMI
Vieira et al. (2003b)	Viçosa-MG	*80 adolescents* One year after menarche *Study group (CFM)*: 40 adolescents with height deficit < percentile 5 *Comparison group*: 40 adolescents with normal height ≥ percentile 50	To identify the factors associated to low height in adolescents	The low height group presented lower HC ($p < 0.05$). No results indicated that CFM presented weight excess or central body fat
Faria et al. (2007)	Viçosa-MG	*100 adolescents* One year after menarche	To study the criteria for diagnosis of metabolic syndrome in adolescents	6% of adolescents presented BMI > percentile 85, 61% had high body fat percentage The prevalence of the syndrome varied from 1% to 28%, depending on criteria and cutoff points used

Referência	Local	Casuística	Objetivo	Resultados
Pereira et al. (2008)	Viçosa-MG	113 adolescents One year after menarche *Study group (CFM)*: 38 adolescents with normal BMI (percentile 5–85) and high body fat percentage (>25%) *Comparison group 1 (GC1)*: 40 adolescents with normal BMI (percentile 5–85) and normal percentage of body fat *Comparison group 2 (GC2)*: 35 adolescents with BMI > percentile 95 and percentage of body fat >25%	To verify the association of body fat measurement sites and cardiovascular risk factors in adolescents	Results demonstrated the relevance of body fat measurement sites in adolescence; among them, waist circumference and waist-to-height ratio were the best predictors of the risk of diseases in the population studied.

Serrano et al. (2008)	Viçosa-MG	113 adolescents One year after menarche *Study group (CFM)*: 38 adolescents with normal BMI (percentile 5–85) and high body fat percentage (>25%) *Comparison group 1 (GC1)*: 40 adolescents with normal BMI (percentile 5–85) and normal percentage of body fat *Comparison group 2 (GC2)*: 35 adolescents with BMI > percentile 95 and percentage of body fat >25%	To study the interference of body fat with risk factors for cardiovascular diseases in female adolescents	The group of adolescents with adequate BMI and high adiposity presented blood pressure, HDL fraction, and glucose levels similar to adolescents with BMI > percentile 95
Carvalho et al. (2008)	Viçosa-MG	113 adolescents One year after menarche *Study group (CFM)*: 38 adolescents of normal BMI (percentile 5–85) and high body fat percentage (>25%) *Comparison group 1 (GC1)*: 40 adolescents with normal BMI (percentile 5–85) and normal percentage of body fat *Comparison group 2 (GC2)*: 35 adolescents with BMI > percentile 95 and percentage of body fat >25%	To assess the metabolic profile of adolescents with overweight, "weight normal metabolically obese" and of adolescents with overweight resistant to insulin	Adolescents metabolically obese and with normal weight presented metabolic and inflammatory profile and body composition similar to those overweight.

This table lists the key facts of nutritional assessment of adolescents according to 1 year or more of menarche
WC circumference of the waist; *HC* circumference of the hip; *Gor kg* gordura in kg; BMI body mass index

82.5 Final Considerations

Evaluating adolescents demands a broad-range knowledge since they are in a stage of total transformation. It is important to search for more detailed information to understand the biopsychosocial aspects of this group since chronological age is not the most relevant indicator to make up a homogeneous sample. To assess females who already had menarche enables homogenization, but it is not possible to extrapolate such data to male or adolescents who presented no menarche.

Summary Points

- *Introduction: Brazilian adolescents*: Adolescence is defined by the World Health Organization (WHO) (2005) as the age group 10–19 years. It is a transition period between childhood and adulthood when many adult characteristics or lifestyle habits are acquired and/or consolidated.
- *Nutritional profile: secular trend of nutritional status of adolescents*: Brazil is a country with large inequalities that impact on the health status of its adolescents, who are directly affected by social and economic conditions.
- *Application to other health and disease areas: consequences of weight excess*: The problems related to insufficient food intake are still relevant in Brazil, but health conditions resulting from weight excess deserve attention.
- *Age of menarche in adolescents*: Data from the National Health and Nutrition Survey (PNSN 1989), a study with national representation, showed the mean age of menarche in Brazil was 13.02 (±0.09) years, and
- *National Health and Nutrition Examination Survey*: The National Health and Nutrition Examination Survey (NHANES) is a program of studies designed to assess the health and nutritional status of adults and children in USA. The survey is unique in that it combines interviews and physical examinations.
- *Studies that used in their methodologies adolescents 1 year after menarche. Final considerations*: Evaluation of adolescents demands a broad-range knowledge because they are in a stage of total transformation. It is important to search for more detailed information to understand the biopsychosocial aspects of this group to measure their nutritional status.
- *Trunk-cephalicheight*: To implement this measure, an individual should be seated with the trunk at an angle of 90° with the legs. The height is then measured, of the outcome subtracting this result the height of the seat.

Key Points

Figure 82.1 – Key features of adolescents who have already performed any paid activity and educational level.

1. According to the last demographic census data, 20.7% of the Brazilian population ($n = 35{,}302{,}972$) is aged 10–20 years, of which 10,516,531 adolescents (29.7%) are economically active. Among the adolescents who have already performed any paid activity, 25% are aged under 15 years, and 31.6% of them work over 40 h/week.
2. Approximately 6% of adolescents aged 10–14 years have never attended school.

Table 82.1 – Key features of nutritional assessment using anthropometric indicators such as: height deficit, body mass index, weight excess, and obesity and its distribution in rural areas and urban areas in Brazil.

1. Use of indicators according to sex, to assess its distribution in rural areas and urban areas.
2. Body mass index (BMI) is a measurement of the relative percentages of fat and muscle mass in the human body, in which weight in kilograms is divided by height in meters and the result used as an index of obesity.

Table 82.2 Key features of influence of income on the nutritional status of adolescents.

1. The poverty threshold, or poverty line, is the minimum level of income deemed necessary to achieve an adequate standard of living in a given country.
2. It is a situation where the per capita income is equivalent to less than 1 international dollar per day
3. The use of index height/age was used to classify the adolescents with height deficit.

Chart 82.1 – Key features of measures of body composition and anthropometric indices to assess nutritional status in adolescents.

1. There are several measurements and body composition or anthropometric indices used to assess nutritional status in adolescents.

Table 82.3 – Key features of three studies using the 1-year period after menarche as inclusion criterion to investigate adolescents.

1. Results of six studies developed with adolescents in Viçosa, Minas Gerais state.

Chapter 83
Anthropometric Indices for Obesity and Hypertension in Indian Affluent Adolescents

Shobha Rao

Abstract Childhood obesity and its health consequences have been attracting more attention in view of the increasing prevalence worldwide and the long term effects of obesity in adults. Earlier, anthropometric indices of obesity were recommended based on their correlation with body fat percent. However, in view of the fact that increasing body fatness is positively associated with blood pressure and other cardiovascular disease risk factors in adolescents, the choice of a cut off for anthropometric indicator should be based on health related criteria. Review of childhood obesity indicates that criteria used for assessing obesity in adolescents varied greatly. Nevertheless, it indicates that despite potential problems with body mass index (BMI), it still remains to be a popular indicator for estimating obesity in adolescents. One of the major limitations of BMI is however, that it does not perform well as a surrogate major of adiposity among thinner children thus affecting its validity in populations where prior undernutrition exists. The need for anthropometric indices for assessing total body fat or its distribution in large population studies is even more, in view of the fact that the existing equipment like Dual X-ray Absorptiometry (DXA) are not affordable and have limited ability outside the research setting. The chapter therefore describes benefits and limitations of different skinfolds and circumferences with the help of the data collected on urban affluent adolescents from Pune, India. It is worthwhile to mention that there is no uniform definition of assessment of overweight and obesity in adolescents and that any index will not fully characterize the impact of body fat patterning on metabolism. In fact, there are recently no guidelines for the classification of obesity related health risks among adolescents. The chapter thus highlights the need for examining the concordance between various indicators used for assessing obesity in adolescents, need for using national BMI reference data and developing cut offs anchored to metabolic risks and validating such indicators across different populations.

83.1 Introduction

Obesity in adolescents is a major public health problem in developed countries and in some parts of developing countries too. It is a growing nutritional concern in countries that are witnessing nutritional transition (Popkin et al. 2001). Obesity's persistence into adulthood, its resistance to treatment, and its health consequences make it critical to understand adiposity in adolescents.

Obesity in adults is known to be a major risk factor for many noncommunicable diseases and especially for cardiovascular disorders. Childhood obesity too has important health consequences for adolescents and is a major antecedent of adult obesity (Popkin and Udry 1998). Persistence of childhood obesity into adulthood has been shown by several studies (Woelk 1994; Bao et al. 1995). Guo et al. (1994) have shown that overweight during childhood, especially beyond 8 years, is an important risk factor for overweight at the age of 35 years. Second, childhood obesity carries important health and social implications. Several epidemiological studies support the hypothesis that the relationship between adiposity and risk of disease begins early in life (Owens et al. 1998; Goran and Gower 1999).

Association between obesity and hypertension in adolescents has been reported in numerous studies among a variety of ethnic and racial groups with virtually all studies finding higher BP and/or higher prevalence of hypertension in obese compared with lean children (Sorof and Daniels 2002). Bogalusa Heart Study revealed that the prevalence of clinically diagnosed hypertension was significantly higher in adult subjects whose childhood BP was in the top quintile. These studies provide ample evidence for the fact that hypertension in adults has its onset in childhood which has caused growing concern with monitoring arterial blood pressure in adolescents in the last few decades. Understanding predictors of BP in adolescents is therefore important because childhood BP has been shown to track in adulthood. Further, obesity in adolescents not only is associated with hypertension and abnormal lipid profile but also shows clustering of risk factors for cardiovascular disease (Chu et al. 1998). Therefore, its prevention in childhood may help in preventing severe disease conditions in later years. This chapter attempts to discuss relative importance of various anthropometric indicators used for assessing adiposity, their limitations, caution in their interpretation, and their association with risk of hypertension in young Indian adolescents (place for key features).

83.2 Assessment of Obesity in Adolescents

The increasing prevalence of childhood obesity and its concomitant health risks justify widespread efforts toward its prevention. Reported studies show large variation in criteria used to assess obesity in adolescents (Dietz and Bellizzi 1999). There is no uniform definition and an indicator for assessment of overweight or obesity in children (Mast et al. 2002). Although DXA or other techniques such as densitometry, magnetic resonance imaging (MRI), and total body water offer reasonably accurate estimates of adiposity, they have limitations to research setting because of their complexity. Various researchers have proposed several anthropometric parameters but ideal measures of body fat in populations should be reliable and should correlate well with body fat in both sexes and across all ages and ethnic groups.

83.2.1 Body Mass Index (BMI)

Knowledge of the characteristic of adolescents who become obese is a matter of public health importance because it may aid both in identifying high-risk adolescents and in targeting primary preventive strategy. Because of lack of simple and accurate methods for assessing body fat directly, anthropometric indices are often used as surrogates for body compositions. BMI defined as a ratio of weight (kg) to height^2 (mt) offers a reasonable measure of fatness in children and adolescents and is widely used because of relative ease and accuracy of basic measurements. For assessing prevalence of 'at risk of overweight' adolescents, the conventional cut off for BMI (age and sex specific) above the 85th percentile (Must et al. 1991) can be used while that for 'obese' above the 95th percentile is considered. Similarly, age-sex specific cut-offs for BMI developed by Cole et al. (2000) are also used to define overweight/obese adolescents. However, these cut-offs are linked with adult cut-offs and extrapolated to childhood as proposed at the International Obesity Task Force (IOTF) meeting in 1997.

83.2.1.1 Limitations of BMI

Although BMI is used as a surrogate measure of adiposity, it is a measure of excess weight relative to height rather than excess body fat and is not without limitations. The foremost among these is the fact that almost all reported data pertain to adolescents from Europe or North America and therefore validation studies in other populations are needed (Dietz and Bellizzi 1999). There is need for an indicator that has acceptability across broad range of populations, because ethnic variation in relative subcutaneous fat distribution and in relative proportion of the trunk and the lower extremities to height are potential confounding factors in use of BMI as an index of adiposity.

Second, interpretation of BMI among adolescents is complicated by the changes that occur in weight, height, and body composition during growth, especially timing and tempo of adolescent growth spurt and sexual maturation may be an additional concern in the interpretation of BMI (Malina and Katzmarzyk 1999). The limitations of BMI as a measure of adiposity in the pediatric population are therefore believed to be larger than those in adult population. Further, it has been shown that it does not perform well as a surrogate measure among thinner adolescents, thus affecting the validity of BMI in populations where prior undernutrition exist (Freedman et al. 2005). Additional studies in undernourished populations are therefore required to show whether increase in weight for height is attributable to increase in body fat. Limitations of BMI are further underscored by the fact that it has high specificity and variable sensitivity in adolescents. Ideally, when designing an obesity screening program the choice

of cut-off should be based on health-related criteria. (Sardinha et al. 1999), because, in Indian adolescents, cut-offs for health risks especially that for high blood pressure are observed to be much lower than the conventional ones used for defining overweight (Rao et al. 2007). Recommendations such as IOTF are made despite the fact that the reference has not been thoroughly evaluated in terms of screening ability and relation to morbidity and mortality (Neovius et al. 2004).

83.2.2 Body Fat (%)

Excess body fat is the hallmark of obesity. DXA has the advantage of direct measurement of fat and lean tissue mass and the ability to evaluate the differences in fat deposition by region (Danials et al. 1999). However, such accurate methods used to assess total body fat and body fat distribution (computed tomography and magnetic resonance imaging) in humans are not suitable for large population studies because of cost, radiation exposure, and limited availability outside the research setting. Equipments based on the principle of bioelectrical impedance analysis (BIA) are often used for assessment of fat mass (FM) in field studies. However, the equations it uses for estimating FM are population specific and therefore may not be valid for other populations. In fact, it has been reported that different prediction formulas suffer from systematic over- or underestimations of %FM in adolescents and, therefore, development of a specific algorithm derived within the study population and validated against a so-called 'gold-standard' (i.e., densitometry) is preferable (Mast et al. 2002). The conventional cut-off as defined by Williams et al. (1992) for estimating prevalence of overweight in adolescents, using body fat (%), is above 25% for boys and above 30% for girls.

83.3 Body Fat Distribution

Skinfolds: In view of the lack of simple, accurate methods for assessing body fat directly, anthropometric indices are often used as surrogates for body composition. Simple skinfold measurement at various sites are often preferred as an alternative to sophisticated equipments for estimating body fat distribution, in field studies. Measurement of subcutaneous layer of fat, namely skinfold, is an easy method of assessing % body fat in adolescents. Conventionally, skinfolds are measured at four (biceps, triceps, subscapular, and suprailliac) to seven different places (additionally at chest, abdomen, and thigh) in humans and are used in isolation or in combination. Prediction of body fat % from skinfold thickness is an acceptable method for assessment of body composition in children and adolescents.

One of the limitations of these measures is that the measurements are subject to large between and within variabilities due to observer bias and, therefore, inter-observer variability (IOV) assessment studies are essential. Further, although skinfolds are shown to be correlated well with body density, the correlation is low in younger adolescents (Deurenberg et al. 1990). Due to changing subcutaneous tissue distribution during maturation, the relations between skinfolds and body density (and hence body fat) could be dependent on biological age, which could hamper assumptions of % body fat by skinfolds.

83.3.1 Skinfold at Triceps

It is reasonably well correlated with body fat and offers best results for assessing and screening obesity in adolescents regardless of disproportionate distribution of adipose tissue in various part of the

Table 83.1 Concordance between various indicators of assessing overweight in urban affluent Indian adolescents (Source: Rao and Apte 2008)

Indicator	No. of adolescents overweight	Adolescents who were also overweight by			
		BMI > 85th percentile *n* (%)	BMI (IOTF) *n* (%)	TSFT > 85th percentile *n* (%)	Body fat%© *n* (%)
Boys					
BMI > 85th Kappa value	315	–	283(89.8) 0.928**	126(40.0) 0.475**	305(97.1) 0.461**
BMI (IOTF) Kappa value	283	283(100.0)	–	124(43.8) 0.518**	277(98.2) 0.423**
TSFT > 85th Kappa value	134	126(94.0)	124(92.5)	–	132(98.5) 0.198**
Body fat%	615	305(49.6)	277(45.0)	132(21.5)	–
Girls					
BMI > 85th Kappa value	220	–	217(98.6) 0.978**	69(31.4) 0.392**	203(92.3) 0.719**
BMI (IOTF) Kappa value	221	217(98.2)	–	70(31.7) 0.396**	207(93.7) 0.739**
TSFT > 85th Kappa value	79	69(87.3)	70(88.6)	–	77(97.5) 0.327**
Body fat%	294	203(69.0)	207(70.4)	77(26.2)	–

This table examines concordance between four different indicators (BMI, IOTF, TSFT, and body fat) used for assessing overweight in adolescents, gives Kappa values indicating the strength of concordance and its statistical significance. There is a good concordance between the indicators BMI, IOTF cut–off, and body fat, while TSFT shows poor concordance with these indicators

BMI Body mass index, *TSFT* Skinfold thickness at tricep, *IOTF* International obesity task force cut-off

**$p < 0.000$, © Using CDC cutoffs – by McCarthy (2006)

body (Kapoor et al. 1991), but has large variability in measuring fatter subjects (Dietz and Bellizzi 1999). The cut-off used for skinfold at triceps for defining overweight is often same as that of BMI, that is, above the 85th percentile given by Must et al. (1991). Observation shows that combination of BMI and skinfold at triceps would also be important to assess the pattern of adipose tissue in adolescents (Sarria et al. 1998). However, it may be mentioned here that in the case of Indian adolescents the prevalence of overweight was highest using body fat percent cut-offs and was lowest based on triceps cut-off (Rao and Apte 2008) and triceps showed the poorest concordance with conventional indicators of assessing adiposity (Table 83.1). Similar observations are reported by Malina and Katzmarzyk (1999) for data from six different study groups.

83.3.2 Subscapular Skinfold

The other important measure is subscapular skinfold and is considered to represent centrally located body fat. However, unlike triceps skinfold, there are no cut-offs or standards defined for subscapular and other skinfolds that can be used for assessing obesity. Nevertheless, researchers have used the combinations of skinfolds and have also used them in combination with BMI to study the associations with adiposity and health risks in adolescents.

The observations from Bogalusa Heart Study show that centrally located body fat (subscapular skinfold) is independently correlated with blood pressure even after controlling for triceps skinfold. As subscapular skinfold increased, mean SBP increased, and the difference in mean SBP among adolescents in its lowest and highest quartile was of 8.5 mmHg (Shear et al. 1987). By contrast, no independent association was observed between peripheral fat (as measured by triceps skinfold) and blood pressure. The relationship was stronger in younger subjects and in males. More accurate measurement of trunkal fat recorded in this study using DXA (four regions considered for measurement were subscapular, waist, hip, and thigh) have shown positive association with triglycerides and negative with

Table 83.2 Correlation of skinfolds and circumferences with indicators of adiposity and SBP in urban affluent Indian adolescent boys

Indicators	BMI	Body fat†	Systolic BP
BMI	–	0.714**	0.145**
Triceps	0.754**	0.717**	0.191**
Biceps	0.708**	0.701**	0.167**
Subscapular	0.808**	0.650**	0.228**
Suprailiac	0.785**	0.629**	0.193**
Sum of all skinfolds	0.836**	0.721**	0.216**
Peripheral adiposity (triceps + biceps)	0.763**	0.735**	0.188**
Central adiposity (Suprailiac+subscapular)	0.825**	0.663**	0.218**
Waist circumference	0.903**	0.603**	0.359**
Hip circumference	0.857**	0.435**	0.386**
Waist to Hip ratio	0.250**	0.404**	0.031

This table illustrates correlation of BMI and body fat with different skinfolds, circumferences, and waist–hip ratio. Correlations of all the skinfolds were high and significant with conventional indicators of adiposity, that is, BMI and body fat and all these indicators also show significant correlations with systolic blood pressure

BMI Body mass index, *BP* Blood pressure

†Body fat estimated using OMRAN-HBF-300

**$p < 0.01$

high-density lipoprotein (HDL) cholesterol levels, indicating that relative preponderance of fat in the upper body including abdominal fat is an important determinant of cardiovascular risk factor status in adolescents (Daniels et al. 1999). It is, however, worthwhile to mention that methods used to estimate fat distribution (skinfolds and DXA) do not specifically measure the visceral fat depot.

Combinations of skinfolds as sum of two, defining central adiposity (subscapular and suprailiac) versus peripheral adiposity (triceps and biceps) or sum of all four and their different combinations have also been considered. In our study on urban affluent adolescents from Pune, India, it was observed that all the skinfolds are well correlated with adiposity indicators, that is, BMI and body fat percent (Table 83.2), yet the prevalence estimates of overweight based on them differ significantly from those based on either BMI or body fat (Table 83.1). Thus, the skinfolds represent mainly fat distribution, which is known to differ greatly for a given BMI. Further, all these indicators have lower correlations with health risks, for example, systolic blood pressure.

83.4 Circumferences

Recent studies in adolescents showed that a greater deposition of central fat is correlated with less favorable patterns of serum lipoprotein concentrations and blood pressure. Although early identification of adolescents with high central adiposity is important, studies on efficacy of anthropometric techniques for this purpose are scarce (Fox et al. 1993; Goran et al. 1998).

83.4.1 Waist Circumference (WC)

Whereas BMI is thought to be an indicator of overall adiposity, WC has been advocated as an indicator of abdominal fat content. Among the different circumferences considered in our study on urban affluent adolescents, WC correlated well with body fat and BMI (Table 83.2). However, there is a

Table 83.3 Age-specific WC percentile values reported for adolescent boys from various countries in comparison to urban affluent Indian adolescent boys

	Present study

15+	146	77.19	79.26	85.2	95.9	81.1	79.0	79.6

Source: [a]Katzmarzyk (2004); [b]Li et al. (2006); [c]Nihal et al. (2008); [d]McCarthy et al. (2001); [e]Sung et al. (2008)
This table compares 90th percentile values for waist circumference of affluent adolescents from India with those reported for Canada, US, Turkey, UK, and Hong Kong population. Although BMI for Indian adolescents is known to be lower compared to those from developed countries, it is interesting to note that the 90th percentile values for WC are in fact higher. WC- Waist circumference

dearth of information on the clinical utility of WC in addressing obesity-related health risk among adolescents and no guidelines are available for the classification of obesity-related health risks using WC. Despite increasing interest in the measurement of regional fat distribution, commonly accepted cut-offs for classifying subjects with high central adiposity do not yet exist with any assessment method (Taylor et al. 2000). Nevertheless, studies have examined the risk cut-offs for WC using receiver operating characteristic (ROC) analysis. ROC analysis is a way of evaluating the accuracy of a diagnostic test by summarizing the potential of the test to discriminate between the absence and presence of a health condition. In the case of 10–14-year-old adolescents from Cyprus, WC cut-off of 'above the 75th percentile' predicted high blood pressure, high cholesterol, high LDL (low-density lipoprotein) cholesterol, and high triglycerides (Katzmarzyk et al. 2004), while the cut-off for clustering of risk factors in adolescents was observed to be above the 90th percentile (Maffeis et al. 2001).

Clearly, studies are required to determine whether WC also performs well as an index of central adiposity in adolescents from different populations. Despite large differences in BMI and body fat percent in populations of developed and developing countries, it is interesting to note that 90th percentile values for WC observed in urban affluent Indian adolescents are closer to those reported for Canadian adolescents and in fact higher compared to UK adolescents (Table 83.3). The prevalence of overweight based on triceps skinfold is lowest and that based on body fat percent is highest in Indian adolescents indicates that, for a given BMI, adolescents have relatively higher body fat, not deposited at triceps but perhaps at abdomen, the observation well documented in the case of Indian adolescents. The relatively higher 90th percentile values of WC in urban Indian adolescents support this postulation. Far less is known about the combined influence of BMI and WC on health outcomes among adolescents. BMI and WC change during normal growth and maturation, at times rapidly; therefore, age-specific cut-off points are needed to classify adiposity status among adolescents (Janssen et al. 2005).

Use of other circumferences (abdomen, hip, thigh, etc.) have been reported in literature but in our study hip circumference showed low correlation with body fat (Table 83.2). Therefore, ratios based on them such as waist–hip ratio (WHR) or waist-to-height ratio are also considered for identifying central obesity or health risks but evidence is scarce. Among these, WHR has been explored to some extent but it can be seen that its correlation with BMI and body fat percent was lowest compared to WC (Table 83.2). It is therefore felt that ratios may not be appropriate because they are highly age dependent (Power et al. 1997) and may obscure stronger relations that may be present with separate circumference measurements.

83.5 Hypertension in Adolescents

Childhood blood pressure is related to adult levels and together with changes in BMI is a significant predictor of adult blood pressure. As the pathological process of atherosclerosis and essential hypertension begins in childhood and as obesity is related to both blood pressure and lipid levels in adolescents, the setting of cardiovascular disease (CVD) in adults is possibly accelerated with the mature obesity and fat deposition in adolescents (Shear et al. 1987).

Comparative data on blood pressure among adolescents from different populations indicate that South Asian adolescents have higher body mass adjusted blood pressure levels than white adolescents in US. Ethnic differences in blood pressure trajectories persisted after adjusting for socioeconomic status or growth or adiposity in both males and females (Dekkers et al. 2002). Therefore, targeting intervention in adolescents may be a critical opportunity for preventing ethnic differences in BP in later life.

Blood pressure variation is so closely associated with growth that these factors must be taken into account when assessing blood pressure in childhood and adolescents. The more recent update from Task Force on Hypertension Control in Children and Adolescents has provided population-based percentiles for blood pressure values in children adjusted for age, sex, and height. Values that exceed the 90th and 95th percentiles are defined as 'high normal' blood pressure and 'hypertension', respectively. Thus, identification of blood pressure threshold for hypertension in a child first requires determination of height percentile followed by interpretation of a dense table of blood pressure values with a separate threshold for each combination of gender, age, and height percentile (Update on the 1987 Task Force Report, National High Blood Pressure Education Program 1996).

83.5.1 Adiposity Indicators and Risk of Hypertension

Several epidemiological studies support the hypothesis that the relationship between adiposity and risk of disease begins early in life. Therefore, it is necessary that the choice of cut-off for obesity screening indicator should be based on health-related criteria. One of the criteria suggested (Kraemer et al. 1990) for choosing a measure of adiposity is a clinical validity, that is, ability to predict morbidity. The data on Indian urban affluent adolescents show that higher adiposity using any indicator is associated with higher systolic blood pressure (Fig. 83.1). It can be seen that the prevalence of high systolic blood pressure (HSBP) is almost similar when skinfolds are used either individually or as sum of two or four skinfolds. Similarly, the prevalence of HSBP and high diastolic blood pressure (HDBP) when examined (Fig. 83.2) in relation to percentiles of WC (age adjusted) show sudden increase in the prevalence beyond the 85th percentile, indicating that WC can also predict the risk of high blood pressure. It is however beyond doubt that the different indicators need to be compared for their potential to discriminate the health risks (i.e., HSBP) associated with adiposity. The correlations of different skinfolds and their combinations with systolic blood pressure were identical but were higher in younger age groups. It has been attributed to a greater detrimental effect of adipocyte hyperplasia, which occurs during youth versus adipocyte hypertrophy that occurs later in life (Hirsch et al. 1966).

In view of the fact that correlation analysis is blind to systematic bias and cannot describe the nature and magnitude of mis-classification, sensitivity and specificity of these indicators using ROC analysis have been studied by few researchers (Sardinha et al. 1999; Rao and Apte 2008). These studies have indicated that conventional cut-offs (IOTF, WHO, etc.) are highly specific but

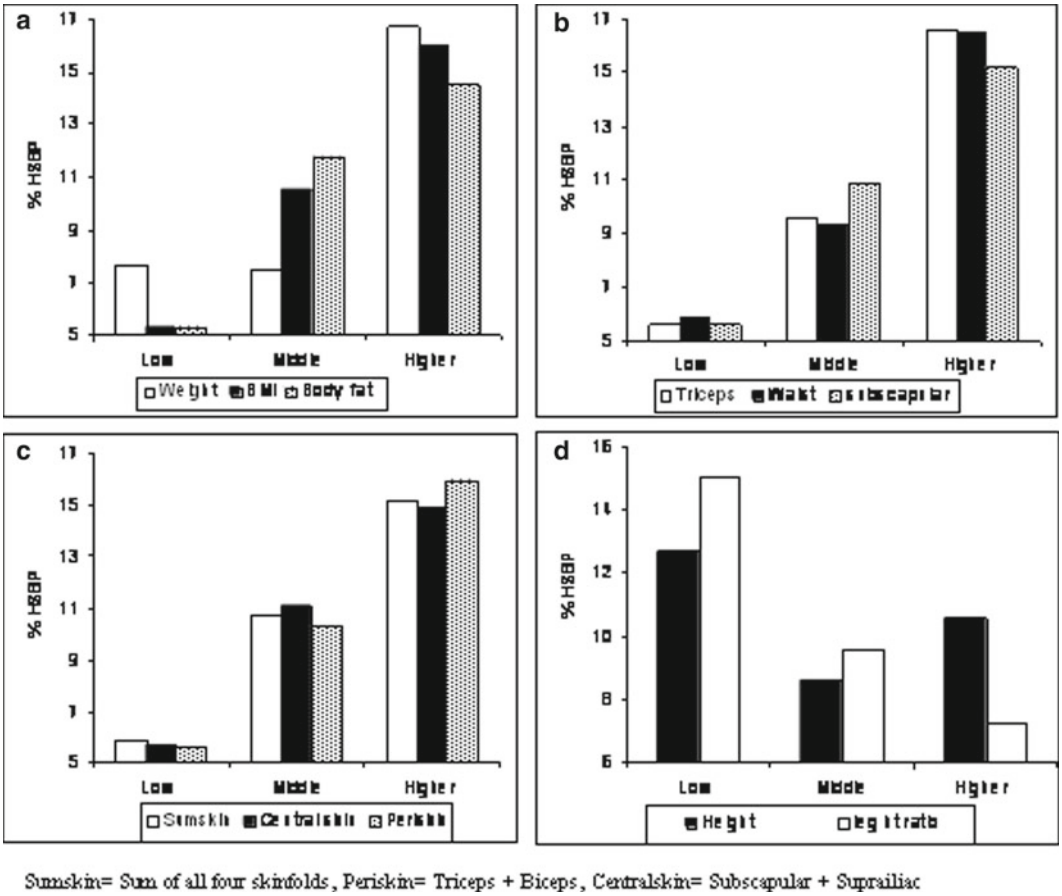

Fig. 83.1 Prevalence (%) of HSBP among urban affluent Indian adolescent boys according to (**a**) tertiles of Weight, BMI and body fat or (**b**) tertiles of triceps, subscapular and waist circumference or (**c**) tertiles of sumskin, central skin and periskin or (**d**) tertiles of height and leg height ratio. The prevalence of HSBP is almost similar when skinfolds are used either individually or as sum of two or four skinfolds. The adiposity thus showed positive association while leg height ratio showed inverse association with higher systolic blood pressure. *Sumskin* Sum of all four skinfolds, *Periskin* Triceps + Biceps; *Centralskin* Subscapular + Suprailiac

have low sensitivity. In the case of Indian adolescents, the ROC cut-offs for BMI improved the sensitivity of the indicators but they were much lower compared to conventional cut-offs and highlight ethnic variations in body composition (Table 83.4). Clearly, diagnostic demands intended for a clinical practice are different from those needed for public health use or monitoring. The implication is that there is a need for population-specific customized classification systems for assessing obesity in view of the probable population differences in relative risks of noncommunicable adult diseases.

83.5.2 Poor Skeletal Growth and Risk of Hypertension

Although adiposity is a major factor that confers risk for increased blood pressure in adolescents, there is a growing interest in investigating developmental origins for hypertension. One

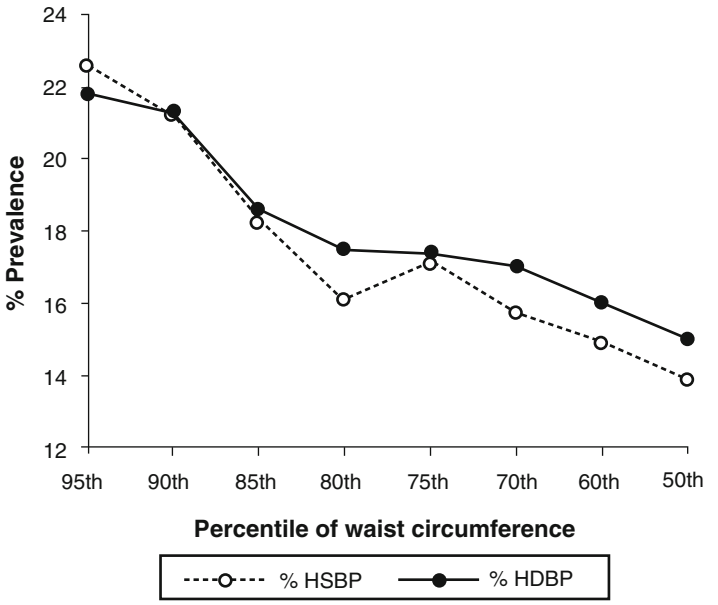

Fig. 83.2 Prevalence (%) of HSBP/HDBP above different percentiles for waist circumference. Prevalence of both HSBP and HDBP increased significantly 85th percentile among urban affluent Indian adolescents. *HSBP* high systolic blood pressure; *HDBP* high diastolic blood pressure

HSBP -high systolic blood pressure, HDBP - high diastolic blood pressure

Table 83.4 Predictive features for risk of high SBP for various indicators using conventional cut-offs as well as ROC cut-offs for urban affluent Indian adolescents

	Conventional			ROC		
Variable	Cutoff	Sensitivity (%)	Specificity (%)	Cutoff	Sensitivity (%)	Specificity (%)
Boys						
BMI	>85th 21.0	58.3	76.1	19.7	74.2	65.1
	(IOTF) 21.4	55.8	79.0			
TSFT	>85th 17.1	30.8	90.6	10.1	67.5	64.9
Body fat	>85th 22.4	73.3	48.6	23.8	66.9	60.1
Girls						
BMI	>85th 22.5	64.4	83.4	21.2	75.3	74.6
	(IOTF) 22.7	64.4	83.3			
TSFT	>85th 21.7	31.7	95.0	14.5	71.3	68.8
Body fat	>85th 29.2	72.1	76.4	28.4	74.0	72.6

This table gives the sensitivity and specificity of conventional cut offs of BMI, TSFT and body fat for predicting risk of high systolic blood pressure. Further it shows that the cut offs for these indicators obtained by the ROC technique had higher sensitivity and that they were lower than the conventional cut offs in case of Indian adolescents
BMI Body mass index, *TSFT* Skinfold thickness at tricep, *ROC* Receiver operating characteristics

of the potential areas that needs attention is the early life growth retardation. It is interesting to note that though South East Asian children were shorter and weighed less than Blacks and Whites, they had greater mean systolic blood pressure than Blacks and Whites across all weight strata (Munger et al. 1991). Similarly, high diastolic blood pressure has been reported in the case of adolescents from India, Pakistan, and Bangladesh by several researchers (Agyemang et al. 2004; Harding et al. 2006; Rao and Apte 2009). It is believed that poor childhood height growth may be associated with adult systolic blood pressure through socially patterned factors such as early nutrition, infection, or stress (Hardy et al. 2004). Further, these factors may,

Table 83.5 Odds Ratio (OR) for HSBP and HDBP by tertiles of various components of height among urban affluent Indian adolescent girls

		LSE				HSE			
		HSBP		HDBP		HSBP		HDBP	
		Adjusted for[a]		Adjusted for[a]		Adjusted for[a]		Adjusted for[a]	
Variable	Tertile	BMI	BF	BMI	BF	BMI	BF	BMI	BF
Leg Ht	L	2.05	2.59	1.43	1.56	1.77	1.94	2.62	2.85
	M	1.18	1.24	1.33	1.39	0.86	0.88	2.26	2.33
	H	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
Leg Ht	L	1.38	2.11	2.00**	2.28**	2.05**	2.27**	2.10	2.23
Ht	M	1.18	1.70	1.52	1.61*	1.35	1.42	1.73	1.71
	H	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0

This table gives odds ratios for risk of HSBP and HDBP for adolescents by tertiles of leg height and leg height to height ratio considering higher tertile as a reference category. These ORs are computed after adjusting for BMI/body fat. It shows that rather than absolute leg height, it is the ratio of leg height to height which was able to predict risk for HDBP among girls from LSE class and risk for HSBP among girls from HSE class

BMI Body mass index, *BF* Body fat, *Ht* Height, *LSE* Low socioeconomic class, *HSE* High socioeconomic class, *HSBP* High systolic blood pressure, *HDBP* High diastolic blood pressure, *L* Lower tertile, *M* Middle tertile, *H* Higher tertile

[a]All odds ratios are obtained after adjusting for height in addition to BMI or BF

through endocrine control, simultaneously influence growth of the arteries and of the bones at specific hormonally controlled phases of development, leading to both short height and high blood pressure in adult life (Leeson et al. 2001).

Slower growth in childhood may result from adversity extending into adult life and accumulated risks associated with this disadvantage may influence blood pressure. Differentials in blood pressure widen over life, possibly amplifying the effect of exposures in early life. Environmental exposures during periods of rapid growth are likely to be of particular importance in influencing subsequent blood pressure. Slow growth is a marker of vulnerability to stress. It is an indicator of exposures that also influences BP control mechanisms (Montgomery et al. 2000).

Short stature, limb height as well as altered skeletal proportions that may reflect interrupted early growth are associated with several metabolic disorders (Han et al. 1997). It has been recently reported that associations between components of height and coronary heart disease were largely unchanged in models controlling for parental height, indicating that genetic factors may not underlie the observed height–risk associations (Gunnell et al. 2003; Lawlor et al. 2004). Leg height is considered a better marker for the diversity of exposure which affects the childhood growth than the measures of childhood socioeconomic status themselves (Gunnell et al. 1998). Therefore, in populations where prior undernutrition may affect validity of body mass index, examining associations of simple measurements such as height or components of height with metabolic risks appears to be a promising alternative.

In Indian urban affluent adolescent boys, the prevalence of HSBP was highest (Fig. 83.1) in lowest tertile of height (age adjusted) but showed a stronger association with leg height to height ratio. The comparison of adolescent girls from high socioeconomic (HSE) and low socioeconomic (LSE) class further revealed that while HSBP was more prevalent in the HSE class (9.7% vs. 4.4%), HDBP was more prevalent in the LSE class (15.3% vs. 2.7%). However, it is essential to mention that leg height to height ratio showed (Table 83.5) significantly high odds ratio (OR) for HDBP in the case of girls from the LSE class and for HSBP in the case of girls from HSE class (Rao and Kanade 2007). This indicates that leg height to height ratio has predictive capability for respective risks across the two social classes. Since stunting is a major problem in many Asian countries, it is necessary to

examine whether somatic disproportions have the same predictive power for CVD risk across different populations.

In conclusion, assessing obesity in adolescents is highly essential in view of the global trends indicating increasing CVD risks in young adults. Clearly, there are several anthropometric indicators used for assessing adiposity in adolescents but concordance between them and their validity in different populations remains to be a major area for future research. Second, international reference standard is a compromise to obtain acceptable, comparable prevalence estimates at the global level. However, the rush to use an apparently universal definition of childhood obesity is premature and probably clinically detrimental. Defining pediatric obesity using national BMI reference data provides a safe, practical, and evidence-based approach. Further, due to probable population differences in relative risk, such customized classification systems derived from national data are likely to be more efficient. Finally, in view of the fact that evidence for screening obesity in relation to morbidity is scarce, developing cut-offs anchored to metabolic risk appears to be the prominent challenge for researchers.

Summary Points

- BMI is widely used as a surrogate measure of fatness in adolescents. It has high specificity but variable sensitivity and needs to be validated across broad range of populations.
- Body fat distribution is relatively more important than total body fat for assessing health risks associated with obesity.
- Skinfolds are well correlated with adiposity indicators, that is, BMI and body fat percent, yet the prevalence estimates of overweight based on them differ significantly from those based on either BMI or body fat.
- Waist circumference as an indicator of adiposity appears promising but needs to be tested for its clinical utility.

Key Features

Key features about Indian adolescents

1. India is one of the largest Asian countries which is passing through nutritional transition that is drastically affecting both the food basket and the lifestyle
2. Obesity among children (below 9 years) and among adolescents (9–16 years) is on the rise, mainly in big cities of India. In view of the increasing prevalence of cardiovascular disease risks in India and that adolescent obesity tracks into adulthood, investigations on adolescent obesity are highly essential
3. Our study covered adolescents from extremes of social classes. For example, low social class (LSE) was characterized by lower education of parents, low unskilled jobs of parents, less proportions having ownership of the house, higher number of persons per room, poor income, and no possession of economic assets such as four wheelers as compared to those from high socioeconomic class (HSE) which are referred to as affluent adolescents

This table gives key facts of affluent adolescents, their age group, and social factors that discriminated from lower social class

Chapter 84
Anthropometry in Relation to Sexual Maturation

Silvia Diez Castilho and Antonio de Azevedo Barros-Filho

Abstract The wide variability in timing, sequence, duration and magnitude of pubertal events determines the need for assessing adolescents in relation to sexual maturation instead of age. During the maturation process there is a growth spurt, characterized by acceleration on growth velocity with an increase in weight, height and body mass index, change in body proportions and diameters and increase in muscle and fat tissue, which will determine the phenotype of each sex. Acknowledging this process, allows the correct understanding and assessment of anthropometric changes that may pose risks to an adolescent's current and future health. During the spurt, they gain ~20% of final height and ~50% of final weight. While muscle mass doubles in boys, it increases only 50% in girls, who in turn accumulate more adipose tissue, reaching ~25% of relative body fat (%BF), while boys reach ~15% in adulthood. Therefore, during maturation, girls gain fat-free mass index and fat mass index while boys gain fat-free mass index and lose fat mass index. Proportionally girls gain fat and lose fat-free mass, while boys present a large increment of fat-free mass and lose fat mass. These findings appoint toward the need to assess body composition of adolescents for a correct nutritional diagnosis.

84.1 Introduction

Anthropometry is a tool for measuring body dimensions. It not only describes the nutritional conditions of individuals or groups, but also assesses them throughout time. The peculiarity of anthropometry during adolescence derives from the change-related factors that influence the understanding of these measurements during the period, and which should be acknowledged in order to correctly assess pathological findings, nutritional risks, or future diseases.

Adolescence has been defined as the transition between childhood and adulthood, during which biopsychosocial transformations occur. Puberty represents the biological component (physical) of adolescence and stands out among the anatomical and functional changes that are responsible for growth and development, aiming at maturation and the ability to procreate. Puberty encompasses variations in the velocity of skeletal growth, development of gonads and secondary sexual features, development of other viscera, and changes in body composition. Thus, an increase in measurements and a variation of body proportions during this phase are expected.

This chapter will discuss how each measurement, accessed through anthropometry, behaves during puberty.

84.2 Anthropometry During the Sexual Maturation Process of Well-Nourished Children

84.2.1 Growth

Growth refers to increase in the physical size of individuals. Weight and height, projected on charts, provide support for nutritional assessment, taking into account the fact that health hazards and/or environmental factors are reflected in growth and, consequently, in these charts.

Growth charts are normally plotted in terms of distance, that is, height and weight, in relation to age. Data of each individual are plotted over a reference curve based on longitudinal, cross-sectional, or mixed studies, carried out on a population at a good socioeconomic level.

Reference curves provide indispensable data for monitoring growth; however, it is necessary to interpret data correctly.

Charts from cross-sectional studies are based on population surveys, in which a large number of individuals were measured once, providing mean values and normal ranges for the population studied. These curves allow the assessment of health and growth, by showing where each subject stands within the wide normal range for sex and age.

The current curves recommended by the World Health Organization (WHO) for assessing adolescents are the "WHO Growth Reference 2007 for boys and girls, 5–19 years," which encompass weight-, height-, and body-mass-index-for-age curves from 5 to 10 years, and height- and body-mass-index-for-age curves from 5 to 19 years of age. These curves derive from the rebuilding of the

NCHS/WHO 1977 curves (a cross-sectional study for this age group), using the original sample (5–19 years, nonobese sample with expected height) supplemented by the WHO Child Growth Standards 2006 data, to facilitate a smooth transition at 5 years of age (Onis et al. 2007).

During adolescence, any deviation from the norm (percentile) should be interpreted carefully because charts built with cross-sectional data do not represent individual curves correctly, especially for adolescents who mature faster or slower than average.

Most of the knowledge that we have today on pubertal phenomena is based on longitudinal studies, in which a group of children is followed up and measured repeatedly during growth. The difficulty in this type of study lies in the high cost and high dropout rate, which makes it difficult to standardize normal limits, as the number of individuals followed up is insufficient at the end (of the study). This type of follow-up, however, allows calculating the increments of height in units of centimeter per year (cm/year) that occur in relation to age, associating them to the body changes that accompany the maturation process.

The first growth velocity curve was published in 1942 by D'Arcy Thompson in *On Growth and Form.* Thompson calculated the increments in measurements made by Philibert Montbeillard, who recorded his son's height from birth to age 18 years (between 1759 and 1777). These data were initially published as tables by Buffon (1777). Exactly 150 years later (1927), Scammon converted these measurements into the metric system and placed them on a height-for-age chart. According to Thompson's publication, growth velocity decreases from birth to 6 or 8 years, when there is a mid-growth spurt (more evident in boys), then continues to decrease until the beginning of the adolescent growth spurt. During this phase, there is an intense acceleration for ~2 years, followed by deceleration, and the end of growth. Since the first edition of Growth at Adolescence (1955), when Tanner combined the height-for-age- and height-growth velocity curves, they have been considered the best illustration of human growth (Tanner 1962).

In view of the great variability regarding the beginning and duration of pubertal events, the acceleration and deceleration of growth have a stronger correlation with sexual maturation stages than with age, which makes growth velocity useful in puberty evaluation.

In order to calculate growth velocity, we use the formula: growth velocity = (current height – previous height)/(# of months between measurements/12). Tanner, however, recommended using the time interval in decimal places instead of in months, to make it easier to calculate velocity. According to this system, the year is divided into ten parts and not into 12.

84.2.2 Growth in Height

Growth is the product of continuous and complex interactions between hereditary and environmental factors.

When a child grows in favorable conditions, the final height strongly correlates with the height of parents, manifesting the child's genetic inheritance.

From birth to 2 years, height reflects conditions of life inside the uterus. As of this age and throughout childhood, the correlation between the height of the child and that of their parents is moderate ($r = 0.5$), decreasing afterward during adolescence due to the great variability in relation to the onset of puberty. When one wants to estimate the final height of a boy, 13 cm should be added to the mean height of parents. For girls, 13 cm should be subtracted, according to the formula: final height = [(height of father + height of mother)/2] (±) 13 cm. Expected height is the mean of both values after adjustment, and whose value is determined by the difference of height between genders at adult age. Correlation with parents' height increases after the growth spurt, reaching a moderately

Table 84.1 Breast development stages in girls, genitalia development stages in boys, and pubic hair stages (P) in girls and boys according to Tanner (1962) (Does not require copyright permission)

Stages	Secondary sex characteristics (Tanner stages)
	Breast in girls
B1	Infantile stage that persists from birth until the changes of puberty begin.
B2	The bud stage; breast and papilla are elevated as a small mound and there is an increase of the areolar diameter.
B3	The breast and areola are enlarged with no separation of contours.
B4	The areola and papilla enlarge to form a secondary contour of the remaining breast.
B5	Adult breast; projection of papilla only; the secondary mound present in B4 disappears.
	Genitalia in boys
G1	Infantile stage that persists from birth until the changes of puberty begin.
G2	Enlargement of testes and scrotum, with changes in color (red) and texture of the scrotal skin.
G3	Enlargement of penis in length and to a lesser extent in breadth. Further growth of testes and scrotum.
G4	Enlargement of penis in length and in breadth. Further growth of testes and scrotum, with darkening in color of scrotal skin.
G5	Adult genitalia in size and shape.
	Pubic hair in girls and boys
P1	The vellus over the pubes is similar to that over the abdominal wall.
P2	Sparse growth of long, slightly pigmented and curled hair along the labia or at the base of the penis.
P3	Darker, coarser, and curled hair spreads over pubis.
P4	Pubic hair resembles adult type but covers a smaller area than in most adults.
P5	Adult pubic hair distributed in an inverse triangle (horizontal pattern); spread to medial surface of thighs.
P6	The pubic hair spreads up to the linea alba, onto the abdominal wall.

This table describes breast development in girls, genitalia development in boys, and pubic hair development in both genders, during sexual maturation according to Tanner (1962)
B breast stage; *G* genitalia stage; *P* pubic hair stage

high value (0.7) in adult age. Equations that take into account bone age, current height, and age, and for girls, information on the occurrence of menarche, improve accuracy in the prediction of final height (Tanner 1986).

Among the most important environmental factors that interfere with growth are nutrition, diseases, urbanization, physical activity, and stress. These factors are somehow related to the socioeconomic class that the child belongs to.

A prolonged physical injury in the beginning of life may determine delay in growth and eventually cause a height-for-age deficit (stunting). Children, who have had their growth compromised (severely malnourished) for a long period during the initial years of life, do not recover from this "loss," even if the injury ceases. In these cases, the height in adult age will be below the genetic potential. Therefore, the growth spurt does not recover from height losses; it is actually independent from growth in previous phases.

Height increase reflects the increase in fat-free body mass.

In terms of height for age, adolescents grow faster during puberty before reaching their final height. This rate may be identified through the tangent that touches the curve. When the curve of growth velocity is analyzed, an initial acceleration, with posterior deceleration, is observed. Before the growth spurt, during the latent period, a child grows at a rate of 4–6 cm/year.

The adolescent growth spurt is associated with the appearance of secondary sex characteristics that can be evaluated by Tanner stages, as described in Table 84.1. This evaluation may also be done by comparing adolescent sexual characteristics to illustrations.

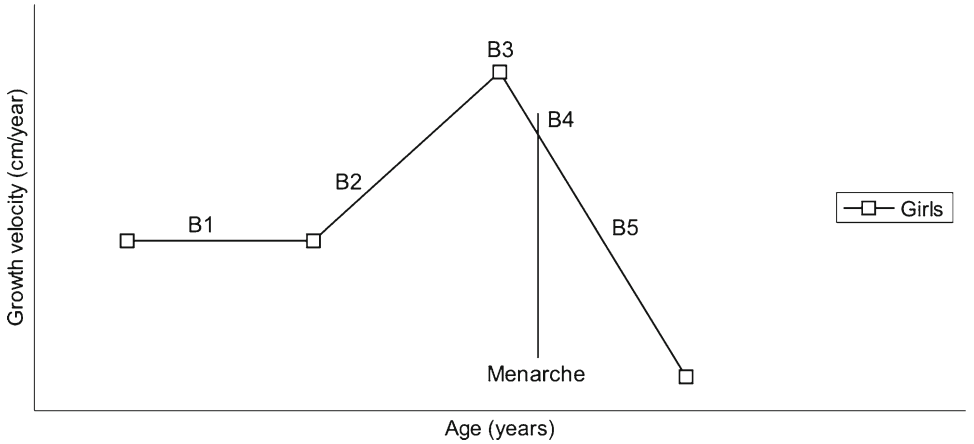

Fig. 84.1 Relation between height growth spurt and Bs (girls). A theoretical diagram of the height growth spurt (acceleration, PHV, and deceleration phases) in relation to Tanner stages in girls. B1–B5 refer to Bs (Diagram made by authors; does not require copyright permission)

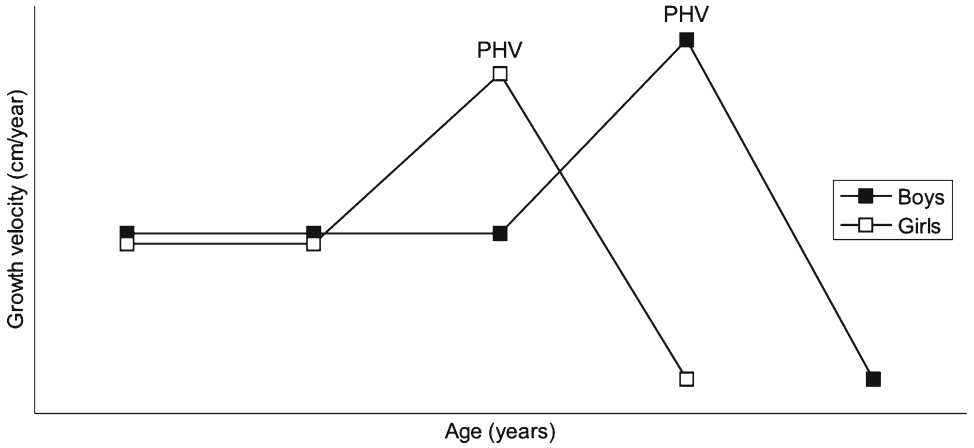

Fig. 84.2 Growth spurt of boys and girls. A theoretical diagram of the height growth spurt (acceleration, PHV, and deceleration phases) of girls and boys, showing that boys usually begin it, on average, 2 years after girls and grow more during the PHV. PHV: peak height velocity (Diagram made by authors; does not require copyright permission)

In girls, the spurt identifies the beginning of puberty and coincides with the appearance of the breast bud – breast stage (B) 2 (Tanner 1962). At this point, they have reached ~80% of their final height. During peak height velocity (PHV), they grow 7–11 cm/year and usually reach the B3 stage (Marshall 1977). Peak timing varies greatly from one population to another. Therefore, girls may reach this point between 10 and 14 years of age, depending on the age at which puberty began. Menarche occurs in the deceleration phase, at B4. By this point, they have ~95% of adult height and will continue to grow for ~4 years (Roche and Davila 1972). The mean duration of the growth spurt is 3 years, two-thirds of which are spent in the acceleration phase (Largo et al. 1978) (Fig. 84.1).

Boys begin to increase growth velocity, on average, 2 years after girls (Fig. 84.2). Thus, girls are temporarily taller than boys, who continue to grow at their preadolescent rate. Growth acceleration in

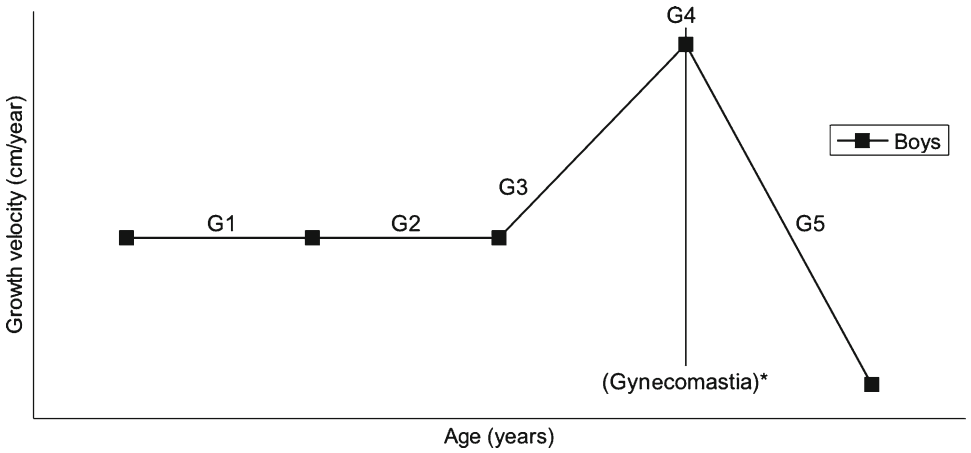

Fig. 84.3 Relation between height growth spurt and Gs (boys). A theoretical diagram of height growth spurt (acceleration, PHV, and deceleration phases) in relation to Tanner stages in boys. G1–G5 refer to Gs. *Gynecomastia may occur in boys, during PHV, when they are at G4 (Diagram made by authors; does not require copyright permission)

boys does not coincide with the beginning of sexual development. Growth velocity only accelerates when they are in genitalia stage (G) 3 (Tanner 1962) (Fig. 84.3). During PHV, boys grow 3 cm more than girls (Largo et al. 1978) and are in stage G4. At this time, they grow by 7–13 cm (~10 cm) (Marshall 1977) and are between 12 and 16 years (~14 years), depending on the age puberty began. The difference in the final height between boys and girls (13 cm) is due to the additional centimeters boys gain during the PHV, and also due to the growth during the 2 extra years before the spurt, a period in which boys grow at a rate of ~5 cm/year. The height growth in boys tends to continue longer after PHV. Men, in general, reach their final height at around 20 years of age. Largo et al. (1978) consider that individuals achieve their final height when increments become smaller than 0.5 cm in 2 years. Meanwhile, Roche and Davila (1972) prefer to define final height as being reached when there are consecutive measurements less than 0.5 cm in the past four semesters.

Children with an earlier PHV (early maturers within normal variability) reach a peak of greater magnitude than those who mature later, but there is no relation between the age in which the peak occurs and an individual's final height. The earlier puberty begins, the greater the magnitude of their PHV, and, afterward, they will grow more and for a longer period until reaching final height. Late maturers gain some centimeters before reaching PHV, which presents a smaller magnitude, and, after the peak, they grow for a shorter time period until reaching adult height (Tanner 1962).

84.2.3 Secular Trend of Growth

In the past 150 years, there has been a trend toward a reduction in the age in which the growth spurt and sexual maturation occur, in addition to an increase in the final height of the population, known as a positive secular trend. This trend has alternated with periods in which height increments tend to slow down, without stopping, whereas maturation may stop or even reverse. These periods correspond to phases in which the population suffered nutritional deprivation. The secular trend has been identified in all social levels, and is more evident in the less privileged classes, mainly in the Third World, when children are offered better life conditions.

84.2.4 Weight Gain

Weight increases as adolescents grow and develop. This increase is reflected in both fat-free mass (largest component) and fat mass, mainly in women.

Weight gain goes through an acceleration phase and posterior deceleration phase during puberty, similar to what occurs in height. In males, the velocity of weight gain practically coincides with the PHV, whereas, in girls, it occurs a few months (~6 months) after the PHV is reached.

84.2.5 Body Proportions

The increase in an adolescent's height results from a nonuniform acceleration in the growth of lower limbs and trunk. There is an initial limb spurt, following a distal–proximal direction, that is, first, feet and hands; ~6 months later, legs and forearms; and, finally, thighs and arms. Although the trunk grows ~6 months after the limbs, it contributes in an expressive manner to the height gain during puberty, increasing the trunk–limbs ratio (Marshall 1977). Hence, at 3 years of age, the upper segment/lower segment ratio is 1.3, and, in puberty, 0.9. These measurements may be estimated through the assessment of the upper segment (sitting height: measured from the distance between the surface where the individual is seated and the vertex) and lower segment or subischial height (difference between stature and sitting height).

There are gender differences in the growth of biacromial (shoulder breadth or scapular waist) and bi-iliac (hip width or pelvic breadth) diameters, in which the former grows more in males, whereas the latter is similar for both genders. These diameters reach maximum growth levels concomitantly with the trunk (Marshall 1977). This leads to the adult phenotype of each gender in which men have broad shoulders (android shape) due to increase in the biacromial/bi-iliac ratio and women broad hips (gynecoid shape), as the biacromial/bi-iliac ratio decreases and fat accumulates in the region of the hips (Loomba-Albrecht and Styne 2009). In females, as the hip grows, the waist-to-hip ratio also decreases, accentuating the curves of the female body. These diameters should be measured using a skeletal anthropometer or caliper (sliding or spreading), and circumferences measured with a non-expandable tape. Waist circumference has usually been measured at the smallest portion of the torso, and hip circumference, preferably, at the level of maximum posterior extension of the buttocks (Heyward and Stolaczyk 1996).

From birth to 18 years, the head circumference grows ~20 cm. Half of this growth occurs up to the ninth month and three-fourths up to the second year. The remaining growth is slow; a small acceleration can be detected during adolescence. In a small proportion, the skull also takes part in the spurt (Marshall 1977). During this growth, the eye globe grows, predominantly in the sagittal plane, which may determine the development or increase in myopia. More marked face changes are observed in males, with growth in the forehead, nose, mandible, and lower jaw, which frequently contribute to dental malocclusion.

84.3 Changes in Body Composition

During adolescence, individuals acquire 20% of their final height and double (50% increase) their body mass (weight). Most sexual differences that occur during this phase and lead to the adult phenotype result from the characteristic growth pattern of each gender, which is molded by the endocrine system. Whereas girls deposit more fat, boys gain more muscle and bone mass. In adult

age, men have 1.5 times the fat-free mass (FFM) of women, who, in turn, have twice as much body fat as men (Loomba-Albrecht and Styne 2009).

Most children go through a repletion phase between 8 and 10 years of age. At this time, both genders gain fat, increasing skinfold (SKF) thickness. In the beginning of the growth spurt, fat gain slows down. The deceleration is concomitant to the increase in bone and muscle tissue and it reaches the lowest point at PHV. The difference between genders consists of the fact that girls always have a higher fat deposit rate than boys. During the deceleration phase, they continue to gain fat, whereas boys lose adipose tissue.

Tanner et al. (1981) studied the behavior of adipose and muscle tissues, having calculated the respective cross-sectional areas in arm X-rays. The figures obtained were grouped around the PHV and not the chronological age, making the analysis of correlations between spurt and growth in these tissues easier, as the dispersion of ages for growth spurt is eliminated. At 9 years of age, both genders have about 15% fat in their bodies. At the time of PHV, the amount is 12% in boys, remaining the same for some years, and 19% in girls, reaching 25% after menarche.

Muscle mass corresponds to 25% of a newborn's weight and 40% of the weight of an adult. The major gain in the muscle tissue of men occurs mainly during the growth spurt and is associated with biochemical changes that are part of the functional differences between both genders (Marshall, 1977). From 11 to 16 years of age, muscle mass doubles in boys, whereas it only increases by 50% in girls. The increase in muscle tissue is concomitant to the acceleration in growth velocity and reaches its maximum at the time of PHV or a few months later. The peak of muscular strength gain, which can be measured by a dynamometer, occurs a few months later, and is higher in boys than in girls due to sexual hormones (Tanner 1962).

84.3.1 Skinfolds

Clinically, adiposity can be assessed by SKF measurements in several body sites. It estimates body density from which relative fat derives and estimates the regional distribution of fat mass (FM). Measurements are preferably made by using a metal caliper, such as the Harpenden or Lange. Approximately 3–9% of the variability of these measurements is due to technical errors. Errors vary according to site, with 8.8% in the abdomen, 7.1% in thigh, 3% in triceps, 3–5% in the subscapular, and 4% in suprailiac SKF sites (Heyward and Stolarczyk 1996). Thus, it is recommended that each SKF be measured at least twice at each site and that new measurements be made in cases where there is a difference greater than 10%.

During the pubertal process, there is a decrease in the fat gain rate in both genders, being less intense in the trunk than in limbs. This explains why the thickness of the subscapular SKF also continues to grow slightly in males, unlike the tricipital SKF. Regarding the latter, a progressive increase in females and a decrease in males are observed (Forbes 1986).

The easy access to subcutaneous fat by measuring SKFs (two or more) has allowed the development of many equations to estimate relative body fat (%BF) considering a variety of sites. Prediction equations developed by Slaughter et al. (1988), using the sum of triceps SKF and subscapular SKF, were aimed at children 8–18 years old. They take into account sex, ethnicity, maturation stage, and chemical changes in body composition (Table 84.2). Relative body fat makes it possible to calculate FM and FFM:

$$\% \text{ BF} = (\text{FM}/\text{weight}) \times 100$$
$$\text{FM} = (\% \text{ BF} \times \text{weight})/100$$
$$\text{FM} = \text{weight} - \text{FFM}$$
$$\text{FFM} = \text{weight} - \text{FM}$$

Table 84.2 Slaughter et al. (1988) SKF equations recommended for predicting %BF in children 8–18 years of age (Does not require copyright permission)

Σ triceps SKF + subscapular SKF < 35 mm			
Sex	Tanner Stage	Ethnicity	Prediction equation
Male	G1 and G2	White	% BF = 1.21 (Σ SKF) – 0.008 (Σ SKF)^2 – 1.7
		Black	% BF = 1.21 (Σ SKF) – 0.008 (Σ SKF)^2 – 3.2
	G3	White	% BF = 1.21 (Σ SKF) – 0.008 (Σ SKF)^2 – 3.4
		Black	% BF = 1.21 (Σ SKF) – 0.008 (Σ SKF)^2 – 5.2
	G4 and G5	White	% BF = 1.21 (Σ SKF) – 0.008 (Σ SKF)^2 – 5.5
		Black	% BF = 1.21 (Σ SKF) – 0.008 (Σ SKF)^2 – 6.8
Female	Independent of stage	All	% BF = 1.33 (Σ SKF) – 0.013 (Σ SKF)^2 – 2.5
Male	Independent of stage	All	% BF = 0.783 (Σ SKF) + 1.6
Female	Independent of stage	All	% BF = 0.546 (Σ SKF) + 9.7

84.3.2 Body Mass Index

Weight for age is inappropriate for monitoring growth beyond childhood due to the inability to distinguish body mass in relation to height (Onis et al. 2007).

The body mass index (BMI) has been used to assess nutritional status mainly in adults given that, at this age, it has a stronger correlation with FM and a weak correlation with height. It is also an appropriate predictor of morbidity and mortality. During adolescence, there are limitations for its use due to certain characteristics of this age group. It does not reflect the changes in body composition and does not correlate with height. Despite these limitations, it has been recommended for monitoring children and adolescents with overweight and obesity, as there is a lack of other cheap, fast, easy, noninvasive methods that could provide immediate results.

The increase in BMI values during adolescence should be interpreted as a marker of organic maturation, expressing the increase in the trunk-to-limb ratio, body mass, height, and changes in body composition. Actually, the index reflects more the increase in weight expected at this stage rather than the excess of fat, making it difficult to interpret data. Sexual differences in maturation rate, such as female precocity, explain the pattern found in the curves. Median BMI/age values for girls are systematically higher than those found for boys between 12 and 20 years of age, present increasingly higher differences up to 15 years of age, and drop afterward, as the sexual maturation stages of boys and girls grow closer. After 20 years of age, the index is higher in males. This is because the muscle tissue that prevails in men is heavier than the adipose tissue that prevails in women.

BMI-for-age curves of the "WHO Growth Reference 2007 for boys and girls, 5–19 years" are currently recommended as a reference for adolescents. The cutoff points for overweight and obesity are respectively +1 SD (25.4 kg/m^2 for boys and 25.0 kg/m^2 for girls), which is the equivalent to the cutoff point for overweight in adults (≥25 kg/m^2), and + 2 SD (29.7 kg/m^2 for both genders), which corresponds roughly to the cutoff point for obesity (≥30 kg/m^2) (Onis et al. 2007).

Table 84.3 Body mass index percentile distribution according to Bs

BMI (kg/m²) – Girls												
Breast stages	*n*	Mean	SD	Min	p5	p15	p25	p50	p75	p85	p95	Max

BMI body mass index; *G* genitalia stage; *n* number of subjects; *SD* standard deviation; *min* minimum; *p* percentile; *max* maximum (Reprinted from Castilho et al. 2008. With permission)

The interpretation of BMI values should consider that adolescents of the same sex, with the same weight and height, may go through identical phases of development at different ages, mainly between 10 and 14 years of age. Therefore, there are studies correlating BMI with sexual maturation stages for both genders (Castilho et al. 2008) – Tables 84.3 and 84.4. While the BMI increases when girls advance from B1 to B5, it is fairly constant from G1 to G3 in boys, increasing in G4 and G5. This correlation, similar to when the BMI is assessed in relation to age, is low for males (0.2) and moderate for females (0.4) (Castilho et al. 2008). In order to improve this evaluation, it would be better to correlate BMI with age, and check the variability of the index according to the maturational stage for each age, but there are no data available.

If, in adults, the increase in BMI generally reflects the increase in adiposity, in adolescents, it occurs at the expenses of fat and FFM (muscle, bone, and viscera). This index, however, does not distinguish among these compartments, making it difficult to interpret its value; thus, it is necessary to associate data from SKF measurements or bioimpedance, assessing fat-free mass index (FFMI) and body FM index (BFMI).

Bioimpedance makes clinical assessment easier, as it does not require previous training or the use of prediction equations to access body compartments, given that the equipment is linked to a computer that calculates these values. Leg-to-leg bioimpedance is appropriate, and has been validated for assessing body fat, mainly in field studies. In clinical practice, hand-to-foot bioimpedance is preferable given that the current flow that crosses the whole body provides an indirect estimation of %BF, unlike leg-to-leg bioimpedance where fat accumulated in the lower segment can be privileged.

The assessment of body compartments leads to conclude that girls gain FFMI and BFMI in absolute terms during the sexual maturation process, whereas boys gain FFMI and lose BFMI (Figs. 84.4 and 84.5).

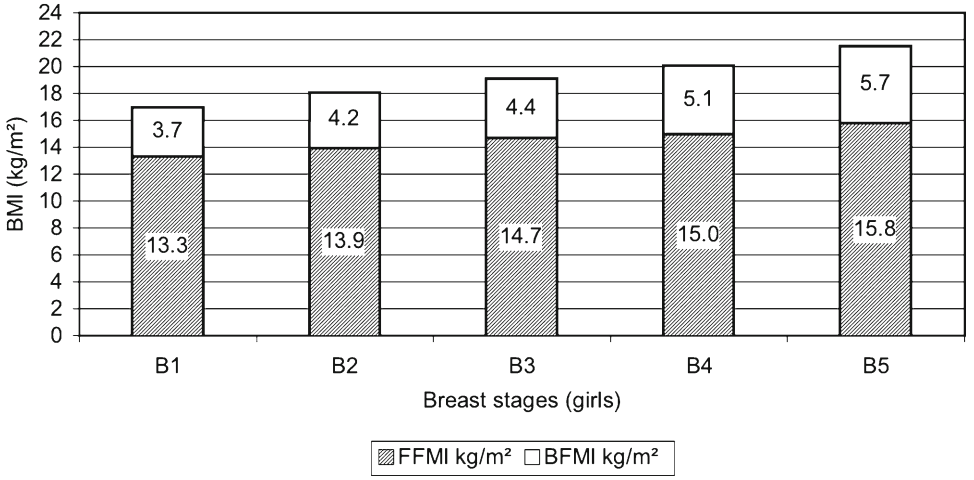

Fig. 84.4 Body mass index, FFM index and BFMI according to Bs. Body mass index increases in relation to sexual maturation stages. Girls gain FFM index and BFMI from the infantile stage to the adult stage. *BMI* body mass index; *FFMI* fat-free mass index; *BFMI* body fat mass index; *B* breast stage; BMI + FFM/height^2 = FM/height^2 = FFMI + BFMI. BMI based on p50 of Table 84.3 (Reprinted from Castilho et al. 2008. With permission)

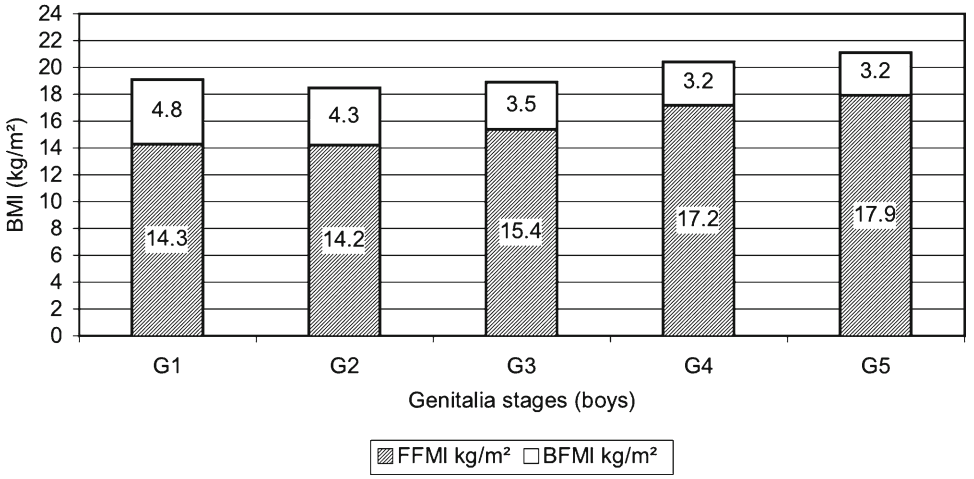

Fig. 84.5 Body mass index, FFM index, and BMI according to Gs. Body mass index is fairly constant from G1 to G3, increasing in G4 and G5. Boys gain FFM index and lose BMI from infantile stage to adult stage. BMI: body mass index, FFMI: fat-free mass index, BFMI: body fat mass index, G: genitalia stage, BMI + FFM/height^2 = FM/height^2 = FFMI + BFMI. BMI based on p50 of Table 84.4 (Reprinted from Castilho et al. 2008. With permission)

In relative terms, girls gain FM, going from 21.3% in B1 to 26.6% in B5 and lose FFM (78.7% in B1 and 73.4% in B5), whereas boys have greater increments of FFM (75.9% in G1 and 84.8% in G5) and lose FM, going from a %BF of 24.1% in G1 to 15.2% in G5 (Figs. 84.6 and 84.7). Not only BMI, but also FFMI and BFMI should be measured to monitor weight gain in adolescents in order to identify overweight and obesity, especially in boys who have not lost FM as they mature (Castilho et al. 2008).

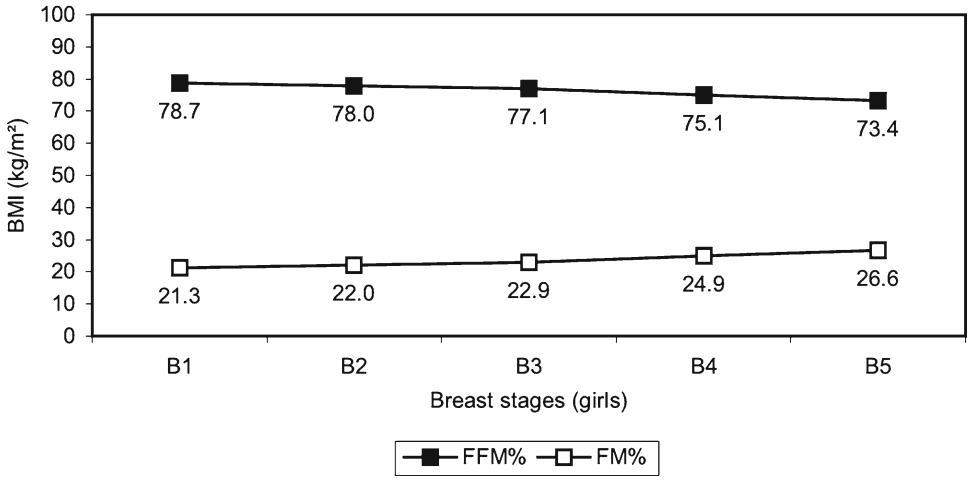

Fig. 84.6 Percentages by which FFM and FM contribute to body mass index increase according to Bs. As girls mature, the proportion of body mass index components changes. They gain FM and lose FFM. *BMI* body mass index; *FFM* fat-free mass; *FM* fat mass; *B* breast stage (Reprinted from Castilho et al. 2008, with permission)

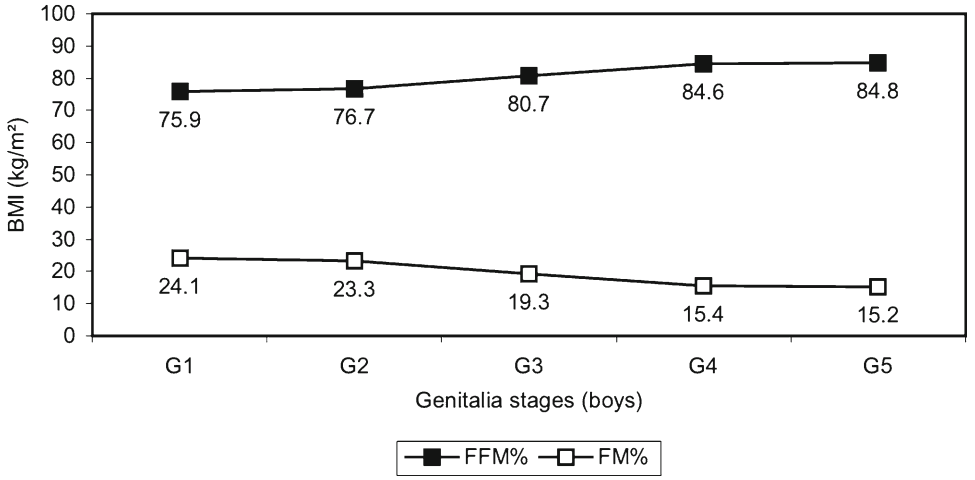

Fig. 84.7 Percentage by which FFM and FM contribute to body mass index increase according to Gs. As boys mature, the proportion of body mass index components changes. They gain FFM and lose FM. *BMI* body mass index; *FFM* fat-free mass; *FM* fat mass; *G* genitalia stage (Reprinted from Castilho et al. 2008. With permission)

84.3.3 Visceral Development

During puberty, the heart, lungs, liver, spleen, kidneys, pancreas, thyroid, adrenals, gonads, and other organs grow in different proportions (Tanner 1962). The central nervous system grows little and only the lymphoid tissue involutes. Several physiological adjustments of the cardiovascular system, pertinent to this phase, contribute to the increase in blood pressure, stabilization of heart rate, expansion of plasma volume, and increase in heart output and peripheral vascular resistance (Marshall 1977).

84.4 Maturation

84.4.1 Sexual Maturation

During puberty, sexual maturation encompasses the development of gonads, reproduction organs, and secondary sexual features. Sexual maturation reflects the adolescents' biological age.

The sequence in which secondary features emerge was classified by Tanner (1962), taking into account the development of breast in females, genitals in males, and pubic hair in both. Variables are classified into five stages that range from the prepubertal stage (infantile body, stage 1) to the adult phase (adult body, stage 5). With regard to pubic hair, the event progresses up to stage 6, when hairs spread toward the umbilical scar. The assessment of breast or genital maturation and pubic hair should be performed separately, as there may be disagreement between the stages (Table 84.1).

84.4.2 Females

In general (85%), girls begin puberty with thelarche (appearance of the breast bud), although pubarche (appearance of pubic hairs) may sometimes precede it (Wheller 1991). As breasts develop, the uterus, tubes, vagina, and vulva undergo anatomical and functional changes. These changes result from estrogen produced by the ovaries. The ovaries, which grow slowly and progressively since birth, begin to grow faster in the months preceding menarche. Axillary hair appears later (~6 months). Menarche is a late event within the pubertal process occurring on average 2 years after the appearance of the breast bud and also after PHV, during the phase of growth deceleration (Wheller 1991). Several factors may influence the onset of menarche (Castilho and Barros Filho, 2000). Usually, girls of a higher socioeconomic level, those living in urban regions, in warmer climates, and at lower altitudes menstruate earlier. The smaller the size of the family, the earlier they menstruate, and the youngest daughter tends to menstruate earlier than her older sisters. The influence exerted by ethnicity is difficult to be quantified, given that nutritional status, culture, and climate may influence the age of menarche. This event has been occurring 3–4 months earlier each decade (Table 84.5).

Frisch and Revelle (1970) proposed a critical weight theory that relates menarche to weight. According to these authors, girls must reach 47.8 ± 0.51 kg in order to menstruate. Afterward, Frisch and McArthur (1974) concluded that a minimum weight for height was necessary to establish the menstrual cycle. This weight would reflect a minimum of 17% stored fat, which would change the metabolism and decrease hypothalamic sensitivity to circulating steroids. Increase in gonadotropins and estrogen would lead to ovarian and uterine maturation, resulting in menarche. Ellison (1982), however, found evidence that growth velocity is a better predictor of menarche than weight and

Table 84.5 Key features of puberty in girls

- Girls generally begin puberty with the appearance of breast buds (thelarche) at B2.
- Pubic hair may sometimes precede thelarche.
- Axillary hair appears ~6 months later.
- Menarche usually occurs 2 years after thelarche and after PHV, during deceleration of growth velocity.
- Girls usually do not ovulate soon after menarche. It takes some time for them to become fertile.

This table lists the key facts of puberty in girls including the sequence of appearance of the secondary sex characteristics

PHV peak height velocity; *B* breast stage

Table 84.6 Key features of puberty in boys

Boys generally begin puberty with scrotum and testes enlargement (4 mL).
Pubic hair usually appears later.
Axillary and facial hair and hair in remaining parts of the body emerge ~2 years later.
Testes reach 12 mL at PHV.
Size of testes usually varies between 12 and 25 mL in adults.
Spermarche usually occurs before PHV, in stage G2 or G3.
Boys are fertile at this time (after spermarche).
Gynecomastia may occur during PHV, when they are at G4.

This table lists the key facts of puberty in boys including the sequence of appearance of the secondary sex characteristics
PHV peak height velocity; *G* genitalia stage

suggested that the event is determined by the rate of maturation and not by the size of the body. More recently, studies on leptin have once again evoked the critical weight theory.

84.4.3 Males

The beginning of testes enlargement indicates the onset of puberty in boys (G2). The volume of the testes can be assessed, by comparison, using the Prader orchidometer that consists of a series of ellipsoid-shaped models mounted on a cord in order of increasing size (from 1 to 25 mL). In prepubertal boys, the volume varies little (1–3 mL). At the beginning of puberty, it reaches 4 mL and rapidly increases its size reaching a mean volume of 12 mL at PHV. In adults, it varies between 12 and 25 mL. The emergence of pubic hairs occurs a few months (~6 months) after the initial increase of the volume of testes, whereas the hair in axillas, face, and remaining parts of the body appears later. The prostate, bulbo-rectal glands, and seminal vesicles have marked growth during puberty. Spermarche is rarely studied, as boys usually do not report it. A study identified that it occurs before PHV, in stage G2 or G3 (Guízar-Vázquez et al. 1992). Voice change subsequent to larynx growth due to androgenic action occurs later. One-third of adolescents may present increase in mammary tissue during puberty. In general, this increase occurs when boys are in stage G4 is restricted to the subareolar mammary tissue, and may be unilateral or bilateral (Tanner 1962). Gynecomastia used to be transient (1–1.5 years). On average, boys take 2 years to reach G2–G4 and 2 more years to reach G5 (Table 84.6).

84.4.4 Bone Maturation

Similar to sexual maturation, bone age also reflects the adolescents' biological age. It shows how far an individual has gone toward adulthood.

Skeletal growth is processed through progressive mineralization of ossification centers (nuclei) of short bones and epiphyses of long bones. Complete ossification of a nucleus or an epiphyseal center (conjugation cartilage) marks the end of the bone growth phase. Skeletal maturation is processed through a predictable sequence of ossification of different nuclei, allowing to rate different bone ages. Despite the great variability of when ossification nuclei emerge, the order of appearance is more constant. Radiographic models were created to assess which bone age corresponds to a qualitative and quantitative pattern of certain nuclei of one or more sites of the skeleton. Population standards

of chronological ages for the emergence of each ossification nucleus (Greulich & Pyle Atlas) or centers associated with a score that represents a certain stage of skeletal maturity (TW2) are the methods of reference for this assessment.

84.4.5 Variability

The physical changes in puberty usually occur in the second decade of life (10–19 years), but timing, sequence, duration, and magnitude of these events tend to vary. Individuals of the same age may present different physical aspects, especially in younger ages, because they are going through different developmental phases. This makes anthropometric assessment difficult, given that available charts and tables relate height, weight, SKFs, and BMI measurements to chronological age.

Genetic inheritance that encompasses ethnic and nutritional factors determines the age at which the body triggers puberty. Thus, adolescents with early or late maturation generally have parents or grandparents who report a similar development. This may be observed in relation to menarche, an event that is generally acknowledged by the family.

The assessment of any precocity or delay in the beginning of puberty, due to great variability and secular trend, should in clinical practice be based on updated references for each population. Therefore, one must only define puberty as precocious or delayed, if initial secondary sexual characteristics appear before or after the normal limits of the standard reference for the population to which the assessed adolescent belongs.

Children, who enter puberty before average, but within expected variability, are considered early or advanced maturers. Late or slow maturers are those who begin the pubertal process after the average, but are within the expected variability for events. Sexual maturation maintains a strong correlation with growth velocity; therefore, both early and late maturers, despite being taller or shorter than their colleagues at initial puberty, will end growth with the same adult height mean.

The timing spent progressing from one maturation stage to another varies. When an adolescent quickly passes from stages 2 to 3, it does not mean that this will happen at the same velocity in the following stages.

Although girls generally present thelarche before pubarche, the order of these events may change, with pubic hairs emerging first. Menarche that normally occurs in stage B4 may also occur in B3, and is less frequent in B5. Although not usual, some boys can present axillary hair concomitantly to pubic hair.

The size of breasts, hips, genitals, distribution of fat, muscle mass, weight, final height, and distribution and amount of hairs are also influenced by genetics. These differences are a matter of concern, especially in this day and age in which beauty references are stricter.

84.5 Anthropometry During the Sexual Maturation Process of Children with Nutritional Problems (Malnourished and Obese)

84.5.1 Nutrition, Growth, and Maturation

Malnourishment, due to low ingestion of calories, proteins, and/or certain nutrients, such as iron or vitamin D, may limit growth (Marshall 1977) and delay skeletal maturation. When the period of food

deprivation is short, there is a deceleration in weight gain that may be fully recovered with the reintroduction of an adequate diet. However, when food deprivation is extended throughout the growth phase, the genetic potential is no longer reached because the deficit in height gain, more evident during the faster growth phase, cannot be recovered, not even during the spurt.

Conversely, the height gain in obese girls has been found to be greater during childhood; therefore, they are taller in the beginning of puberty. Nonetheless, they reach the same final height as nonobese girls, highlighting a smaller gain during the spurt (Villar Villar et al. 2004). Complementing these data, Castilho et al. (2005) observed, by studying a cohort of Brazilian girls, that obesity does not interfere in post-menarcheal growth.

The nutritional status also interferes in the sexual maturation process. The critical weight theory (Frisch and Revelle 1970) suggests both a delay in the menarche of malnourished children and the anticipation of puberty in obese girls. The observation that these girls tend to mature earlier led to the assumption that body fat determines neuroendocrine changes, measured by leptin, triggering puberty (Shalitin and Phillip 2003). Although these findings are well documented in girls (Himes 2006), there is controversy regarding the effects of overweight and obesity on maturation in boys. Wang (2002), analyzing NHANES III data, observed a negative correlation with obesity delaying boys' maturation, whereas Denzer et al. (2007) did not observe any change in the timing for genital development or in the emergence of pubic hair, even though levels of testosterone were low. In the sample studied, these authors identified a slight anticipation in breast development.

Although the secular trend of anticipation of menarche is evident, studies have suggested that the age of menarche in well-nourished children has become stable, reaching its potential with improvement of nutritional conditions. The current positive trend may be due to increase in the prevalence of obesity (Ong et al. 2006).

Adolescence has been considered a critical period for the development of obesity. The risk is higher in girls, mainly when parents are overweight. The growth in obesity and the importance of its consequences for health – in a society where food habits and physical activity are changing – point toward the need to monitor the trend of BMI, FFM, and FM, as well as the changes in fat distribution. BMI increase has not been proportional to height gain (Mészáros et al. 2008). It is occurring at the expense of fat – mainly central fat (Dollman and Olds 2006) – which plays an important role in the development of chronic diseases (diabetes, hypertension, and cardiopathies) compromising adolescents' health.

84.5.2 Difficulties in Taking Measurements

Anthropometry is challenging in individuals in extreme nutritional conditions.

In the obese individuals, measuring SKF thickness may be difficult because the SKF can exceed the maximum opening of calipers and not be separated easily from underlying muscle. Likewise, access to body fat, by measuring SKF in malnourished individuals, may be compromised because they have proportionally more internal fat than subcutaneous fat. In these individuals, internal fat tends to decrease when they gain weight, and their total body fat increases. Equations developed by Slaughter et al. (1988) (suggested as appropriate to assess body composition in this age group) do not take into account maturation stage when the sum of folds is higher than 35 mm. In face of these difficulties, bioimpedance may be helpful.

In order to determine the risk of disease, fat distribution is more important than the estimation of total body fat. The impact of this distribution resides in the fact that visceral fat (located in the

abdominal cavity) increases the risk of morbidity–mortality (Esmaillzadeh et al. 2006). The term android obesity is used when fat prevails in the upper segment, and gynecoid obesity is applied when the fat is located in the lower segment. Android obesity is more typical in males and gynecoid obesity is characteristic of females, even though men and women can be classified in either group. Skinfold measurements should be taken in the trunk (umbilical, suprailiac, and subscapular) in order to estimate fat distribution in these cases. When this is not possible, measurements of waist and hip circumferences and/or the relationship between them are used. As waist circumference is strongly associated with visceral fat, and hip circumference is only influenced by subcutaneous fat, the use of the waist-to-hip ratio is preferred. Aside from the lack of universal standardization of measurement sites, there is also a lack of reference curves for assessing adolescents.

Limitations are also observed in height measurements of obese individuals, given that it is frequently difficult for shoulder blades, buttocks, calves, and heels to touch the vertical plane, generating errors in data.

After the first decade, weight loses importance for nutritional assessment. It should be considered in relation to height by assessing BMI. This index does not distinguish FFM from FM; hence, it is important to assess these components in order not to underestimate the increase in fat.

84.5.3 Difficulties in Assessment of Maturation

Parents of obese boys usually seek pediatricians when their children are teenagers, expressing two concerns: delay in puberty compared to classmates and the size of their penis. What actually happens is that the suprapubic fat deposit makes the genital, usually of normal size, seem small (Lee and Reiter 2002).

Unilateral or bilateral, benign gynecomastia is transient during puberty in boys, causing great distress. In obese individuals, excess of fat may suggest gynecomastia or determine its occurrence in a higher proportion, requiring the correct assessment of mammary tissue (Ma and Geffner 2008).

The same difficulty may be seen in females, mainly when follow-up is not longitudinal. One must avoid confounding the excess of fat with mammary tissue. Thus, breast contour and not size should be valued. Studies that compare maturational self-assessment with the assessment made by a trained professional have highlighted the difficulty in assessing Bs in obese children.

84.6 Applications to Other Areas of Health and Disease

Due to a wide variation in puberty events, it is important to acknowledge the normal onset limits for the population assessed. When puberty begins before or after the expected time, it may reflect endocrine problems that need to be carefully investigated.

Changes in the growth channel (weight/age or height/age percentiles) should draw professionals' attention. They can reflect either the lack of growth hormone or thyroid hormone or an acute process of malnourishment.

The growth spurt does not recover from previous losses of height gain. When children change growth channel to higher percentiles, it is important to assess if this is due to earlier, normal, or pathological puberty or to an actual increase in weight, given that adolescence is a favorable period for the development of obesity.

84.7 Practical Methods and Techniques or Guidelines

Bioimpedance makes the assessment of body composition easier, as it does not demand specific training, unlike SKF measurements. It also does not require using mathematical formulas in order to calculate %BF, FM, and FFM, given that the equipment already provides these data. Due to its practicality, leg-to-leg equipment is used to access body composition in field surveys. Meanwhile, hand-to-foot bioimpedance is restricted to individual assessment because it requires not only the correct placement of electrodes but also that the subjects be lying down. This method also favors the assessment of patients with nutritional problems, as it is difficult to assess SKF in obese patients (due to limitation in the opening of calipers) and in the malnourished (who may have their relative fat underestimated because they generally have more central fat when compared to others).

Summary Points

- During adolescence, boys and girls should be assessed in relation to sexual maturation.
- It is normal to gain weight, height, and body mass index, change body proportions, and increase FFM and FM because these parameters will lead them to acquire the characteristic phenotype of each gender.
- Puberty in boys begins on average 2 years after girls; therefore, girls are temporarily taller.
- The 2 years that boys take to begin their spurt, and the extra centimeters they gain during PHV determine the difference of final height between genders.
- The peak velocity of weight gain in boys coincides with height gain; in girls, this happens ~6 months later.
- Limbs grow before the trunk, although the trunk contributes substantially to height increase.
- Men have wide shoulders due to the increase in the biacromial/bi-iliac ratio diameter, and women have wide hips, due to the decrease in this ratio and fat accumulated in the hip region.
- During adolescence, youngsters achieve 20% of their final height and 50% of their final weight.
- Fat gain decreases during the spurt. This decrease is concomitant to the increment of FFM and reaches minimum velocity during PHV. There is more fat deposit in girls than in boys, and even when the rate of growth decreases, they continue gaining FM, whereas boys may lose FM.
- At 9 years of age, both genders have about 15% of body fat. At the time of PHV, it is 12% in boys and 19% in girls, reaching 25% after menarche.
- The gain of muscle tissue in males occurs mainly during the growth spurt. From 11 to 16 years, muscle mass doubles in boys, whereas it only increases 50% in girls.
- The increase in BMI reflects the weight gain expected in this phase, rather than fat excess; therefore, it is necessary to assess FFMI and BFMI.
- During maturation, girls gain FFMI and BFMI, whereas boys gain FFMI and lose BFMI. In relative terms, girls gain FM and lose FFM, whereas boys have a large increment in FFM and lose FM.
- In girls, the beginning of sexual maturation (B2) coincides with growth acceleration. Boys begin their growth spurt from G2 to G3.
- Nutrition influences sexual maturation. Whereas malnourishment delays puberty in both genders, excess weight in general anticipates puberty in girls and delays it in boys, due to hormonal changes.
- Obesity makes it difficult to take anthropometric measurements and assess sexual maturation in both genders.

Chapter 85
Reference Curves of Waist Circumference in Children and Adolescents

Peter Schwandt and Gerda-Maria Haas

Abstract The global increase of adiposity in youth necessitates early diagnosis and intervention. Among other anthropometric measures waist circumference assessment has become increasingly important as an easy, non-invasive and inexpensive routine tool since waist circumference is a measure of central adiposity. The waist circumference is essential for a correct definition of abdominal obesity and consequently for a common definition of the metabolic syndrome in childhood and adolescence in order to allow for considerable ethnic variations. Furthermore, central obesity and therefore the waist circumference are predictive for cardiovascular risk.

To compensate for gender- and age-specific variations in development and ethnic origin of children and adolescents percentiles rather than absolute values are used for comparison with adults. This contribution paper has taken over the task of collating equivalent world-wide data as far as they have been published until now (October 2009, PubMed). However, the authors apologize in advance for having possibly missed some important publications.

Abbreviations

BMI	Body mass index
CT	Computed tomography
DXA	Dual-energy X-ray absorptiometry
F	Female
LMS	Smooth (L) curve, trends observed for the mean (M), an coefficient of variation (S)
M	Male
MRI	Magnetic resonance imaging
PEP	Prevention Education Program
WC	Waist circumference
WHO	World Health Organization

85.1 Introduction

In USA, the prevalence of obesity in children has increased from about 5% in 1963–1970 to 17% in 2003–2004 (Ogden et al. 2008) measured against a stable cutoff point, ≥ 95th percentile body mass index (BMI) for gender and age (Cole et al. 2000). In addition, mean waist circumference among 2–19-year-old youth increased between 1988 and 2004 (Li et al. 2006). Trends in waist circumference (WC) as a highly sensitive and specific measure of central fatness during the past 10–20 years have given more significant results than measures using BMI in Great Britain (McCarthy et al. 2003). For a uniform definition of the metabolic syndrome in children and adolescents, the International Diabetes Federation proposed using the ≥90th percentile as a cutoff for WC for gender and age (Zimmet et al. 2007), but without the ethnicity-specific recommendations as proposed for adults (Alberti et al. 2005). An expert committee has concluded that: "Waist circumference is not recommended for routine use because measurement is difficult and appropriate cut-off values are uncertain, although it may be useful to characterize risks for obese children" (Barlow 2007). Indeed, central obesity is associated with an increased cardiometabolic risk in children and adolescents (Katzmarzyk et al. 2004).

National reference values are urgently needed in order to build global reference curves for waist circumference in children and adolescents similar to those for body mass index (Cole et al. 2000). However, the validity of comparisons between different populations critically depends on the comparability of the survey methods. This has recently been shown by a collaborative study from five European countries (Pigeot et al. 2009). Therefore, this paper collects corresponding data from all over the world and builds subsections as far as possible where comparability is considered to be more important than completeness.

85.2 Practical Methods and Techniques

85.2.1 General Remarks

In adults, normal weight, overweight, and obesity are globally defined as <25 kg/m², 25 to <30 kg/m² and ≥30 kg/m² body mass index (BMI), but waist circumference as an indicator for central adiposity is still waiting for a worldwide-accepted definition by gender and ethnicity (Alberti et al. 2005). This is also the case for children and adolescents for whom age–gender–ethnicity-specific centile values have to be defined for waist circumference, especially because of different rates of growth and development between males and females of different ages and ethnic groups.

85.2.2 Reference Methods

The comparisons with invasive methods in youth are sparse because of ethical and technical concerns. WC has been cross-validated against MRI (Brambilla et al. 2006). Further imaging techniques are computed tomography (CT) and dual X-ray absorptiometry (DXA). Bioimpedance is a rapid and inexpensive method to measure body fat and has been validated against DXA. It was used to construct LMS reference curves for body fat in UK children. (McCarthy et al. 2006).

85.2.3 Sites of Measurement

Sites of measurement is a very critical point, which needs urgent attention because this may cause substantial misleading informations of the lack of comparability of the sites of measurements made results in false reference data and wrong diagnosis, as demonstrated by the following examples. In adults, the prevalence of abdominal obesity (≥102/88 cm) varies between 22.1–33.2% in men and 30.1–55.5% in women, depending on the measurement site (Mason and Katzmarzyk 2009). In 1,140 Japanese subjects, the mean WC values in men/women were 85.2/73.1 cm at the midpoint, 86.8/78.8 cm at the umbilical level, and 87.2/82.5 cm at the iliac crest (Matsushita et al. 2009). The superior border of the iliac crest, midpoint between the iliac crest and the lowest rib, the umbilicus, and minimal waist are the four commonly used anatomic sites for measuring waist circumference. In 111 subjects aged from 7 to 83 years, WC values differed in magnitude depending on gender, but were highly reproducible and were correlated with total body and trunk adiposity. Separate analyses for children were not carried out (Wang et al. 2003). Among Japanese children, two measurement sites were used (maximum waist narrowing and top of the iliac crest) with significantly higher values for the iliac crest; the differences were much larger in girls than in boys (Inokuchi et al. 2007).

85.2.4 Practical Procedure

WC was measured to the nearest 0.1 cm, according to WHO recommendation, at the end of expiration with a nonelastic flexible tape placed directly on the skin horizontally at the midpoint between the lowest rib and the iliac crest and the hip over the major trochanters. Participants were standing erect with the abdomen relaxed. They were balanced on both feet with the feet touching each other and both arms hanging freely, with special attention being paid to ensure that the tape was positioned perpendicular to the longitudinal axis of the body and was parallel to the floor.

Common sites of measurement:

1. Midpoint between lowest rib and iliac crest (natural waist) (WHO 1995)
2. Umbilicus level (Norris and Wilson 1994)
3. Superior border of the iliac crest and
4. Minimal waist

85.3 Global Age–Gender–Ethnicity-Specific Waist Circumference Values

This review is necessarily incomplete because several national surveys are in the process of being published. Furthermore, to provide better comparability, WC percentiles are presented in separate tables, according to their calculation either by the LMS method (Cole et al. 1990) or by other methods. Nevertheless, comparisons between the percentile curves are complicated, as they cover different age ranges without separate classification for children (3–11 years) and adolescents (12–18 years), as proposed by the International Diabetes Federation (Zimmet et al. 2007). Thus, in infancy, gender differences for WC were small, but WC was significantly higher in boys than in girls from the age of 11 years onwards (Fredriks et al. 2005) (Fig. 85.1).

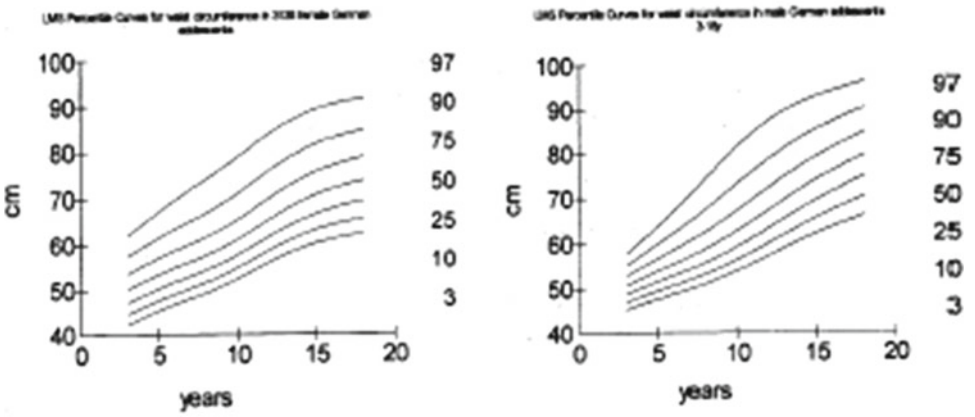

Fig. 85.1 Smoothed reference curves of 3–18-year-old German females (n = 3,136) and males (n = 1,421)

Generally, WC curves increase continuously with age in both genders; males have higher WC than females, especially in adolescence. In Spanish children, WC was higher at late puberty than in early and mid-puberty (Moreno et al. 2007). Compared with adolescents from Spain, the percentiles were higher in USA (Fernandez et al. 2004) and lower in Australia (Eisenmann 2005), Canada (Katzmarzyk 2004), and the UK (McCarthy et al. 2001). The Chinese 50th and 90th percentiles were lower than the curves for Iranian children, but closer to those of British children, except the 90th percentile curve for boys which had higher values (Sung et al. 2008). However, the shapes of the curves are variable, for example, the curves for Japanese boys aged 9–12 years demonstrated a prominent hump to the 97th percentile curves, which significantly differed from that of UK, Dutch and USA youth (Inokuchi et al. 2007). Between 7–8 years and 12–13 years, WC increased more than total adiposity (Garnett et al. 2005). At the 50th percentile, 5–19-year-old Nigerians had lower WC values than American and Spanish children, whereas Nigerian boys up to 9 years and girls up to age 14 years were similar to UK children (Senbanjo et al. 2009). Among 6–18-year-old Bulgarians, WC percentile values were higher than for British and Turkish children, but lower than for US children (Galcheva et al. 2009) (Fig. 85.2a, b).

Although measurement sites and the time of data collection were not too different, the main cause for the differences found might be ethnicity (genetic and environmental). Particularly after the age of 10 years, white males tended to have higher WC thresholds than the other groups (Katzmarzyk et al. 2004). Data from USA representing different ethnicities (Fernandez et al. 2004) pose some concern due to the use of the wide age range of 0–21 years, which means that comparisons between babies and young adults are being made. However, the Bogalusa Heart Study clearly demonstrates that the cutoff percentiles are fairly close in white and black 5–18-year-olds (Table 85.1).

As of now, the debate on appropriate cutoff points will continue so long as no global age-gender-ethnicity-specific cutoff points have been defined. Until then, several options have been proposed: a WC of 71 cm corresponded to a 14 times higher likelihood to have an adverse risk factor profile in prepubertal children aged 4–11 years (Higgins et al. 2001). The 90th or 95th percentiles were provisionally proposed to denote central obesity in Canadian adolescents (Katzmarzyk 2004). The 56th and 57th percentiles were suggested for white and the 50th and 52nd percentiles for black 5–18-year-old US males and females (Katzmarzyk et al. 2004) (Tables 85.1–85.3).

Summary Points

- Both overweight and obesity in children and adolescents are increasing worldwide.
- Especially central obesity is associated with an increased risk of cardiovascular disease.
- Therefore, early detection of adiposity in children and adolescents is mandatory.

- This should be the basis for simple, exact, reproducible, noninvasive and inexpensive diagnostic tools.
- For central obesity, this is obviously the measurement of waist circumference.
- Contrary to adults, the growing and developing body of children and adolescents requires cutoff values, which can be adapted to accommodate this special situation.
- The first step is the development of age- and gender-specific percentile curves, necessitating identical measurement methods.
- The second step is the determination of cutoff values, which have to be associated with cardiovascular risk factors, for example, by receiver operating characteristic (ROC) curves.
- The third step is the consideration of ethnic and national influences, which take into account the worldwide epidemic of adiposity in children and adolescents and which should result in national age–gender–ethnicity-specific percentile curves.
- The final step is developing a globally accepted definition of WC, as has been done for BMI.

Anthropometry of Middle-Aged and Aged in Health and Disease

Chapter 86
Anthropometric Aspects and Common Health Problems in Older Adults

Prasert Assantachai

Abstract The fast-growing numbers of older people worldwide and their health needs is coming under greater scrutiny, especially in developing countries where the rate of such growth is in the highest range. When compared to other age groups, nutritional problems are the most prevalent within older age group. Anthropometry is one of the ideal tools for nutritional assessment, either for under- and over-nutrition since it is cheap, easy to use and practical even in remote communities, comparable and requires no need for any sophisticated laboratory test or staff training. Although the traditional body mass index is commonly used for nutritional assessment both in clinical and research practices, its denominator, height, decreases rapidly in older age giving rise to a falsely high value in older people especially those who suffer from kyphoscoliosis. An alternative set of anthropometric measurements, namely, demiquet for older men and mindex for older women, is developed to compensate for this fault. Apart from nutritional assessment, more studies recently also highlight the potentials of anthropometry in assessing some other common health risks in older people such as atherosclerosis-related disorders, cognitive decline, osteoporosis, poor activity of daily living and all-cause mortality. However, in view of the physiologic aging changes and other confounding factors, the information found in younger age groups cannot be projected to and used directly in older adults. Some alternative anthropometric measurements and their interpretation must be recognized and developed.

Abbreviations

ADL	Activity of daily living
BMI	Body mass index
MAC	Mid-arm circumference
MAMC	Mid-arm muscle circumference
MMSE	Mini-Mental State Examination
MJ	Megajoule

86.1 Introduction

The fast-growing number of older people worldwide and its health needs are highlighted by every related discipline of medicine. When compared to other age groups, nutritional problems are the most prevalent among older people due to underlying factors, such as physiologic aging changes, chronic illness, as well as socioeconomic changes (Scrimshaw 1989). Although many advanced techniques to assess nutritional status have been developed over the last decade, anthropometry is an easy-to-use, unsophisticated, cheap, as well as practical tool, even when applied in the community, when compared to body composition analysis. However, many anthropometric parameters are subject to aging changes, for example, redistribution of fat in older women (Perissinotto et al. 2002). Moreover, gender difference, underlying global health status, urban versus rural community setting, and community dwelling versus institutionalized setting also influence the normative data in each particular group (Oguntona et al. 2000; Shatenstein et al. 2001). Therefore, the extrapolation of anthropometric standards derived from a younger age group is not appropriate for application directly in older people. The development of specific reference data collected from a large sampling population of older people is needed in almost every country (Chumlea et al. 1993).

To date, anthropometry has been studied in older people in various settings in terms of physiologic aging changes, alternative anthropometric measurements, and nutritional assessment and its associations with other health problems. Some common health problems prevalent among older adults, which relate to anthropometry, namely malnutrition (both undernutrition and overnutrition), hypertension, diabetes mellitus, cardiovascular disorders, cognitive dysfunction, osteoporosis, functional decline, and all-cause mortality, will be addressed in this chapter. Understanding all these topics is essential in applying anthropometric measurement in both clinical practice and epidemiologic studies for older people.

86.2 Physiologic Aging Changes of Anthropometric Measurements

86.2.1 Weight

Body weight is one of the most important and useful indicators of nutritional status, especially if it is followed up over time. If it is not intentionally lost, weight loss of 5% or more over the preceding 3 months indicates undernutrition. Weight declines longitudinally both in community-dwelling older people (Barbosa et al. 2005) and in the institutionalized setting (Shatenstein et al. 2001), in both Asian (Woo et al. 2001) and European people (Perissinotto et al. 2002). Although the prevalence of overweight increases with increasing age in developed countries for both men and women (to a greater degree in women), longitudinal body weight measurements taken 10 years apart tend to indicate weight loss in those aged 55 years or more (Williamson 1993).

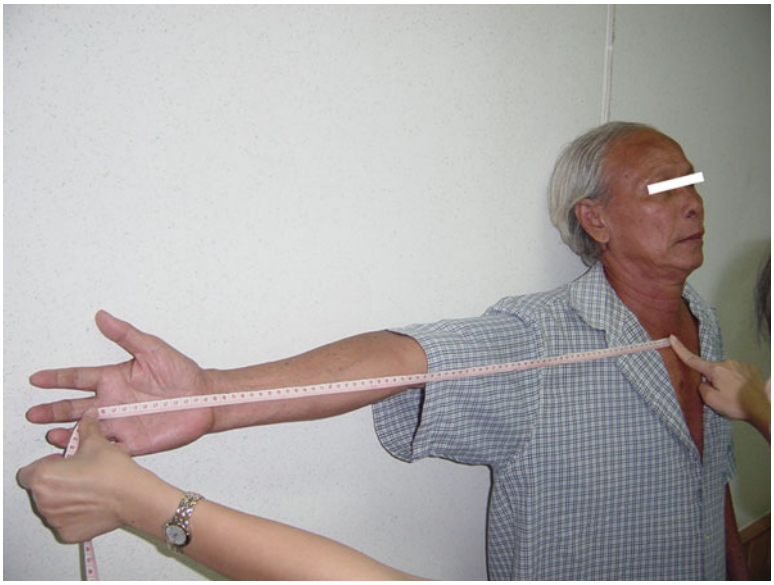

Fig. 86.1 Demispan measurement: the length between the center of suprasternal notch and the metacarpophalangeal joint between the third and fourth fingers while the subject stands against a flat wall, with the arm extended laterally and kept at shoulder height

86.2.2 Height

Height is the most widely used measure of skeletal size, which also decreases 1–2 cm/decade, but more rapidly at older ages due to associated vertebral compression, disk change, and postural changes. Therefore, careful measurement and interpretation of height in older people with kyphoscoliosis should be done.

86.2.3 Body Mass Index

Similar to body weight change, body mass index (BMI) declines with age, and it tends to be higher in women than in men. This reflects decline in weight to a greater extent than in height, as height also decreases. The turning point of BMI was observed at the age of 75 years in Europeans (Perissinotto et al. 2002). Although BMI has been widely used to reflect global nutritional status in the general population, some age-related changes make the use of the standard classification system for BMI less reliable in older people. First, the loss of height with age due to age-related osteoporosis, kyphoscoliosis and degenerative disk changes, and, second, the increase in fat-to-lean ratio in older people are the two main causes. There is, however, a set of alternative indices using demispan (the length between the center of suprasternal notch and the metacarpophalangeal joint between the third and fourth fingers while the subject stands against a flat wall, with the arm extended laterally and kept at shoulder height) to replace height in the calculation formula, giving rise to two alternative indices, namely mindex and demiquet. Figure 86.1 demonstrates the correct way to measure demispan. The relationship between arm span and body weight remains constant in older people with normal morphology.

86.2.4 Mindex and Demiquet

Mindex (mindex = body weight divided by demispan) is for use in women, whereas demiquet (demiquet = body weight divided by demispan squared) is for use in men. This is based on the study by Lehmann (1991) that weight increases proportionately with arm span in women and arm span squared in men. There are some studies indicating the usefulness of both of these Quetelet indices in predicting undernutrition in older people.(Donkin et al. 1998; Murphy et al. 2000) It is easier to measure demispan in older people than height, using a small-sized, convenient-to-carry, measuring tape, even in the sick elderly who cannot stand up.

86.2.5 Upper-Arm Anthropometric Circumference

The circumference of the mid part of the upper arm (mid-arm circumference or MAC), is a useful alternative to body weight, if the subject cannot be weighed as in the case of sick or frail older people. Two other indices reflecting lean body mass, mid-arm muscle circumference (MAMC) and mid-arm muscle area, can be calculated from MAC, as shown below. Again, all these three parameters also show significant decline with increasing age in both genders (Falciglia et al. 1988; Izawa et al. 2009).

$$\text{MAMC} = \text{MAC} - (\pi \times \text{triceps skinfold})$$

$$\text{Mid-arm muscle area} = (\text{MAMC})^2 / 4\pi$$

86.2.6 Skinfold Thickness

Skinfold thickness is the most widely used direct measure of body fat mass. It is proposed that the amount of subcutaneous fat stored in four favorite sites, that is, triceps skinfold, biceps skinfold, subscapular skinfold, and suprailiac skinfold can represent total body fat (Durnin and Womersley 1974). However, as there is age-related fat redistribution, with subcutaneous fat on the limbs tending to decrease but intra-abdominal fat tending to increase, which is especially more pronounced in older women, skinfold thickness cannot be used to assess changes in body fat mass in older people (Hughes et al. 2004).

86.2.7 Waist Circumference

Although fat redistribution occurs with aging, waist circumference (WC) decreases longitudinally in both genders (Barbosa et al. 2005). In men, both WC and waist–hip ratio were higher for the youngest age group than for the oldest age group. Meanwhile, in women, waist–hip ratio was higher in the oldest age group, indicating marked visceral fat redistribution within older women (Perissinotto et al. 2002).

86.3 Anthropometric Measurements and Malnutrition in Older Adults

As there is a limitation in using BMI to assess nutritional status in older people, the two alternative indices have been proposed, as mentioned earlier. Using the normative data of height and demispan from 2,324 older Thai people aged 60 years or more, who were randomly recruited from each region of Thailand and the cutoff points of BMI denoting underweight, overweight, and obesity proposed by the Steering Committee of the Regional Office for the Western Pacific Region of WHO, the International Association for the Study of Obesity, and the International Obesity Task Force (Anuurad et al. 2003), the cutoff points of mindex and demiquet indicating global nutritional status (Table 86.1) have been created by simple arithmetic equations as shown below (Assantachai et al. 2006a):

$$\text{BMI} = \text{body weight} / (\text{height})^2 \text{ and}$$

$$\text{body weight} = \text{BMI} \times (\text{height})^2$$

$$\text{while, demiquet} = \text{body weight} / (\text{demispan})^2 \text{ and}$$

$$\text{body weight} = \text{demiquet} \times (\text{demispan})^2;$$

$$\text{therefore, body weight} = \text{BMI} \times (\text{height})^2 = \text{demiquet} \times (\text{demispan})^2 \text{ and}$$

$$\text{demiquet} = \text{BMI} \times (\text{height})^2 / (\text{demispan})^2$$

From normative data of 2,324 older Thai people aged 60 years or more:

$$(\text{height})^2 / (\text{demispan})^2 = 4.0863 \ (\text{men}) \text{and}$$

$$(\text{height})^2 / (\text{demispan}) = 3.0241 \ (\text{women})$$

As the cutoff point of BMI denoting undernutrition = <18.5, the cutoff point of demiquet denoting undernutrition in older men

$$= < 18.5 \times 4.0863$$

$$= < 75.60 \text{ kg.} / \text{m.}^2$$

Table 86.1 The corresponding values of three Quetelet indices for each category of nutritional status, based on the Steering Committee of the Regional Office for the Western Pacific Region of WHO, the International Association for the Study of Obesity, and the International Obesity Task Force

	BMI (kg/m^2)	Mindex (kg/m)	Demiquet (kg/m^2)
Underweight	<18.5	<55.95	<75.60
Normal range	18.5–22.9	55.95–69.25	75.60–93.58
Overweight at risk	23–24.9	69.55–75.30	93.98–101.75
Obese I	25–29.9	75.60–90.42	102.16–122.18
Obese II	≥30	≥90.72	≥122.59

Table 86.2 Characteristics of three Quetelet indices of Asian and Caucasian older adults in terms of mean (standard deviation), 50th percentile and their correlation coefficients to each relevant parameter (Asian (Assantachai et al. 2006a): 644 men, 1,013 women and Caucasian (Smith et al. 1995): 182 men, 212 women)

	Mean (SD)		50th percentile		Pearson correlation coefficient (r)			
	Asian	Caucasian	Asian	Caucasian	Asian		Caucasian	
					mindex	demiquet	mindex	demiquet
BMI: men	21.5(4.0)	26.0(3.1)	21.4	25.9	n/a	0.88	n/a	0.89
BMI: women	22.8(4.5)	25.9(4.3)	22.8	25.6	0.93	n/a	0.96	n/a
mindex	68.3(15.5)	88.6(14.7)	69.3	86.6	n/a	n/a	n/a	n/a
demiquet	86.7(20.2)	121.1(15.6)	88.1	120.0	n/a	n/a	n/a	n/a

and the cutoff point of mindex denoting undernutrition in older women

$$= < 18.5 \times 3.0241$$

$$= < 55.95 \text{ kg./ m}$$

The Pearson correlation coefficients between BMI and mindex and demiquet in older people are satisfactorily very high, with the r-value of 0.93–0.96 for mindex and 0.88–0.89 for demiquet (Smith et al. 1995; Assantachai et al. 2006a). Comparisons of the normative data between various Quetelet indices of Caucasian older adults (data from Canada reported by Smith et al. 1995) and Asian older adults (data from Thailand) are shown in Table 86.2. It is quite obvious that the normative data between these two ethnics are markedly different. Any universal cutoff points of these Quetelet indices proposed to indicate a similar health parameter in the future should be invalid. This situation has been proven by the current effort of health authorities trying to set a population-specific cutoff point for BMI (WHO expert consultation 2004).

Comparing the correlations between these three Quetelet indices and other nutritional parameters based on Thai older people, body fat mass achieves the highest r-value of 0.94 for BMI in females; the other r-values are 0.93 for mindex, 0.83 for BMI in males, and 0.74 for demiquet (Table 86.3). Likewise, MAC, as an alternative to body weight, also achieves the second highest r-value of 0.87 for mindex and the others are 0.86 for BMI in females, 0.85 for BMI in males, and 0.76 for demiquet. Subcutaneous fat, in line with fat mass, also correlates satisfactorily with these Quetelet indices, especially when the subscapular skinfold thickness reaches the highest r-value of 0.74 for BMI in males and mindex, followed by the suprailiac skinfold thickness, whereas the biceps skinfold thickness has the poorest correlation with all these three Quetelet indices. This pattern is also seen in a study in USA, which concluded that BMI is positively correlated with subscapular and triceps skinfold thickness to a higher degree than with suprailiac skinfold (Yearick 1978).

Based on the national survey among Thai older people, the correlations between two alternative Quetelet indices (demiquet and mindex) and other anthropometric measurements and body composition analysis are demonstrated in Figs. 86.2–86.5 (Assantachai and Lekhakula 2000). When the r-values of each pair of Quetelet index and other nutritional parameters are compared for any statistical significance, there is no difference between the degree of correlations of MAC and skinfold thickness with mindex and BMI, whereas, for demiquet, this is not so. Therefore, mindex is a better index of obesity, in parallel with BMI, than demiquet (White et al. 1991; Assantachai et al. 2006a).

Regarding the correlations with both hematological and biochemical parameters in older people, lymphocyte count acquires the highest r-value of correlation with demiquet (0.37), followed by mindex (0.35), BMI in females (0.31), and BMI in males (0.25). Blood total cholesterol and low-density lipoprotein are among the blood chemistry parameters that correlate better with all these three Quetelet indices, in both men and women. Interestingly, serum albumin, a non-specific nutritional

Table 86.3 Pearson correlation coefficients of BMI, mindex, and demiquet with various anthropometric measurements and other nutritional parameters ((Assantachai et al. 2006a): 644 men, 1,013 women and (Yearick 1978): 25 men, 75 women: only for skinfold thickness data)

	BMI

4. Vitamin status				
Thiamin pyrophosphate effect**	–0.09	–0.10	–0.22	–0.16
Vitamin A	–0.08	–0.10**	–0.20**	–0.18**
α-Tocopherol	0.03	–0.08**	–0.10**	–0.15**

*$p < 0.001$, **$p < 0.05$

parameter commonly used in daily clinical practice, also correlates satisfactorily with demiquet, mindex, BMI in males, and BMI in females, with *r*-values of 0.42, 0.27, 0.27, and 0.19, respectively. Furthermore, their degree of correlations with demiquet and mindex is higher, with statistical significance, than with BMI. In summary, although mindex and demiquet do not correlate with fat parameters, that is, body fat mass, MAC, and skinfold thickness as well as BMI, they perform better than BMI as general nutrition and metabolic indices, such as, lymphocyte count, serum albumin, and lean body mass.

Compared to other nutritional parameters, many kinds of vitamins obviously show little or no relationship with all three Quetelet indices, based on data of Asian older adults ($r < 0.25$). The majority of them even show inverse relationships, especially in older women (Assantachai et al. 2006a). In Caucasian older adults, there was also no association between low micronutrient status (vitamin B12, erythrocyte folate, vitamin C, and vitamin D) and having BMI, mindex, demiquet or MAC in the lowest third of these measurements (McNeill et al. 2002). However, within Thai older adults, the thiamin pyrophosphate effect (TPP effect) acquires the highest *r*-value of –0.22 ($p < 0.05$) for demiquet and –0.16 ($p < 0.05$) for mindex, whereas cyanocobalamin level has the least relationship with mindex ($r = 0.02$, $p > 0.05$) Interestingly, the correlation coefficient of demiquet and the TPP effect ($r = –0.22$) is significantly higher than those for BMI and the TPP effect ($r = –0.09$), with a p-value of 0.025. It seems that demiquet may be superior to BMI in indicating thiamin level. When using multiple logistic regression analysis to explore independent factors determining various vitamin deficiencies, thiamin is found to be the only vitamin with which the anthropometric variable, BMI, is significantly associated with the case with adjusted OR = 0.959 (95% CI: 0.938–0.981) (Assantachai et al. 2007). As the main sources of thiamin for the Thai people are rice and legumes, which are also

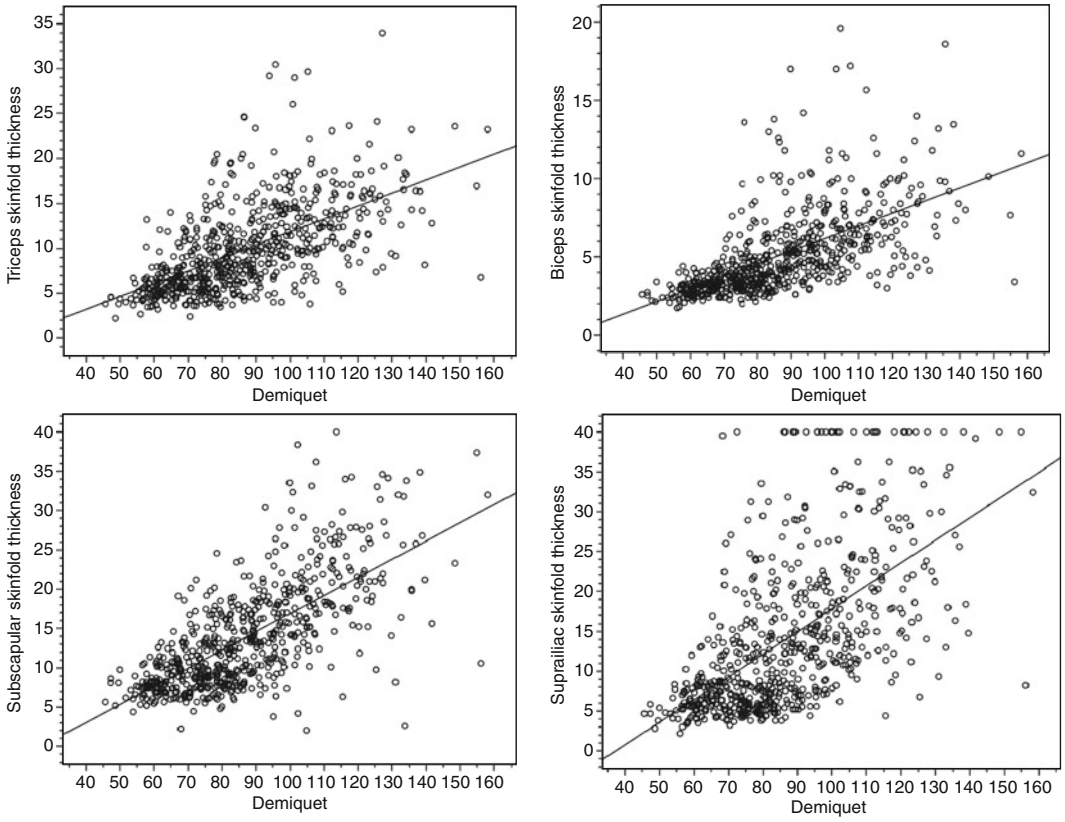

Fig. 86.2 Correlations with regression lines between demiquet and four common sites of measured skinfold thickness among older men

the main ingredients in daily Thai food, those who cannot consume these traditional dishes, therefore, suffer from both thiamin deficiency and global undernutrition, which the Quetelet index can also predict. The discordance of the relationships between all three Quetelet indices, and protein–energy nutritional parameters, and vitamin levels, except thiamin, may be explained by the different food sources rich in each specific nutrient and the inability of older adults to consume a heterogeneous daily diet. In conclusion, anthropometry can suggest vitamin deficiency, but only the one which is closely related to protein–energy malnutrition, that is, Quetelet indices and thiamin deficiency. Demiquet seems to be better than BMI regarding this specific condition.

86.3.1 Epidemiology of Malnutrition in Older Adults Based on Anthropometry

86.3.1.1 Undernutrition

With the use of BMI < 18.5 kg/m^2 to indicate undernutrition, as recommended by WHO, epidemiological data reveal the high prevalence of undernutrition in older adults ranging from less than 5% in

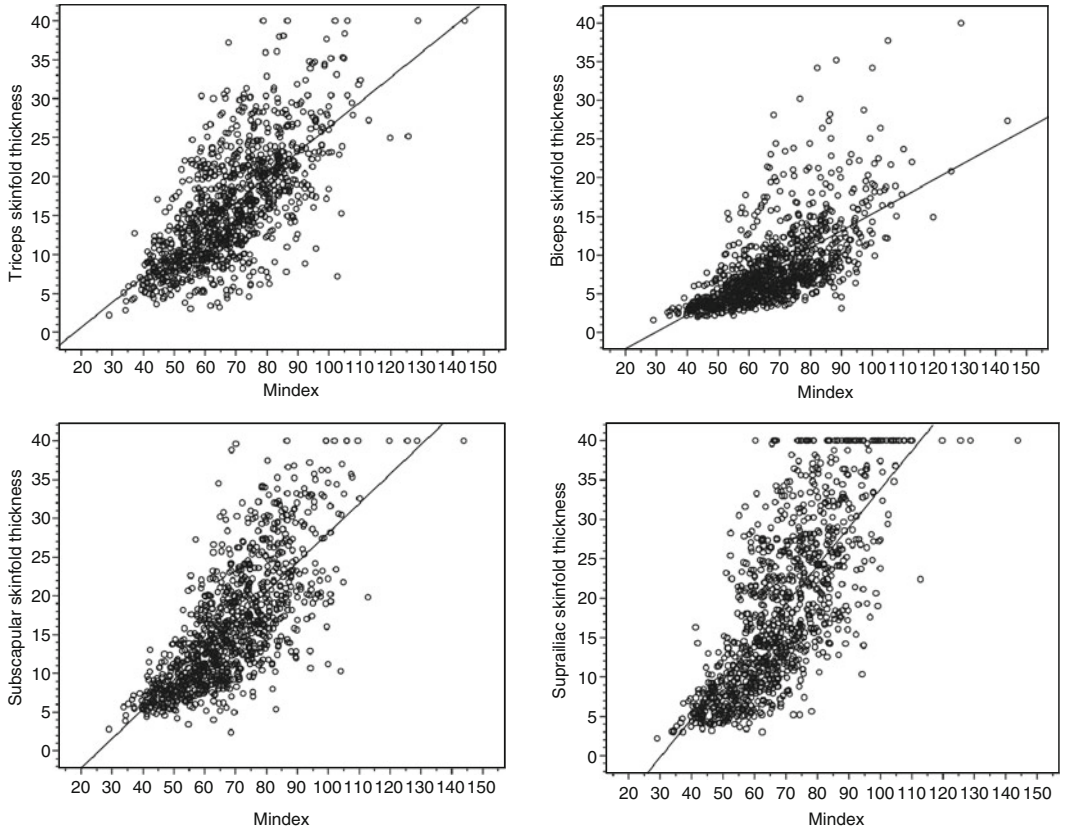

Fig. 86.3 Correlations with regression lines between mindex and four common sites of measured skinfold thickness among older women

Italy to 7.8–8.4% in Brazil and 33.3% in Uganda (Tavares et al. 1999; Perissinotto et al. 2002; Kikafunda et al. 2005). Although BMI in older women tends to be higher than in older men, the last study reveals the prevalence of malnutrition of up to 68% in women, whereas it is only 32.4% in men. As such, there are some factors which can affect the prevalence of undernutrition, as detected by anthropometry, and they need to be highlighted as follows.

Age Group

The proportion of older adults with BMI < 20 kg/m^2 increased with age in a study involving 19 geographically and ethnically varied populations. The prevalence of underweight in women aged 80 years or more was 1.5 times higher in Brazil and 6.0 times higher in Italy than those aged 60–69 years old (Launer et al. 1996). In a cross-sectional study involving Thai older adults living in a rural area, BMI and mindex started to decline significantly at the age of 70 years or more in women, but there was no BMI and demiquet difference between age groups in older men (Assantachai and Lekhakula 2000). This may be the result of early death of older men who have lower BMI, and only those who have higher BMI are able to survive up to the oldest age group. Therefore, careful interpretation of a cross-sectional study regarding the age-specific Quetelet indices should be undertaken.

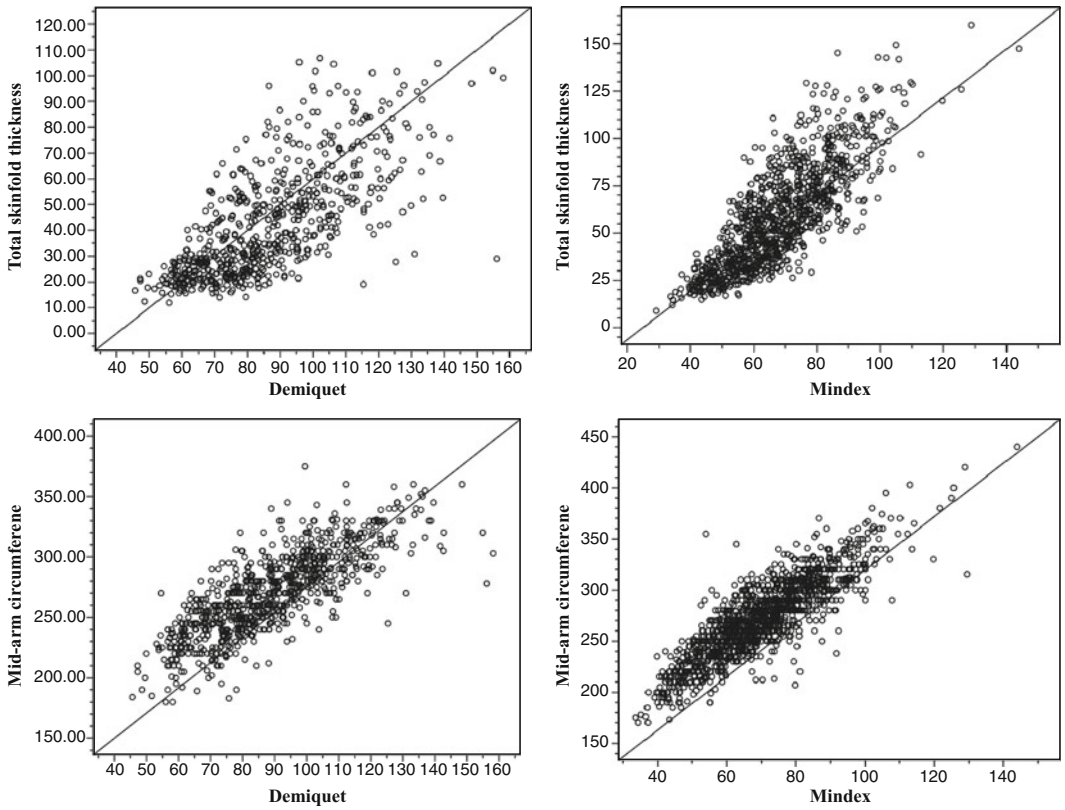

Fig. 86.4 Correlations with regression lines between Quetelet indices (demiquet and mindex) and other anthropometric parameters (MAC and total skinfold thickness: biceps, triceps, and subscapular and suprailiac skinfold thickness)

In conjunction with the longitudinal study in Hong Kong, which found that lower anthropometric indices were associated with higher mortality though waist–hip ratio was not, this point also highlights the greater importance of undernutrition over weight gain in older adults (Woo et al. 2001).

Gender

Although the majority of studies reveal that BMI is significantly higher in older women than in men, the study in Uganda shows the opposite direction (Kikafunda et al. 2005). This indicates the interaction between gender and other factors, for example, sociocultural issues, which can influence the nutritional status of older people in an unexpected direction.

Institutionalized Setting

The prevalence of protein energy malnutrition is comparatively high, up to 45–85%, in older people living in institutions. The prevalence of underweight (body weight less than 80% of ideal), lower triceps skinfold, and MAMC less than 90% or more of standard is 12%, 21%, and 55%, respectively

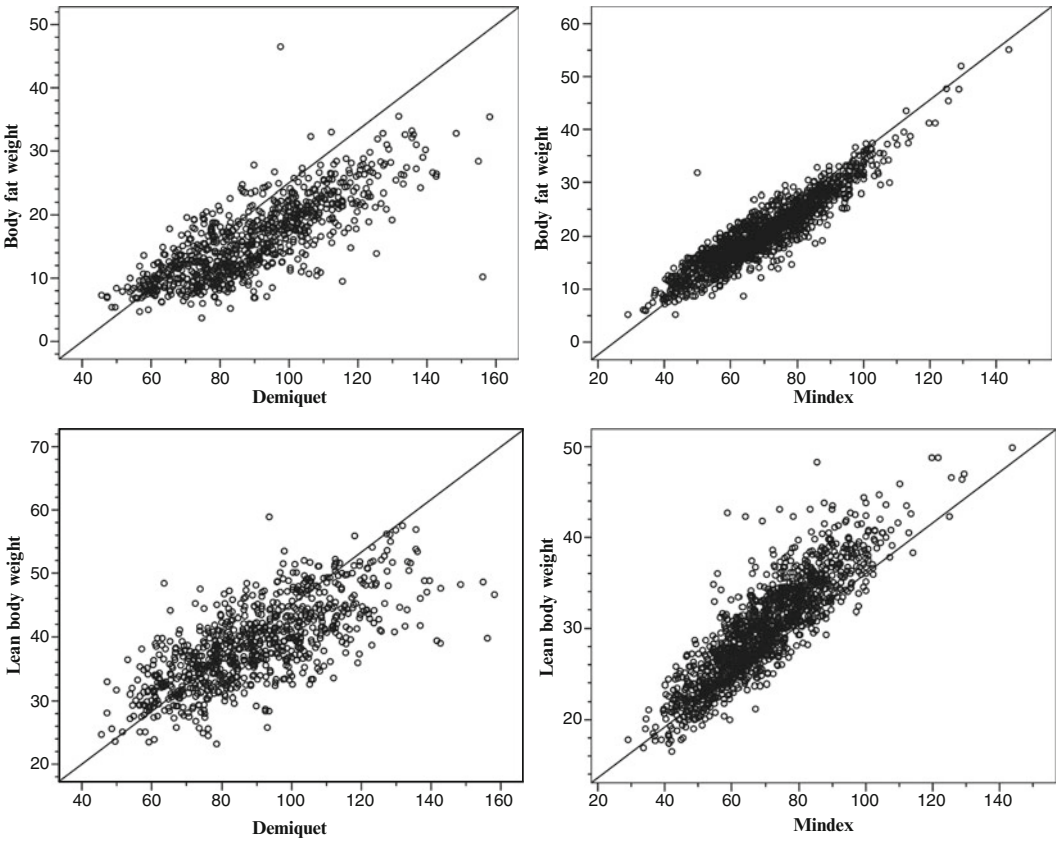

Fig. 86.5 Correlations with regression lines between Quetelet indices (demiquet and mindex) and body composition parameters (body fat weight and lean body weight)

(Abbasi 1995). In a 5-year longitudinal comparative study, height declined by an average of 2 cm in institutionalized subjects, which was significantly more than their counterparts, who lived in the community and lost height by an average of 1.4 cm (Shatenstein et al. 2001). The common causes of decreased food intake among nursing home populations include advanced age, higher degree of functional decline, higher prevalence of chronic diseases and their associated poor physical and mental health as well as polypharmacy, monotonous food, and, lastly, unmet need for assistance.

Community Setting

Available studies from three continents indicate that the prevalence of underweight found in rural areas is persistently higher than those found in urban settings (Side et al. 1991; Tavares et al. 1999; Oguntona et al. 2000). Waist circumference, hip circumference, and MAC in older women living in rural areas of Nigeria are also lower than for those in urban areas (Table 86.4). The study from China revealed that both older men and women in rural areas consumed lower amounts of protein, fat, calcium, iron, retinol, thiamin, riboflavin, and nicotinic acid than those from urban areas. Meanwhile, the study from Nigeria also showed that the daily food intake in rural subjects was 4.23 MJ, significantly lower than the amount consumed by urban subjects (5.86 MJ). The waist–hip ratio in older

Mid-arm circumference	23.8	23.3	22.6	20.2	28.1	26.3	24.8	24.0	yes	yes	no	yes

*p value of comparisons between area difference in each country: yes – $p < 0.05$; no – $p > 0.05$

women correlates best with 24-h dietary recall, in both rural and urban settings, with *r*-values of 0.34 and 0.39, respectively. Waist circumference in older men appears to be correlated best with dietary recall in rural and urban settings, with *r*-values of 0.26 and 0.31, respectively. The underlying causes of lower food intake in the rural environment relate to low income, low educational level achieved, and poor access to a variety of food.

86.3.1.2 Overweight and Obesity

Although BMI is the anthropometric variable suggested by WHO to identify overweight or obesity in the general population, application of its original cutoff point of ≥25 kg/m^2 suggesting overweight to non-Caucasian population, especially for those whose body builds are much smaller, is controversial (Anuurad et al. 2003). In the year 2004, WHO expert consultation had published their consensus, which not only agreed with the different associations between BMI, percentage of body fat, and health risks of Asian and European populations, but also identified further potential public health action cutoff points of 23.0, 27.5, 32.5, and 37.5 kg/m^2 along the BMI continuum (WHO expert consultation 2004). The result of a national survey in Mexico showed that use of the current BMI thresholds to identify being overweight may lead to an overestimation of the number of overweight elderly (Sánchez-García et al. 2007).

An important longitudinal study involving subjects aged ≥75 years (n = 14,833) in the UK found that current BMI-based health-risk categories used to define the burden of disease related to adult overweight and obesity are not valid for older people aged ≥75 years. In this same situation, waist–hip ratio is suggested to be used, as it has a positive relation with risk of death at the cutoff points of >0.99 for nonsmoking men and >0.90 for nonsmoking women (Price et al. 2006). Whether these cutoff points can also be applied to non-Caucasian older people needs further longitudinal study recruiting a large population sample. However, in a study using anthropometry to predict abdominal visceral fat in older people, WC was found to be the best overall predictor, with areas under the ROC curves of 0.88–0.92, higher than BMI and waisthip ratio (WHR) did (Rankinen et al. 1999). The better performance of WC compared to the waist–hip ratio in predicting mortality was supported by a study, which revealed that, in men aged 55 years or more, a large WC was a better predictor of higher 5-year mortality than waist–hip ratio or BMI (Visscher et al. 1999). Theoretically, the waist–hip ratio is subject to other confounding factors leading to hip muscle wasting, which is much more pronounced in older people, resulting in more difficult interpretation of this anthropometric parameter in older people. As such, WC reflecting abdominal obesity performs as a better anthropometric indicator than BMI or, probably, waist–hip ratio, in predicting obesity-related health risk in older adults.

86.4 Applications to Other Areas of Health and Common Diseases in Older Adults

86.4.1 Functional Decline

The relationship of anthropometry and functional decline in older adults can be seen in both directions of nutritional status indicated by its parameters.

86.4.1.1 Undernutrition

In a longitudinal study involving community-dwelling frail elderly, the decline of BMI and MAC over 2 years of follow-up associates with the loss of activity of daily living (ADL) (Izawa et al. 2009). Low BMI (<18.5 kg/m^2) is also found to be one of the independent factors predicting hospital admission over the last 1 year in community-dwelling older adults (Assantachai and Maranetra 2005). Regarding details of ADL affected by anthropometry, impaired mobility, incontinence, and difficulty in feeding were significantly associated with BMI (Kikafunda et al. 2005).

86.4.1.2 Overnutrition

Higher BMI, either current or from past record, has been associated with increase in self-reported functional decline in older people. BMI was also found to be negatively related with some physical performance tests, for example, get-up-and-go test, walking speed, chair stands, and reach test in a study involving 705 older Japanese women in Hawaii (Jensen 2005). Information from a large cross-sectional study (56,510 women aged 45–71 years) revealed a significant dose-response relationship between increasing levels of BMI and increased function limitations (Coakley et al. 1998). Likewise, data from a large prospective cohort study (6,632 women aged ≥65 years) also showed that obesity was one of the modifiable predictors of self-reported functional decline over a 4-year period (Sarkisian et al. 2000).

86.4.2 Cognitive Dysfunction

There were two longitudinal studies that evaluated the effects of BMI and body weight upon cognitive function, two longitudinal studies that examined the effects of regional adiposity, whereas another study examined the relationships of both BMI and regional adiposity upon cognitive function simultaneously. The association of anthropometry and cognitive dysfunction in older adults is subject to gender-specific difference. Higher BMI at baseline was found to be associated with cognitive decline in men alone (Elias et al. 2003; Kanaya et al. 2009). In older women, it had a protective effect against cognitive decline (Kanaya et al. 2009) and those who lost the most weight suffered from the worst cognitive function (Bagger et al. 2004).

As far as the regional adiposity is concerned, there were three prospective cohort studies in which anthropometric measurements were used to assess the relationship between regional adiposity and cognitive decline. A total of 1,814 subjects were followed up in the Framingham Offspring Study; of these, those who had the uppermost quartile of waist–hip ratio performed executive function and visuomotor skills testing (Trails B, Visual Reproductions–Immediate and Delayed Recall) significantly poorer after 12 years of follow-up (Wolf et al. 2007). In another interesting study, where 6,583 members of Kaiser Permanente were followed up for an average of 36 years, those in the uppermost quintile regarding sagittal abdominal diameter had a threefold increase in risk of dementia independently of BMI and other cardiovascular risk factors (Whitmer et al. 2008). However, the study reported by Kanaya et al., as mentioned earlier, also examined the relationship between the modified version of Mini-Mental State Examination (MMSE) and regional adiposity measured by both anthropometry and abdominal computed tomography (CT) scan. Interestingly, the anthropometric measures of visceral fat (WC and abdominal sagittal diameter) had a better relationship with cognitive decline than visceral fat measured directly by CT scan in men alone (Kanaya et al. 2009).

When anthropometry is used to assess nutritional status in demented and non-demented older people, body weight, BMI, skinfold thickness, and MAC were significantly lower among patients with dementia, especially those hospitalized, than normally cognitive older adults. This was not the result of low nutritional intake among patients with dementia, as all dementia patients had higher intake of energy, protein, vitamins, and minerals than control subjects (Burns et al. 1989).

86.4.3 All-Cause Mortality

The relationship between mortality and BMI in the general population is U-shaped, with a tendency for mortality to increase at both extremes of the range, that is, very low or very high BMI. However, because of fat redistribution toward more abdominal visceral fat in older adults and reduced lipolysis in the visceral fat of older people (this being less harmful as compared to young adults), high BMI has a less pronounced relationship with mortality in older than in younger populations.

Conversely, low BMI and weight loss in the older adults are persistently strong predictors of mortality. As mentioned in the section discussing the epidemiology of malnutrition, undernutrition carries a greater risk for mortality than does overweight in older people. Common consequences of undernutrition in older people involve a wider range of adverse outcomes, namely, alteration in immune function and its associated infections, cognitive decline, pressure ulcer, delayed wound healing, functional decline, poor quality of life, and, ultimately, death (Table 86.5). In a nutritional survey in a 200-bed nursing home, triceps skinfold and MAC were two anthropometric variables identified by univariate analysis as significant predictors of death (Abbasi 1995).

86.4.4 Hypertension

According to The Bangkok Longitudinal Study by Siriraj Hospital for the Older Men and Women (BLOSSOM) Study, in 2,201 community-dwelling older adults who were initially normotensive and followed up for 3 years, high BMI was found persistently as a significant risk factor predicting the emerging of hypertension, with RR = 1.074 (95% CI: 1.043–1.107) and RR = 1.049 (95% CI: 1.018–1.081) at the second year and third year of follow-up, respectively (Assantachai et al. 2008). Likewise, a nationwide cross-sectional study in Thailand (n = 2,336) also revealed that body weight, BMI, demiquet, mindex, MAC, all four sites of skinfold thickness, and waist–hip ratio of older adults who had hypertension were significantly higher than in those who were normotensive, except for height and MAMC (Assantachai and Lekhakula 2000). However, hypertension was associated with obesity based on BMI (OR = 1.98) to a greater degree than with overweight (OR = 1.42), high-WC (OR = 1.62), and tertile 3 of the conicity index (OR = 1.53) (Sánchez-Viveros et al. 2008).

In the Framingham Heart Study where 1,814 subjects were followed up for 12 years, those who had hypertension or were receiving anti-hypertensive treatment performed executive function and visuomotor skills (Trails B, Visual Reproductions–Immediate and Delayed Recall) significantly poorer than those who did not suffer from hypertension. Meanwhile, when hypertension and regional adiposity were combined, the hypertensive cases, who had waist–hip ratio in the uppermost quartile, had poorer neurocognitive performance than their counterparts, whereas those who had a waist–hip ratio in the range of the first to the third quartiles did not show this relationship (Wolf et al. 2007). Nevertheless, there were positive correlations between systolic blood pressure and the waist–hip ratio for both older men and women (Side et al. 1991).

Table 86.5 Adverse outcomes of abnormal anthropometric measurements among older people, apart from the direct effect of malnutrition

Adverse outcome	Anthropometric measurement	Study		
		Setting	Outcome	Author
Functional decline	↓ BMI, ↓ MAC	Community, frail	ADL loss	Izawa et al. (2009)

86.4.5 Diabetes Mellitus

The nationwide cross-sectional study in Thailand (n = 2,336) showed that those who suffered from diabetes mellitus had significantly higher levels of the majority of anthropometric indices, namely, body weight, BMI, mindex, demiquet, subscapular skinfold, suprailiac skinfold, biceps skinfold, and MAC, except for triceps skinfold, height, and MAMC, than those who were not diabetic (Assantachai and Lekhakula 2000). The other two studies done in Caucasian older women reported that, those who had type-2 diabetes had statistically significantly higher body weight, BMI, triceps skinfold thickness, and WC than nondiabetic women (Kubena et al. 1991; Onisto et al. 2009). Relative weight (observed body weight expressed as a percentage of the suggested weight for adult men or women of similar height and medium frame) also correlated with serum glucose level in nondiabetic women with the r-value of 0.44 ($p < 0.01$) (Yearick1978).

Comparing among anthropometric parameters, WC was associated with type-2 diabetes to a higher degree than overweight and obesity (Sánchez-Viveros et al. 2008). Central adiposity measured by anthropometry is also employed by the International Diabetic Federation (IDF) using WC at the cutoff points of ≥90 cm in Asian men (≥94 cm in Caucasian men) and ≥80 cm in women as a prerequisite for diagnosis of metabolic syndrome.

86.4.6 Fall

The older adults who had a history of falls over the previous 6 months had lower height (152.6 ± 8.1 cm) than non-fallers (154.9 ± 7.9), with statistical significance ($p < 0.001$) (Assantachai et al. 2003).

86.4.7 Osteoporosis

Height is found to be one of the five factors, which can predict the calcaneal bone mineral density measured by peripheral dual energy X-ray absorptiometry in institutionalized older people with the regression coefficient of 0.003 for every 1 cm of height change ($p < 0.001$) (Assantachai et al. 2006b).

As body weight and increasing age are two strong risk factors of osteoporosis, a screening tool for osteoporosis based on these two factors was originally developed for postmenopausal Asian women and named the Osteoporosis Self-Assessment Screening Tool for Asians (OSTA) (Koh et al. 2001). The risk index can be calculated with the equation shown below:

$$\text{Risk score} = [\text{body weight in kg.} - \text{age in year}] \times 0.2, \text{ truncated to an integer}$$

Based on defining osteoporosis as a T score of -2.5 or less of bone mineral density at the vertebrae, total hip, or femoral neck, a cutoff point of OSTA at –1 provided a sensitivity of 70–90% and a specificity of 70%. When this tool (at the cutoff point of 3) was applied to American older men at a veterans hospital, the sensitivity and specificity were 93% and 66%, respectively (Adler et al. 2003).

Summary Points

- More studies involving the application of population-specific alternative Quetelet indices are needed for nutritional assessment as well as for health promotion and nutrition-related disease prevention in older adults.
- Mid-arm circumference is a good alternative nutritional parameter to body weight, if the patient cannot be weighed; subscapular skinfold thickness is the best site to assess subcutaneous fat in older adults.
- Although mindex is a better index of obesity, parallel with BMI, than demiquet, both mindex and demiquet reflect general nutritional status more accurately than BMI. While WC is better than BMI in predicting the adverse outcome of obesity, mindex and demiquet are better than BMI in predicting the occurrence of undernutrition in older adults.
- Nutritional assessment in older adults requires comprehensive coverage of various nutritional parameters including protein and energy intake as well as micronutrients, due to their inability to consume various types of food resulted from edentulism, physiologic aging changes, associated chronic illness, and socioeconomic changes. As anthropometry correlates poorly with micronutrient status, it should be accompanied by other aspects of nutritional assessment, such as, dietary recall, body composition analysis, and biochemical tests.
- Although there exists the U-shaped relationship between BMI and mortality in the general population, undernutrition in older adults, as identified by anthropometry, should be of greater concern compared to overweight, as it associates with higher mortality.
- Functional decline in older adults can be affected by either under- or overnutrition, as suggested by BMI and other related indices.
- Apart from nutritional assessment, anthropometry can be used to assess other common health problems in the older adults, for example, functional decline, cognitive decline, hypertension, diabetes mellitus, fall, osteoporosis, and all-cause mortality.

Chapter 87
Anthropometrical Changes in Older Taiwanese and Diet and Exercise

Alan C. Tsai

Abstract The aging process involves changes in weight, height, body mass index (BMI), muscle mass, and a redistribution of body fat. These anthropometrical measures are closely related to nutrition, functional ability and health. However, most studies conducted on aging-associated anthropometrical changes so far involve Western populations. Knowledge on population-specific changes is necessary for understanding the population-related differences. This article aims to review anthropometrical changes important to geriatric nutritional assessment including weight, height, BMI, and mid arm (MAC) and calf circumferences (CC) in older Taiwanese. BMI is probably the most widely studied anthropometrical indicator but mid arm and CC have also received increasing attention in recent years. The pattern of age-associated anthropometrical changes in Taiwanese generally parallels the Western populations. BMI, an indicator of body weight relative to height, is often considered an indicator of body fatness. Currently, the World Health Organization (WHO) sets a uniform standard of BMI 25–29.9 kg/m^2 for overweight and ≥30 for obesity. However, there is evidence that these thresholds may underestimate the prevalence of overweight and obesity in Taiwanese. The Department of Health of Taiwan has adopted modified thresholds of BMI 24–26.9 kg/m^2 for overweight and ≥27 for obesity for Taiwanese. Similarly, because of stature differences, elderly Taiwanese appear to have different cut-points of MAC (22.5/21 cm for Taiwanese men/women vs. 21/21 cm for Western men/women) and CC (28/25 cm for Taiwanese men/women vs. 31/31 cm for Western men/women) for undernutrition. Several social, lifestyle and dietary factors have been observed to impact these indicators in older Taiwanese. Age has the strongest impact on BMI, MAC and CC. Routine physical exercise is associated with higher BMI, MAC and CC. Cigarette-smoking is associated with lower BMI and CC but not MAC. Consumption of dairy products is associated with lower BMI and MAC but not CC. Consumption of fruit is associated with greater BMI and CC but not MAC whereas consumption of tea is associated with greater BMI, MAC and CC. These anthropometrical indicators are useful nutritional and health indicators for old persons or hospitalized patients and are included in many major geriatric nutritional assessment tools. MAC and especially CC, in addition to reflecting general nutritional status, also reflect body muscle mass or the

87.1 Introduction

The aging process involves physiological and nutritional changes that are highlighted by height, weight, and muscle mass losses, and body fat redistribution. Age-associated changes in body size, body composition, and body shape occur throughout various life stages. In older adults, body shape and composition can change even without change in body weight. Changes in body composition differ in men and women at different life stages. Different anthropometric indicators are used at different life stages to evaluate them. Certain body measurements can reflect over- or undernutrition status and can be indicative of specific health conditions. Excessive body weight or obesity has been shown to be associated with a number of chronic health conditions in various age groups (Seidell and Flegal 1997). Thus, there has been a strong interest in finding an anthropometrical indicator that best reflects obesity. In older adults, body mass index (BMI) is probably the most widely used or most thoroughly studied anthropometrical indicator. It is calculated from two easily accessible indicators, height and weight, using the simple equation of kg/m^2. There are also other indicators, such as waist circumference, hip to waist ratio, and waist to height ratio, that have been shown to reflect body fatness well.

In older adults, circumferences of extremities, such as arm and calf, are particularly useful. Mid-arm circumference (MAC) and calf circumference (CC) both reflect subcutaneous fat and therefore are at least, to some extent, similar to BMI, indicative of overall body fatness. However, MAC and CC are also indicative of body muscle mass. Thus, MAC and CC reflect both body fatness and physical functional ability. A severe decrease in CC can result from severe illness or the aging-related functional decline and greatly limits mobility, whereas a severe decrease in MAC often occurs during the final stage of functional decline. Aging-related mobility impairment often limits the activities of daily living and that can have an impact on nutritional status (Mason et al. 2008).

Most studies conducted on aging-related anthropometric measurements to date involve subjects of Western populations and are heavily concentrated on the BMI–body fatness–health relationship. Relatively few studies have been conducted in Asian populations, especially related to MAC and CC. Anthropometrical variations among populations, especially between the Western and the Asian populations, are well recognized (Chumlea 2006; Wen et al. 2008). Data derived from Western populations may not be directly applicable to Eastern populations. Therefore, the objective of this chapter is to examine the recent findings on the aging-associated changes in anthropometrical parameters, especially BMI (or weight and height), MAC, and CC in the Chinese population in Taiwan. This information will be valuable for providing better care and support to an increasing number of elderly persons.

87.2 Age-Associated Changes in Anthropometrical Parameters

87.2.1 Aging-Related Anthropometrical Changes

Aging in later life is associated with decreases in both height and weight but the starting point and the rate of decline differ between men and women. Age-related anthropometrical changes in Taiwanese have so far received only limited attention. Recently, Chiu et al. (2000) examined the age-related weight, height, and BMI changes in a cross-sectional sample of elderly Taiwanese, 65 years or older, whereas Tsai et al. (2007b) analyzed age-related changes in mid-arm and CC, in addition to height, weight, and BMI in another cross-sectional sample of Taiwanese, 53 years or older. Tsai et al. (2007b) also analyzed the association of diet and lifestyle with anthropometrical measures. These two studies found that the patterns of the age-associated changes in weight, height, and BMI in older Taiwanese are quite comparable to those observed in Western populations.

Taiwanese women generally start losing height earlier and more severely than their male counterparts. Height loss starts roughly around the late sixth decade of life for women, but in the early seventh decade of life for men. During the period from the age of 60–80 years, average height loss was approximately 1.5 cm and 1 cm/decade for Taiwanese women/men, respectively (Fig. 87.1). Contrary to height changes, body weight peaks during the late 50s in men, but early in the 60s in women (Tsai et al. 2007b). During the period from the age of 60 to 80 years, the average total weight loss is about 5.6 kg (8%) for men and 6.4 kg (12%) for women. Although both height and weight decrease during old age, the magnitude of weight loss is greater than height loss. As a result, BMI generally also decreases during this stage. In the groups surveyed/measured for this study, Taiwanese men reach a peak BMI of 24.0 kg/m^2 in their late 50s, whereas the females reach a peak BMI of 24.4 kg/m^2 in their early 60s (Tsai et al. 2007b). During the period from the age of 60 to 80 years, the average BMI decrease is about 1.5 kg/m^2 in men and 1.9 kg/m^2 in women (Fig. 87.1).

In addition to weight, height, and BMI changes, aging is also associated with a decrease in body muscle mass and that presumably is due to aging-related physiological changes in thyroid hormone, human growth hormone, and testosterone concentrations, and decreased physical activity. Aging-associated body muscle loss is evident in the changes in mid-arm and CC. These changes have not yet been extensively studied in older Taiwanese until our recent attempt to develop a nutrition assessment, the Mini Nutritional Assessment (MNA), for this population. Our analysis of the cross-sectional data indicates that both MAC and CC also decrease during aging. MAC seems to decrease rather slowly (0.71 cm for men and 0.65 cm for women) from the age of 60–75 years, but seems to decrease rather sharply afterward, especially for women (decrease 1.09 cm for men and 1.42 for women in the next 5 years) (Fig. 87.2). The aging-associated decrease in CC appears more gradual, roughly about 0.5 cm/5 years before the age of 75 years and more than 1 cm/5 years afterward (especially for women). Women seem to have more severe MAC and CC losses compared to men after the age of 80 years.

In older Taiwanese, MAC reaches an average peak size of 29.5 cm for men in their late 50s and 28.6 cm for women in their early 60s. From the age of 60–80 years, the proportion of elderly with small MAC (arbitrarily defined as <25 cm) increases from approximately 6.9% to 21.9% in men and from 11.1% to 34.8% in women (Fig. 87.3). The average MAC decreases to 27.0 cm in men and 26.5 cm in women, 80–84 years old (Tsai et al. 2007b). In a 3-year longitudinal study, Woo et al. (2001) observed an average loss of MAC approximately 0.2 cm for Hong Kong Chinese men and 0.6 cm for women. The losses were greater (0.24 and 0.8 cm, respectively) for those who had disease at baseline.

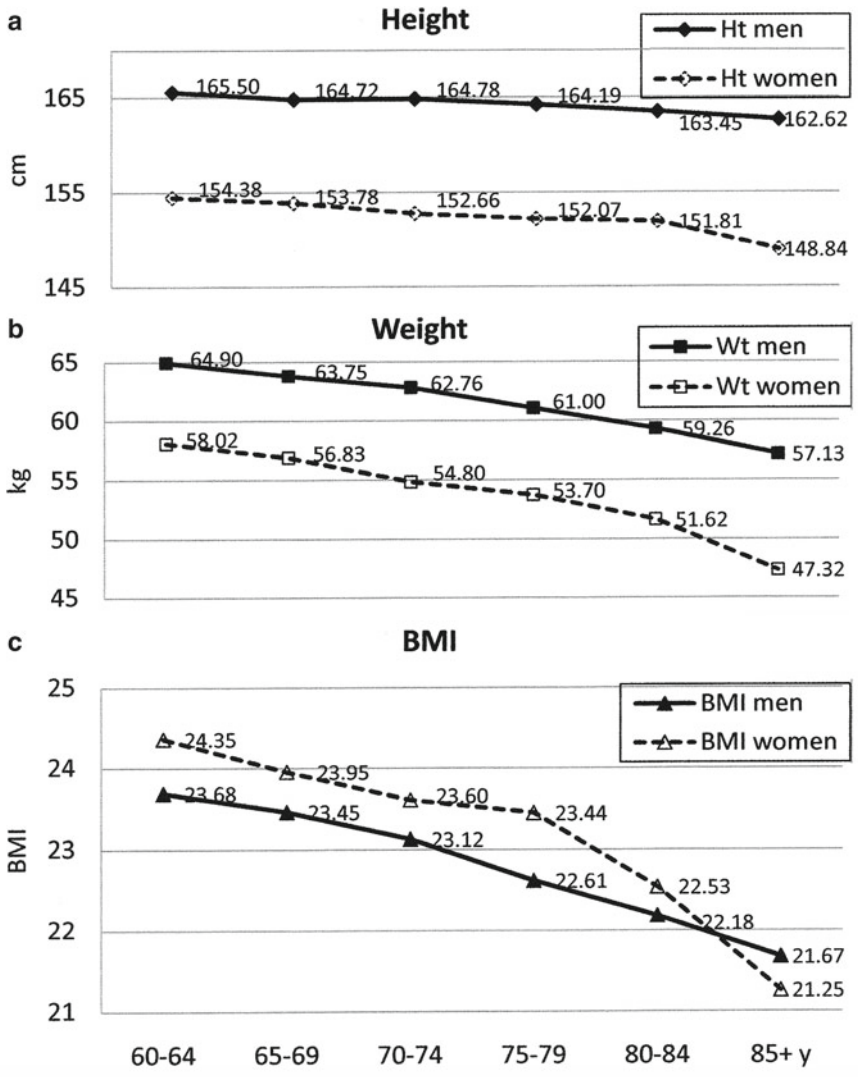

Fig. 87.1 Age-associated changes in height, weight, and BMI in Taiwanese 60 years or older. Mean height, weight, and BMI stratified by gender and 5-year age ranges of men and women, 60 years or older, in Taiwan. n = 315, 284, 640, 385, 165, and 90 for men and 316, 244, 435, 335, 162, and 94 for women, for the respective age groups. Significant ($p < 0.05$) age effects were observed in weight, height, and BMI in both men and women on the basis of one-way ANOVA

The average CC peaks at around 36 cm in the late sixth decade of life and reaches a low of roughly 32.7 cm in the early ninth decade of life. Women start losing CC earlier than men (at around the mid-50s vs. the early 60s for men). As a result, from the age of 60 to 80 years, the proportion of elderly having small CC (arbitrarily defined as <30 cm) increases from 3.6% to 16.5% for men and from 8.9% to 41.9% for women (Fig. 87.3). Significantly greater proportions of elderly women than men have small MAC or CC ($p < 0.05$). These results suggest that, during advanced aging, increasingly larger proportions of the elderly have more severe body muscle mass loss and are therefore encountering an ever-increasing risk of mobility impairment.

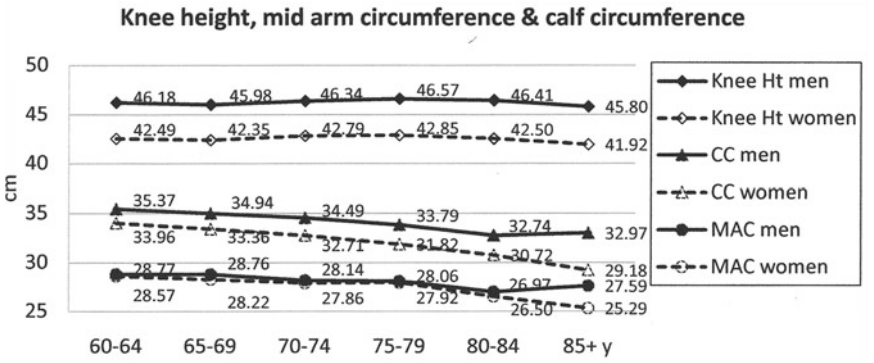

Fig. 87.2 Age-associated changes in knee height, mid-arm circumference (MAC), and calf circumference in Taiwanese 60 years or older. Mean knee height, MAC, and calf circumference (CC) stratified by gender and 5-year age ranges of men and women, 60 years or older, in Taiwan. n = 315, 284, 640, 385, 165, and 90 for men and 316, 244, 435, 335, 162, and 94 for women, for the respective age groups. Significant ($p < 0.05$) age effects were observed in MAC and CC in both men and women on the basis of one-way ANOVA

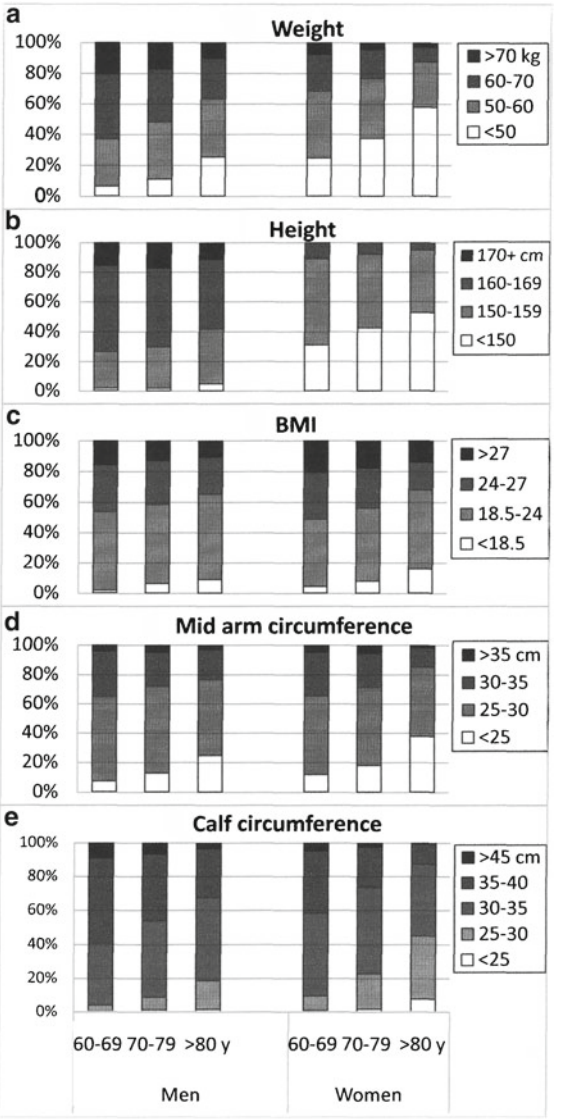

Fig. 87.3 Age-associated changes in the distribution of weight, height, BMI, MAC, and CC in Taiwanese 60 years or older. Cumulative distribution (%) of (**a**) body weight, (**b**) corrected standing height, (**c**) corrected BMI, (**d**) MAC, and (**e**) CC stratified by gender and 10-year age ranges in men and women, 60 years or older, in Taiwan. n = 1879 men and 1586 women. Significant ($p < 0.05$) age effects were observed in all three parameters in both men and women on the basis of one-way ANOVA

Knee heights are relatively constant throughout all age ranges, approximately 46.0–46.5 cm for men and 42.0–42.5 cm for women (Fig. 87.3).

The aging-associated height and weight losses observed in older Taiwanese are comparable to those observed in Western populations (Sorkin et al. 1999). Weight and height losses have also been confirmed in a 3-year longitudinal study in Hong Kong Chinese 70 years or older, with or without disease at baseline (Woo et al. 2001). Aging-associated height and weight losses have been observed in both cross-sectional (Davison et al. 2002) and longitudinal studies in Western populations (Sorkin et al. 1999). The rate of decrease in height has been reported to be between 0.5 and 1.5 cm/decade in Western populations, estimated from trends or slopes of regressions on age using cross-sectional data.

87.2.2 Age-Related Anthropometrical Changes in Distribution

As a result of these changes, the proportions of heavier men and women have decreased and proportions of lighter men and women have increased ($p < 0.05$) (Fig. 87.3). The change in the distribution of height appears less drastic in men than in women. Aging also affects BMI distributions. The proportions of underweight (BMI < 18.5 kg/cm^2) men and women are relatively small, 1.8% and 4.4%, respectively, in 60–64-year-old elderly but increase rather drastically after the age of 70 years. After the age of 80 years, 8.8% of elderly men and 16% of elderly women are underweight, according to the Taiwanese definition (BMI < 18.5 kg/cm^2). The proportions of overweight (BMI = 24.0–26.9 kg/cm^2) men and women decrease drastically after the age of 80 years. A greater proportion of women than men are obese (BMI ≥ 27 kg/cm^2) throughout all age ranges studied.

87.3 Factors Associated with Anthropometrical Changes

Because of the important health implication of the anthropometrical measures, there is a strong interest in delineating the factors that are associated with or can impact these changes. The factors associated with BMI changes, especially in areas related to weight control and obesity treatment in younger age groups, have been well studied in both Western and Eastern populations. However, for older adults, the main concern is weight loss (and its impact on functional ability, morbidity, and mortality), and not weight gain or overweight (Adams et al. 2006). The prevention of excessive weight loss, especially body muscle mass, is a major issue in geriatric nutrition.

87.3.1 Sociodemographic Factors

Associations of the sociodemographic, lifestyle, and dietary factors with BMI, MAC, and CC in subjects who were 60 years or older of the Survey of Health and Living Status of the Elderly in Taiwan (SHLSET) were analyzed and are presented in Table 87.1. Gender has a significant impact on all three measures. The female gender is associated with higher BMI but lower MAC and especially CC. Physiologically, females have a higher percentage of body fat and (as discussed earlier) their body weight peaks later than men but have earlier and more severe height loss than men.

The level of the associations of sociodemographic, lifestyle, and dietary factors with BMI, MAC and CC in Taiwanese men and women, 53 years or older

For gender, male was the reference. "Beta" = standardized coefficient and "t" = the level of significance of the associations. *, ** and *** designate $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively. Adjusted R^2 values are 0.060, 0.042, and 0.159 for BMI, MAC, and CC, respectively

[a]All variables except gender were treated as continuous numbers

Women generally have smaller MAC and CC than men, perhaps due to stature differences and physiological differences in muscle mass.

Old age is strongly associated with lower BMI, MAC, and CC. Among all factors examined, age has the strongest impact on the three anthropometrical measures. The decreases in BMI, MAC, and CC are, in general, the result of the overall aging-associated physiological decline. Aging impairs metabolic capacity, appetite, and immune competency, resulting in an overall functional decline and an increase in the susceptibility to infections and chronic diseases. In older Taiwanese, socioeconomical status (indicated by years of formal education) is not significantly associated with BMI or MAC, although it is positively associated with CC. The exact reason for the association of higher socioeconomic status with higher CC warrants further investigation.

87.3.2 Lifestyle Factors

Among the lifestyle factors, routine exercise is positively associated with all three anthropometrical factors, but the association is much stronger with CC than with BMI or MAC. This may be because CC is a better indicator of mobility ability than BMI or MAC. The association is bidirectional, as those who exercise routinely can maintain or strengthen CC, whereas those who have good CC are able to maintain physical activity or functional ability. Lower-extremity muscle mass is an important determinant of physical performance among functionally limited elders (Reid et al. 2008). Cigarette

smoking is negatively associated with BMI and CC but not MAC and cessation of smoking is known to result in weight gain. Munafo et al. (2009) have shown that never-smokers and ex-smokers differ in BMI from current smokers by an average of 1.6 kg/m^2 and smoking cessation is associated with a corresponding average increase of 1.6 kg/m^2. It is possible that cigarette smoking affects appetite regulation and therefore reduces energy intake. The negative association between smoking and CC is probably multifactorial. In addition to the dietary factors, smoking has been shown to impair muscle protein synthesis and increase the expression of genes associated with impaired muscle maintenance (Petersen et al. 2007; Stavropoulos-Kalinoglou et al. 2008). Smoking, therefore, is likely to increase the risk of sarcopenia. It is not known whether it is mediated through a direct impact on tissue protein synthesis or through a change in lifestyle pattern, such as less routine physical activity. Alcohol drinking is not significantly associated with the anthropometric indicators.

87.3.3 Dietary Factors

Dietary factors have also been shown to be associated with BMI, MAC, and CC of the elderly. The consumption of meat/poultry is positively associated with BMI but not MAC or CC, whereas the consumption of fish shows a strongly positive association with MAC but not with BMI or CC. It is of interest to note that meat/poultry and fish have different associations with the anthropometrical parameters. Although both are considered protein-rich foods, meat/poultry generally has a higher fat content than most fish. Frequent fish eaters are also generally considered to be more conscientious about health. The consumption of dairy is negatively associated with both BMI and MAC, but not with CC. In Taiwan, most of the current older adults do not habitually drink milk or consume dairy products, mainly due to the unavailability of these products in early years and also due to relatively high prevalence of lactose intolerance. Dairy products have not been widely available or affordable until recent decades in Taiwan. Generally, older adults supplemented their diet with formulated or fortified dairy products only during general weakness or illness. Thus, the negative association is at least in part a result of this negative connection that people consume dairy products when they are considered malnourished or during illness. Conversely, there are reports that dairy consumption is associated with lighter body weight in Western populations and the mechanism is thought to be mediated through its calcium content (Zemel et al. 2004; Zemel 2005). However, this observation remains to be confirmed with more robust studies. Consumption of legume food (mainly soy products) is also negatively associated with BMI and MAC but not with CC. While the exact explanation is not known, it might be related to the fact that legume consumption is related to vegetarianism. A wide variety of soy products, such as tofu and soy milk, is the staple food of most vegetarians in Taiwan. Vegetarians are generally considered to pay greater attention to diet and lifestyle and more closely watch their weight. There is also a notion that soy foods may contribute to weight loss. However, the currently available evidence is still controversial (St Once et al. 2007; Cope et al. 2008). The intake of vegetable is not associated with any of the three parameters, but the intake of fruits is positively associated with BMI and CC but did not reach a statistical significance with MAC. The intake of grain, mainly rice and wheat products in Taiwan, is positively associated with CC but not with BMI or MAC. It is of interest to note that tea (*Camellia*) drinking is associated with greater BMI, MAC, and CC. A possible explanation for this association is that, usually, only people who are relatively healthy will drink tea. People who are weak, on medication, or have sleep disorders do not drink tea, for fear of causing further sleep difficulty.

87.4 Applications to Other Areas of Health and Disease

87.4.1 BMI as an Indicator of Body Fatness

BMI, defined in terms of kg/m^2, is a measure of relative weight to height. Although the indicator does not directly reflect the level of body fat, it is often used to indicate body fatness because people usually gain fat when they gain weight. The WHO defines BMI < 18.5 kg/m^2 as underweight, 18.5–24.9 as normal weight, 25–29.9 as overweight, and ≥30 as obesity. However, there is evidence that the same definition cannot be uniformly applied to all world populations. Studies have shown that, at a given BMI, Asians (Taiwanese, for example) have a higher percentage of body fat than their Western counterparts. On the other hand, at a given level of body fatness, Asians have lower BMI (by about two BMI units). Thus, the WHO definition of overweight and obesity normally under-reflects the prevalence of many obesity-related chronic diseases in Asians. Asians have a higher risk of chronic diseases, such as hypertension and dyslipidemia, at lower BMI (Wen et al. 2008). To correct for these differences, the Department of Health of Taiwan has proposed a set of body fatness definitions for the Taiwanese: BMI < 18.5 kg/m^2 as underweight, 18.5–23.9 as normal weight, 24–26.9 as overweight, and ≥27 as obese. Using these criteria, 13.6% of Taiwanese elderly men and 18.2% of women are obese, instead of 2.8% of men and 5.8% of women based on the WHO definition (Table 87.2).

87.4.2 Accessibility of BMI in Frail Elderly

BMI is a useful indicator because both body weight and height are relatively accessible and easy to measure for most people. However, this indicator may not be very practical for frail or old individuals. As mentioned earlier, both weight and height decrease starting around the seventh decade of life. BMI can change without actually changing body weight. Accuracy of measurements could also be an issue in frail or old individuals. Thus, for old persons, BMI may not be as accessible as it seems. Another drawback about BMI is that it reflects mainly body fatness and not so much functional ability.

Table 87.2 Prevalence rates of overweight and obesity of elderly Taiwanese according to the WHO and the Taiwanese definitions

	WHO definition		Taiwan definition	
Study	Overweight BMI 25–29.9	Obesity BMI ≥ 30	Overweight BMI 24.0–26.9	Obesity BMI ≥ 27.0
1999 SHLSET[a] (%)				
Men	28.3	2.8	29.5	13.6
Women	27.8	5.8	27.2	18.2
1989–1991 Geriatric survey[b] (%)				
Men	27.3	3.2	NA	NA
Women	34.9	6.3		

The percentage of subjects classified overweight or obesity according to two definitions: World Health Organization (WHO) definition or the Taiwan definition

[a]From Tsai et al. (2007b): Subjects were 2,205 men and 1,933 women, 53 years or older

[b]From Chiu et al. (2000): Subjects were 1,322 men and 1,278 women, 65 years or older

Table 87.3 Spearmen's correlations among BMI, MAC and CC of Taiwanese elderly under various living settings

	1999 national sample[a]		Community living[b]		Care center-living[c]		Nursing home-living[c]	
Parameter	MAC	CC	MAC	CC	MAC	CC	MAC	CC

[c]Tsai et al. (2009c) for the care-center- and nursing-home studies

87.4.3 Applicability of Mid-Arm and Calf Circumferences in Nutritional Assessment

BMI reflects mainly body weight or body fatness, whereas MAC and CC reflect subcutaneous fat (or body fatness) and local muscle mass (functional ability). Thus, weight loss in older adults will be reflected in reduced MAC and CC, in addition to BMI. In fact, there is a relatively high degree of correlation among the three indicators. In Taiwanese elderly, the correlation coefficients (r) among the three variables generally run in the range of 0.6–0.8 (Table 87.3).

Because MAC and CC reflect body muscle mass and, thus, functional ability, in addition to body fatness, MAC and/or CC may offer an advantage over BMI in serving as a component in a nutrition/health assessment tool. For older individuals, good functional ability is important in maintaining good nutritional status. A small CC will suggest poor nutritional state and failing functional ability. Impaired functional ability can impact the ability to shop, prepare foods, or even self-feed. Thus, CC and MAC, in addition to BMI, are increasingly being included in nutritional and health assessment tools (Donini et al. 2007). A very good example is the MNA, a popular geriatric nutrition assessment tool (Guigoz et al. 2002).

87.4.4 Anthropometrics in Nutritional Assessment

Geriatric assessment is essential for quality geriatric care, and nutritional assessment is an essential component of geriatric assessment. Anthropometrical indicators play key roles in geriatric nutritional assessment and one good example is the MNA, one of the most widely used geriatric nutritional assessment tools. The tool was developed in the 1990s in Europe based on clinical data of Western populations. It has a long form (18 questions) for assessment and a short form (including the first six questions of the long form) for screening. The long-form MNA includes four anthropometrical indicators (recent weight loss, BMI, MAC, and CC) and accounts for 8 of the 30 total points, whereas the short form includes two anthropometrical items (recent weight loss and BMI) and accounts for 6 of the total 14 points in the screen. The tool does not involve any invasive indicator and is simple and effective, and thus has gained wide acceptance as a geriatric nutrition assessment tool. Malnutrition Universal Screening Tool (MUST) (Scott 2008) is another popular tool and it relies solely on two anthropometrical indicators (BMI and unplanned weight loss) for grading nutritional risk. However, in both tools, the thresholds for determining undernutrition are based on clinical data of Western populations. Because of the differences in stature, lifestyle, and healthcare systems, it has been cautioned that population-specific modifications should be carried out before applying these tools to populations other than those that the tools are intended for (Chumlea 2006). Given the well-recognized

Table 87.4 Pearson's correlation coefficients (r) of the nutritional status (scores) assessed with the Mini Nutritional Assessment (MNA) using BMI, MAC, and CC in elderly Taiwanese under various settings

Parameters	National sample[a] (N = 2,429)	Community living[a] (N = 501)	Care center[a] (N = 109)	Nursing home[a] (N = 103)
BMI	0.190	0.277***	0.29**	0.518***
MAC	0.244	0.271***	0.31**	0.418***
CC	0.341	0.320***	0.54***	0.564***

Pearson's correlation coefficients (r) showing the strength of correlations between BMI (body mass index), MAC (mid-arm circumference), and CC (calf circumference), with the nutritional status represented by the score of the MNA of older Taiwanese under various healthcare settings. ***significant correlation at $p<0.001$

[a]To avoid the condition that an independent variable is a component of the dependent variable, the testing anthropometric variable was removed from the total MNA score (the independent variable). Data for these analyses were from Tsai et al. (2007b) for the national sample study, from Tsai et al. (2009b) for the community living study, and from Tsai et al. (2009c) for the care center and nursing home studies

differences in body size and composition between the Caucasian and the Asian populations, it would be necessary to adopt the population-specific anthropometrical thresholds in order to maintain the content equivalence of the tool. Thus, Tsai et al. (2008a) have derived Taiwanese-specific BMI, MAC, and CC thresholds for undernutrition from a nationally representative sample of elderly Taiwanese. The minimum threshold for BMI is 17 kg/m^2, instead of 19 kg/m^2 for Caucasians. The threshold for MAC is 22.5 cm for elderly Taiwanese men and 21 cm for women, instead of 21 cm for both Caucasian men and women, and the threshold for CC is 28 cm for elderly Taiwanese men and 25 cm for Taiwanese women, instead of 31 cm for both Caucasian men and women (Tsai et al. 2006) A series of studies by Tsai and his coworkers have demonstrated that the adoption of these population-specific anthropometrical thresholds indeed improves the predictive ability of the MNA (Tsai et al. 2008a, 2007a, 2008b, 2009a, b, 2010a, b; Tsai and Ku 2007).

It should be mentioned that, although MAC and CC are useful nutritional and functional status indicators, only relatively few nutrition assessment tools have included these two indicators. Theoretically, there are advantages in including MAC and CC in addition to BMI or recent weight loss in a nutritional assessment tool. As mentioned earlier, MAC and CC, in addition to reflecting the overall nutritional status, also reflect muscle mass or the functional ability of the upper and lower extremities, respectively. Thus, nutritional tools that include MAC and CC can also reflect mobility ability. However, compared to calf circumference, MAC is not as good an indicator of body muscle mass because movement of the arms in daily living activities occurs until the very late stages of functional decline, which helps to maintain arm muscle mass. Thus, calf circumference is a better indicator of overall muscle mass. The legs contain over half of the muscle mass of the body, and a reduction in calf circumference can happen rather quickly during wasting, severe undernutrition, functional decline, illness, or frailty (Chumlea 2006).

In elderly persons, malnutrition is often accompanied by functional decline. Thus, an anthropometrical indicator that can reflect functional decline in addition to undernutrition would presumably be better than one that can reflect merely undernutrition. We have recently tested such a hypothesis by substituting CC and MAC for BMI in the long-form MNA, or CC for BMI in short-form MNA or MUST and confirmed that CC (and MAC in the case of long-form MNA) not only can substitute for BMI, but also improve the overall predictive ability of the short-form MNA and the MUST in Taiwanese elderly under various living settings (Tsai et al. 2009a). CC is most strongly associated with the overall nutritional scores assessed with the MNA in the elderly under various settings (Table 87.4). These results support the findings observed in hospitalized patients by Coelho et al. (2006) that CC is a stronger indicator of undernutrition than BMI and is a useful noninvasive and economical indicator of nutritional status.

Key Features

Table 87.5 Key facts of anthropometrical changes in older Taiwanese

1. The pattern of changes in weight, height, BMI, and MAC and CC of the Taiwanese elderly is comparable to what is observed in Western populations.
2. The thresholds for undernutrition for BMI, MAC, and CC for older Asians (Taiwanese) are different those for from their Western counterparts.
3. Because Taiwanese have a higher percentage of body fat-to-BMI relationship relative to Western populations, the WHO overweight/obesity definition based on BMI will underestimate the prevalence of overweight/obesity of Taiwanese.
4. BMI is mainly an indicator of relative body weight or body fatness, whereas MAC and, especially, CC reflect body muscle mass or functional ability, in addition to body fatness. Thus, BMI is a useful indicator for overnutrition, whereas MAC and, especially, CC are useful indicators of undernutrition and functional decline.
5. Because of the well-recognized population differences in anthropometrical measures, care should be taken in applying a uniform standard for classifying body fatness or undernutrition in countries where population-specific anthropometrical cut-points are not yet available.

This table lists the key facts of anthropometrical changes in older Taiwanese 60 years or older
BMI body mass index; *MAC* mid-arm circumference; *CC* calf circumference; *WHO* World Health Organization

87.5 Further Studies

To meet the need of increasing geriatric population in most societies and the demand for better quality of care on the one hand, and the increasing workload of caregivers on the other, the development of a simpler and more efficient tool for routine monitoring of the health and nutritional status of frail elderly or hospitalized persons is urgently needed. The anthropometrical measures should probably be a basic component in the construction of such a tool because these indicators are accessible, easy to measure, noninvasive, and, most importantly, indicative of one's nutritional status and functional ability. However, because of the cultural and anthropometrical differences, and the variation in healthcare systems, further effort should be made to develop population-specific tools. The population-specific aging-associated changes in MAC, CC, and other key anthropometrical indicators and their modification by diet, lifestyle, living environment, and health condition or diseases also need to be more extensively explored.

Summary Points

- Body mass index (BMI, calculated from weight (kg)/height (m^2)) and mid-arm and CC are simple anthropometrical measures that reflect the nutritional state of elderly persons.
- Weight, height, and mid-arm and CC are easily accessible, simple to measure, and non-invasive indicators.
- BMI, MAC, and calf circumference decrease during advanced aging.
- The patterns of these changes in Taiwanese are similar to those observed in the Western populations, but the magnitude of changes varies.
- The WHO definition of overweight (BMI 25–29.9) and obesity (BMI > 30) based on BMI values may underestimate the prevalence of overweight and obesity in the Taiwanese. Thresholds of BMI 24–26.9 for overweight and BMI > 27 for obesity have been adopted for Taiwanese by the Department of Health of Taiwan.

- In addition to age, lifestyle factors and diet are associated with the BMI and mid-arm and CC. Routine physical activity is positively associated with these indicators. However, cigarette smoking is negatively associated with BMI and calf circumference.
- Consumption of meat/poultry is associated with higher BMI but not mid-arm or CC.
- Consumption of dairy and legume foods is negatively associated with BMI and MAC but not calf circumference.
- Consumption of fruits but not vegetables is positively associated with BMI and calf circumference alone.
- Consumption of camellia tea is associated with higher BMI and mid-arm and CC.
- Calf circumference reflects body muscle mass better than BMI or MAC during advanced aging. Thus, it is a better indicator of functional decline.
- Because of their simple, accessible, and non-invasive character, and most importantly, the ability to reflect nutritional status, BMI and mid-arm and CC will be the key components in developing a tool for geriatric nutritional and functional assessment.
- Because of the race/ethnic-related anthropometrical variations and differences in healthcare systems, efforts should be made to develop population-specific assessment tools.

Acknowledgment The author of this chapter wishes to express his appreciation to (a) Ms. Tsui-Lan Chang for performing most of the statistical analyses and (b) the Bureau of Health Promotion of the Department of Health, Taiwan for providing the SHLSET data set used in this chapter.
